ICT, Internet and Worker Productivity

Irene Bertschek

Abstract

This article provides a brief overview of the role of information and communication technologies (ICT) as a driver of productivity. In particular, it focuses on the diffusion of computers and the Internet at the workplace and discusses the relationship with wages, the task composition of occupations and labour productivity at the firm level.

Information and communication technologies (ICT) enhance productivity and growth, as shown by various studies at the macroeconomic and microeconomic levels (see for instance Draca et al. 2007 or Kretschmer 2012, for a comprehensive overview). As so-called general purpose technologies (Bresnahan and Trajtenberg 1995), they diffuse throughout the whole economy and enable innovation in adopting firms and sectors (see for example Brynjolfsson and Saunders 2010), leading to higher productivity.

From a technological perspective, we can differentiate three basic stages of ICT: personal computers, the Internet, and more recently, mobile Internet.

When personal computers started to diffuse to workplaces, economists became interested in analysing whether the use of computers makes workers more productive. There are basically two approaches to measuring worker productivity. One approach takes an individual perspective. It is based on the concept of wage functions and assumes that wages reflect individual productivity. The other approach takes a firm-level perspective. It builds on production functions and analyses the relationship between labour productivity and firms' input factors, labour, non-ICT capital and ICT capital, as well as other firm characteristics. Some studies go beyond these main approaches by taking into account job-related tasks, project-based information or regional aspects.

Worker Productivity at the Individual Level

Computer Use and Wages

In his seminal paper, Krueger (1993) analyses whether workers who use a computer at work earn higher wages than workers not using a computer at work. The following kind of wage equation is estimated:

$$\ln W_i = \beta_0 + \beta_1 \text{Computer}_i + \beta_2 X_i + u_i$$

where W_i is hourly wage for employee i, Computer_i is a dummy variable taking the value one if employee i uses a computer at work and the value zero otherwise, and X_i represents a vector of employee characteristics, such as education, age and gender. Krueger uses data from the Current Population Survey (CPS) collected in the USA in 1984 and 1989 and from the High School and Beyond Survey for the years 1980, 1982, 1984, 1986. The findings reveal that the wage rate of computer users is about 10–15% higher than that of the non-computer users. In 1984, about 25% of the employees used computers at work, whereas the number has increased to 37% in 1989. Krueger points out that it is not clear from the data and from his analysis whether using computers makes employees more productive and therefore means that they earn higher wages, or whether there are unobserved individual characteristics that correlate with computer use and wages. For instance, high-skilled employees may have abilities that make them earn higher wages and increase the probability of using computers. Owing to the fact that Krueger has only cross-sectional data he cannot control for individual unobserved heterogeneity using fixed effects regression.

DiNardo and Pischke (1997) replied provocatively to Krueger's paper by asking: 'Have pencils changed the wage structure too?'. They replicate Krueger's estimations for the USA but extend the analysis to a further cross-section (1993) of the Current Population Survey. Furthermore, they use German employee-level data from the Qualification and Career Survey for the time periods 1979, 1985/86 and 1991/92 and compare the results to those found for the USA. In addition to looking at computers at work, the authors also consider the effect of other working tools such as calculators, telephones, writing tools like pens or pencils, and sitting on the job. They call these tools 'white-collar tools', since they are more probably used by white-collar than by blue-collar workers. The results for Germany, with respect to the wage premium for computer use, confirm the results found for the USA. However, similar wage differentials are found for pens and pencils, calculators, telephones and working while sitting. The authors draw the conclusion that the wage differential found for computer use cannot reflect true returns to computer use or skills, since otherwise no similar effects would have been found for the other white-collar tools. Similar results are found by Borghans and Ter Weel (2004) for British employee data collected in 1997. Computer use only at the advanced level is related to wage premiums, whereas mathematics and writing skills show significant wage premiums.

The study by Entorf et al. (1999) has the advantage over previous studies that it relies on panel linked employer–employee data for 1991 to 1993. This allows individual fixed effects that control for unobserved heterogeneity across employees to be taken into account. Moreover, the authors can observe what happens if an employee starts using a computer at work. The wage differential observed in the cross-sectional French data is more or less the same as in the USA and lies between 15 and 20%. Panel regressions, however, show that this wage differential decreases to only up to 2%, a result that confirms evidence found before for the 1980s (Entorf and Kramarz 1997). Moreover, employees were already better paid before they started using computers. This result implies that firms allocate computers to selected workers and these workers seem to have unobserved skills that are complementary with computer use. According to the French dataset, this seems to hold particularly for low-skilled workers. Wage premium estimates are summarised in Table 1.

The Task-Based Approach

In order to obtain deeper insights into the unobserved characteristics that are complementary

ICT, Internet and Worker Productivity, Table 1 Overview of wage premium estimates

Authors	Data	Estimated wage premium
Krueger (1993)	US Data: Current Population Survey, 1984, 1989; High School and Beyond Survey, 1980, 1982, 1984, 1986	Between 10% and 15% for computer use
DiNardo and Pischke (1997)	US Data: Current Population Survey, 1984, 1989, 1993; West German Data: Qualification and Career Survey, 1979, 1985–1986, 1991–1992	For the USA 1989: 19% For West Germany 1991: 17% for computer use Similar effects for pencils and other white-collar tools
Entorf and Kramarz (1997)	French Labour Force Survey 1985–1987 and firm-level information	Cross-section analysis: 16% for computer-related new technologies, decomposed in 6% for workers with zero experience and 2% for each year of experience for the first years
		Longitudinal individual data: effect not related to experience disappears 1% for each year of experience
Entorf et al. (1999)	French Labour Force Survey 1991–1993 and firm-level information	Cross-section analysis: 15–20% Panel data: 2%
Borghans and Ter Weel (2004)	Skills Survey of the Employed British Workforce 1997	Wage returns only if computers are used at the advanced level (e.g. programming) Positive and significant wage premiums for mathematical and writing skills

with computer use, Autor et al. (2003) suggested a so-called task-based approach. This approach assumes that work consists of a series of routine and non-routine tasks. While manual and cognitive routine tasks can be performed and thus substituted by a computer, non-routine tasks cannot. Analytical and interactive non-routine cognitive tasks are, by contrast, supported (i.e. complemented) by computers. For instance, doing research or advising customers are non-routine cognitive tasks that can be better performed using a computer. By contrast, bookkeeping or controlling machines can be performed by computers (see Spitz-Oener 2006, p. 243, for a classification of tasks). Autor et al. (2003) and Spitz-Oener (2006) have shown for the USA and Germany, respectively, that the diffusion of computers goes hand in hand with a shift in the content of work from manual and cognitive routine tasks towards non-routine cognitive tasks. This shift implies an increase in the demand for skilled employees (in line with the hypothesis that technological change is skill-biased), leading to increased wages for these skills. Another, more direct, channel for how computers affect wages is that employees become increasingly productive when complementing their tasks with computer use.

This latter aspect corresponds to the complementarities between computer use and organisational change found at the firm level by Bresnahan et al. (2002) (see next section). For the empirical analysis of the task-based approach, task compositions within occupations are calculated for each employee i (see Spitz-Oener 2006, p. 242 for the following definition):

$$\text{Task}_{ijt} = \frac{\text{number of activities in category } j \text{ performed by } i \text{ at time } t}{\text{total number of activities in category } j \text{ at time } t}$$

where j represents the tasks, i.e. $j = 1$ (nonroutine analytic tasks), $j = 2$ (nonroutine interactive tasks), $j = 3$ (routine cognitive tasks), $j = 4$ (routine manual tasks) and $j = 5$ (nonroutine manual tasks), and t reflects the cross-section for which data is available. According to the example

given by Spitz-Oener, if employee *i* performs two out of four analytical activities, his or her analytical task measure is 50. Based on these task measures the change in the shares of tasks within occupations over time can be calculated, showing which of the tasks have become more or less important.

Spitz-Oener (2008) extends her previous analysis conducted in 2006 to take up the issue raised by DiNardo and Pischke (1997), i.e. that there is also an effect of pencil use on wages. She shows for West German employee data, again from the Qualification and Career Survey in 1998/99, that wage premiums are observed for employees with skills that are complementary with computer use. In contrast with the study by DiNardo and Pischke (1997), no similar effects are found for the use of pencils. This result underpins what has been found before: computer use has shifted the task composition of occupations towards analytical and interactive tasks and away from routine cognitive and manual tasks. While computers complement the first, they tend to substitute for the latter.

Worker Productivity at the Firm Level

ICT and Labour Productivity

Taking a firm-level perspective, the relationship between labour productivity and ICT can be captured by a production function approach. Output Q is related to the input factors of labour, non-ICT capital and ICT capital. Although sometimes materials explicitly are taken into account, we do not consider them here. If we assume a Cobb-Douglas form of the production function, the function for firm i looks as follows:

$$Q_i = AL_i^{\beta_1} K_i^{\beta_2} C_i^{\beta_3}$$

where Q is output, L is labour, K is capital, C is ICT capital and A represents a technology or efficiency parameter. The parameters β_1, β_2 and β_3 represent the output elasticities of the respective input factors. Taking logarithms, setting $\ln A = \beta_0$ and adding an error term u_i leads to the following equation:

$$\ln Q_i = \beta_0 + \beta_1 \ln L_i + \beta_2 \ln K_i + \beta_3 \ln C_i + u_i$$

Subtracting $\ln L$ from both sides results in

$$\ln\left(\frac{Q_i}{L_i}\right) = \beta_0 + (\beta_1 - 1)\ln L_i + \beta_2 \ln K_i + \beta_3 \ln C_i + u_i$$

where $\ln\left(\frac{Q_i}{L_i}\right)$ represents labour productivity, i.e. output per worker. This equation can be estimated by econometric methods using firm-level data. If panel data are available, an index t is added. Panel data usually allow taking account of firm-specific fixed effects and thus unobserved heterogeneity across firms. Depending on the available data, labour productivity is measured by sales per employee, sales per hour worked, value added per employee or value added per hour worked. ICT capital often is not observable in firm-level data sets. In this case, it may be approximated by ICT investment or by the percentage of employees working with computers. If panel data is available and information about ICT investment, then ICT capital stocks can be calculated according to the so-called perpetual inventory method (see for example Bloom et al. 2012, or Hempell 2005). Some studies, instead of using measures of ICT capital, analyse the relationship of labour productivity with specific ICT applications such as B2B e-commerce that are measured by dummy variables (see for example Bertschek et al. 2006).

There is meanwhile a large number of firm-level studies analysing the role of ICT for labour productivity. Draca et al. (2007) provide a comprehensive overview of the studies published between 1996 and 2005 and summarise the main results. One main finding of most studies is that labour productivity is positively and significantly related with ICT. The average of the estimated coefficients of ICT is about 5% to 6% and has increased over time (see Kretschmer 2012). This relationship, however, might be heterogeneous with respect to firms and industries, i.e. some firms or industries are more successful in employing ICT than others.

This firm-specific heterogeneity in reaping the potential of ICT might be due to differences in

complementary investment in organisational capital and human capital across firms, an argument put forward for instance in Bresnahan et al. (2002) and underpinned in several further studies. The relationship between productivity and ICT is stronger if investment in ICT is supported by investment in organisational capital (for the particular role of organisational capital see for example Black and Lynch 2001, for the USA; Bertschek and Kaiser 2004, for Germany). Since ICT lowers the cost of communication, employees can communicate and exchange information more efficiently. Thus, working in teams and with a low number of hierarchies becomes more feasible and organisational structures may become more decentralised and flexible. Moreover, communicating and coordinating with customers and suppliers become easier and costs may decrease. Investment in human capital is considered to be complementary with ICT since the implementation of a new ICT system or application in a firm often requires that firms train their employees in order to be able to work with these new technologies or applications. Recent evidence on the relationship between ICT, organisational capital and human capital and its productivity-enhancing effect is presented by Bloom et al. (2012) who find that US multinationals located in Europe obtain higher productivity effects from using ICT than their non-US counterparts due to better people management practices. Bartel et al. (2007) analyse specific ICT applications in valve-producing plants, and Aral et al. (2012) present econometric evidence on a three-way complementarity between firms' adoption of software for human capital management, performance pay and firms' practice of human resource analytics (including worker monitoring, performance feedback, the integration of workforce support data, and talent management). Hall et al. (2012) consider investment in ICT and in research and development (R&D) as potential sources of innovation which in turn may enhance labour productivity. They use four cross sections of Italian manufacturing firms covering the period 1995–2006. The econometric results show that R&D and ICT contribute directly to labour productivity but also indirectly through enabling innovation.

One big issue empirically working economists are faced with is endogeneity. It is *a priori* not evident whether investment in ICT increases labour productivity or whether productivity growth implies more investment in ICT. Depending on the available datasets, the studies are more or less able to tackle this issue.

Looking at the Internet as a specific ICT, there is not so much empirical work yet as exists for ICT in general. The following section will summarise some of the empirical results.

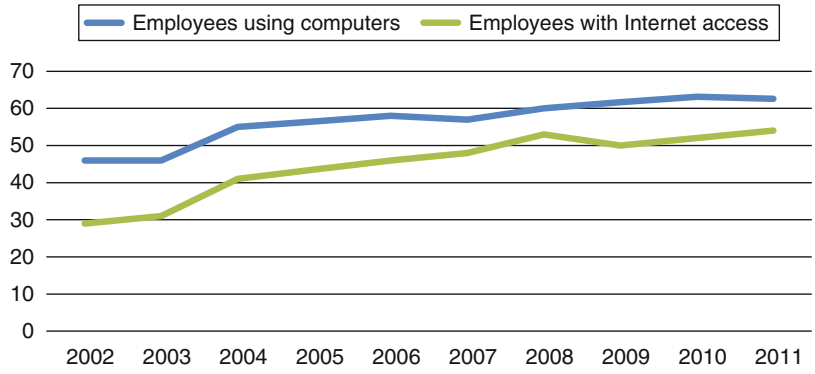
Internet and Labour Productivity

The Internet started to diffuse to workplaces later than computers. If a firm connects to the Internet, it does not necessarily mean that all employees have Internet access, but this might rather be restricted to a certain group of persons such as the chief executive officers or the administration staff. Also, Internet use as well as computer use varies considerably between manufacturing and services industries.

Figure 1 shows the diffusion of computers and Internet access in German firms. The percentage of employees using a computer at least once per week at work has increased from 46% in 2002 to 63% in 2011. In the same period, the percentage of employees with connection to the Internet has increased from 29% in 2003 to 54% in 2011.

What does the Internet add to only having a computer? It allows access to information and connects employees with each other, facilitating the search and exchange of information. Moreover, Internet technologies or web-based applications such as wikis or collaboration platforms facilitate processing of information, documentation and cooperation.

For the case of New Zealand, Grimes et al. (2012) find based on a firm-level cross section collected in 2006 that firms using broadband Internet have a 7 to 10% higher labour productivity. By contrast, for the early phase of broadband diffusion in Germany, 2000 to 2002, Bertschek et al. (2011) find positive and significant effects of broadband on firms' innovation activity but not on labour productivity. Polder et al. (2010) analyse the role of ICT and R&D for innovation success. Their estimations are



ICT, Internet and Worker Productivity, Fig. 1 Percentage of employees using computers and Internet in German firms, 2002–2011. In 2008, NACE code classification has changed

based on three data waves of Dutch firms. ICT is measured as investment in ICT per employee. Additionally, they use a measure for Internet use (the percentage of employees having access to broadband Internet), and include e-commerce as a specific ICT application. The results show that broadband Internet is particularly important for service firms, where broadband is positively related to product and process innovation as well as to organisational innovation. By contrast, in the manufacturing sector, broadband is significant only for product and organisational innovation. For process innovation, it is e-commerce that plays a significant role. These results support the hypothesis of complementarity between ICT and innovation or organisational change. Moreover, they show that it also depends on what firms concretely do with their ICT or with their Internet access to enable innovation. This latter issue is taken up in a recent paper by Colombo et al. (2012). The authors show for a sample of small Italian firms that it is not the broadband connection itself that makes firms more productive. It depends rather on the kind of application as well as on complementary organisational and strategic changes whether or not firms profit with respect to their productivity.

Internet and Wages: A Regional Perspective

Studies looking at Internet and wages are still scarce. Forman et al. (2011) take a regional perspective. Their initial hypothesis is that Internet lowers the cost for economic engagement also in geographically isolated regions. Thus, Internet should have effects on the performance of firms and employees also in regions whose performance was comparably low before the diffusion of the Internet. The study does not look at broadband Internet itself but at business investment in advanced Internet technologies. These comprise investment in enterprise resource planning (ERP), customer service, education, extranet, publications, purchasing and technical support. The time span of the analysis is from 1995 to 2000, a time period when Internet had just started to diffuse more broadly and when there was still a lot of variation in the use of broadband Internet or Internet-based applications with respect to firms, individuals and regions. The authors use data from different sources on firms with more than 100 employees as well as county-level data.

The estimations show that although advanced Internet applications diffused widely in the USA from 1995 to 2000, the economic benefits in terms of wage growth were concentrated in a few well-performing counties only. More precisely, only 6% of US counties profited from investment in Internet technologies in terms of wage growth. This wage growth amounted to 28% from 1995 to 2000, whereas the average growth over all counties was 20%. These counties, however, had a better performance already before 1995, i.e. they were characterised by relatively high income, large population, high skills and high IT intensity. The results of the study thus do not support the initial hypothesis

that the Internet contributes to economic regional inclusion, but rather imply that the Internet aggravates regional wage inequality.

Including Social Network Data

In order to analyse the relationship between multitasking, knowledge networks and productivity, the approach by Aral et al. (2012) goes beyond the firm level and the individual level. The authors focus on only one firm, a mid-size executive recruiting firm. They use detailed data on employees' characteristics, on their project output and team membership for projects, and on email messages sent and received by these employees, i.e. on the workers' digital network. A recruiting firm offers services, and for services, measuring output, input and productivity is harder than in manufacturing firms. The authors of the study have accounting records for all projects covering the period 2001 to 2005, including the number of projects completed and the revenue generated by individual recruiters. They measure output as the number of projects completed per month, i.e. the number of days a recruiter works on the project per month divided by the total number of days for which the project runs. Completing a project means that the recruiter has found an appropriate candidate for the client and the candidate has signed a contract. Output is set into relation with the heterogeneity of multitasking measured as the number of projects recruiters work on per month and the heterogeneity of recruiters' contacts resulting from the work on prior projects as well as from the number of email contacts.

There are several interesting findings from this analysis: Recruiters' output is increasing with multitasking, but only up to a certain threshold. A further increase of multitasking then implies diminishing rates of return. Although heterogeneity of contacts is negatively related with output, it complements task heterogeneity. Having access to heterogeneous information via email makes multitasking recruiters more productive. This result again supports the hypothesis of complementarity between workplace organisation and IT as well as the complementarity between specific tasks and IT.

Current Technological Trends

While computers allow for digitisation, and the Internet for connectedness, the mobile Internet, which has started to diffuse only recently, additionally offers the possibility to work at any time from any place. For example, in Germany, on average 25% of employees have broadband access via a mobile device such as a smartphone or a tablet (Statistisches Bundesamt 2011, p. 21). This development is supported by so-called cloud computing – the concentration of computing capacity, data and software in data centres that employees can connect to from anywhere. There are so far no empirical econometric studies based on large-scale data analysing whether mobile Internet adds to worker productivity additionally to computers and Internet. We can imagine what might happen if working environments get more and more flexible and independent from time and space. On the one hand, this technological opportunity, by decreasing information and communication costs, supports further decentralisation of work as suggested in Bresnahan et al. (2002). On the other hand, these flexible working environments require a high degree of self-reliance and coordination. Very probably, new studies will soon give insights into the net effects of these new technological advances.

Ideal Indexes

Kazuo Sato

Among many index numbers, the two most favoured because of algebraic simplicity and ease of computation are those advocated by E. Laspeyres in 1864 and by H. Paasche in 1874. There are n commodities, indexed from 1 to n. At time point t, the price vector is $p_t = \{p_{1t}, \ldots, p_{nt}\}$ and the quantity vector $q_t = \{q_{1t}, \ldots, q_{nt}\}$. $p_s q_t$ denotes $\sum_{i=1}^{n} p_{is} q_{it}$. Let P_{st} and Q_{st} be the price and quantity indexes from time s to t. Then, these two indexes are

$$\text{Laspeyres} P_{st}^{L} = p_t q_s / p_s q_s, \quad Q_{st}^{L} = p_s q_t / p_s q_s$$
$$\text{Paasche} P_{st}^{P} = p_t q_t / p_s q_t, \quad Q_{st}^{P} = p_t q_t / p_t q_s$$

There are several desirable properties that an index ought to satisfy (Samuelson and Swamy 1974; Allen 1975, pp. 40–47). Three basic tests (stated for the price index) which any reasonable index must meet are:

1. Identity test: $P_{tt} = 1$.
2. Proportionality test: $P_{st'} = kP_{st}$, when $p_{it'} = kp_{it}$, $q_{it'} = q_{it}$ for all i.
3. Dimensional test: changes of units do not affect the index value. The next three are not always satisfied:
4. Time-reversal test: $P_{st}P_{ts} = 1$.
5. Circular test: $P_{rs}P_{st} = P_{rt}$.
6. Factor-reversal test: $P_{st}Q_{st} = E_{st}$, where $E_{st} = p_t q_t / p_s q_s$ is the expenditure index and P and Q are matching indexes in the sense that they share a common form except that p and q are interchanged between them.

Irving Fisher (1922), who most energetically pursued the topic of index numbers, emphasized the factor-reversal test and regarded PQ/E (where P and Q are matching indexes) as the bias of an index. Very few indexes satisfy (6). For the Laspeyres and Paasche indexes, the following identities are seen to hold:

$$P_{st}^{L} Q_{st}^{P} = P_{st}^{P} Q_{st}^{L} = E_{st},$$

i.e., the Laspeyres and Paasche indexes are 'factor antitheses'. Then, their geometric averages

$$P_{st}^{F} = \sqrt{P_{st}^{L} P_{st}^{P}}, \; Q_{st}^{F} = \sqrt{Q_{st}^{L} Q_{st}^{P}}$$

satisfy (6). Fisher regarded this index to be the best or 'ideal' among 134 indexes he compared. This index has been known as Fisher's ideal index even though he was not the only one who discussed this index at the time.

A log-change index has also been popular. It is given the form

$$\ln P_{st} = \sum_i s_i (\ln p_{it} - \ln p_{is}),$$

$$\ln Q_{st} = \sum_i s_i (\ln q_{it} - \ln q_{is})$$

where $s_i \geq 0$, $\sum s_i - 1$. Expenditure shares are used for weights. Let w_{it} be the share of good i in total expenditure at time t. Loglinear analogues of the Laspeyres, Paasche, and Fisher indexes are obtained by setting (i) $s_i = w_{is}$, (ii) $s_i = w_{it}$, and (iii) $s_i = \frac{1}{2}(w_{is} + w_{it})$. The last one, which is attributed to Törnqvist, does not satisfy the factor-reversal test.

Log-change indexes may be considered as discrete approximations to the continuous Divisia index obtained by integrating

$$d \ln P = \sum_i w_i d \ln p_i, \quad d \ln Q = \sum_i w_i d \ln q_i$$

from s to t.

Suppose that (p, q) represents the behaviour of a consumer maximizing utility. Assume that the consumer's utility is represented by a preference function of a certain homogeneous form. It can then be shown that the Divisia index also assumes a certain form. This index is said to be 'exact' with the preference function (Diewert 1976). (The Laspeyres is exact with a linear utility function, the Paasche with a Leontief-type utility function, and the Törnqvist with a translog utility function.)

The correspondence between a preference function and an index can be given the following heuristic argument: The preference ordering can be represented either in a direct form $[U(q)]$ or in an indirect form $[V(E/p)]$. Interpreting the quantity index as a constant-utility index, we have $Q_{st} = U(q_t)/U(q_s)$. By the same token, the price index is associated with the indirect utility function so that $P_{st} = V(E/p_t)/V(E/p_s)$. When U and V are alternative representations of a preference function, they form a dual pair. P and Q which are exact with them are factor antitheses, namely, $P_{st}Q_{st} = E_{st}$. As P and Q are not in general

matching indexes, they do not meet the factor reversal test.

When the duel pair, U and V, share a common functional form, they are called 'self-dual' (Houthakker 1965). It then follows that Q and P which are exact with the dual pair must also share a common form, i.e., they are matching indexes. Thus, an important proposition holds: there are as many ideal index numbers as there are self-dual preference functions as they are equivalent to each other. There are only three known self-dual preference functions: (-a) Cobb–Douglas, (b) quadratic, and (c) constant-elasticity-of substitution (CES). Ideal indexes which correspond to these are as follows:

(a) A log-change index with fixed weights. The weights are exponents of the Cobb–Douglas. Since expenditure shares do not remain constant over time, this index violates reality.
(b) Fisher's ideal index. This correspondence was noted by Konüs and Byushgens already in the 1920s (Afriat 1977).
(c) A log-change index with variable weights where s_i is given by $(w_{it}–w_{is})/(\ln w_{it}–\ln w_{is})$, divided by its sum over i. Though complicated in form, these weights are seen to be in the nature of geometric averages. This index was discovered independently by Sato (1976) and Vartia (1976).

No other self-dual preferences not ideal indexes have been discovered since.

Ideal Output

J. V. de Graaff

Abstract

Pigou's notion of 'the ideal output' as 'the output in any industry which maximizes the national dividend, and, apart from the differences in the marginal utility of money to different people, also maximises satisfaction' has long been eclipsed by the 'general optimum of production and exchange', in which the welfare of each member of the community is maximized in turn, subject to certain constraints – even though the more modern theory, despite its advantages, does not necessarily reach any substantially different conclusions. But ideal output theory is by now no more than an episode in the history of economic thought.

Pigou, writing in *The Economics of Welfare,* calls 'the output in any industry which maximizes the national dividend, and, apart from the differences in the marginal utility of money to different

people, also maximises satisfaction, the ideal output'. He goes on to argue that 'this output is attained – the possibility of multiple maximum positions being ignored – when the value of the marginal social net product of each sort of resource invested in the industry under review is equal to the value of the marginal social net product of resources in general'. And, finally, it 'will be that output which makes the demand price of the output equal to the money value of the resources engaged in producing a marginal unit of output' (1932, pp. 802, 803).

The line of argument that comes through so clearly in these quotations can be traced back to Pigou's earlier *Wealth and Welfare* (1912) and indeed to Marshall; but since the 1930s it has been overtaken by the development of a more powerful strand of analysis that stems from Pareto (1897) and Barone (1908) and has culminated in the theory of the general optimum of production and exchange. In it one maximizes in turn the welfare of each member of the community, subject to the constraint of the social production function and to holding on each occasion the welfare of each other member constant. The resulting first-order conditions include the marginal equivalences enumerated in the theory of ideal output (Graaff 1957). Any modern discussion of the theory must therefore be set against the background of the one that has incorporated and replaced it.

The more modern theory has the virtues of elegance, simplicity and generality. It embraces exchange as well as production. It deals with commodities and firms (or event plants) instead of industries. It does not need the doctrine of maximum satisfaction, or any assumption about interpersonal comparisons of utility. But at the end of the day it does not reach any substantial conclusion that the theory of ideal output, correctly employed, would not itself have reached.

The problem, especially in the early development of the theory, was that it was not all that easy to apply it correctly. It was not originally recognized that (at least in a closed economy) the correct way to reckon the value of a marginal social net product is at *constant* prices. The same remark applies to the calculation of marginal social cost. If higher prices have to be offered to factors of production to attract them to an industry undergoing expansion, the element of the cost of the expansion caused by the higher prices represents a transfer payment to the factors (in the form of a rent or quasi-rent), not a cost to society. The cost to society is the value of the output sacrificed when the factors are withdrawn from their previous use. That value was reckoned at the original prices of the factors. Those prices must therefore be used in reckoning their cost to society in their new use.

Clarification of this issue was the result of a famous debate of the 1920s – much of it reprinted in *Readings in Price Theory* (Stigler and Boulding 1953) – on the desirability of taxing industries subject to diminishing returns, and paying bounties to those subject to increasing returns, a result to which the theory of ideal output at one stage seemed to point. As competitive conditions were meant to be prevailing, the industries enjoying increasing returns had to be assumed to comprise firms whose unit costs were falling because of *external* economies; and as external economies were themselves recognized as possible reasons for a divergence between private and social net products, the opportunities for getting muddled were legion. It is to the credit of the participants – among them D.H. Robertson, G.F. Shove, F.H. Knight and J. Viner – that these dangers were largely avoided.

Much of the motivation for the theory of ideal output seems to have been a desire to see when competitive output was ideal, and when interference in a competitive economy would be justified. Today we ask, rather more formally (cf. Debreu 1959), when a competitive equilibrium would also be a general optimum. The answer, very briefly, is when the technology is convex, there are no external effects in production or consumption, no public goods and no foreign trade.

Apart from the fact that the existence of public goods was glossed over, ideal output theory would not have given a very different answer. The importance of the foreign trade exception was recognized. (The marginal social cost of importing goods subject to rising supply price is higher than the marginal private cost. The rents that accrue to *foreigners* are not mere transfers

within the domestic community, but a part of social cost). Divergences between private and social costs due to external economies and diseconomies in production, and between private and social benefits due to external economies and diseconomies in consumption, were fully discussed. The counterpart of the modern insistence on a convex technology was the painstaking treatment of increasing returns. The conditions under which competitive output would approach the ideal were pretty clearly defined.

Pigou also discussed the deviation from the ideal of the outputs of discriminating monopolists. (Not surprisingly, they fell short.) R.F. Kahn (1935) extended the analysis to imperfect competition. He argued that (taking diseconomies as negative economies) all industries could be arranged in descending order on a scale according to the extent of the external economies they generated and the degree of monopoly (measured by the gap between price and marginal cost) they enjoyed and that at a certain point on the scale there would be an average industry. Above this point all should expand to produce ideal outputs; below it all should contract. Adjustment could be achieved by a set of taxes and bounties. When all industries had expanded or contracted to conform to the average degree of monopoly and the average capacity to create external economies, their marginal social products would diverge from their marginal private products to the same extent and ideal output would be attained.

Note that this treatment avoids the error of making 'piecemeal' recommendations of the sort so often found in partial analysis. All industries must move to the average. It may not help if one or two do. That may just increase the gap between those that conform and those that do not. (In technical terms, the first-order conditions for a maximum must be satisfied simultaneously.)

In this sense Kahn's treatment is very general. In another it is not general enough. Proportionality of marginal products is not sufficient. For a full optimum, equality is essential (Lerner 1944, ch. 9). This may require an adjustment in the number of hours worked, and an expansion or contraction in the level of output as a whole.

The view that suitable corrective taxes and bounties can and should be used to bring marginal private products into line with marginal social products, when they diverge, was once very popular. On the whole it has weathered less well than ideal output theory itself, although the latter is by now no more than an episode in the history of economic thought.

ideal type

David Beetham

This is the term used by Max Weber to describe the distinctive concepts and models developed by economic and social theorists, and employed in the activity of empirical analysis. The term also defines

the characteristic method which Weber saw as distinctive of the social sciences. Social life is infinitely complex and can never be exhaustively described or explained. In order to make sense of it, the social scientist uses artificially pure concepts, e.g. 'natural economy', 'handicraft', 'capitalism', which are intellectual constructs involving a high degree of abstraction from the actual world. They comprise the most typical elements which have been isolated from a historically repeated pattern of action, relationship or institution, as seen from a partial point of view (economic, political, etc.), and combined into an internally consistent and inherently intelligible unity. With the help of such constructs the social scientist is able to characterize a particular object of study, and make its complexity intelligible according to its degree of conformity to the stipulations of the relevant concept or model. Often a particular social complex will require a combination of such concepts for its elucidation, as for example the class structure of a given society can be understood as a combination of the analytically separable elements of property ownership ('class'), social esteem ('status') and authority position ('power'). Ideal types have nothing to do with ideals (though there can be ideal-type of ideals, e.g. 'individualism') and could perhaps less confusingly be called 'pure types'.

Weber's characterization of the ideal-type method is best understood in the context of the 'Methodenstreit' between the historical and theoretical schools of German political economy. He developed it to rebut what he saw as a mistaken understanding of theory on the part of certain members of the historical school. In their view economic theory should involve the quest for universal laws of a natural-scientific kind, arrived at inductively on the basis of exhaustive empirical studies of economic phenomena. They saw the work of the historical school as the necessary preliminary stage to the discovery of such laws. Measured against this conception, the theoretical work of Carl Menger and the marginal utility school was judged to be excessively abstract, one-sided in its assumptions about human nature, and above all premature.

Weber's ideal-type method provided a critique of this 'scientistic' understanding of economic and social theory. The focus of interest of the social scientist, he argued, lay in the historically specific, not the most general, aspects of phenomena. The latter were both the most banal and the least useful for explanatory purposes. The distinctive method of social-scientific abstraction involved not a quest for universal laws, but a process of isolating what was most typical and essential to a pattern of action or social relation, and rendering it intelligible as an internally coherent whole. It was by the same method of abstraction that the typical historical preconditions and consequences of a given social institution were to be elucidated. Weber argued that this was in practice the method adopted by economic theoreticians, Marxists and marginalists alike, though they did not always recognize its implications. The error of the former was to treat their theoretical deductions about the typical consequences of capitalist competition as actual historical tendencies or laws, in advance of any empirical confirmation. The error of the latter was their failure to recognize the actual historical preconditions for the rigorous calculation and maximization of economic interests, which made their theoretical models historically specific rather than applicable to all times and places (Weber 1903; 1904a).

In this manner Weber's account of the ideal-type method offered a resolution of the controversy between the historical and theoretical schools. On the one hand it demonstrated the historical specificity of even the most abstract theorizing. On the other hand it revealed the irreducibly theoretical character of the concepts used in historical economics, which was anything but a merely descriptive activity on whose successful 'completion' the construction of theory was itself supposedly dependent. Properly understood, the respective emphases of theory and history were mutually complementary, a conjunction which Weber's own work such as *The Protestant Ethic and the Spirit of Capitalism* (Weber 1904b) or the more theoretical formulations of *Economy and Society* (Weber 1921) amply demonstrated.

Subsequent discussion of the ideal-type method has taken place within sociology and political science, rather than within the discipline

of economics, which provided its original intellectual location. Most social scientists would accept the necessity for typological construction, but disagree over both its manner and the criteria for its assessment. Weber's approach has been criticized for its inherent subjectivity, in two quite different senses. First, his method of 'Verstehen' or 'understanding', which is necessary for assessing the internal coherence of idealtype constructs, has been seen as unavoidably arbitrary. To this it can be simply replied that the criteria for the intelligibility of social action are interpersonal, not private, despite the obvious difficulties in respect of alien cultures.

Secondly, following the neo-Kantianism of Heinrich Rickert, Weber argued that the objects of study and hence the concepts used in the social sciences are determined according to their 'value-relevance', i.e. their significance for our values. Unlike Rickert, however, he did not believe that these value standpoints could be objectively grounded in human reason. Some commentators have therefore concluded that it is impossible to rescue Weberian concept formation from the subjectivity of the investigator's own values. Such a conclusion overlooks Weber's insistence that ideal-type constructs must satisfy the criterion of explanatory power as well as of significance, and thus 'be valid for all who seek the truth'. The ultimate test for idealtype construction must be an objective one: its fruitfulness in identifying and resolving explanatory problems.

Identification

Jean-Marie Dufour and Cheng Hsiao

Abstract

The problem of identification is defined in terms of the possibility of characterizing parameters of interest from observable data. This problem occurs in many fields, such as automatic control, biomedical engineering, psychology, systems science, the design of experiments, and econometrics. This article focuses on identification in econometric models, which typically involve random variables. Identification in general parametric statistical models is defined, and its meaning in a number of specific econometric models is considered: regression (collinearity), simultaneous equations, dynamic models, and nonlinear models. Identification in nonparametric models, weak identification, and the statistical implications of identification failure are also discussed.

In economic analysis, we often assume that there exists an underlying structure which has generated the observations of real-world data. However, statistical inference can relate only to characteristics of the distribution of the observed variables. Statistical models which are used to

explain the behaviour of observed data typically involve parameters, and statistical inference aims at making statements about these parameters. For that purpose, it is important that different values of a parameter of interest can be characterized in terms of the data distribution. Otherwise, the problem of drawing inferences about this parameter is plagued by a fundamental indeterminacy and can be viewed as 'ill-posed'.

To illustrate, consider X as being normally distributed with mean $E(X) = \mu_1 - \mu_2$. Then $\mu_1 - \mu_2$ can be estimated using observed X. But the parameters μ_1 and μ_2 are not uniquely estimable. In fact, one can think of an infinite number of pairs (μ_i, μ_j), $i, j = 1, 2, \ldots (i \neq j)$, such that $\mu_i - \mu_j = \mu_1 - \mu_2$. In order to determine μ_1 and μ_2 uniquely, we need additional prior information, such as $\mu_2 = 3\mu_1$ or some other assumption. Note, however, that inference about the variance of X remains feasible without extra assumptions.

More generally, *identification failures* –or situations that are close to it – complicate considerably the statistical analysis of models, so that tracking such failures and formulating restrictions to avoid them is an important problem of econometric modelling.

The problem of whether it is possible to draw inferences from the probability distribution of the observed variables to an underlying theoretical structure is the concern of econometric literature on identification. The first economists to raise this issue were Working (1925, 1927) and Wright (1915, 1928). The general formulations of the identification problems were made by Frisch (1934), Marschak (1942), Haavelmo (1944), Hurwicz (1950), Koopmans and Reiersøl (1950), Koopmans et al. (1950), Wald (1950), and many others. An extensive treatment of the theory of identification in simultaneous equation systems was provided by Fisher (1976). Surveys of the subject can be found in Hsiao (1983), Prakasa Rao (1992), Bekker and Wansbeek (2001), Manski (2003), and Matzkin (2007); see also Morgan (1990) and Stock and Trebbi (2003) on the early development of the subject.

In this article, we first define the notion of identification in general parametric models (Sections "Definition of Parametric Identification" and "General Results for Identification in Parametric Models") and discuss its meaning in a number of specific statistical models used in econometrics, such as regression models (collinearity), simultaneous equations, dynamic models, and nonlinear models (Section "Some Specific Parametric Models"). Identification in nonparametric models (Sections "Definition of Identification in Nonparametric Models" and "Examples of Nonparametric Identification"), weak identification (Section "Weak Instruments and Weak Identification"), and the statistical implications of identification failure (Section "Statistical Consequences of Identification Failure") are also considered.

Definition of Parametric Identification

It is generally assumed in econometrics that economic variables whose formation an economic theory is designed to explain have the characteristics of random variables. Let y be a set of such observations. A structure S is a complete specification of the probability distribution function of y. The set of all a priori possible structures, T, is called a model. In most applications, y is assumed to be generated by a parametric probability distribution function $F(y, \theta)$, where the probability distribution function F is assumed known, but the $q \times 1$ parameter vector θ is unknown. Hence, a structure is described by a parametric point θ, and a model is a set of points $A \subseteq \mathbb{R}^q$.

Definition 1 *Two structures, $S^0 = F(y, \theta^0)$ and $S^* = F(y, \theta^*)$ are said to be observationally equivalent if $F(y, \theta^0) = F(y, \theta^*)$ for ('almost') all possible y. A model is identifiable if A contains no two distinct structures which are observationally equivalent. A function of θ, g(θ), is identifiable if all observationally equivalent structures have the same value for g(θ).*

Sometimes a weaker concept of identifiability is useful.

Definition 2 *A structure with parameter value θ^0 is said to be locally identified if there exists an open neighborhood of θ^0, W, such that no other θ in W is observationally equivalent to θ^0.*

General Results for Identification in Parametric Models

Lack of identification reflects the fact that a random variable has the same distribution for some if not all values of the parameter. R.A. Fisher's information matrix provides a sensitivity measure of the distribution of a random variable due to small changes in the value of the parameter point (Rao 1962). It can therefore be shown that, subject to regularity conditions, θ^0 is locally identified if and only if the information matrix evaluated at θ^0 is nonsingular (Rothenberg 1971).

It is clear that unidentified parameters cannot be consistently estimated. There are also pathological cases where identified models fail to possess consistent estimators (for example, Gabrielson 1978). However, in most practical cases, we may treat identifiability and the existence of a consistent estimator as equivalent; for precise conditions, see Le Cam (1956) and Deistler and Seifert (1978).

Some Specific Parametric Models

The choice of model structure is one of the basic ingredients in the formulation of the identification problem. In this section we briefly discuss some identification conditions for different types of models in order to demonstrate the kind of prior restrictions required.

Linear Regression with Collinearity

One of the most common models where an identification problem does occur is the linear regression model:

$$\mathbf{y} = X\beta + \mathbf{u} \tag{1}$$

where $\mathbf{y}$ is an $n \times 1$ vector of dependent observable variables, X is an $n \times k$ fixed matrix of observable variables, β a $k \times 1$ unknown coefficient vector, and $\mathbf{u}$ is an $n \times 1$ vector of disturbances whose components are (say) independent and identically distributed according to a normal distribution $N(0, \sigma^2)$ with unknown positive variance σ^2.

In this model, the value of β must be determined from the expected value of $\mathbf{y}$: $E(\mathbf{y}) = X\beta$. If the latter equation has a solution for β (that is, if the model is correct), the solution is unique if and only the regressor matrix X has rank k. If X has rank zero (which entails $X = 0$), all values of β are equivalent *(β is completely unidentifiable).* If $1 \leq \text{rank}(X) < k$, then not all the components can be determined, but some linear combinations of the components of β (say $c'\beta$) can be determined (that is, they are *identifiable*). A necessary and sufficient condition for $c'\beta$ to be estimable (identifiable) is that $c = (X'X)d$ for some vector d. Linear combinations that do not satisfy this condition are not identifiable. The typical way out of such collinearity problems consists in imposing restrictions on β (identifying restrictions) which set the values of the unidentifiable linear combinations (or components) of β.

Correspondingly, when X does not have full rank, the equation $(X'X)\hat{\beta} = X'\mathbf{y}$, which defines the least squares estimator $\hat{\beta}$, does not have a unique solution. But all solutions of the least squares problem can be determined by considering $\hat{\beta} = (X'X)^{-}X'\mathbf{y}$ where $(X'X)^{-}$ is any generalized inverse of $(X'X)$. Different generalized inverses then correspond to different identifying restrictions on β. For further discussion, see Rao (1973, ch. 4).

Linear Simultaneous Equations Models

Consider a theory which predicts a relationship among the variables as

$$B\mathbf{y}_t + \Gamma\mathbf{x}_t = \mathbf{u}_t, \quad t = 1, \ldots, n, \tag{2}$$

where $\mathbf{y}_t$ and $\mathbf{u}_t$, are $G \times 1$ vectors of observed and unobserved random variables, respectively, $\mathbf{x}_t$ is a $K \times 1$ vector of observed non-stochastic variables, B and Γ are $G \times G$ and $G \times K$ matrices of coefficients, with B nonsingular. We assume that the $\mathbf{u}_t$ are independently normally distributed with mean 0 and variance-covariance matrix $\sum$. Equations (2) are called structural equations. Solving for the endogenous variables, $\mathbf{y}$, as a function of the exogenous variables, $\mathbf{x}$, and the disturbance u, we obtain:

$$\mathbf{y}_t = -B^{-1}\Gamma\mathbf{x}_t + B^{-1}\mathbf{u}_t = \Pi\mathbf{x}_t + \mathbf{v}_t, \quad (3)$$

Where $\Pi = -B^{-1}\Gamma, E\mathbf{v}_t = 0, E\mathbf{v}_t\mathbf{v}_t' = V = B^{-1}\sum\left(B^{-1}\right)'$. Equations (3) are called the *reduced form* equations derived from (2) and give the conditional likelihood of $\mathbf{y}_t$ for given $\mathbf{x}_t$ that summaries the information provided by the observed ($\mathbf{y}_t$, $\mathbf{x}_t$,). The variables in $\mathbf{x}_t$ are often also called 'instruments'.

From (3), we see that the simultaneous equations model can be viewed as a special case of a multivariate regression model (MLR), such that the regression coefficient matrix Π satisfies the equation:

$$B\Pi = -\Gamma. \quad (4)$$

Provided the matrix $X = [x_1, \ldots, x_n]'$ has full rank K (no collinearity), the regression coefficient matrix Π is uniquely determined by the distribution of $Y = [y_1, \ldots, y_n]'$ (it is *identifiable)*. The problem is then whether B and Γ can be uniquely derived from Eq. (4). Premultiplying (2) by a $G \times G$ nonsingular matrix D, we get a second structural equation:

$$B^*\mathbf{y}_t + \Gamma^*\mathbf{x}_t = \mathbf{u}_t^*, \quad (5)$$

where $B^* = DB$, $\Gamma^* = D\Gamma$, and $\mathbf{u}_t^* = D\mathbf{u}$. It is readily seen that the reduced form of (5) is also (3). So Eq. (4) cannot be uniquely solved for B and Γ, given Π. Therefore, the two structures are observationally equivalent and the model is *non-identifiable.*

To make the model identifiable, additional prior restrictions have to be imposed on the matrices B, Γ and/or $\sum$. Consider the problem of estimating the parameters of the first equation in (2), out of a system of G equations. If the parameters cannot be estimated, the first equation is called *unidentified* or *underidentified*. If given the prior information, there is a unique way of estimating the unknown parameters, the equation is called *just identified.* If the prior information allows the parameters to be estimated in two or more linearly independent ways, it is called *over-identified.* A necessary condition for the first equation to be identified is that the number of restrictions on this equation be no less than $G - 1$ (order condition). A necessary and sufficient condition is that a specified submatrix of B, Γ and $\sum$ be of rank $G - 1$ (rank condition) (see Fisher 1976; Hausman and Taylor 1983). For instance, suppose the restrictions on the first equation are in the form that certain variables do not appear. Then this rank condition says that the first equation is identified if and only if the submatrix obtained by taking the columns of B and Γ with prescribed zeros in the first row is of rank $G - 1$ (Koopmans and Reiersøl 1950).

Dynamic Models

When both lagged endogenous variables and serial correlation in the disturbance term appear, we need to impose additional conditions to identify a model. For instance, consider the following two equation system (Koopmans et al. 1950):

$$y_{1t} + \beta_{11}y_{1,t-1} + \beta_{12}y_{2,t-1} = u_{1t}, \quad \beta_{12}y_{1t} + y_{2t} = u_{2t}. \quad (6)$$

If (u_{1t}, u_{2t}) are serially uncorrelated, (6) is identified. If serial correlation in (u_{1t}, u_{2t}) is allowed, then

$$y_{1t} + \beta^*{}_{11}y_{1,t-1} + \beta^*{}_{12}y_{2,t-1} = u^*{}_{1t}, \quad \beta_{12}y_{1t} + y_{2t} = u_{2t}, \quad (7)$$

is observationally equivalent to (6), where $\beta_{11}^* = \beta_{11} + d\beta_{21}$, $\beta_{12}^* = \beta_{12} + d$, and $u_{1t}^* = u_{1t} + du_{2t}$.

Hannan (1971) derives generalized rank conditions for the identification of this type of model by first assuming that the maximum orders of lagged endogenous and exogenous variables are known, then imposing restrictions to eliminate redundancy in the specification and to exclude transformations of the equations that involve shifts in time. Hatanaka (1975), on the other hand, assumes that the prior information takes only the form of excluding certain variables from an equation, and derives a rank condition which allows common roots to appear in each equation.

I

Nonlinear Models

For linear models, we have either global identification or else an infinite number of observationally equivalent structures. For models that are linear in parameters, but nonlinear in variables, there is a broad class of models whose members can commonly achieve identification (Brown 1983; McManus 1992). For models linear in the variables but nonlinear in the parameters, the state of the mathematical art is such that we only talk about local properties. That is, we cannot tell the true structure from any other substitute; however, we may be able to distinguish it from other structures which are close to it. A sufficient condition for local identification is that the Jacobian matrix formed by taking the first partial derivatives of

$$\omega_i = \Psi_i(\theta), i = 1, \ldots, n, 0 = \phi_j(\theta), \; j = 1, \ldots, R, \tag{8}$$

with respect to θ be of full column rank, where the ω_i are n population moments of y and the ϕ_j are the R a priori restrictions on θ (Fisher 1976).

When the Jacobian matrix of (8) has less than full column rank, the model may still be locally identifiable via conditions implied by the higher-order derivatives. However, the estimator of a model suffering from first-order lack of identification will in finite samples behave in a way which is difficult to distinguish from the behaviour of an unidentified model (Sargan 1983).

Bayesian Analysis

In Bayesian analysis all quantities, including the parameters, are random variables. Thus, a model is said to be identified in probability if the posterior distribution for θ is proper. When the prior distribution for θ is proper, so is the posterior, regardless of the likelihood function of y. In this sense unidentifiability causes no real difficulty in the Bayesian approach. However, basic to the Bayesian argument is that all probability statements are conditional, that is, they consist essentially in revising the probability of a fixed event in the light of various conditioning events, the revision being accomplished by Bayes' theorem. Therefore, in order for an experiment to be informative with regard to unknown parameters (that is, for the posterior to be different from the prior), the parameter must be identified or estimable in the classical sense and identification remains as a property of the likelihood function (Kadane 1975).

Drèze (1975) has commented that exact restrictions are unlikely to hold with probability 1 and has suggested using probabilistic prior information. In order to incorporate a stochastic prior, he has derived necessary rank conditions for the identification of a linear simultaneous equation model.

Definition of Identification in Nonparametric Models

When the restrictions of an economic model specify all functions and distributions up to the value of a finite dimensional vector, the model is said to be parametric. When some functions or distributions are left parametrically unspecified, the model is said to be semiparametric. The model is nonparametric if none of the functions and distributions are specified parametrically. The previous discussion is based on parametric specification. We now turn to the issue of whether economic restrictions such as concavity, continuity and monotonicity of functions, equilibrium conditions, the implications of optimization, and so on, may be used to guarantee the identification of some nonparametric models and the consistency of some nonparametric estimators (see Matzkin 1994).

Formally, an econometric model is specified by a vector of observable dependent and independent variables, a vector of unobservable variables, and a set of known functional relationships among the variables. When such functional relationships are unspecified, the nonparametric identification studies what functions or features of function can be recovered from the joint distribution of the observable variables.

The set of restrictions on the unknown functions and distributions in an econometric model

defines the set of functions and distributions to which these belong. Let the model T denote the set of all a priori possible unknown functions and distributions. Let m denote a vector of the unknown functions and distributions in T and $P(m)$ denote the joint distribution of the observable variables under m. Then the identification of m can be defined as follows.

Definition 3 *The vector of functions m is identified in T if for any other vector, m* ∈ T such that* $m \neq m^*$, $P(m) \neq P(m^*)$.

Let $C(m)$ denote some feature of m, such as the sign of some coordinate of m.

Definition 4 *The feature C(m) of m is identified if* $C(m) = C(m^*)$ *for all m,* $m^* \in T$ *such that* $P(m) = P(m^*)$.

Examples of Nonparametric Identification

Contrary to the parametric model, there is no general result for nonparametric identification. We shall therefore give some examples of how restrictions can be used to identify nonparametric functions.

Generalized Regression Models

Economists often consider a model of the form

$$y = g(\mathbf{x}) + u. \tag{9}$$

When $E(u|\mathbf{x}) = 0$ and $g(\cdot)$ is a continuous function $g : x \to \mathbb{R}$, then $g(\cdot)$ can be recovered from the joint distribution of (y, **x**) because $E(y|\mathbf{x}) = g(\mathbf{x})$.

In some cases, the object of interest is not a conditional mean function g(.), but some 'deeper' function, such as a utility function generating the distribution of demand for commodities by a consumer. For example, **x** in (9) can be a price vector for K commodities and the income of a consumer. Mas-Colell (1977) has shown that we can recover the underlying utility function from the distribution of demand if we restrict $g(\cdot)$ to be monotone increasing, continuous, concave and strictly quasiconcave functions.

Simultaneous Equations Models

Suppose (**y**, **x**) satisfies the structural equations

$$\mathbf{r}(\mathbf{x}, \mathbf{y}) = \mathbf{u}, \tag{10}$$

where **y** and **u** denote $G \times 1$ vectors of observable endogenous and unobservable variables, respectively, **x** is a $K \times 1$ vector of observable exogenous variables, **r** denotes the G unknown functions, and let $p(\mathbf{r})$ and $p(\mathbf{r}^*)$ represent the joint distributions of the observables under **r** and **r*** respectively. Assume also that: (i) $\forall(\mathbf{x}, \mathbf{y})$, $\partial\mathbf{r}/\partial\mathbf{y}$ has full rank, (ii) there exists a function $\pi(\cdot)$ such that $y = \pi(\mathbf{x}, \mathbf{u})$ (for conditions ensuring this, see Benkard and Berry 2006), and (iii) **u** is distributed independently of **x**. Then a necessary and sufficient condition guaranteeing that $p(\mathbf{r}^*) = p(\mathbf{r})$ is that

$$\operatorname{rank} \begin{pmatrix} \dfrac{\partial \mathbf{r}_i^*}{\partial(\mathbf{x}, \mathbf{y})} \\ \dfrac{\partial \mathbf{r}}{\partial(\mathbf{x}, \mathbf{y})} \end{pmatrix} < G + 1, \tag{11}$$

for all (**x**, **y**) and $i = 1,\ldots,G$, and all, where $\mathbf{r}_i^*$ denotes the i-th coordinate function of $\mathbf{r}^* \in T$ (see Roehrig 1988; Matzkin 2007).

Latent Variable Models and the Measurement of Treatment Effects

For each person i, let (y_{0i}^*, y_{1i}^*) denote the potential outcomes in the untreated and treated states, respectively. Then the treatment effect for individual i is

$$\Delta_i = y_{1i}^* - y_{0i}^*$$

and the average treatment effect (ATE) is defined as

$$E(\Delta_i) = E\left(y_{1i}^* - y_{0i}^*\right); \tag{12}$$

see Heckman and Vytlacil (2001).

Let the treatment status be denoted by the dummy variable d_i where $d_i = 1$ denotes the

receipt of treatment and $d_i = 0$ denotes nonreceipt. The observed data are often in the form

$$y_i = d_i y_{1i}^* + (1 - d_i) y_{0i}^*. \tag{13}$$

Suppose $y_{1i}^* = \mu_1(\mathbf{x}_i, u_{1i})$, $y_{0i}^* = \mu_0(\mathbf{x}_i, u_{0i})$ and $d_i^* = \mu_D(\mathbf{z}_i) - u_{di}$, where $d_i = 1$ if $d_i^* \geq 0$ and 0 otherwise, $\mathbf{x}_i$, and $\mathbf{z}_i$, are vectors of observable exogenous variables and (u_{1i}, u_{0i}, u_{di}) are unobserved random variables. The average treatment effect and the complete structural econometric model can be identified with parametric specifications of $(\mu_1(\cdot), \mu_0(\cdot), \mu_D(\cdot))$ and the joint distributions of (u_{1i}, u_{0i}, u_{di}) even though we do not simultaneously observe y_{1i}^* and y_{0i}^*. In the case that neither $(\mu_1(\cdot), \mu_0(\cdot), \mu_D(\cdot))$ nor the joint distribution of (u_1, u_0, u_d) are specified, certain treatment effects may still be nonparametrically identified under weaker assumptions. For instance, under the assumption that d_i is orthogonal to $\left(y_{1i}^*, y_{0i}^*\right)$ conditional on a set of confounders (x, z) (conditional independence or ignorable selection), the ATE is identifiable and estimable by comparing the difference of the average outcomes from the treatment group and from the untreated (control) group (Heckman and Robb 1985; Rosenbaum and Rubin 1985). If the focus is on the average treatment effect for someone who would not participate if $p(\mathbf{z}) \leq p(\mathbf{z}_0)$ and would participate if $p(\mathbf{z}) > p(\mathbf{z}_0)$ (the local average treatment effect (LATE)), where $p(\mathbf{z}) = \text{Prob}(d = 1|\mathbf{z})$ (propensity score), Imbens and Angrist (1994) show that under the assumptions of separability of the effects of observable factors and unobservable factors and independence between observed factors and unobserved factors, they can be estimated by the sample analogue of

$$\Delta^{LATE}(\mathbf{x}, p(\mathbf{z}), p(\mathbf{z}_0)) \equiv \frac{E(y|\mathbf{x}, p(\mathbf{z})) - E(y|\mathbf{x}, p(\mathbf{z}_0))}{p(\mathbf{z}) - p(\mathbf{z}_0)} \tag{14}$$

where, without loss of generality, we assume $p(\mathbf{z}) > p(\mathbf{z}_0)$. The limit of LATE provides the local instrumental variable (LIV) estimand (Heckman and Vytlacil 1999):

$$\Delta^{LIV}(\mathbf{x}, p(\mathbf{z})) \equiv \frac{\partial E(y|\mathbf{x}, p(\mathbf{z}))}{\partial p(\mathbf{z})}. \tag{15}$$

Heckman and Vytlacil (2001) give conditions that suitably weighted versions of LIV identify the ATE.

Weak Instruments and Weak Identification

The most common way of trying to achieve identification consists in imposing exclusion restrictions on the variables of a structural equation. In model (2), suppose that $\mathbf{y}_t$ and $\mathbf{x}_t$ are partitioned as $\mathbf{y}_t = \left(y_{1t}, \mathbf{y}_{2t}', \mathbf{y}_{3t}'\right)'$ and $\mathbf{x}_t = \left(\mathbf{x}_{1t}', \mathbf{x}_{2t}'\right)'$ where y_{1t} is a scalar, $\mathbf{y}_{it}$ has dimension $G_i (i = 2, 3)$ and $\boldsymbol{x}_{it}$ has dimension $K_i (i = 1, 2)$. If $\mathbf{y}_{3t}$ and $\mathbf{x}_{2t}$ are excluded from the first equation and the coefficient of y_{1t} is normalized to one, this yields an equation of the form:

$$y_{1t} + \mathbf{y}_{2t}'\beta_1 = \mathbf{x}_{1t}'\gamma_1 + u_{1t}, \quad t = 1, \ldots, n. \tag{16}$$

Let us also rewrite the reduced equation for $\mathbf{y}_{2t}$ in terms of $\mathbf{x}_{1t}$ and $\mathbf{x}_{2t}$:

$$\mathbf{y}_{2t} = \Pi_{21}\mathbf{x}_{1t} + \Pi_{22}\mathbf{x}_{2t} + \mathbf{v}_{2t}. \tag{17}$$

Then, substituting (17) into (16), we see that the reduced form for y_{1t} is:

$$y_{1t} = \Pi_{11}\mathbf{x}_{1t} + \Pi_{12}\mathbf{x}_{2t} + \mathbf{v}_{1t}, \tag{18}$$

where $\mathbf{v}_{1t} = u_{1t} + \mathbf{v}_{2t}'\beta_1$, $\Pi_{11} = \Upsilon_1' + \beta_1'\Pi_{21}$ and

$$\Pi_{12}' = \Pi_{22}'\beta_1. \tag{19}$$

Since γ_1 is free, Π_{11} is not restricted, but Eq. (19) determines the identifiability of β_1, hence also of γ_1. Provided Eq. (19) has a solution (that is, if Eq. (16) is consistent with the data), the solution is unique if and only if the rank of the $G_2 \times K_2$ matrix Π_{22} is equal to G_2, the dimension of β_1:

$$\text{rank}(\Pi_{22}) = G_2. \tag{20}$$

If $\text{rank}(\Pi_{22}) < G_2$, the vector β_1 is not identifiable. However, it is completely unidentifiable only if $\text{rank}(\Pi_{22}) = 0$, or equivalently if $\Pi_{22} = 0$. If $1 < \text{rank}(\Pi_{22}) < G_2$, some linear combinations $c'\beta_1$ are identifiable, but not all of them. Failure of the identification condition means that the regressors (or the 'instruments') $\mathbf{x}_{2t}$ do not move enough to separate the effects of the different variables in $\mathbf{y}_{2t}$. Condition (20) underscores two important things: first, exclusion and normalization restrictions – which are easy to check – are not sufficient to ensure identification; second, identification depends on the way the exogenous variables $\mathbf{x}_{2t}$ *excluded* from the structural equation of interest (16) are related to endogenous variables $\mathbf{y}_{2t}$ included in the equation. The latter feature is determined by the matrix Π_{22} whose rows should be linearly independent. Since Π_{22} is not observable, this may be difficult to determine in practice.

A situation that can lead to identification difficulties is the one where the identification condition (20) indeed holds, but, in some sense, Π_{22} is 'close' not to have sufficient rank. In such situations, we say that we have *weak instruments.* In view of the fact that the distributions of most statistics move continuously as functions of Π_{22}, the practical consequences of being close to identification failure are essentially the same. Assessing the closeness to non-identification may be done in various ways, for example by considering the eigenvalues of the matrices which measure the 'size' of Π_{22}, such as $\Pi_{22}\Pi'_{22}$, $\Pi_{22}X'_2M(X_1)X_2\Pi'_{22}$, or a *concentration matrix* $\sum_{22}^{-1/2}\Pi_{22}X'_2M(X_1)X_2\Pi'_{22}\sum_{22}^{-1/2}$ where $X_1 = [\mathbf{x}_{11}, \ldots, \mathbf{x}_{1n}]'$, $X_2 = [\mathbf{x}_{21}, \ldots, \mathbf{x}_{2n}]'$, $\sum_{22}$ is the covariance matrix of v_{2t}, $\sum_{22}^{-1/2}$ is its square root, and $M(X_1) = I_n - X_1\left(X'_1X_1\right)^{-1}X'_1$. More generally, any situation where a parameter may be difficult to determine because we are close to a case where a parameter ceases to be identifiable may be called *weak identification.* Weak identification was highlighted as a problem of practical interest by Nelson and Startz (1990), Bound et al. (1995), Dufour (1997), and Staiger and Stock (1997); for reviews, see Stock et al. (2002) and Dufour (2003).

Statistical Consequences of Identification Failure

Identification failure has several detrimental consequences for statistical analysis:

1. Parameter estimates, tests and confidence sets computed for unidentified parameters have no clear input; this situation may be especially misleading if the statistical instruments used do not reveal the presence of the problem.
2. Consistent estimation is not possible unless additional information is supplied.
3. Many standard distributional results used for inference on such models are not anymore valid, even with a large sample size (see Phillips 1983, 1989; Rothenberg 1984).
4. Numerical problems also easily appear, due for example to the need to invert (quasi) singular matrices.

Weak identification problems lead to similar difficulties, but may be more treacherous in the sense that standard asymptotic distributional may remain valid, but they constitute very bad approximations to what happens in finite samples:

1. Standard consistent estimators of structural parameters can be heavily biased and follow distributions whose form is far from the limiting Gaussian distribution, such as bimodal distributions, even with fairly large samples (Nelson and Startz 1990; Hillier 1990; Buse 1992).
2. Standard tests and confidence sets, such as Wald-type procedures based on estimated standard errors, become highly unreliable or completely invalid (Dufour 1997).

A striking illustration of these problems appears in the reconsideration by Bound et al.

(1995) of a study on returns to education by Angrist and Krueger (1991). Using 329,000 observations, these authors found that replacing the instruments used by Angrist and Krueger (1991) with randomly generated (totally irrelevant) instruments produced very similar point estimates and standard errors.

This result indicates that the original instruments were weak. Recent work in this area is reviewed in Stock et al. (2002) and Dufour (2003).

Concluding Remarks

The study of identifiability is undertaken in order to explore the limitations of statistical inference (when working with economic data) or to specify what sort of a priori information is needed to make a model estimable. It is a fundamental problem concomitant with the existence of a structure. Logically it precedes all problems of estimation or of testing hypotheses.

An important point that arises in the study of identification is that without a priori restrictions imposed by economic theory it would be almost impossible to estimate economic relationships. In fact, Liu (1960) and Sims (1980) have argued that economic relations are not identifiable because the world is so interdependent as to have almost all variables appearing in every equation, thus violating the necessary condition for identification. However, almost all the models we discuss in econometrics are only approximate. We use convenient formulations which behave in a general way that corresponds to our economic theories and intuitions, and which cannot be rejected by the available data. In this sense, identification is a property of the model but not necessarily of the real world. It is also important to be careful about situations where identification almost does not hold (weak identification), since these are in practice as damaging for statistical analysis as identification failure itself.

The problem of identification arises in a number of different fields such as automatic control, biomedical engineering, psychology, systems science, and so on, where the underlying physical structure may be deterministic (for example, see Aström and Eykhoff 1971). It is also aptly linked to the design of experiments (for example, Kempthorne 1947; Bailey et al. 1977). Here, we restrict our discussion to economic applications of statistical identifiability involving random variables.

A person's *identity* is broadly defined as a person's self-image or sense of self. The concept of identity has wide use in most social sciences outside economics, especially sociology, anthropology and psychology. Many social scientists hold that preserving or enhancing identity is a prime motivation for individual and group behaviour. At the time of this writing, economists are beginning to explore the implications of identity for economic outcomes.

To do so, researchers primarily include identity as an aspect of utility. In this view, a person's actions and consumption of goods and services not only affect their material well-being, but also their psychological well-being. Researchers then ask how the inclusion of identity in utility can affect economic outcomes, such as charitable contributions (Bénabou and Tirole 2006), information acquisition (Kőszegi 2006), schooling rates (Akerlof and Kranton 2002), and the design of workplace incentives (Akerlof and Kranton 2005).

We can divide the economic research on identity into two strands. The first considers an individual's self-image, as in Bénabou and Tirole (2005) and Kőszegi (2006). The second considers an individual's self-image as it relates to societal norms and ideals (Akerlof and Kranton 2000, 2002, 2005).

The first strand of research explores the simple proposition that people like to feel good about themselves. There are then trade-offs between standard economic costs and benefits, and the costs and benefits for one's own self-image. Kőszegi (2006) uses such a utility function to explain why people may not undertake profitable investment projects, as the downside payoffs also reduce a person's sense of his own abilities. Bénabou and Tirole (2005) use identity to explain why monetary compensation can reduce the levels of pro-social activities (such as volunteer work and blood donations), as found in several studies and experimental work. They posit a utility function where an individual's action yields a monetary payoff and an 'intrinsic' payoff. Individuals can have different valuations/preferences for the monetary payoff and the intrinsic payoff. Individuals like to think of themselves as placing, and like to think others think they place, high values on intrinsic payoff. That is, they want to think of themselves as enjoying the pro-social action for its own sake. But preferences are not observable, perhaps even to oneself. As individuals choose different actions, they and others make inferences about preferences. Hence, actions serve as 'self-signal' and a signal to others. The main results concern the trade-off between monetary payoffs and the signalling value of an action. When the

monetary compensation for an action increases, the signal conveys less information about a person's underlying value for intrinsic payoffs. Hence, introducing monetary rewards can lower the levels of pro-social activity.

The second strand of research considers identity and norms. Sen (1985) and Elster (1989) were among the earliest proponents of the importance for economics of utility-based norms. Akerlof and Kranton (2000, 2002, 2005) relate a person's self-image to societal norms and ideals for different people in society. Whether or not a person feels good about herself depends on how that person *should* act, according to her place in society. Thus, to take the most obvious example, men are supposed to act differently from women, and identity utility will depend on the match between a person's actions and these gender norms. This notion of identity reflects a large body of research on 'social identity' in psychology, reviewed in Haslam (2001). Philosophy has also been another important influence on the connection between identity and norms, especially for Elster (1989) and Sen (1985).

Akerlof and Kranton (2000) posits the following utility function for an individual j:

$$U_j(a_j, a_{-j}, I_j)$$

where a_j are j's actions, a_{-j} are others' actions, and I_j is j's 'identity utility' which is itself a function:

$$I_j(a_j, a_{-j}; c_j, \varepsilon_j, N)$$

where c_j denotes j's *social category*, N denotes the norms of behaviour and ideal attributes for different social categories, and ε_j denotes j's own attributes. The inclusion of others' actions allows for identity externalities. In the simplest case, an individual j chooses actions a_j to maximize utility U, taking as given c_j, ε_j, and N and the actions of others. In some applications, individuals may also choose the category assignment c_j, as social categories may be more or less ascriptive. Individual actions may also affect the norms, N, the set of social categories, C, as well as the status of different categories reflected in $I_j(\cdot)$. With respect to gender, for example, the women's movement strived to reduce status differences between men and women and change prescribed behaviour. Gender categories themselves have become varied and complex over time. There may be no universal agreement about social categories and prescriptions. Indeed, they are the subject of much debate and controversy and the source of new externalities.

This utility function highlights a different motivation for behaviour from a standard model, and shows how social identity can affect economic outcomes. For example, in the workplace different workers may feel more or less part of an organization (*insiders* versus *outsiders*), and work incentives will depend on norms for these different categories of workers. This utility function has implications for supervisory and management policy, as in Akerlof and Kranton (2005). A firm could choose a strict supervisory policy where a supervisor reports to upper management on workers' behaviour. This policy yields greater information, but can lead to workers adopting an *outsider* identity, with lower work norms. A looser supervisory policy yields less information to management, but workers develop a work group identity with possibly higher work norms. We use our utility function to explore the implications of identity in other realms, including race and poverty (Akerlof and Kranton 2000), gender in the labour market (Akerlof and Kranton 2000), and schools, student identity and education (Akerlof and Kranton 2002).

Ideology

Kurt Klappholz

Now and then one comes across the claim that, unlike, for example, physics, 'economics is thoroughly permeated by ideology . . .' (Ward 1979, p. viii). The exact import of this claim regarding the epistemological status of economics is not clear, since the noun 'ideology' is employed in a variety of senses. However, it should be stressed at once that, despite occasional criticisms (e.g. McCloskey 1983, p. 334), most economists long ago accepted Hume's insistence that policy proposals cannot be deduced from descriptive statements alone (Klappholz 1964) and have therefore stressed the distinction between positive and normative economics. The claim discussed in this essay appears to be directed at both the positive, as well as the normative, parts of economics, but we shall be concerned mainly with its import for positive economics. In section I we interpret the claim that economics is ideological as the view that economic theories can be explained by the social position and attitudes of those who put them forward, that is, by the Sociology of Knowledge (discussed critically in Popper 1957, chs 23 and 24). In section II we consider the suggestion that ideology is pseudo-science. In section III we consider it as consisting of non-scientific views. Finally, in section IV, we draw on the preceding discussion to appraise the claim that economists' policy proposals are ideological.

I. The pursuit of scientific research is a social activity, and thus must have a sociological dimension. In an epistemological and methodological context, however, interest centres, not on the sociological aspects, but on how to appraise scientific theories. In that context any explanation, even a successful one, of how people's social position causes them to hold certain views and beliefs does not imply anything about the truth of those beliefs (Popper 1959, pp. 31–2). To see this, consider the proposition, sometimes called 'the principle of sociologism', that *all* theories are ideological. It is sometimes argued (e.g. Popper 1957, notes 7 and 8 to ch. 24, pp. 353–6) that this proposition implies the contradictory view 'all statements are false', but this may not be the case. It is sufficient to make the more modest inference that all theories are equally arbitrary. But if all theories are ideological, then so is this claim about all theories. Hence this particular theory of ideology is arbitrary, and must be rejected if the idea of objective truth is to be retained. Indeed, this is implicitly conceded when physics is deemed not to be ideological. It then follows that the socio-psychological motives which may induce people to advance certain factual views cannot imply anything about the truth of those views. To suppose the contrary is to commit the genetic fallacy, the fallacy that the truth of statements is decidable on the basis of their originators' motives in uttering them and, perhaps, believing them to be true (Rosenberg 1976, pp. 202–3). Of course, if it could be shown that economists' adherence to particular theories is conditioned by their social position, or other extraneous factors, and is unrelated to logical and empirical considerations, their methods would indeed be unscientific. Attempts to show this can be found (e.g. Wiles 1979–80), but they cannot be appraised here. Mention must be made of an idea related to, but not identical with, the

view that all theories are ideological. This view asserts that people can communicate successfully, even within a given subject such as economics, only if they share a common intellectual framework. Sir Karl Popper styled this view 'The Myth of the Framework' (1976). If this view were true, it would imply, for example, that supporters of the rational expectations, market-clearing paradigm of the functioning of a market economy could not communicate successfully with those economists who do not work within that paradigm. A glance at the professional literature shows that the view is false.

II. We saw that, if we use 'ideological' in the sense of section I, we must reject the statement, 'all statements are ideological'. This nevertheless leaves open the possibility that economics itself consists of statements which express 'biased' (i.e. false) views, although whether they *are* false is not decidable on the grounds of their originators' psychological motives, or social position. Without committing the genetic fallacy, writers who think of economics as 'impregnated with ideology' have suggested that ideological utterances be regarded as pseudo-scientific.

One suggestion is that 'ideological statements . . . be . . . defined as value judgments parading as statements of facts' (reported by Blaug 1980, p. 138), i.e. as *covert* prescriptions, all the more suspect, since they are supposedly motivated by attempts to promote some 'class interest' (Rosenberg 1976, pp. 203–4, examines this claim). It has been suggested that economics does, or must, consist only of such ideological pseudo-statements, and therefore cannot be scientific (a suggestion criticized in Klappholz 1964). No doubt a careless reader could mistake disguised value judgements for factual statements, but this possibility is a subject for psychological, rather than methodological, consideration, despite occasional suggestions to the contrary (e.g. Blaug 1980, p. 138).

Turning to statements which are descriptive, i.e. have a truth value, the following are among other suggested jointly sufficient conditions for economic statements to be ideological, i.e. pseudo-scientific: (a) that they be false; (b) that they support a given political philosophy, or be convenient for those with an interest in perpetuating some political or social order; (c) that the given political philosophy, or the convenience of the belief, be the cause of the false statements being believed (Mingat et al. 1985, pp. 353–5 and Rosenberg 1976, pp. 204–9, critically discuss these characterizations).

The philosophic problem of demarcating scientific from other kinds of discourse cannot be discussed here. It must suffice to point out that the above characterizations would render (a set of) statements pseudo-scientific if one subscribed to the epistemological view that 'true science' consists of statements known to be true by being logically derived from facts (Lakatos 1978, ch. 1). Few, if any, philosophers subscribe to this infallibilistic view of science and, in its absence, the above characterizations do not render statements pseudo-scientific (although, as noted above, (c) alone would not be a methologically satisfactory reason for an economist to support a theory). Thus, if statements are judged ideological, not because they are false, but because they are possibly false, then one could not say they are pseudo-scientific, since all scientific theories are possibly false. Again, if a universal theory is viewed as ideological because it is regarded as false, for example, as is Newton's theory, but at the same time is accepted for certain technological purposes (Klappholz and Agassi 1959, pp. 31–3), it is still not pseudo-scientific. Indeed, if such theories are regarded as pseudo-scientific, the view of ideology considered here leads to the no doubt unintended, but nevertheless absurd consequence that the available stock of pseudo-science increases with scientific progress. References to the 'convenience' of certain views, i.e. to (b), as alleged explanations of why supposedly false theories are believed, i.e. to (c), direct criticism towards individuals' conscious or unconscious motives, in

the spirit of the Sociology of Knowledge, rather than to the objective scientific issues.

So far we have discussed the possible or actual falsity of theories. Theories are falsified if observations come to light which are in conflict with them. These observations are reported in what have been called basic statements (Popper 1959, chs IV, V), i.e. statements the acceptance of which does not give rise to controversy.

For example, economists advance theories about the determinants of unemployment. These theories might be thought to be testable with the help of observations of unemployment, which, for example, lead to observation reports such as 'the level of unemployment in the UK in March 1985 was 13.3 per cent or 3.2 million people'. This is not an explanatory statement and therefore, presumably, not pseudo-scientific. However, as is well known, it is also not a basic statement, since it is controversial. Controversy is aroused, not only because the statement raises problems of statistical interpretation, but also theoretical problems, such as the observations which would be needed to measure the extent of involuntary unemployment (although, given the way unemployment is measured, large changes in the measured figures have led economists to reconsider their theories of unemployment). This is merely an example of some of the well-known problems encountered in attempts to test economic theories. Therefore, these theories are not obviously false, as seems to be required of a theory if it is to be ideological in the sense of the present Section. However, this discussion suggests that economics contains factual theories which may not be scientific, i.e. testable.

III. Factual theories which are not scientific – rather than pseudo-scientific – have been called ideological (e.g. Schumpeter 1949; Robinson 1962.) If one does not view scientific theories as consisting of statements known infallibly to be true, but rather as tentative hypotheses, which can be revised in the light of new evidence, then one can easily think of statements which are not scientific, but which nevertheless play a role in discussions of economic theories. Here we are referring to metaphysical statements, as well as to expressions of belief regarding the truth of competing theories among which do decisions can be made on the basis of tests.

Some economic theories may be testable (for example, the appearance of stagflation must be regarded as an anomaly for *all* previous economic theories that are relevant to the subject). However, many appear not to be testable. For instance, it has been held that general equilibrium theories are not testable (e.g. Hausman 1981). This consideration may account for Friedman's well-known remark that reports of the corroboration of some economic theories he endorsed are 'hard to document' (Friedman 1953, p. 22). Indeed, it has been argued that, since economic data are derived from situations which cannot be controlled for disturbing factors, statistical inference is possible only on the basis of *prior* beliefs, the differences among which cannot be objectively justified (Leamer 1983).

Where theoretical conflicts of views cannot be resolved by available evidence, it is possible to suspend judgement. However, those engaged in research need to choose a programme, that is, to judge which theory is most likely to offer the best prospects for scientific progress. This choice may be influenced by people's Weltanschauung and preferences, in short, their ideologies. In this respect the situation in economics does not seem to differ from that in other sciences, and the mere fact that ideology, in the sense of the present section, may play a part in discussions of economic theory need not give rise to 'concern for [its] conceptual status' (Rosenberg 1976, p. 202). Concern may be expressed with good reason if and when unwarranted claims to scientific knowledge are made.

IV. Historically, the charge of 'ideological bias' has been directed especially at economists' views on desirable economic policies, as suggested by remarks that economists have tended to 'justify the ways of Mammon to

men' (Robinson 1962, p. 25). We now consider this issue in the light of the preceding discussion.

It was noted above that policy recommendations cannot be deduced solely from economic theory: in addition, some value, i.e. non-scientific, premises are required. The Paretian value premise, widely adopted by economists, reflects an individualistic political philosophy and may be regarded as ideological (Klappholz 1968).

Apart from adopting the Paretian value premise, economists have advocated policies which show a preference for organizing economic activities through markets (Kearl et al. 1979). However, it is difficult to take seriously the view, referred to in sections I and II, that this stance is to be explained by those economists' 'position in the social structure' or by their 'interest in perpetuating the system'. If the preference for market-organized economic activity is less marked among, for example, sociologists, wherein lies the difference in their social position, or their interest in perpetuating the system, compared to that of economists? Thus, it is more plausible to suppose that economists' preference for markets has been shaped by the dominant paradigm of the invisible hand, and by the fact that there is the most widespread professional consensus on the consequences of overriding markets, by, for example, such policies as rent control.

It was noted that, where theoretical differences cannot be resolved, judgement may be suspended. In the case of policy, policy makers and their advisers cannot suspend judgement, since decisions cannot be avoided, even if the implicit decision is to take no action. Assuming no well-grounded consensus regarding the consequences of alternative courses of action, it seems plausible that ideological views will influence judgements on the most likely consequences, thus influencing decisions, quite apart from the value premises which are logically indispensable for reaching them. In general, there seems to be less consensus regarding the effects of policies in the area of economics than in policies based mainly on the natural sciences, although lack of consensus in the latter case is not unknown. Thus, not surprisingly, there is more scope for ideological influence in decisions about economic policy.

However, given the absence of consensus, and the relevance of economics to public policy, differences in ideological views, (be they differences in value judgements or differences in beliefs about the outcome of policies) can be viewed as part of the mechanism of the public aspect of scientific activity which promotes criticism and, through it, may help us to learn more about the issues at hand. Those for, and those against, a given policy *all* may have an ideologically based incentive to try to show, as objectively as possible, the practical consequences any given policy will have. This view is opposed to the conventional wisdom, according to which ideology is a 'Weltanschauung felt passionately *and defended unscrupulously'* (Wiles 1978–80, p. 61, italics added). Ideological views need not lead to dogmatism, or to lack of scruples, and there is, in any case, no way of ensuring the absence of dogmatic people. All one can do is to shun discussion with them.

Illicit Drugs, Retail Market

Manolis Galenianos

Abstract

Three key features of the retail trade for illicit drugs are documented: moral hazard, repeated interactions and price dispersion. An interpretation of this evidence based on search and informational frictions is presented. Various policy implications of the suggested interpretation are discussed.

Keywords

Drugs; Cocaine; Heroin; Informational friction; Narcotics

Introduction

In addition to being illegal, the retail trade for narcotics is subject to severe moral hazard. Moral hazard results from the ease with which a seller can covertly dilute ('cut') the product, while the illegality of trade prevents the emergence of institutions that solve similar informational problems in legal markets (e.g. third-party certification, product guarantees, customer reviews). Nevertheless, the market for illicit drugs does operate, albeit in a very different way from the textbook Walrasian paradigm. The purpose of this article is to review the evidence about how this market operates, to discuss ways to interpret the evidence and to consider policy against the background of the suggested interpretation.

The Evidence

This section's evidence concerns the retail trade for heroin, crack cocaine and powder cocaine. Three central features of trade will be documented: moral hazard, repeated interactions and price dispersion.

The first feature is that retail transactions for illegal drugs are subject to moral hazard. Table 1, taken from Galenianos et al. (2009), is based on the **STRIDE** dataset of undercover Drug Enforcement Administration purchases and documents an extreme instance of the moral hazard – the *rip-off*, a transaction in which the buyer is sold essentially zero-purity drugs. A significant fraction of 'street-

Illicit Drugs, Retail Market, Table 1 Rip-offs in trades with value <= $100 in 1983 dollars

Drug	Average purity	Percentage of all trades that are rip-offs (i.e., <= 2% purity)	Average price of rip-offs (std. dev. of price)	Average price of non rip-offs (std. dev. of price)
Heroin	31%	10.3%	$53 (22.8)	$57 (20.6)
$N = 12{,}716$				
Crack	68%	7.8%	$32 (21.3)	$38 (24.6)
$N = 16{,}202$				
Cocaine	54%	5.1%	$35 (21.8)	$53 (25.8)
$N = 5{,}362$				

level' transactions are seen to be total rip-offs. Most important, the price paid in a rip-off is not appreciably different from that of a non-rip-off transaction, suggesting that buyers cannot observe dilution.

The practice of selling drugs in branded bags ('dope stamps') is further corroborating evidence of a quality problem in the illicit drugs trade. Wendel and Curtis (2000) describe the usage of dope stamps in New York City in a very interesting ethnographic study. The purported effect of a dope stamp is quality certification. The stamps could be boasts of quality ('America's Choice', 'Dynamite'), status brands ('Dom Perignon', 'Gucci') or even corporate names ('Exxon'). However, because they can be faked by 'unscrupulous' competitors, the certification value of a dope stamp is limited and short-lived (a couple of days, often). It therefore seems clear that dope stamps do not solve the quality certification problem.

The prevalence of long-term relationships is the second key feature of the drugs trade. The Table 2 provides direct evidence as to the prevalence of repeated interactions from the ADAM dataset. The data is based on voluntary interviews with a random sample of arrestees who self-report their drug habits. Conditional on purchasing drugs, the respondents report engaging in multiple transactions during the previous month, but use only a small number of suppliers.

The process by which buyers manage, over time, to hook up with a seller with whom they develop a long-term relationship is described in the ethnographic study by Hoffer (2005). However, not all sellers need have repeat business. The ethnographic literature reports on sellers who specialise in selling rip-offs. Hamid (1992) refers to these sellers as 'zoomers', a street expression due to the practice of selling bogus drugs and then disappearing.

Illicit Drugs, Retail Market, Table 2 Repeated transactions

Previous month	Heroin $N = 3{,}249$	Crack $N = 8{,}321$	Cocaine $N = 4{,}302$
Average number of purchases	18.7	13.2	7.2
Average number of suppliers used	2.7	3.3	1.8

The market's third feature is the very substantial dispersion in the price/quality ratio. Price dispersion in the drugs market is documented in Reuter and Caulkins (2004), where it is shown to be several times higher than that observed in markets for licit goods. Table 3 (reproduced from Galenianos et al. 2009) shows that there is substantial variation in the amount of pure drugs that can be had for $100. Additionally, it shows that dispersion occurs mostly within a location and time unit and hence is not due to time or local price variation.

Models and Policy

There is an extensive literature that focuses on the *demand* for illicit drugs, discussing the role of harmful addiction, rationality and discounting (Becker and Murphy 1988). Formal theoretical models of the *market structure* are tied to

Illicit Drugs, Retail Market, Table 3 Price dispersion

Drug	Sample cities with => 400 obs.	Mean pure grams per $100	Standard deviation	Coefficient of variation
Heroin	Full	0.38	0.58	1.45
$N = 19{,}072$	w/o city-year fixed effect	0	0.47	1.24
Crack	Full	1.73	1.49	0.86
$N = 20{,}262$	w/o city-year fixed effect	0	1.32	0.76
Cocaine	Full	2.14	1.98	0.93
$N = 18{,}862$	w/o city-year fixed effect	0	1.59	0.74

traditional economic assumptions of perfect information and centralised markets (e.g. Becker et al. 2006). Within that framework, all types of enforcement at all levels of the supply chain are generally lumped together and modelled as a 'cost of doing business' for the dealer. However, these assumptions abstract from important features of the market by ignoring the choice of purity (moral hazard) and search costs.

An alternative approach is to explicitly model the search and informational frictions that are present in this market. Galenianos et al. (2009) develop an equilibrium search model of repeated trade with unobservable quality. In that model consumers of drugs engage in costly search for sellers and the level of purity is chosen by each seller. A key assumption is that buyers can only determine the quality of drugs *after* the trade is consummated, which distinguishes this model from Burdett and Mortensen (1998), its counterpart from the labour search literature. The focus of the analysis is on determining the level of quality that will be traded for a given amount of money, that is, the *affordability* of (high-quality) drugs in equilibrium.

The informational frictions lead to severe quality problems, putting the market at risk of collapse. Indeed, the incentives for opportunistic behaviour by sellers are only mitigated by the possibility of forming long-term relationships with buyers: a seller who wants to keep a customer will not rip him off and, as a result, moral hazard does not necessarily foreclose the possibility of trade. In equilibrium, some sellers will offer good quality to increase their sales; others, however, will specialise in ripping off their customers. Introducing moral hazard, therefore, goes a long way towards accounting for the key stylised facts presented above: the mass of sellers who cheat their customers by providing zero-purity drugs, the importance of long-term relationships and the wide dispersion in the price/quality ratio.

In evaluating policy, the conventional view is rather generic: tougher penalties and more law enforcement, at any level of the supply chain, should help reduce the affordability of drugs. In fact, there is little evidence that recent efforts to increase penalties and law enforcement have measurably reduced the availability of drugs. The price of a pure gram of cocaine or heroin has declined substantially during the periods when budgets on law enforcement rose and penalties increased (Caulkins et al. 2004). In Galenianos et al. (2009) different enforcement instruments can impact the retail affordability of drugs in complex and sometimes counterintuitive ways. For example, to the extent that police enforcement makes it more risky for buyers to search for new sellers, the long-term relationship between buyers and sellers is strengthened, which in turn alleviates moral hazard and expands the possibility of trade. These findings highlight the need for developing models that are tailored to the characteristics of the market before evaluating policy.

Finally, at a somewhat more speculative level, the analysis in Galenianos et al. (2009) suggests alternative channels to suppress the market. If it is

true that the market is undermined by moral hazard then economic theory suggests *leveraging the moral hazard*, i.e. inducing sellers to *dilute more*. Within the model, a policy of reducing the sentences of sellers who sell low-purity drugs leads to an increase in 'cheating' and hence an increase in the average price of a pure gram of drugs. In addition, this is accomplished by actually reducing incarceration rates relative to current levels, thus simultaneously achieving two seemingly contradictory desiderata.

Immigration and the City

Anna Hardman

Abstract

At the end of the 20th century, international migrants, legal and undocumented, were a highly visible and economically significant feature of major cities in high- and middle-income countries, including the United States. As numbers of immigrants rose, many were concentrated spatially in a small number of cities ('ports of entry') and within those cities in ethnically homogeneous neighbourhoods, enclaves or ghettos. An extensive literature documents the impact of immigrants on host cities, examines their patterns of assimilation and explores their interactions with native-born populations and previous immigrants.

Keywords

Economies of agglomeration; Ghettoes; Housing markets; Information sharing; Internal migration; International migration; Labour market discrimination; Migrants in cities; Neighbourhoods; Network externalities; Residential assimilation; Residential segregation; Selection bias and self-selection; Spatial correlation; Urban agglomeration; Urban economics

At the end of the 20th century, international migrants, legal and undocumented, were again a highly visible and economically significant feature of major cities in high- and middle-income countries, including the United States. As numbers of immigrants rose, many were concentrated spatially in a small number of cities ('ports of entry') and within those cities in ethnically homogeneous neighbourhoods (enclaves or ghettos).

That was not a new phenomenon: in the 'first great migration' to the United States in the late 19th and early 20th centuries immigrants were highly concentrated and a highly visible feature of the largest cities. In 1870, the foreign-born constituted 35.6 per cent of the population of US cities over 100,000 and almost 50 per cent of the population of San Francisco and Chicago, though only 14.4 per cent of the national population. By 1940 the immigrant share had declined to 16.2 per cent of the population of cities over 100,000 and 8.8 per cent of the total population (Gibson and Lennon 1999, Tables 18 and 23).

In 15 Organisation for Economic Co-operation and Development (OECD) countries at the beginning of the 21st century the foreign-born made up between 8.3 and 32.6 per cent of the national population (Dumont and Lemaitre 2005, Table 1). In the United States in 2000, the foreign-born constituted 26.9 per cent of the population in the central cities of metropolitan areas with a population of five million or more and 16.2 per cent in the suburbs. In the cities of New York and Los Angeles the foreign-born made up 35.9 and 40.9 per cent of the population respectively. In the ten metropolitan areas with the largest immigrant populations the foreign-born were between 35 and 54.9 per cent of the population. The foreign-born were correspondingly rare outside large cities: less than four per cent of the population in metropolitan areas with a population of 500,000 or less and even rarer outside metropolitan areas (US Census of Population 2000). Similarly in the UK in 2001 8.3 per cent of the total population was born overseas. In the same year, the foreign- born were about 25 per cent of the London metropolitan area's total population, and were concentrated in a few neighbourhoods. For example, in Southall, Wembley, Hyde Park and Kensington, over 45 per cent of the population was foreign-born (National Statistics 2005; BBC News 2007).

As a result, whereas until the 1970s race and ethnicity were typically absent from analyses of urban economies (in Europe) or modelled as a black–white dichotomy (in the United States), by the mid-1980s economists had begun to explore the impact of immigrants from a wide range of source countries on cities beyond their effect on the wages and employment of natives. Urban economists have explored residential assimilation, looking at location choices, crowding and housing tenure and asked whether the location and housing consumption of immigrants relative to natives has differed because of selection, country of origin or changing make-up of successive cohorts of immigrants. The literature is dominated by studies of the United States both because of its rapidly growing immigrant population and because of micro (individual or household-level) and spatially disaggregated data on immigrant status, race and ancestry.

Immigrants are attracted to ports of entry or places with a stock of previous immigrants, because migration is path-dependent, because immigrants in enclaves benefit from *network externalities* and because immigrant enclaves offer *economies of agglomeration.* As a result, immigrants and particularly unskilled immigrants are less mobile within host societies than the native-born. The behaviour of the native- born in the host economy also drives spatial outcomes, both because of *discrimination* or avoidance of immigrants in labour and housing markets and because natives' location decisions across cities within a host country are more sensitive to wages than those of immigrants. There is evidence that the concentration of immigrants in ports of entry has led some US natives to leave gateway cities or to move to alternative destinations (Filer 1992).

Early empirical work on immigration and wages estimated the impact of immigration on the labour market using a cross-sectional 'spatial correlations' approach that compared wages over time in metropolitan areas with different proportions of immigrant stocks and flows. The spatial correlations approach generally found weak links at best between the immigrant share and the wages and on employment of natives, both in the USA (Borjas 1994) and more recently in the UK (Hatton and Tani 2005). If natives' location decisions are more sensitive to labour conditions than immigrants', then the observed wage impact of immigration is attenuated because it is dispersed across the whole economy rather than concentrated in the port of entry cities.

The impact of immigration on internal migration has been pursued by geographers and demographers (Wright et al. 1997; Kritz and Gurak 2001) with some expressing fear that the United States faced demographic or spatial 'balkanization' or the concentration of immigrants in a few cities shunned by natives (Frey 1995, 1996). However, in the United States immigrants' location patterns are changing. In the 1990s growing numbers of immigrants moved to urban and suburban areas remote from the traditional ports of entry. The immigrant population grew more rapidly in non-traditional destinations. For example, the US 2000 Census found that in ten metropolitan areas (with a median population of over 160,000) over two-thirds of the foreign-born population had entered the USA in the previous decade. The new immigrants were moving to metropolitan areas where only a median 4.55 per cent of the population was foreign-born by 2000. Some were in states without a recent tradition of immigration (Iowa, Indiana, North and South Dakota and Nebraska); others were in or close to states with a significant immigrant presence already (Arizona, Georgia, North Carolina and Tennessee).

A notable feature since 1985 is the increasing dispersion of Mexican immigrants, who for a long time were highly concentrated in Los Angeles and elsewhere in Southern California and Texas (Alba et al. 1999). That migration is also credited with changing the industry mix in destination regions (Card and Lewis 2007). Immigrants who move again within the USA have higher skills than other new immigrants. Moreover, migration beyond immigrant gateways and enclaves is associated with faster assimilation, although this is in part probably attributable to reverse causation since secondary migrants are self-selected (Zhang 2004, 2006).

In the absence of detailed information on the immediate spatial areas where immigrants live, most of the analysis of residential location, however, focuses on individuals. Immigrants often live in households with partners or family members who are natives or second- or third-generation immigrants. Household-level analysis of confidential Current Population Survey data for Los Angeles shows much greater dispersion of immigrants living in mixed households (Ellis and Wright 2005).

The urban economics literature on immigrants in cities has been concerned with 'residential assimilation': the progress of new immigrants towards parity with natives in housing tenure, consumption of housing and intra-city location, in or outside of ethnic enclaves (see, for example, Painter et al. 2001). While US immigrant homeownership rates are consistently lower than natives', they rise with age and years. Increases in the gap between natives and immigrants in homeownership rates between 1980 and 2000 are explained by differences in location decisions and by changes in the national origin mix of the immigrant population that are associated with lower skills and wages for the most recent immigrant waves (Borjas 2002).

In contrast to labour markets, where impacts of immigration on wages have been elusive, there is evidence that the arrival of immigrants raises metropolitan area housing prices and rents (Saiz 2003). Saiz and Wachter (2006) also find immigration associated with relatively slower house price appreciation in immigrant enclaves. The latter is attributed both to native avoidance and to low-income immigrants' preference for the cheapest housing.

Another facet of housing consumption and hence residential assimilation is residential 'crowding' (large numbers of occupants per dwelling or per room). Crowding increased in the USA in the 1980s and the 1990s, after decreases in every decade from 1940 to 1980; the increases were almost all in areas with large concentrations of immigrants. Cohort studies have found that immigrants initially choose higher densities, which decline with time in the United States for most ethnic groups with the exception of Hispanic immigrants (Myers and Lee 1996; Simmons 2002).

Economists have begun to explore the role of ethnic enclaves, neighbourhoods with a high concentration of immigrants, usually from the same source country or region. They are characterized by forces that parallel those that drive the formation of cities and concentrations of firms: shared

inputs (enclaves offer stores which provide ethnic foods, clothing, goods used both for consumption and for production by local firms); information-sharing as immigrants in enclaves benefit from news of job opportunities and learn skills essential in the job market and for everyday life in the host country; lastly, new and particularly unskilled immigrants as well as entrepreneurs in the enclave benefit from labour-market pooling in the enclave labour market.

Empirical studies of enclave economies provide evidence that immigrants value location near others from the same source country or region and that there are measurable economic benefits. Gonzalez (1998) estimated the implicit 'price of culture' using 1990 Census data for California and Texas, and found both lower earnings and higher rents for Mexican immigrants in enclaves with larger concentrations of Mexicans. Other studies find that immigrants within enclaves earn less than those outside, but a problem with such studies is that immigrants in enclaves are self-selected. A notable recent finding comes from Edin et al. (2003) who exploit a natural experiment in Sweden in which asylum- seekers and refugees were randomly assigned to different cities. They find evidence that selection bias leads to significant underestimates of the value of living in enclaves, with an earnings gain in the order of four to five per cent for migrants living in enclaves, compared with the earnings losses observed before correcting for selection.

JEL Classifications

F1

The theory of immiserizing growth has been developed by theorists of international trade, though it has recently been the focal point of research also by mathematical economists. It is central to understanding several important paradoxes in economic theory and has significant policy implications.

That growth in a country could immiserize it is a paradox that was first noted by trade theorists such as Bhagwati (1958) and Johnson (1955) in the context of the post-war discussions of dollar shortage. They established conditions under which, in a two-country, two-traded-goods framework of conventional theory, the growth-induced deterioration in the terms of trade would outweigh the primary gain from growth. It was shown that this paradox, unlike the paradox of donor-enriching and recipient-immiserizing transfers, was compatible with Walras-stability.

The phrase 'immiserizing growth' was invented by Bhagwati (1958) and has now been widely accepted (including by literary editors who have long ceased to insist on changing it to the correct English versions such as 'immiserating'), the theory itself being generally attributed (for example, Johnson 1967) to this 1958 article. Interestingly, as often in economics, Bhagwati happened to chance upon an early contribution by Edgeworth (1894), where Edgeworth developed an example of what he called 'indamnifying' growth; and the controversy surrounding this result at the time and its relationship to the Bhagwati–Johnson analyses of the 1950s was reviewed in Bhagwati and Johnson (1960).

Later, Johnson (1967) demonstrated another paradox of immiserizing growth. If a small country had a distortionary tariff in place, and then exogenously it experienced growth, the result again could be to immiserize the country. Later, Bertrand and Flatters (1971) and Martin (1977) established formally the conditions under which this new paradox of immiserizing growth could arise.

Bhagwati (1968) got to the bottom of these paradoxes and produced the central insight that explains why these, and other immiserizing-growth paradoxes, can readily arise. He showed that, if an economy was suboptimally organized, the primary gain from growth, measured

hypothetically as if the economy had an optimal policy in place before and after the growth, could be outweighed by accentuation of the loss from the distortion-induced suboptimality when growth occurred. In the original Bhagwati (1958) example, since the terms of trade could deteriorate, the economy had monopoly power in trade but was following free trade policy which is evidently suboptimal. In the Johnson (1967) example, the tariff was being used by a small country with given terms of trade and was therefore also a suboptimal policy. In both cases the suboptimal policy produced losses which were accentuated by the growth and then managed to outweigh the primary gains from growth that would have occurred if optimal policies were in place. The result was a powerful generalization that placed the theory of immiserizing growth squarely into the central theory of distortions and policy intervention (Srinivasan 1987) that lies at the core of the modern theory of trade and welfare. Evidently, immiserizing-growth paradoxes could arise only if there was a distortion present.

This central result has immediate implications. If an economy has a suboptimal money supply, growth could be immiserizing. If trade policy is highly distorted, growth could be immiserizing. The well-known results of trade theory, which show that free trade need not be welfare-improving relative to autarky (for example, Haberler 1950) under distortions are also seen as instances of immiserizing-growth theory; free trade augments the availability set relative to autarky, implying 'as-if' growth, and if distortions are present, then there is no surprise to the immiseration that free trade brings. Again, if a country uses tariffs to induce foreign investment (the so-called tariff-jumping investment that developing countries often used in the post-war period), such investment could immiserize the host country: this being a simple extension of the Johnson (1967) demonstration, argued to be relevant to analysis of developing countries in Bhagwati (1978), and analysed extensively in Bhagwati (1973), Brecher and Alejandro (1977), Hamada (1974), Minabe (1974), Uzawa (1969) and Brecher and Findlay (1983). Yet another important insight from the immiserizing-growth theory is that, in the new and growing theory of DUP (directly-unproductive profit-seeking) activities, which incorporates several quasi-political activities essentially into the corpus of economic theory, a DUP activity that wastes resources directly need not cause ultimate loss of welfare. This is because the waste may occur from a suboptimal situation, thus resulting in welfare-improvement paradoxically. This is the obverse of immiserizing growth: in one case, growth immiserizes; in the other, throwing away or wasting resources enriches. This is at the heart of the contention in Bhagwati (1980) that an exogenous tariff at t per cent may be welfare-superior to an endogenous tariff, procured by tariff-seeking lobbies that have diverted uses to such DUP activity, also at t per cent. Several such implications of the theory of immiserizing growth are discussed in Bhagwati and Srinivasan (1983, ch. 25).

Two further developments need to be cited. First, the dual of immiserizing growth, when such growth is due to factor accumulation, clearly yields negative shadow factor prices. This aspect is relevant to certain formulations in cost–benefit analysis; see, in particular, Findlay and Wellisz (1976), Diamond and Mirrlees (1976), Srinivasan and Bhagwati (1978), Bhagwati et al. (1978) and Mussa (1979).

Next, mathematical economists such as Aumann and Peleg (1974), and then Mas-Colell (1976) and Mantel (1984) among others, have rediscovered the original immiserizing-growth paradox, illustrating how economists working apart or in different traditions may rediscover one another's findings, often decades apart. A synthesis of the two literatures has been provided in Bhagwati et al. (1984). A complete and formal reconciliation of the conditions established in Bhagwati (1958) and in Mas-Colell (1976) and Mantel (1984) for the original immiserizing-growth paradox is provided by Hatta (1984).

Impatience

Larry G. Epstein

Impatience refers to the preference for earlier rather than later consumption an idea which stems from Böhm-Bawerk (1912) and Fisher (1930), among others. Preference orderings that exhibit impatience are also described as being myopic or as embodying discounting. Because in many contexts the future has no natural

termination date, an infinite horizon framework is most appropriate and convenient for the analysis of many problems in intertemporal economics. The open-endedness of the future raises several issues surrounding impatience (its presence, degree, and the precise form it takes) which do not arise in finite horizon models.

Consider a world with a countable infinity of time periods or generations, $t = 0, 1, \ldots, T, \ldots$, where there is a single good which can be consumed or accumulated. Let $x = (x_0, \ldots, x_t, \ldots)$ represent a consumption programme where x_t denotes the consumption of the representative consumer for the tth generation. Given an initial (capital) stock k_0 of the good, and a technology that transforms capital into a flow output, the set of feasible consumption programmes, denoted $S(k_0)$, is determined.

At issue is the optimal programme of consumption and accumulation. Suppose it is determined by a central planner who ranks programmes in $S(k_0)$ according to the utility functional

$$U(x) = \sum_0^\infty (1+\rho)^{-t} u(x_t). \tag{1}$$

This is a common specification. For $\rho = 0$ it dates from Ramsey (1928); for the general case see Koopmans (1966). The instantaneous utility function $u(\cdot)$ is increasing and concave (diminishing marginal utility).

The parameter ρ equals the rate of time preference. Impatience (in the sense of any of the precise definitions given below) is present if (and only if) $\rho > 0$. There is a preliminary technical problem with (1) for some values of ρ. When $\rho = 0$, for example, the infinite sum in (1) diverges for many of the paths to be compared. Ramsey provides one device for getting around this difficulty. Another device is von Weizsäcker's (1965) overtaking criterion, according to which x^* is *optimal* in $S(k_0)$ if it is feasible and if for any other feasible path x,

$$\sum_0^T (1+\rho)^{-t} u(x_t^*) \geq \sum_0^T (1+\rho)^{-t} u(x_t),$$

for all sufficiently large T. This notion of optimality is welldefined for any value of ρ, even for negative values; and an optimal x^* maximizes U on $S(k_0)$ if $U(x^*)$ is finite.

The specification of ρ is crucial and presumably reflects the ethical principles of the planner. Ramsey (1928) objects to discounting on ethical grounds and thus assumes $\rho = 0$. But Koopmans (1966, 1967) argues that there are technical limitations on the specification of ρ which are imposed by the requirement that an optimal plan x^* exist for a range of choice environments. The potential difficulty is readily understood: a positive return to saving provides an incentive to postpone consumption. Positive (negative) discounting provides an offsetting (reinforcing) incentive. Finally, diminishing marginal utility and diminishing marginal productivity in production induce a smoothing of consumption over time. For many specifications, the net incentive is to postpone and to do so idefinitely, which is clearly not optimal. Consequently an optimal programme fails to exist. The existence problem is mitigated the larger is ρ, in the sense that if $\rho_1 < \rho_2$ and if an optimum in $S(k_0)$ exists when $\rho = \rho_1$, then it exists also when $\rho = \rho_2$. In particular, in order that an optimum exist in several simplified but commonly specified choice environments, it is necessary that $\rho > 0$ and hence that the future be discounted. (See also von Weizsäcker 1965.)

The existence of solutions to optimization problems is a basic question in mathematical programming which is most commonly resolved by application of the Weierstrass Theorem (or its many extensions). The Theorem guarantees existence of a solution if the objective function is continuous and the constraint set is compact. It is valid in general topological spaces and so is applicable also to the present setting where the choice variable x lies in an infinite dimensional space. The Theorem is the basis for the proof by Magill (1981) of the existence of an optimum to infinite horizon optimization problems. When specialized to the constant discount rate functional (1), his analysis confirms the consequences for existence of large ρ. Moreover, it shows 'why' a large ρ is beneficial – the larger is ρ, the more stringent the

form of continuity satisfied by the utility functional and hence the broader the class of constraint sets to which the Weierstrass Theorem is applicable.

To pursue the link between impatience and continuity, it is necessary to consider the latter more carefully. First, however, restrict attention to bounded consumption profiles, that is, to the set

$$L_+^\infty = \{x = (x_0, \ldots, x_t, \ldots) : \quad x_t \geq 0 \text{ for all } t \text{ and } \sup x_t < \infty\}.$$

Secondly, the existence of a utility function is an unnecessarily restrictive assumption. Thus consider preference relations $\succcurlyeq$ on L_+^∞, with strict preference denoted by $\succ$.

To discuss continuity, we need to specify a topology for L_+^∞; that is, we need to define what it means for two consumption paths to be 'close' to one another. This is most simply done by specifying when a sequence of consumption paths $\{x^n = (x_0^n, x_1^n, \ldots, x_t^n, \ldots)\}_{n=1}^\infty$ *converges* to a path x in L_+^∞. (Strictly speaking, generalized sequences called nets should be used, but the use of sequences is adequate for this informal discussion.) *For* many topologies that are of interest in economics 'closeness' can be measured by a *metric* or distance function d such that $d(x, y)$ measures the 'distance' between x and y. When such a metric exists, convergence of $\{x^n\}$ to x means simply that $d(x^n, x)$ approaches 0 as $n \to \infty$, in which case we refer to the *d-convergence* of the sequence.

Table 1 defines four topologies by specifying the conditions for convergence imposed by each. When a metric exists, it is also specified. Of course many other plausible topologies could be considered.

Continuity of a preference relation means roughly that consumption paths that are close to one another are ranked similarly vis-a-vis other paths. More formally, say that the relation $\succcurlyeq$ is continuous in the topology Γ (or Γ-continuous) if for each x and y in $L^\infty{}_+$, and for any sequences $\{x^n\}$ and $\{y^n\}$ that converge to x and y respectively according to Γ, it is the case that

$$x \succ y \Rightarrow x \succ y^n \quad \text{and} \quad x^n \succ y$$

for all sufficiently large values of n.

Which topology should be adopted? The question does not arise in finite dimensional contexts. The reason is simply that all 'natural' topologies on finite dimensional Euclidean spaces are *equivalent* in the sense that the corresponding convergence definitions are logically equivalent to one another. This is the case, for example, with the four topologies in the table if they are adapted in the obvious way to a finite horizon context. In all cases, convergence is identical to the usual notion based on the Euclidean metric. Thus the corresponding notions of continuity are also identical.

In contrast, in the infinite horizon model, the noted equivalence fails. It is easily shown that

$$\begin{aligned} d_s - \text{convergence} \quad &\Rightarrow d_\infty - \text{convergence} \\ &\Rightarrow \text{Mackey} - \text{convergence} \\ &\Rightarrow d_p - \text{convergence}. \end{aligned} \tag{2}$$

But none of the reverse implications is true. For example, define the sequences $\{x^n\}$, $\{y^n\}$, and $\{z^n\}$ as follows:

Impatience, Table 1

Topology	Definition of convergence of $\{x^n\}$ to x	Metric
Product	$x_1^n \xrightarrow[n\to\infty]{} x_t$ for all t	$d_p(x,y) = \sup_t \dfrac{2^{-1}\lvert x_t - y_t\rvert}{\{1 + \lvert x_t - y_t\rvert\}}$
Mackey	$\sup_t \lvert a_t \cdot (x_t^n - x_t)\rvert \xrightarrow[n\to\infty]{} 0$ for all sequences of real numbers $\{a_t\}_0^\infty$ that converge to 0	—
Supremum	$\sup_t \lvert x_t^n - x_t\rvert \xrightarrow[n\to\infty]{} 0$	$d_\infty(x,y) = \sup_t \lvert x_t - y_t\rvert$
Svensson	$\sum_0^\infty \lvert x_t^n - x_t\rvert \xrightarrow[n\to\infty]{} 0$	$d_s(x,y) = \min\left(1, \sum_0^\infty \lvert x_t - y_t\rvert\right)$

$$x_t^n = 0 \quad \text{if} \quad 0 \le t \le n \quad \text{and} \quad = n \quad \text{if} \quad t > n$$
$$y_t^n = 0 \quad \text{if} \quad 0 \le t \le n \quad \text{and} \quad = 1 \quad \text{if} \quad t > n$$
$$z^n = (n^{-1}, n^{-t}, n^{-1}, \ldots).$$

Then $\{x^n\}$ converges to (0, 0,...) in the product topology but not in the Mackey topology. In the former case x^n is viewed as being close to the zero consumption path for large n, because the first n generations all have zero consumption. Thus the product topology discounts the fact that in x^n infinitely many generations enjoy large consumption levels which are unbounded as n grows. It is the latter feature which explains why x^n and (0, 0...) are not viewed as being close to one another by the Mackey topology. (Take $a_t = t^{-1/2}$ in the definition of Mackey convergence.) Thus, for example, in the case of $\{y^n\}$ where the consumption of future generations is bounded in n, the sequence is Mackey-convergent to the zero consumption path. The sequence $\{y^n\}$ is not d_∞-convergent since not all generations have consumption near 0. Finally, $\{z^n\}$ converges to (0, 0...) in the sup topology, but it is not d_s-convergent since the 'aggregate' deviation of consumption levels between the two paths is large (indeed $\Sigma_0^\infty |z_t^n| = \infty$).

When topologies are not equivalent continuity of a preference relation has different meaning depending upon which topology is adopted. Thus (2) implies immediately that

$$\begin{aligned} d_p - \text{continuity} \quad &\Rightarrow \text{Mackey} - \text{concergence} \\ &\Rightarrow d_\infty - \text{continuity} \\ &\Rightarrow d_s - \text{continuity}, \end{aligned} \tag{3}$$

and none of the reverse implications is valid. In finite dimensional analysis continuity is a purely technical assumption which is innocuous from an economist's point of view. But the discussion of convergence in the above four topologies strongly suggests that in infinite horizon models the specification of a topology and the assumption of continuity can have economic content. Indeed, continuity in some topologies can imply impatience.

One demonstration of the crucial role played by a topology is provided by Diamond (1965) and Svensson (1980). Call a preference relation *equitable* if it provides equal treatment for all generations in the sense that for all x and y in L_+^∞, $x \succcurlyeq y \Leftrightarrow x \succcurlyeq \pi y$, where πx (or πy) is obtained from x (or y) by permuting finitely many of its components. A preference relation is weakly monotonic if $x_t \succcurlyeq y_t$ for all $t \Rightarrow x \succcurlyeq y$. Diamond shows that there does not exist an equitable and weakly monotonic preference relation that is also continuous in the product metric. This preclusion of equity is perhaps not surprising given the discounting of the future that is built into the definition of d_p. But even given the apparently 'time neutral' metric d_∞, the scope for equity is limited. Diamond proves that equity and d_∞-continuity are incompatible given strong monotonicity ($x_t \ge y_t$ for all t and $x_\tau > y_\tau$ *for some* $\tau \Rightarrow x > y$.) If only weak monotonicity is imposed, then all postulates are satisfied by the maximin ordering, whereby

$$x \succcurlyeq y \Leftrightarrow \inf x_t \ge \inf y_t. \tag{4}$$

The view, based on finite dimensional analysis, that continuity is an innocuous technical assumption, would lead one to interpret Diamond's results as demonstrating the non-existence of equitable orderings that satisfy minimal additional regularity conditions. But, the correct interpretation is the Diamond's theorems demonstrate the strong ethical content of d_p-continuity and d_∞-continuity. The latter view is fortified by Svensson (1980). He shows that if the d_s metric is adopted, then there exist equitable and strongly monotonic orderings which are d_s-continuous. Since d_s is a priori plausible, the onus is clearly shifted to the metric. At the extreme, continuity can be imposed with total impunity if the metric d_0 is adopted, where

$$d_0(x, y) = \begin{bmatrix} 0, & \text{if} & x = y \\ 1, & \text{if} & x \ne y \end{bmatrix}.$$

The topology corresponding to d_0 is called the discrete topology. According to this metric

distinct consumption paths cannot be close to one another, so continuity is automatic. A natural open question is the characterization of metrics d (and more general topologies) such that d-continuous, equitable and (weakly or strongly) monotonic preference relations exist.

At this point it is worth recalling a principal reason that continuity is of interest – namely that by (an extension of) the Weierstrass Theorem, it will guarantee the existence of optimal elements in compact sets. Given a topology Γ on L_+^∞, a set $K \subset L_+^\infty$ is *Γ-compact* if every (generalized) sequence of points in K has a (generalized) subsequence that converges according to Γ to a point in K. As the topology changes in such a way as to permit more continuous functions, the family of compact sets shrinks (see (2) and (3)). Thus as continuity becomes easier to achieve it also becomes less significant. (For example, K is *d_0-compact only if it consists of finitely many points; and there exist many economically relevant sets K* that are compact in the product topology but not in the sup topology. One example arises in an exhaustible resource model where feasible consumptions plans satisfy $\Sigma_0^\infty x_t \leq w$, and w is the initial stock of the good.) If there is a class of constraint sets where the existence of optimal elements is desired, then the 'useful' topologies are those that make each of the constraint sets compact. This approach (emphasized by Campbell, 1985) would remove some of the arbitrariness from the choice of a topology.

Diamond's results suggest that continuity may imply 'some form of impatience', since equity can be viewed as the lack of impatience. A more precise definition of impatience is required for a clearer demonstration of the link between the latter and continuity. For example, impatience could be taken to mean that interchanging the consumption levels of generations 1 and t results in a strictly preferred plan if period t consumption was initially larger. If the preceding statement is valid only for t sufficiently far into the future, then *eventual impatience* could be said to prevail. This latter notion captures not only a preference for the advancement of the timing of satisfaction, but also the idea that the taste for future consumption diminishes as the time of consumption recedes into the future. These and related definitions appear in Koopmans (1960), Koopmans et al. (1964) and Diamond (1965). Their proofs that appropriate continuity implies (eventual) impatience depend, with the single exception of Diamond (p. 174), on maintained separability assumptions on the preference relation. The separability assumptions can be deleted if the existence of a differentiable utility function is assumed (Burness 1973).

Brown and Lewis (1981) define some notions of asymptotic impatience. For example, they call a preference relation *strongly myopic* if for all x, y and z in L_+^∞, $x \succ y \Rightarrow x \succ y + {}_nz$ for all sufficiently large n, where ${}_nz = (0,\ldots,0,z_{n+1}, z_{n+2}, \ldots)$. In other words, the preference for x over y is unchanged by an increase in the latter programme in the consumption of infinitely many generations, as long as the increase occurs only for generations that are situated sufficiently far into the future.

Interpret a preference relation as belonging to a consumer rather than to a central planner. Consumption programmes in L_+^∞ descendants; the latters' consumption levels matter because of intergenerational altruism. This is a common framework in the capital theory literature where the behavioural assumption of impatience is often maintained. This suggests that from the perspective of capital theory, economically interesting topologies are those which (through continuity) imply myopia. For example, any preference relation which is d_p-continuous is necessarily strongly myopic. But the implication is false if the product metric is replaced by d_∞ or d_s. Brown and Lewis show that the Mackey topology bears a special relationship to strong myopia. Mackey-continuity is the weakest continuity requirement (corresponding to topologies in a broad and convenient class) that can be imposed on a preference relation in order that strong myopia be implied. Thus it is a 'natural' topology if strong myopia is desirable.

There is an important link between the Mackey topology and strong myopia on the one hand and general equilibrium analysis in the framework of

'infinitely lived' agents on the other. Bewley (1972) points out that the Mackey topology is particularly appropriate for general equilibrium analysis because continuity requirements weaker than Mackey-continuity do not guarantee the existence of equilibria with price systems that can be represented by absolutely summable sequences $(p_0, \ldots, p_t, \ldots)$, rather than merely for more general mathematical constructs that have no economic interpretation. In light of the relationship between Mackey-continuity and strong myopia, the latter seems necessary for meaningful general equilibrium analysis.

Brown and Lewis sharpen the link between impatience and general equilibrium analysis. They prove that if individual preferences are suitably monotonic, then Mackey-continuity and strong myopia are unnecessarily strong assumptions. But a form of asymptotic impatience is still relevant. Call a preference ordering *weakly myopic* if the implication defining strong myopia is valid for all constant programmes z. Then even if individual preferences are weakly monotonic, the existence of economically interpretable equilibrium price systems as above can be guaranteed only by continuity requirements which imply weak myopia.

Suppose that we are willing to accept more general constructs (linear functionals on L_+^∞) as price systems. Can we then dispense with impatience? Araujo (1985) provides a negative partial answer. He restricts attention to a well-defined subset of those continuity conditions which lie 'between' d_∞-continuity and d_p-continuity. Then he shows that the existence of such general price systems can be guaranteed only if continuity requirements are imposed which imply strong myopia, or, when suitable monotonicity is maintained for preferences, weak myopia. Existence of equilibria cannot be guaranteed in such cases as the maximin ordering (4) which exhibits no impatience.

We offer one final comment. In a planning context, continuity of the social preference relation may be desirable not necessarily for its own sake nor because it may imply myopia, but primarily to guarantee that the preference relation be *effective*, that is, that optimal consumption paths exist. From this perspective, it seems more pertinent to investigate the link between effectiveness and impatience directly, without involving continuity which is, after all, at best sufficient and definitely not necessary for the existence of optimal paths. Thus, for example, a pertinent question is whether impatience (in some precise sense) is necessary for effectiveness in a relevant set of choice environments. While this question has been addressed to some extent in the growth theory literature cited earlier based on the additive utility functional (1), an analysis comparable in generality to that of Brown and Lewis or Araujo has yet to be performed.

Imperfect Competition

Louis Makowski

Imperfect competitors are individuals or firms who face downward-sloping demand curves or upward-sloping supply curves for some product (s). This is to be contrasted with perfect competitors who, by definition, face perfectly elastic demand and supply curves for all products. Notice we define perfect competitors not just as price-takers, but as rational price-takers: perfect competitors cannot influence the levels of market clearing prices. By contrast imperfect competitors, by their presence, can influence some equilibrium prices. As simple as these definitions sound, they hold within themselves a world of meaning that we will explore a little in this entry.

Since the early days of economics as a science, the importance of the force of competition has been stressed. Adam Smith viewed the force of competition as a central benefactor of society, which both (a) guards people against the possibility of monopolistic exploitation by insuring that the long run price will not exceed the cost of production; and (b) automatically provides for long-run progress by firing entrepreneurs' restless search for new profit potentials. In contrast to Smith, modern-day economists are becoming increasingly uncertain whether the force of competition is entirely beneficent. The image of wasteful competition between individuals and between firms is gaining repute. Theories of imperfect competition are becoming increasingly popular, reflecting a dissatisfaction with the predictive power of the perfectly competitive model of economic reality.

The insight that competition can be wasteful, not necessarily beneficent, was popularized by Edward Chamberlin, who along with Joan Robinson is typically credited with renewing economists' interest in imperfect competition beginning in the 1930s (Chamberlin 1933; Robinson 1933). As a contender to the perfectly competitive image of economic reality, Chamberlin offered his image of many firms selling differentiated products, contending with one another, but nevertheless each facing a downward-sloping demand curve. His famous 'excess capacity theorem' was the caricature he offered of wasteful competition.

As in Chamberlin, the current modelling of imperfect competition tends to be partial equilibrium. A popular practice is to make the assumption that firms will interact in a Cournot–Nash fashion. Perhaps more ambitious and interesting are current explorations at the interface of game theory and industrial organization theory. Many (small group) models of imperfectly competitive interactions are available, each with its own idiosyncratic, stylized features. These models are a beginning toward analysing imperfect competition between individuals and between firms as an active process. But there does not currently exist a standard paradigm of imperfect competition (either partial equilibrium or general equilibrium). This contrasts sharply with the case of perfect competition, which is typically idealized using a Walrasian general equilibrium model. Perhaps models of imperfect competition must necessarily be legion and case-specific?

We will not try to survey existent models of imperfect competition here. Rather, we will try to offer some overview in terms of a unifying principle. In particular, we will argue that *increasing returns* is the usual source of imperfect competition. Knowledge of such a unifying source will hopefully help the reader make sense of the plethora of available idiosyncratic models. It should also help the reader understand why imperfect competition, in contrast to perfect competition, may be wasteful.

The Meaning of Increasing Returns: From Perfect Competition to Imperfect Competition

To understand the concept of increasing returns, as applied to the economy as a whole (rather than to a particular firm), it is useful to first understand how economists usually ensure that a model of the economy as a whole will be *perfectly competitive*. This will provide us with a benchmark from which to proceed since, as we shall see, a perfectly competitive economy typically exhibits constant returns, in contrast to increasing returns. (The observation that constant returns typifies perfect competition is also central to Samuelson (1967). He proceeds in a somewhat different fashion, but his article may be read as a useful complement to this one.) To ensure that an economy will be perfectly competitive economists typically assume a finite number of homogeneous private goods. Then, keeping the set of goods fixed, they *replicate* the economy by increasing the number of buyers and sellers of each commodity indefinitely. The resulting, limiting economy will be perfectly competitive in the sense that the force of competition between the many alternative sellers of each commodity and the many alternative buyers will be sufficient to ensure that no one individual will possess any monopoly or monopsony power. That is, no one individual will be able to influence the levels of the prices that equilibrate supply and demand. For example, if some seller tries to exploit some buyer there will be plenty of perfect substitute sellers available ready to take the buyer away from him. Notice that the image of 'thick markets', i.e. homogeneous private goods with many small sellers and buyers of each good, is central to economists' image of perfect competition. It is this image of thick markets that Chamberlin found to be a grotesque caricature of our economic reality. It is easy to see that a large, replicated private-good economy exhibits constant returns to scale in the sense that a small subset of its participants could do as well on their own as they could participating in the economy as a whole. The economy can be 'disintegrated' without loss of consumers' surplus or gains from trade.

The analogy to ordinary production theory can be made more precise in an idealized special case, that of transferable utility – where utility can be regarded as cardinal and additive over individuals. (Notice this is essentially equivalent to assuming that everyone always enjoys constant marginal utility from income.) In this case, one can construct an analogy to an ordinary firm production function for the economy as a whole (a sort of 'aggregate production function'), and one can show that in the limit, replication will result in this function exhibiting constant returns. Further, in a perfectly competitive equilibrium all individuals will be rewarded with their marginal products to the economy as a whole, calculated from this 'aggregate production function'.

This idealized special case is useful for gaining parable-like insights into the nature of not only perfect competition, but also imperfect competition. So we shall first sketch some of the claims made for it above (for further details, see Makowski and Ostroy 1987). The basis for its usefulness is that, if we assume utility is cardinal and additive over individuals, then we can formalize the idea that the economy as a whole is in the business of producing *utility* for its participants. In particular, with this assumption we can let g(S) equal the total potential gains from trade possible in a subeconomy consisting only of the set of individuals S; i.e. g(S) equals the maximum total utility achievable by S when it can only trade within itself. Then we can regard g, the total potential gains from trade *function* (defined over all possible subeconomies S) as the economy's 'aggregate production function'. Notice that the range of g is defined in utility space: the economy as a whole produces utility as its output. And the domain of g is subsets of individuals: individuals are the 'inputs' used to produce utility, by exploiting the gains from trade. (In cooperative game theory, the g function would be called a 'characteristic function'. But we shall restrict our attention to non-cooperative, bilateral interactions; this may be rationalized by assuming that multilateral coalition formation is prohibitively costly.)

Just as with any production function, we can define the marginal product of each factor of

production – now each individual rather than each commodity since the domain of g is subsets of individuals. In particular, it is natural to define the potential marginal product of individual i to the economy as a whole, MP_i, as the difference between the potential gains from trade in the economy as a whole, $g(A)$ (where A is the set of all individuals) and the potential gains from trade in the absence of individual i, $g(A^i)$ (where A^i is the set of all individuals in the economy except i); i.e. $MP_i \equiv g(A) - g(A^i)$. Notice MP_i just equals individual i's contribution to the total potential gains from trade in the economy.

It can be shown that in any perfectly competitive economy, each individual's final utility level (say u_i) just equals his potential marginal product to the economy as a whole. That is, the total gains from trade are distributed under perfect competition that $u_i = MP_i$ for each individual i. Thus the analogy to ordinary production theory under perfect competition, where each factor earns its *MP*, is complete. Since any perfectly competitive equilibrium is efficient (i.e. the actual gains from trade equal the maximum potential gains), this implies there must be 'adding-up' in any perfectly competitive economy: the sum of all individuals' *MP*'s to the economy as a whole must equal the total potential product of the economy, g(A).

Constant returns and adding-up are intimately related. Both are achieved by replication as follows. Typically the above g function will initially exhibit increasing returns in the sense that the sum of all individuals' *MP*'s will exceed the total potential 'output'. But, for larger and large economies this sum approaches $g(A)$. The process is idealized in the limit – when we can regard individuals as infinitesimal, i.e. points on a line. In this limiting, continuum-of-individuals case the g function will be homogeneous: multiplying all 'inputs' by any factor will just multiply the total achievable gains from trade by the same factor. Hence, 'adding-up' in the limit is ensured by Euler's Theorem. (Individual i's potential marginal product in the limiting, continuum economy just equals the partial derivative of g with respect to that individual, evaluated at A, rather than the finite different $g(A) - g(A^i)$.)

Thus, the connection between replication, constant returns, and the nature of perfectly competitive economies is clarified. In particular, we now see that such economies exhibit, in the limit, constant returns *over* (the 'inputs') *individuals*. One deeper result from perfect competition theory will also be useful, before we leave this benchmark case for the domain of imperfect competition. It can be shown that not only does perfect competition imply

(i) $u_i = MP_i$ for each individual i; and (ii) $\Sigma MP_i = g(A)$, but conversely, (i) and (ii) also imply perfect competition. Thus, perfectly competitive economies are essentially *equivalent* to ones in which constant returns over individuals prevails. In the absence of such constant returns, we could not rely on Euler's Theorem to ensure adding-up, (ii); consequently, it would be a mere accident if one could reward everyone with their *MP*'s to the economy as a whole.

This last, equivalence observation provides us with a key for transiting into the realm of imperfect competition. Since the presence of constant returns over individuals essentially characterizes perfectly competitive economies, its absence essentially characterizes economies without perfect competition, i.e. economies in which competition must necessarily be *imperfect*. But under what circumstances will competition necessarily be imperfect? Or, expressed in terms of our idealized special case, under what circumstances will the g function not exhibit constant returns over individuals?

The replication image of perfect competition gives us our first insight into such imperfectly competitive economies. They are economies in which there are not sufficient perfect substitute sellers or buyers for the force of competition to ensure that no individual can influence the levels of market clearing prices. But what does this mean in terms of our gains from trade function? As noted above, in the absence of perfect competition (e.g., in small economies) the g function will typically exhibit *increasing returns* over individuals, in the sense that the sum of all individuals' *MP*'s will typically exceed the total potential gains from trade. To illustrate with a paradigmatic example of imperfect competition – bilateral

monopoly – consider an economy with just one buyer and one seller, and with potential gains from trade between them. Then each individual is *crucial* to realizing the gains from trade. In particular, without either there would be zero gains from trade, so the *MP* of *each* equals the total potential gains from trade, $g(A)$. But then the sum of their *MP*'s exceeds the total potential gains from trade since $\Sigma MP_i = g(A) + g(A) = 2\,g(A)$. So, there are increasing returns over individuals in bilateral monopoly situations. Obviously each person cannot appropriate all of $g(A)$.

That the sum of the two individuals' *MP*'s exceeds the potential gains from trade between them has the following interpretive significance. Imagine the buyer and seller contending with one another over their respective shares of the total economic pie, $g(A)$. Each might insist on receiving his full potential contribution to the size of the pie, his *MP*. But in cases of imperfect competition, this is impossible to achieve. (Note that, by contrast, under perfect competition each seller (respectively, buyer) receiving his full *MP* would be the *inevitable outcome of competition* between alternative competing buyers of the seller's output (respectively, alternative competing sellers to the buyer). The consequence in terms of prices is that under perfect competition no one buyer (respectively, seller) can influence the level of market clearing prices.) We might next imagine each individual engaging in devious bargaining tactics to win at least as much of the pie for himself as he can. Such manoeuvrings are generally resource costly, hence the whole size of the pie may well diminish in the process of bargaining for shares of it. This is the image of wasteful competition! Our story indicates how increasing returns over individuals, and the consequent failure of adding-up of individuals' *MP*'s to the economy as a whole, can give rise to wasteful competition. That the potential economic pie cannot be naturally imputed to individuals, via their contributions to the size of the pie (their *MP*'s), makes the potential gains from trade a common property resource to be contended over wastefully.

An Example of Wasteful Competition

To make the discussion more concrete, we now present a more explicit example involving bilateral monopoly. Imagine an economy with just one barber B and one customer, C. B can cut hair costlessly, and C is willing to pay up to w dollars for one haircut (he does not want more than one); hence $g(A) = w$ which, recall, also equals each individual's *MP*. Will the full potential gains from trade be realized?

Suppose at the beginning of the world nature picks C's willingness to pay for a haircut from a distribution between 0 and 10, so that any w in this interval is an equally likely choice by nature. Suppose further that Mr C knows his actual type, w, but Mr B only knows the distribution from which nature has picked C's type. Then bilateral bargaining will not generally result in all the potential gains from trade being realized. To see why suppose B is a tough bargainer and can commit himself to a take-it-or-leave-it price for a haircut.

Then, given his incomplete information about C's type, it is easy to see he will commit himself to a price of \$5/haircut; this maximizes his expected profits. But then, whenever C's true willingness to pay is less than \$5, he will not get a haircut although it is efficient for him to do so given B's cost of haircuts is zero; $g(A)$ will not be realized. For example, suppose $w =$ \$4, then although C may go to B and say 'I am willing to get a haircut if you will lower the price to something less than \$4,' B will rationally not believe him and change his price, since if he believed C in this case then C would rationally pretend to have a w less than \$5 even when his true w is greater than \$5.

Notice that the basic source of the inefficiency when $w <$ \$5 is the potential deviousness by C about his true willingness-to-pay – in an effort to induce a lower price and hence a bigger share of his full potential marginal product, w – coupled with B's contrary effort to extract the biggest possible share of *his* potential marginal product, w, by making a price commitment that reflects his ignorance about w. Summarizing, (wasteful)

competition between B and C over the potential gains from trade results in the actual gains, zero, falling short of the potential gains, *w*, whenever *w* $5. Wasteful competition is reflected in the *underproduction* of haircuts.

In contrast, notice that in a replicated economy with many identical B's and C's, (perfect) competition between barbers for customers would force the price of haircuts down to their true cost, zero. Hence, the full potential gains from trade would be realized without devious, wasteful competition. (The reader can check that in this replicated case the *MP* of any one barber equals zero while that of any one customer equals *w*; hence there is 'adding-up' in this case.)

The fact that imperfect competition is generally inefficient – it frustrates Adam Smith's Invisible Hand – is so central to our understanding of the economic import of imperfect competition that it is perhaps useful to re-phrase the source of market failure under imperfect competition in terms of 'externalities' since it is well-understood that externalities give rise to market failures. Under perfect competition each individual appropriates his full potential contribution to society, his *MP*. Consequently, he creates *no externalities*, beneficial or harmful, to others. By contrast, under imperfect competition not everyone can appropriate his full potential contribution to society, his MP. Consequently, if an equilibrium allocation with imperfect competition is to be efficient, some individual(s) must create external benefits *for others* (since some individuals must receive less than their marginal products). But no one cares about *external* benefits, only about the benefits he can internalize (i.e. appropriate). Consequently, in trying to internalize as much of his contribution as possible, an imperfect competitor will engage in wasteful market tactics most of whose harmful consequences others must bear.

Multilateral examples of imperfect competition, more in the spirit of Chamberlin, can also be constructed. In such examples, increasing returns lead to the gains from trade between producers and consumers being a common property resource that cannot be naturally imputed to agents using the *MP* reward principle. This can lead to 'excess capacity' as some industries' potential profits become a common property resource to be contended over wastefully via over-entry. In contrast, under perfect competition entry is efficiently guided since each firm's profits just reflect *its MP*; not any share of some other firm's potential *MP* that it can steal away by entering the industry.

Notice that throughout this article we are supposing there do not exist any non-market external effects between economic agents. So, all interactions are voluntary and involve exchange. But this does not exclude the possibility of external effects between economic agents in their trade relationships, so called 'pecuniary externalities'. Indeed, the possibility of such trade-related externalities is the essence of imperfectly competitive interactions and the source of the Invisible Hand's failure to achieve Pareto efficient outcomes under imperfect competition. (A terminological note: We refer to imperfect competition as 'wasteful' relative to the benchmark of achieving pure Pareto efficiency. A related question that we do not address in this entry is: Can one find institutions that could improve on the market outcome in the presence of imperfect competition? Some economists would argue that the answer is 'no'; hence that the market outcome provides the best *realistic* benchmark even in the presence of imperfect competition, for example see Demsetz 1959.)

Indivisibilities, Complementarities and Increasing Returns

There is a tradition in economic theory that views some sort of indivisibility as the main source of increasing returns. In this tradition, if just doubling the amounts of all factors results in more than double the output, the source of increasing returns is interpreted in terms of indivisibilities in some specialized functions of factors.

That indivisibilities are the usual source of increasing returns was disputed by Chamberlin in a famous controversy with Kaldor; the latter

subsequently recanted his position (see Kaldor 1972). Without clouding ourselves in the smoke raised by this issue, we can shed some light on the central substantive aspect. At the heart of the dispute is the question, will sufficiently large economies necessarily be perfectly competitive? (Notice that the idea of indivisibilities suggests that at some sufficiently large level of production all scale economies will be exhausted.) Thus it is interesting to observe that increasing returns can exist even in large economies.

In particular, *how* one replicates an economy is crucial to whether a replicated economy will become closer and closer to a perfectly competitive one. For perfect competition to result in the limit, (1) it is essential that one only allows private goods, not collective goods: replicating an economy with collective goods generally does not diminish the presence of monopsony power on the buyers' side since each buyer never competes with other buyers for units of a *collective* good. This monopsony power gives rise to manifestations of wasteful competition by each buyer – to try to appropriate the biggest possible share of his contribution to the gains from trade, his *MP* – such as 'free rider problems'.

(A bibliographical note: Samuelson introduced the concept of collective goods to Anglo-American economists in a series of articles (Samuelson 1954, 1955 and 1958). He forcefully argues that public goods differ fundamentally from private goods insofar as the ability of the Invisible Hand to allocate them efficiently is concerned. One can detect, in reading his three articles chronologically, a maturing in Samuelson's appreciation of the source of market failure as being due to some sort of increasing returns in public good economies. This point is made in Head (1962), whose article may be read as a useful complement to this one. Head stresses difficulties in appropriation as the source of market failure with collective goods, without explicitly using the MP concept.)

More in the spirit of Chamberlin, (2) it is also essential to keep the set of private commodities relatively fixed while one replicates: if the set of commodities expands at the same rate as the set of buyers and sellers, then perfect competition need not emerge even in the limit. Some sellers may still be 'special' as far as some buyers are concerned; thus a seller may still face a downward sloping demand curve reflecting the tastes of buyers who regard the seller's product as special (e.g., see Hart 1985). In this context, the right image of a large economy is an ever-expanding nexus of complementarities between individuals, that never becomes large enough to be 'disintegrated' without loss in potential gains from trade (Kaldor 1972, and Allyn Young's classic 1928 paper may be usefully read on this point). In this image the possibilities for increasing returns are never exhausted since essential complementarities between individuals are never exhausted. Notice that the reason for increasing returns here is more easily explained in terms of the existence of *complementarities* between individuals, rather than indivisibilities. Expressed in terms of our idealized special case, as long as there exist essential complementarities between individuals, the gains from trade function will continue to exhibit increasing returns *over individuals*. In this common case, the force of competition will not be sufficient to guarantee that everyone has perfect substitutes. Thus competition between individuals may remain imperfect – and wasteful – even in large economies.

Imperfectionist Models

John Eatwell

The term 'imperfectionist' was applied by Eatwell and Milgate (1983) to those models which rely on imperfections or arbitrary constraints in order to analyse the phenomenon under consideration. In other words, an imperfectionist analysis involves the construction of a model which, when innocent of those arbitrary constraints, does not display the phenomenon. The leading species of this genus to be found in economics today are models of unemployment in which imperfections such as sticky prices, or the effects of uncertainty, are imposed on a Walrasian model, thus disrupting the Walrasian relationship between price formation and the determination of levels of output which implies clearing of the markets for endowments of factor services.

The key issues in any consideration of the relationship between the theory of output and the theory of value and distribution can be revealed by the answers given to two questions:

(1) Does the determination of relative prices in a market economy also involve the determination of the size and composition of output and, in particular, is the level of output such that labour is fully employed (in the sense that at the going wage all workers willing to offer labour would be able to find employment)?
(2) Are variations in relative prices associated with variations in output such that the economy tends towards a level of output compatible with the full employment of labour?

Each of these questions can be supplemented with a further question: if not, why not?

The significance of these questions can be illustrated in terms of the most elementary piece of orthodox neoclassical analysis. According to this account, 'equilibrium' is determined at the point of intersection of a function relating price to quantity demanded and another relating price to quantity supplied. When this view of price determination is extended to the economic system as a whole, the equilibrium position of the economy is characterized by a set of market-clearing prices, with associated quantities (levels of commodity output and levels of 'factor' utilization), such that the markets for all commodities and all 'factors of production' clear. In particular, the labour market clears at the equilibrium level of the wage (relative to the associated set of equilibrium prices).

In terms of this familiar approach to the analysis of price formation the answer to the first question is obvious. Equilibrium prices and equilibrium quantities are determined simultaneously. The theory of value, based on demand and supply, is one and the same thing as the theory of output. If there exists an equilibrium set of prices then there exists an equilibrium set of outputs – equilibrium in the sense of market clearing, including the full employment of labour, as defined above. Furthermore, this theory of the simultaneous determination of prices and quantities is typically presented in such a way – by juxtaposing demand and supply functions – that the idea that prices adjust automatically so as to clear markets, thus tending to push the economic system towards a full-employment level of output, seems to follow as a self-evident corollary of the

theory. (It does not in fact follow as readily as might appear at first sight, since the stability of an equilibrium is far more difficult to demonstrate than its existence.)

Here, then, one has the demand-and-supply (neoclassical) analysis of prices and quantities in a nutshell: the equilibrium set of outputs (and levels of 'factor' utilization) is determined simultaneously with the equilibrium set of prices (of commodities and 'factors of production'); variations in relative prices sparked off by an imbalance between demand and supply, will be associated with variations in quantities in a direction which ensures that both prices and quantities tend towards their equilibrium levels. Neoclassical analysis, therefore, answers the first two questions posed above in the affirmative.

An analysis of unemployment may then be derived directly from these relationships between prices and quantities. Any *inhibition* to the tendency of prices and quantities to find their equilibrium (market-clearing) levels will leave the economic system in disequilibrium with, perhaps, either an excess demand for labour or an excess supply of labour (ie unemployment). An enormous variety of analyses of unemployment are constructed in this way.

The general tenor of the neoclassical analysis of the causes of unemployment is that while the economy would be self-regulating in the best of all possible worlds (ie the implicit tendency towards the full employment of labour would be realized) – the market is *inhibited* from fulfilling this task by the presence of certain 'frictions' or 'rigidities'. In the literature on the problem of unemployment, examples of such inhibitions are legion. They include: 'sticky' prices (particularly 'sticky' or even rigidly fixed wages and/or 'sticky' interest rates); institutional barriers to the efficacy of the price mechanism, such as monopoly pricing (by firms or individual groups of workers); inefficiencies introduced into the working of the 'real' economy by the operations of the monetary system; the failure of individual agents to respond appropriately to price signals because of disbelief in those signals, the disbelief being derived from uncertainty about the current or future state of the market, or from incorrect expectations concerning future movements in relative prices, or from false 'conjectures' about the actual state of the market.

Indeed, examples of 'frictions' and 'rigidities' can be multiplied at will – any factor which causes the market to work *imperfectly* will do. It will be convenient, therefore, to group all the authors of the myriad of arguments of this kind together under the general heading of 'imperfectionists'. (It should be noted that by referring to this kind of analysis as 'imperfectionist' I do not intend to imply that the envisaged failure of the market mechanism to operate in the way depicted by the underlying demand-and-supply theory *necessarily* derives from imperfections of competition.)

Underlying them all is a fundamental similarity: that if the particular aspect (or aspects) of the economic system which gives rise to the breakdown of the market mechanism were to be absent, then the system would tend towards the full employment of labour (and other 'factors of production'). Thus, in all cases, the analysis of unemployment is viewed as no more than an aspect of the neoclassical theory of value and distribution. According to this approach, whether a relatively 'optimistic' or 'pessimistic' stance is taken with respect to the efficacy of the market mechanism in promoting full employment, the analysis of output and employment is part and parcel of the theory of relative price determination. This is so even in the case of those imperfectionists who feel that the essential workings of the theory are distorted gravely in the real world.

In marked contrast to the analysis outlined above are those theories of employment which propose no particular functional relationship between prices and quantities. The central proposition of neoclassical analysis, that the theory of value and distribution is also the theory of output, is rejected, together with the connected notion that appropriate variations in relative prices will promote variations in quantities, so moving the economic system in the direction of a full-employment equilibrium.

Unfortunately, this rejection of the neoclassical theory of value and distribution – of the entire apparatus of demand-and-supply analysis – has not always been backed up by rigorous analytical

argument; so much so that it has sometimes been confused with an imperfectionist position. A striking example of this is the rejection by a number of writers of the neoclassical theory of value, and their advocacy of the idea that relative prices, far from being determined by demand and supply, are determined by a mark-up over normal prime cost where this mark-up is insensitive to variations in the conditions of demand (see, for example, Kalecki 1939; Neild 1963; Godley and Nordhaus 1972). Quite apart from the obvious shortcomings of 'mark-up' analysis as a theory of price formation – it is in essence a proposition about the stability of the ratio between prices and costs rather than a theory about the determination of either of those magnitudes, or even of the size of the ratio – this attempt to separate the study of relative price determination from the analysis of output may readily be confused with an imperfectionist argument based on 'sticky' prices arising from the presence of monopolistic or oligopolistic influences in commodity markets. (Thus Malinvaud (1977) cites the results of Godley and Nordhaus (1972) in support of his orthodox imperfectionist position.) Moreover, the bald assertion that prices and quantities do not bear the well-defined functional relationship to one another that is postulated in neoclassical theory does not provide a satisfactory analytical basis upon which to build up a critique of the neoclassical position.

Yet the requisite critique does exist, and is to be found in the outcome of the debate over the neoclassical theory of distribution and, in particular, over its treatment of 'capital' as a 'factor of production' on a par, so to speak, with land and labour. While this debate is seen by many as a rather esoteric controversy in the more abstract realms of economic theory, its implications are more far-reaching than has hitherto been appreciated. The central conclusion of the debate may be summed up, in broad terms, as follows: when applied to the analysis of a capitalistic economy (that is, an economic system where some of the means of production are reproducible), the neoclassical theory is logically incapable of determining the long-run equilibrium of the economy and the associated general rate of profit whenever capital consists of more than one reproducible commodity. Since, in equilibrium, relative prices may be expressed as functions of the general rate of profit, the neoclassical proposition that equilibrium prices are determined by demand and supply (or, more generally, by the competitive resolution of individual utility maximization subject to constraint) is also deprived of its logical foundation.

The relevance of this critique of the neoclassical theory of value and distribution to the problem of the missing critique of the neoclassical theory of output and employment should be apparent from what has already been said. Because the neoclassical analysis of the determination of prices and the determination of quantities is one and the same theory (that of the mutual interaction of demand and supply), the critique of the neoclassical theory of value is simultaneously a critique of the neoclassical theory of output and employment. Therefore, the first of the two questions that were posed at the very outset of this discussion must, on the grounds of the requirement of logical consistency alone, be answered in the negative. The second question, from which neoclassical theory derives the idea that under the operation of the market mechanism there is a long-run tendency towards a determinate full-employment equilibrium, is rendered superfluous.

But this is not all. If the general (or long-run) case of the neoclassical model has been shown to be logically deficient, then all imperfectionist arguments of the introduction of particular (or short-run) modifications into the general case – are incapable of providing a satisfactory analysis of the problem of unemployment. This is not to say that many of the features of the economic system cited by the imperfectionists will have no role to play in a theory of employment based on quite different foundations to those adopted by the neoclassicals. After all, much of the credibility of imperfectionist arguments derives from their pragmatic objections to the direct applicability of the assumptions of the more abstract versions of demand-and-supply theory. But pragmatism is not enough. The implications of more realistic hypotheses must be

explored in the context of a general theoretical framework within which they are integral parts, not imperfections.

Imperialism

Alice H. Amsden

Few subjects of such conspicuous historical importance have so consistently escaped lucid theoretical exposition as imperialism. The neoclassical economists have made no theoretical gains whatsoever in the field, having chosen to ignore the subject altogether. Their starting and ending point is a short essay borrowed from Schumpeter in which imperialism in the nineteenth and twentieth centuries is attributed to the atavism of states, acting on feudal and absolutist impulses from an earlier precapitalist era. The field, therefore, has been dominated by Marxists. 'To write about theories of imperialism is already to have a theory,' states Barratt Brown (1972). In modern times, just to use the word is to label what is said as Marxist. The word – like capitalism itself – also implies a theory of broadly construed economic systems and long historical epochs. The sweep of the subject matter is reflected in the breadth of the two major propositions that Marxists have posed: that imperialism and monopoly capitalism are synonymous; and that capitalism underdevelops the third world. The sweep of the subject matter has lent itself to meaningless generalizations and reductionist arguments. But to ignore imperialism altogether on the ground that it is a political phenomenon is to abrogate a responsibility to study a major dimension of economic life, in particular the relationship between the operations of the market and coercive mechanisms.

Part of the problem lies in the ambiguity of the term. Since there is no agreement on the referent of imperialism, there is none on the meaning of the word itself. Marx and Engels did not discuss imperialism as such so they bequeathed no definition. To one of their followers, Rosa Luxemburg (1913), it was the political expression of the accumulation of capital in its competitive struggle for what is still left of the non-capitalist regions of the world. To another, Nikolai Bukharin (1914), it was a policy of conquest by finance capital that is characteristic of one stage of capitalist development. To a follower of a later generation, Samir Amin (1976), it was the perpetuation and expansion of capitalist relations abroad by force or without the willing consent of the affected people. Schumpeter (1919) defined it as the objectless disposition on the part of a state to unlimited forcible expansion.

While no consensus exists, most definitions share an idea that interactions between two social formations are in some sense imperialist if they depend upon force. And the use of force is all the more likely if the two entities are of unequal strength. This is not to say that only military domination qualifies as imperialism. Or that any exchange, commercial or financial, between two parties of unequal strength is imperialism. Rather, even if the use of force is only implicit, perpetrated by the fountain pen, it qualifies as imperialist if the weaker collectivity is subjected to some sort of control by the stronger. So defined, and such is the definition followed below, imperialism is ultimately a political phenomenon, whatever its underlying tap-root.

There appear to be as many explanations for the motivations underlying imperialism as there have been wars. Yet the economic explanations are qualitatively distinct from the rest – geopolitical, psychological – because they reflect the fact that different economic systems reproduce themselves differently. In societies where reproduction was constrained by the availability of land, territorial expansion was the impetus. In societies dependent upon slavery, there was warring for slaves. To buy cheap and sell dear in the age of mercantilism, there was resort to plunder. Come the capitalist system, imperialism evolved into something more complex than theft. It was embodied in exchange relationships. And since exchange could occur peacefully, without the use of force, some, like Schumpeter, presumed that capitalism and imperialism were antithetical. Yet force has been used to accelerate the onset of exchange relationships, to preserve them, and to improve the terms of exchange. Imperialism under centralized planning involves still another dynamic, since the driving imperative for markets (for economic surplus) is absent. It has been attributed by Ota Sik, the Czechoslovak planner, to the requirement of reducing uncertainty through the control of inputs and outputs (Owens and Sutcliffe 1972). A complex of causes, however, is evident even for an imperialism defined sensibly for a specific historical period. The so-called 'new imperialism', which is the concern here and which dates from the 1870s–80s and onwards, is attributed to economic factors by, say, Hobson (1902) and Hilferding (1910); to European diplomatic rivalries by Fieldhouse (1966) and Langer (1935); and to extreme nationalism by Hayes (1941) and Mommsen (1980).

Precisely where to draw the dividing line between imperialist episodes, however, is contentious; and more than a mere theoretical quibble in the case of the 'new imperialism'. Robinson and Gallagher (1953) argue that there is little that distinguishes the allegedly 'indifferent' mid-Victorian imperialism, when free-trade beliefs were at their height, from the 'enthusiastic' late- Victorian imperialism, when such beliefs were in decline, along with British competitiveness. According to the authors, the indifference–enthusiasm polarization leaves out too many of the facts. There were numerous additions to empire, both formal and informal, in the indifferent decades. Between 1841 and 1851 Great Britain occupied or annexed New Zealand, the Gold Coast, Labuan, Natal, the Punjab, Sind and Hong Kong. In the next 20 years British control was asserted over Berar, Oudh, Lower Burma and Kowloon, over Lagos and the neighbourhood of Sierra Leone, over Basutoland, Griqualand and the Transvaal; and new colonies were established in Queensland and British Columbia. What is more, in the supposedly laissez-faire period, before the 1870s, the economy of India was managed along the best mercantilist lines. Such continuity in nineteenth century imperialism contradicts 'those who have seen imperialism as the high stage of capitalism and the inevitable result of foreign investment . . . [in] . . . the period after the 1880s', Lenin included.

Lenin's towering influence on Marxist theorists derives from his pamphlet, *Imperialism, the Highest Stage of Capitalism,* written in 1916 in response to the outbreak of war. The academic establishment in Europe attributed the First World War mostly to the official mind. Lenin ascribed it to monopoly capitalism, the economic mainspring of imperialist rivalry:

> Railways are a summation of the basic capitalist industries: coal, iron and steel; . . . The uneven distribution of the railways, their uneven development – sums up, as it were, modern monopolist capitalism on a world-wide scale. And this summary proves that imperialist wars are absolutely inevitable under such an economic system . . . (Preface, pp. 4–5).

The economic system of monopoly capitalism is first portrayed by Lenin as being highly productive. According to a US Commission that he cites, the trusts expand their market share on the basis of scale economies and superior technology: 'Their superiority over competitors is due to the magnitude of . . . [their] . . . enterprises and their excellent technical equipment.' This leads Lenin to state: 'Competition becomes transformed into monopoly. The result is immense progress . . ..In particular, the process of technical invention and

improvement becomes socialized' (p. 24). He goes on to argue, however, that industrial capital falls prey to finance capital. He also embraces the prevailing academic view of monopoly, that it is unproductive, although he is far more cautious about this than his followers were to be:

> Certainly, the possibility of reducing cost of production and increasing profits by introducing technical improvements operates in the direction of change. But the tendency to stagnation and decay, which is characteristic of monopoly, continues to operate, and in certain branches of industry, in certain countries, for certain periods of time, it gains the upper hand (p. 119).

Stagnation, in turn, leads to the export of capital, but Lenin is vague in his explanation for why this should be so:

> The necessity for exporting capital arises from the fact that in a few countries capitalism has become 'overripe' and (owing to the backward stage of agriculture and the impoverished state of the masses) capital cannot find a field for 'profitable' investment (p. 74).

The direction of capital exports is to the backward countries:

> . . . surplus capital will be utilized . . . for the purpose of increasing profits by exporting capital abroad to the backward countries. In these backward countries profits are usually high, for capital is scarce, the price of land is relatively low, wages are low, raw materials are cheap (p. 73).

For Lenin, therefore, imperialism becomes organically inseparable from monopoly capitalism. Whereas in common usage imperialism means forced economic gain on a global scale, to Lenin it means much more. The most concise definition he gives is 'imperialism is the monopoly stage of capitalism', uniquely characterized, it should be added, by capital export.

Capital exports rose dramatically after the turn of the twentieth century. Yet neither underconsumption, as expounded by Hobson, nor a superabundance of capital, as Lenin suggested, nor a declining profit rate, a conceivable consequence of rising capital investments at home, provide particularly good explanations. Instead, Magdoff (1972) argues that in addition to the immediate causes of the sudden upsurge of capital exports (more competitors, more exporters; more tariff walls, more foreign investment to jump them), '[t]he desire and need to operate on a world scale is built into the economics of capitalism' (p. 148). Competition creates pressures for the expansion of markets. The emergence of a significant degree of concentration does not mean the end of competition. 'It does mean that competition has been raised to a new level . . ..Since capital operates on a world scale,. . . the competitive struggle among the giants for markets stretches over large sections of the globe' (p. 157). Although the scramble for colonies preceded rather than followed the rise of monopoly and capital exports, annexation was not what Lenin meant by imperialism. On the contrary, Sutcliffe states, in response to Robinson and Gallagher, 'it was a prelude to imperialism . . ..The system changed its character at the end of the century because from then on both expansion and rivalry between the major capitalist powers would have to take new forms since the chances of territorial expansion had been exhausted' (Sutcliffe 1972, p. 314).

Lenin based his analysis of imperialism on the stranglehold of finance capital, by which he meant the leading role that banks came to play in economic decision making. The financiers were perceived to have the biggest stake in imperialism and their hunger for quick returns led to economic chaos. Yet in fact after World War I finance capital decidedly took a back seat as the multinational firm grew in the US, Europe and, belatedly, England. As evidence for this, there was a shift over time away from indirect foreign investment, that is, portfolio or debt capital, to direct foreign investment, or equity capital. Roughly two-thirds of foreign investment took the form of debt capital before World War I. Thereafter, direct foreign investment became predominant, although a new type of portfolio investment rose again sharply in the late 1970s-early 1980s.

Chandler (1980) writes about the *form* that the growth of large-scale firms assumed:

> . . . modern industrial enterprise . . . grew by adding new units of production and distribution, by adding sales and purchasing offices, by adding facilities for producing raw and semi-finished materials, by obtaining . . . transportation units, and even by building research laboratories . . . (p. 397).

These new specializations of large business enterprises are the crux of Hymer's (1976) explanation for why capital exports were increasingly direct rather than indirect. According to him, the specializations that Chandler mentions – management expertise, capability in manufacturing, technology, distribution – constituted firm-specific monopolistic assets. To take full monetary advantage of them, firms exerted direct control over overseas operations, through equity ownership.

Yet foreign investment, whether direct or indirect, did not flow preponderantly to backward regions. In the interwar period and even before 1914, the main destination for overseas funds was Europe and North America. British colonies, including India, accounted for only about 20% and South America, for another 20% (Barratt Brown 1972). After 1929, the share of the advanced countries in the inflow of direct foreign investment rose even further, reaching around 75% of the total in the mid-1970s. The share was higher still for direct foreign investment in the manufacturing sector (USDC various years). Thus, while the locus of socialist revolutions was backward regions, not advanced ones, capital exports flowed increasingly to advanced regions, not backward ones. The direction of foreign investment is significant because it suggests an altogether different centre of gravity in economic activity under monopoly capitalism from the one Lenin's followers entertained.

Beginning at the turn of the century, the principal orientation of the economic activity of advanced countries was, in general, toward each other, not the backward regions. Like foreign investment, foreign trade in manufactures largely engaged the advanced countries. Their competitive struggle involved mainly invasions of each other's markets. The major contest in economic strength after World War II, between the US and Japan, barely stretched to third world shores.

Explanations other than international differences in gross profit rates must be sought for the geographical distribution of foreign investment. No definitive data exist to compare profit rates across countries. Yet profit rates are likely to have been relatively higher in backward countries, as Lenin suggests, because rates of surplus value, in the Marxist accounting sense, were higher there, at least in the 1970s in the manufacturing sector (Amsden 1981). One reason why foreign investment and trade primarily occupied the richer countries is that their per capita incomes were growing faster than the poorer regions; the newly industrializing countries excluded. The higher *level* of income in advanced countries also made them better markets. In turn, high income markets complemented the type of competition that became characteristic of monopoly capitalism. The monopolistic assets of large business enterprises were the competitive weapons. The coming of age of industrial capital witnessed an intensification of competition on the technology front. New products, new processes, new production systems constituted the razor's edge of the competitive battle, moderating the demand for protection and price-fixing cartels.

Such technology was not designed with third world domination in mind. The location of industry in the course of a product cycle from the 1950s at least through the 1980s progressed from the innovating country, to other advanced countries and only belatedly to backward regions (Vernon 1966); and then only if new discoveries did not short circuit the cycle such that production returned to the innovator's country of origin.

The monopolistic assets of large business enterprises did not all work productively, and Marxists pointed to the wasteful effects of advertising and to the ruinous effects of financial manipulation in the form of takeover waves at home and periodic, aggressive bouts of lending to the backward regions. But technological competition was the stuff out of which monopoly capitalism was made after World War II. So to equate monopoly capitalism and imperialism robs both terms of much of their meaning. The two cannot be reduced to one another.

Even if, following Stokes (1969), one attributes to Lenin what has come to be a non-'-Leninist' view, that the contestation of imperialist rivalries occurs not in the third world but in the monopolized countries themselves, then the conflation of monopoly capitalism and imperialism is still obfuscating. Whereas such rivalries engaged Europe in war at the time Lenin was

writing, they were mediated peacefully there for at least 40 years after World War II.

Nor is Lenin especially illuminating on why capital exports are the *specifica differentia* of monopoly capitalism. Was foreign investment more likely to precipitate the use of force than foreign trade? No, because trade in raw materials in the nineteenth century presupposed foreign investment. And what is the significance of the shift from indirect to direct foreign investment? Marxists have not systematically explored the answer. History teaches us that finance capital increasingly falls under the control of a few large banks, but it comprises much less differentiable products than industrial capital and, therefore, is more at the mercy of the laws of supply and demand. To prevent interest rates from falling, the banks look overseas for profitable investment outlets, and when they compete on the basis of price, they look in particular to the backward regions. The upsurge of portfolio investment in the late 1970s–early 1980s was accounted for overwhelmingly by the third world. Presumably the backward regions will become a more important locale for industrial capital as technological competition among advanced countries grows more even and product differentiation converges. Then manufacturers may be expected to locate their production facilities in lower wage, higher profit countries in order to compete better on the basis of price. That they did not do so to any significant extent before the 1980s suggests not a shortage of profitable investment outlets in advanced countries, supposedly a hallmark of monopoly, but a surplus of such outlets. Even though profit rates in the manufacturing sector were lower in the advanced countries, assuming the numbers are correct, marginal profit rates are likely to have been equal or higher, due to an outpouring of innovations.

The backward regions, however, were hardly inconsequential, to either industrial or finance capital. Certain third world raw materials, not least of all petroleum, remained critical business cost factors. The third world's debt crises undermined global monetary stability. The 'defection' of third world countries to socialism precipitated armed intervention. And, while the capital that flowed from the advanced countries to the third world throughout most of the tenure of the 'new imperialism' amounted to a mere trickle, there was a massive net transfer of surplus from the third world to the advanced countries (Bagchi 1982). Capitalism, after all, had become a world system. The relationship between imperialism and the economic development of the backward regions was the subject of as much literature as the relationship between imperialism and monopoly capitalism. Indeed, more was written on the former, because the neoclassical economists contributed; discreetly, the term imperialism never being mentioned.

Imperialism before and after World War II was quite distinct, as formal colonialism ended and large portions of Asia and Africa gained independence. One would expect economic growth in the backward regions to be quite distinct in each period as well, as a consequence of such political change. Yet, curiously, both Marxist and neoclassical economists saw continuity. In the neoclassical view, the backward regions had as good a chance to develop under colonialism as under independent rule so long as they organized their economies in the pursuit of comparative advantage. For the Marxists, underdevelopment was the expected outcome whatever the political regime, so long as the economic mechanisms of imperialism were fundamentally unaltered.

But how did these mechanisms operate? And did they remain unaltered amidst shifts in political circumstance? Schumpeter's argument, that imperialism under capitalism was a throwback to precapitalist impulses, was based on the premise that peaceful exchange was preferable to the use of force for all self-interested parties, and that ultimately reason would prevail over atavism. Yet, at minimum, force might be rational for one party to hasten another's *entry* into capitalist exchange relationships or to prevent another's *exit* into an altogether different economic system. The latter appears to have driven a good deal of US imperialism after World War II, notwithstanding the fact that the US had no precapitalist history. In the war's aftermath, American aid to Greece and Turkey limited leftist activity and the US government helped opponents of socialist and communist

candidates for office in France and Italy. Vietnam apart, the US intervened either directly through the military or covertly through the Central Intelligence Agency to halt what was perceived as socialist aggression in Greece, Iran, Guatemala, Indonesia, Lebanon, Laos, Cuba, the Congo, British Guiana, the Dominican Republic, Chile and possibly Brazil.

The onset of capitalist relations in the third world was also replete with the use of force. In many colonies where foreign enclaves were established in the nineteenth century for the purpose of producing primary products for export, population was scarce, so in retrospect 'overpopulation' cannot be held responsible for the underdevelopment that ensued. Indeed, one would have expected not underdevelopment but the onset of a 'high wage economy', given a scarcity of labour and a growing demand for labour's services in the mines and on the plantations. But wages did not rise (Myint 1964). For the neoclassical paradigm of peaceful market exchange, this constitutes a paradox. For more institutionally oriented economists, this seeming paradox was resolved with the artifice of the 'backward bending labor supply curve'. It was imagined that self-sufficient peasants who migrated to the mines and plantations offered their services with the limited purpose of obtaining only a 'target' income. If higher wages were paid, their objective would be met all the faster, with the consequence of a smaller, not larger labour supply. In fact, foreign firms in the mining and plantation sectors were faced with a decision – of whether to pay in excess of labour productivity in the short run or to coerce an adequate labour supply at a low wage rate equal to (or below) the prevailing level of productivity – and they opted for force. Colonial authorities passed legislation that indirectly compelled natives to work: but taxes were imposed that had to be paid in cash, not kind and alternative income-earning opportunities were limited through encroachments on land and restrictions on the cultivation of cash crops. The result was the onset of a 'low wage economy', that effectively channelled the 'secondary multiplier effects', of enclave production to the advanced countries and doomed the backward regions to a 'vicious circle' of poverty (Myrdal 1957; Nurkse 1953; Singer 1950).

Outright appropriation of land and labour was more blatant in the earlier than the later phases of imperialism and in some backward regions (Indonesia, the Congo) than in others (India, Latin America). But it was often possible to extract more surplus through indirect taxation and through purchase of commodities and sale of manufactures from and to the peasants. 'The British', writes Bagchi, 'may indeed be regarded as the real founders of modern neocolonialism, for both in Latin America and in India in the late nineteenth century they depended more on economic power and political influence than on direct use of political power at every stage for obtaining the lion's share of the surplus of the dominated economies' (1982, p. 78). Land taxes, payable in cash, either reduced the peasants to landless proletarians or required them to produce export crops, with little surplus to diversify in the event of unfavourable terms of trade. Free trade itself destroyed domestic manufactures, made it unprofitable to invest in anything other than export crops and impeded the growth of capitalist classes that could have challenged foreign domination. Even in the bottom of the barrel, backward regions characterized by peasant export economies with little to offer foreigners in the way of raw materials or markets (say, West Africa, Burma, Thailand and Vietnam), the functioning of the market mechanism was not devoid of coercive elements. Peasants who entered the money economy became vulnerable to international commodity price fluctuations. Foreigners, acting as monopolistic middlemen, gained the upper hand and reinvested the surplus elsewhere. Local moneylenders, who controlled credit, foreclosed on indebted peasants where land had become alienable. Railways and other infrastructure supported external rather than internal exchange, thereby discouraging domestic manufactures.

In reality, therefore, no ideal, pure market exchange between rich and poor countries existed that could be delinked neatly from imperialism. Mechanisms of coercion and mechanisms of exchange operated hand-in-hand. From the Marxist perspective it followed that imperialism was

neither atavistic nor limited merely to entry and exit to and from capitalist exchange. Rather, force was pervasive and imperialism was business as usual.

If, to varying degrees, force was pervasive in market relationships, then as force changed its colours in tandem with political change, one would expect some change in market relationships as well. Imperialism, after all, is a political phenomenon. Yet in the post-World War II period, no attempt was made by Marxists to distinguish the intrinsic from the historical effects of different economic practices on growth prospects. Instead, all intercourse with advanced countries was condemned as leading to underdevelopment, in sharp contradistinction to Marx, Engels, and even Lenin. The economic practices singled out for special opprobrium were those in which intercourse between the advanced countries and backward regions was most direct – foreign trade, foreign investment and even foreign aid. As Brenner (1977) put it, Adam Smith was turned on his head.

Yet the effect of any given economic practice on economic development clearly depended on the political setting. Aid helped Europe after World War II but seemingly hurt Bangladesh. Whereas export-led growth based on a primary product or 'staple' led to underdevelopment in the backward regions, it led to prosperity in the regions of recent settlement (Canada, Australia, New Zealand, white South Africa, white Rhodesia, etc.). Evidently there was nothing inherent in exporting that led irrevocably to either development or underdevelopment. Rather, what happened depended on local conditions. Unlike the backward regions, the regions of recent settlement retained the surplus by dint of their 'high wage economies' and reared a manufacturing sector by erecting protective tariffs. In the case of direct foreign investment, the expected gains to the 'host' country were *a priori* indeterminate. On the one hand, direct foreign investment promised a transfer of modern management techniques to backward regions. On the other hand, motivated by a wish to make use of monopolistic assets, there was nothing to insure that the multinationals would share their know-how with local managers. In fact, the outcome depended on the political conditions imposed on foreign capital; so Canada benefited far more than say, Chile, from overseas investment.

If Marxists saw foreign trade and foreign investment as dooming the third world to underdevelopment, neoclassical economists followed the same logic but arrived at an opposite conclusion: that foreign trade and foreign investment were the key to third world prosperity (Little 1982). Now this flew in the face of reality. The economies of the backward regions had long been oriented to foreign trade and foreign investment but were hardly prosperous. Two different tacks were taken to reconcile any seeming inconsistency between theory and practice. One, it was argued that the backward regions had not been sufficiently singleminded in their pursuit of free trade. They had broken faith after World War II in particular, by embracing the 'dogma of dirigisme' (whereupon, it may be added, they grew the fastest ever; Lal 1984). Two, it was argued that, in fact, the backward regions had long been growing at a fairly rapid clip, although to be sure, there were exceptions to the rule. According to Reynolds (1985): '. . . against the view that "life began in 1950," . . . the third world has a rich record of prior growth, beginning for most countries in the 1850–1914 era' (p. 4). In anticipation of the obvious objection, that developing countries are still desperately poor, Reynolds writes:

> Certainly people in Western Europe and the United States are much better off than people in Sri Lanka [the example he uses], though not as much better off as the World Bank tables suggest . . . conversion from local currencies to U.S. dollars at official exchange rates exaggerates the actual difference in consumption levels (p. 40).

Both Marxist and neoclassical analysis suffered from a failure to look beyond either the historical specificities of 'export-led exploitation' (the term is Bagchi's) or the formalism of export-led growth, as the case may be, to the underlying power structures in the backward regions. Beginning with Baran (1957), Marxists portrayed political and social life in the third world simplistically.

The state and whatever local capitalists existed were seen as corrupt puppets of advanced country powers. No scope was given to the possibility of local initiatives to mediate foreign trade, foreign investment and foreign aid to advantage. It is fair to say the neoclassical economists largely ignored local conditions in developing countries, even economic ones. When Jacob Viner (1953) delivered a lecture series in Brazil in 1950, he expressed confidence in a growth strategy based on agricultural exports. As evidence, he pointed to the correlation between high per capita incomes and agricultural exports in the regions of recent settlement, overlooking any other factors in these regions that may also have contributed to growth. The result was an inability to grasp what came to constitute a serious challenge to both theories: the economic development along capitalist lines after World War II of a handful of nations (or nation states) in East Asia, South Korea and Taiwan in particular.

The development of these countries posed a challenge to neoclassical theory because, while all the countries in question were highly oriented to trade, they were by no means committed to laissez-faire (Amsden 1985). They exerted strong centralized control over their economies. They flouted static comparative advantage and were protectionist. Their large private or public conglomerates were a mirror image of concentrations of economic power under monopoly capitalism in advanced countries. They fought force with force, as it were, in dealing with foreign capital. To say that these countries could have grown even faster had they adopted laissez-faire policies is beside the point. The development of these countries posed a challenge to Marxist theory because it wasn't supposed to happen. Such development, therefore, was preemptively dismissed. It was attributed either to a fluke – geopolitics and a superabundance of foreign aid [sic] – or repression of workers, although Engels (1878) cautions against the view that it is possible to industrialize by the gun.

The one dissenting voice among Marxists against the notion that capitalism underdevelops the third world missed the point. For Warren (1980), the problem of underdevelopment was not too much foreign capital but too little. Yet, however great the flow of foreign capital to South Korea and Taiwan (mostly, it may be noted, in the form of finance rather than industrial capital), much more accounted for development in these countries than capital per se.

The intellectual antecedents of Warren's view are traceable directly to Marx, so to suggest that Warren missed the point about economic development is also to suggest that Marx himself missed the point. Marx's point is that colonies like India were destined to develop because the capitalist system was compelled to replicate itself around the globe. With the destruction of the Asiatic mode of production, with the imposition of market relationships and with the arrival of the railroad, India would become another England (Marx and Engels 1960). Yet markets and technology alone do not make for economic development. What appears to be critical are the power relationships and institutions that unfold on their own terms to guide the accumulation process. But Marx is silent about these.

The dirigiste state stands at the opposite extreme of Marx's liberal view of the market as the engine of growth. But neither is a dirigiste regime a sufficient condition for economic development. Dirigisme and underdevelopment are both rampant in the third world. Instead, what Japan and a few South Koreans suggest is that economic development in the twentieth century hinges on a delicate relationship between the operations of the market and coercive mechanisms.

Marxists have focused on this relationship in the general case, which is the starting point for any theory of imperialism, and presuppose that markets and force are impenetrable. Yet their equation of imperialism and monopoly capitalism led them to misjudge the relationship after World War II, because imperialism was not the key to the rapid growth of the advanced countries. And their second *idée fixe,* that capitalism underdevelops the third world, led again to the relationship's misjudgement, because proof of economic development in even a handful of third world countries

deprived their theory of analytical clarity. Nonetheless, to operate with the world view of the neoclassicists – of a separation between markets and power – is to deny the very existence of imperialism and to forego the conceptual tools to analyse it.

Implicit Contracts

Costas Azariadis

JEL Classifications
J41

An implicit contract is a theoretical construct meant to describe complex agreements, written and tacit, between employers and employees, which govern the exchange of labour services when various types of job-specific investments inhibit labour mobility and opportunities to shed risk are limited by imperfectly developed markets for contingent claims. This construct differs from the more familiar one of a neoclassical labour exchange in emphasizing a trading process, frequently over a long period of time, between two *specific* economic units (say a worker and a firm, union and management, and so on) rather than the impersonal, and often instantaneous, market process in which wages decentralize and coordinate the actions of labour suppliers and labour demanders.

Adam Smith's exposition of occupational wage differentials (1776, book I, ch. 10) recognized very early the idiosyncratic nature of the labour market and, in particular, that employment risk affected wages in various occupations. Since then economists have accumulated many facts, raw or stylized, which are best understood if one abandons the traditional view that the shadow price of labour is simply the wage rate. Prominent among explananda are the widespread use of temporary layoffs as a means of regulating the volume of employment (Feldstein 1975); the continuity of jobs by many primary wage earners (Hall 1982); the collective bargaining tradition of leaving the volume of employment at the discretion of management while predetermining money wage rates two or three years in advance.

To these, one must add certain 'impressions' or softer facts about the labour market which arise from the central role labour services possess in macroeconomic models. There is, indeed, among macroeconomists a shared impression (Hall 1980) that, over a typical business cycle, average real compensation per hour fluctuates considerably less than does the marginal revenue-product of labour or, for that matter, the total volume of employment.

One consequence is that wage and price rigidity are among the key assumptions of Keynesian macroeconomics, both in the Hicksian IS-LM framework and in the concept of quantity-constrained equilibrium originally developed by Clower (1965) and formalized by Bénassy (1975) and Drèze (1975). Another is the overwhelming importance of words like 'jobs' and 'unemployment', both in our colloquial vocabulary and in the specialized lexicon of economics. In particular, 'involuntary unemployment' is for many academic economists the *sine qua non* of modern macroeconomics.

The technically minded reader will find many of these issues surveyed in a number of specialized papers of which the most recent are Hart (1983) and Rosen (1985).

Wages and Employment

The earliest literature on implicit contracts exploits an insight of Frank Knight (1921), who argued that inherently 'confident and venturesome' entrepreneurs will offer to relieve their employees of some market risks in return for the right to make allocative decisions. The formal development of this idea began with three independently written papers by Baily (1974), Gordon (1974), and Azariadis (1975), motivated by the seeming puzzle of layoffs. In an unusual coincidence, all three authors took the employment relation not simply as a sequential spot exchange of labour services for money, but as a more complicated long-term attachment; labour services are traded in part for an insurance contract that protects workers from random, publicly observed fluctuations in their marginal revenue-product. The idea was that workers could purchase insurance only from their employers, not from third parties.

Risk-averse workers deal with risk-neutral entrepreneurs who head firms consisting of three departments: a production department that purchases labour services and credits each worker with his marginal revenue-product (MRPL); an insurance department that sells actuarially fair policies and, depending on the state of nature, credits the worker with a net insurance indemnity (NII) or debits him with a net insurance premium; and an accounting department that pays each employed worker a wage, w, with the property that w = MRPL + NII in every state of nature.

Favourable states of nature are associated with high values of MRPL; in these the net indemnity is negative and wage falls short of the MRPL. Adverse states of nature correspond to low values of MRPL, to positive net insurance indemnities, and to wages in excess of MRPL. An implicit contract is then a complete description, made before the state of nature becomes known, of the labour services to be rendered unto the firm in each state of nature, and of the corresponding payments to be delivered to the worker. The contract is implementable if we assume the state of nature is as easily verifiable as events are in a normal insurance contract.

An immediate consequence of this framework is that wages are disengaged from the marginal revenue-product of labour. In fact, if the amount of labour performed by employed workers per unit time is fixed institutionally, then each worker's consumption is proportional to the wage rate; an actuarially fair insurance policy should make this consumption independent of the MRPL by stabilizing the purchasing power of wages over states of nature. Therefore, the real wage rate is rigid.

In traditional macroeconomic models of course, wage rigidity by itself is sufficient to cause unemployment: if wages do not adjust for some reason, then neither does the demand for labour. The argument does not carry over to implicit contracts because of the very separation between wages and the marginal revenue product of labour. A complete theory of unemployment must explain why layoffs are preferred to work-sharing in adverse states of nature, and why laid-off workers are worse off than their employed colleagues.

This is not a simple task if one thinks of implicit contracts as ordinary, explicit, timeless insurance contracts between risk-averse workers and risk-neutral entrepreneurs. All contracts of this type would share a basic property of optimum insurance schemes; namely, keeping the worker's marginal utility of consumption independent of all random, publicly observed events - including such events as 'employment' or 'unemployment'.

To explain layoff unemployment, we need to distort or complicate the insurance contract in some significant way. A distortion that was noted early in the implicit contract literature is the dole. In an extremely adverse state of nature, the flow of insurance indemnities to workers can become a substantial drain on profit; one way to staunch losses is to place the burden of insurance on an outside party, the dole.

The practice of layoffs is simply the administrative counterpart of this insurance-shifting manoeuvre; workers consent in advance that some of them may be separated from their jobs in order to become eligible for unemployment insurance (UI) payments from an outside public agency. Furthermore, no worker will contract his labour unless the expected value (utility) of the total package, taken over all possible states of nature, exceeds the value of being on the dole in every state. This means, in turn that employed workers receive a wage in excess of UI payments and are therefore to be envied by their laid-off colleagues - a situation that many economists would call 'involuntary unemployment'.

The fact that laid-off workers would gladly exchange places with their employed colleagues is not in itself sufficient to establish a misallocation of resources. After all, accident victims may very well envy more fortunate individuals without any implication that the insurance industry works poorly. Layoffs, by themselves, could be no more than the luck of the draw unless we can demonstrate that they constitute, in some sense, socially inefficient underemployment. This is clearly impossible within the Walras-Arrow-Debreu model; and it is for this reason that the early literature on contracts turned to institutions like the dole in order to explain layoff unemployment.

Private Information

One fundamental departure from the Walrasian paradigm that received much attention in the early 1980s was a weakening of the information assumptions: information becomes 'private' or 'asymmetric', which simply means that not everyone is equally informed about the relevant state of nature. This is a perfectly sensible observation, for what justifies the trading of implicit contracts in the first place is that third parties simply are not as well informed about someone's income or employment status as is his employer; the employer, in turn, may be less informed about an employee's non-labour income and job opportunities than is the worker himself.

The thread was picked up by a number of authors who studied the properties of wages and employment for two main cases: in the first, entrepreneurs possess superior information about labour demand (Hall and Lilien 1979; Grossman and Hart 1981; Azariadis 1983; Farmer 1984); in the second case, workers possess superior information about labour supply, as in Cooper (1983). Suppose, for instance, that wages and employment do not depend on the unobservable true state of nature but on what the better informed contractant (say, the employer) *announces* that state to be. The question now becomes how to design contracts that reward entrepreneurs who tell the truth and punish those who lie.

One desirable property of contracts is that the truth should be the value- maximizing strategy for firms: truth-telling ought to be consistent with equality between the marginal cost and the marginal revenue-product of labour. Furthermore, entrepreneurs who misrepresent actual conditions should be punished, say, for knowingly under-reporting demand.

Under-reporting demand does turn out to be a problem in contracts that permit employers to slash both workforce and the wage bill when demand is slack, and do it in such a manner as to reduce cost more than revenue. To avoid this temptation, a properly designed contract specifies a highly variable pattern of employment over states of nature; that is, one in which employment is below what is socially optimal and the marginal product of labour is correspondingly above the marginal rate of substitution between consumption and leisure. It is in this sense that asymmetric information is said to result in socially inefficient underemployment or unemployment.

What relation is there between the layoffs we all know and the inefficient underemployment of a model economy that suffers from asymmetric information? To go from the latter to the former, one must understand first why layoffs are a more common means of reducing employment than is work-sharing. Second, a general equilibrium picture of underemployment would require an explanation of why underemployed (or unemployed) individuals are not hired by other employers. Third, and most important, the unemployment found in this private-information story is a response to private, firm-specific risk; most economists, however, consider the unemployment observed in market economies to be a reaction to social risks, especially to business cycles set in motion by aggregate demand disturbances. Unless one intends to make the far-fetched claim that the general public is unaware of, or cannot observe, whatever disturbances set off business cycles (such as changes in government consumption, money supply or consumer confidence), does it not appear that information-based unemployment simply describes the behaviour of an isolated firm?

The answer is not obvious. Note, however, that in order to have an inefficient volume of equilibrium employment, it is sufficient that *some but not all* information be private. In fact, it is not difficult to imagine general equilibrium extensions of the work we are discussing that would include both public and private information. Such extensions will be useful, especially if they manage to establish a firm link between inefficient underemployment and extreme values of some publicly observed aggregate disturbance.

Empirical Implications

Whether information is publicly shared or in the private domain, wages in implicit contracts do not merely reflect the marginal product of labour or

the workers' marginal rate of substitution between consumption and leisure, as they might in more conventional theories. The empirical implications of this insight are just being worked out, and they seem to be quite considerable. At the most aggregative level, one can make sense of the oft-verified fact (Neftci 1978) that hourly wages in manufacturing show little cyclical variability and are best described as a random walk.

In fact, it seems preferable to have empirical investigations of this sort at a less aggregated level. Aggregate studies are victims of selection bias: they fail to capture changes in the composition of output or of the labour force, which are themselves sufficient to induce substantial cyclical movement in economy-wide wages even if the business cycle does not affect the real wage of any skill grade in any industry.

Consider, for instance, a fictitious economy with homogeneous labour in which almost all industries experience little cyclical fluctuation except one, the quadindustry, which is thoroughly buffeted by the business cycle. If labour mobility is good across industries, quad workers will suffer more layoffs and enjoy a wage higher than elsewhere whenever they are employed. The economy-wide average wage will vary procyclically.

Another phenomenon accounted for naturally by implicit contracts is the behaviour of occupational wage differentials (that is of the unskilled-to-skilled wage ratio). These have shown a definite countercyclical tendency, widening in contractions and narrowing in booms, both in the United States and in the UK.

To see why, suppose that we drop the postulate of labour homogeneity in the economy just described and admit two skill grades. For simplicity, assume that the cycle is of such amplitude that there is no unemployment outside the quad industry, while unemployment in the quad industry falls solely on common labourers. These workers are thus the only group in the economy to suffer layoffs; in return they receive a wage above that of common workers outside the quad industry and below that of skilled workers - in the quad industry or out. As the cycle unfolds, then, the economy-wide wage average for craftsmen remains unaltered, the one for labourers changes procyclically, and occupational wage differentials follow a countercyclical pattern.

Intertemporal labour supply models of the type pioneered by Lucas and Rapping (1969) are another area that may in the future make fruitful use of implicit contracts. Econometric work on intertemporal labour substitution identifies the preferences of a 'typical' working household from time-series data on wages and salaries. The outcome is invariably an estimate of the wage-elasticity of labour supply that is so low as to be inconsistent with time-series data on employment (Kydland and Prescott 1982). In other words, someone who believes that the wage rate represents an important conditioning factor for labour supply and demand will find that wage rates do not vary sufficiently over the business cycle to account for observed fluctuations in employment.

Employment in an implicit contract, however, reflects the underlying value of labour's marginal revenue-product, whereas wages are smoothed averages of the MRPL over time or states of nature. Small fluctuations in contract wages are in principle consistent with substantial variations in contract employment; whether these are mutually consistent *in practice* remains to be seen from empirical work.

Macroeconomic Aspects

From empirical labour economics we turn to the macroeconomic issues that provided the original impetus for the development of implicit contracts. Unemployment, says this theory, is the result of differential information: a credible signal from employers to employees that product demand is slackening, or one from employees to employers that job opportunities are really better elsewhere.

Newer ideas that seem to be building on this basic piece of intuition are outlined later in this article. But whatever progress we have made towards understanding fluctuations in employment has not dispelled the dense fog that still shrouds the issue for wage rigidity. All we have to go on is the early result of Martin Baily that insurance makes the wage rate less variable than it

otherwise might be. This stickiness, however, is a property of the *real* rather than the nominal wage rate, and it is the latter that is assumed to be rigid in Keynesian macroeconomics.

Rigidity, of course, does not necessarily imply complete time-invariance, nor does it require money wages to change less frequently than other prices; it is simply an information-processing failure. The standard procedure in collective bargains, for instance, is to predetermine money wages several years in advance; more often than not those wages are invariant to any information that may accumulate over the duration of the contract. Only in exceptional circumstances are money wages in the United States allowed to reflect *any* contemporaneous developments in the cost of living (indexation) or in the profitability of the employer (bankruptcy).

The mystery of wage rigidity is then the failure of contracts to set money wages as *functions* of publicly available information that is obviously relevant to the welfare of all parties. Why does the wage-setting process choose to ignore this information? One answer is transaction costs and/or bounded rationality: contracts are cheaper to evaluate and implement when they are defined by a few simple numbers rather than by complicated rules that condition employment or wages on contingent events. Another possibility is to exploit the great multiplicity of equilibria that is typical of economies with missing securities markets (Azariadis and Cooper 1985). One of these equilibria features predetermined prices and wages, while employment and other quantity variables adjust fully to short-term disturbances. Wage rigidity here is like a Nash equilibrium: it is the best response of a firm in a labour market in which the wages paid by all other firms fail to reflect new information instantaneously.

Implementation

An implicit contract is formally defined as a collection of schedules describing how the terms of employment for one person or group of persons change in response to unexpected changes in the economic environment. What brings contractants together? How detailed are their agreements? And what mechanisms are there to enforce such agreements once they are reached? After an initial stage of fairly rapid development, research is returning to these elementary questions as if trying to clarify the axiomatic basis of the underlying theory.

What brings potential contractants together is the opportunity jointly to reap substantial returns on investments peculiar to their relationship. The idea is apparent in Becker's theory of specific human capital (1964) and in Williamson's hypothesis (1979) of physical assets that are specific to a given supplier–customer pair. To reap any returns, contractants must wed themselves to one partner, forsaking all others, for some period of time. Maintaining such a special relationship involves the transactions costs of creating an idiosyncratic asset, as well as an implicit contract; that is, a number of rules that define how the partners have decided to share the returns in various possible future circumstances.

There are, of course, circumstances that are not explicitly covered, either because they are not observable at reasonable cost or because contractants think of them as unlikely or unworthy of note. Irrespective of the possible events that are covered and of the prior rules that govern the distribution of returns to shared investments, all contractants are required to bear risk and to subordinate their short– term interest to longer-term considerations.

Workers, for instance, suffer layoffs in recessions while firms hoard labour in order to preserve a long-term relationship. What mechanisms keep contractants together in adverse circumstances?

One mechanism – studied extensively by Radner (1981), Townsend (1982) and others – is reputation: if somebody deviates from the terms of the contract, the deviation becomes widely known, and the deviant finds it difficult to locate trading partners in the future. That works well if the time horizon is fairly long or the future is fairly important relative to the present; reputations are likely to be important for firms, less so for workers.

Another method of enforcement is by a third party: a monitor, arbitrator or court of law. In order for a third party to enforce a contract, it has to be

able to observe all the prices and all the quantities specified in it – the employment status, hours worked and wage rate of every worker. That is an unreasonably large informational burden to place on someone who is outside the special relationship called a contract. Outsiders can be expected to observe at low cost only certain aggregates or averages, but not very much in the way of idiosyncratic detail.

How does one design and enforce contracts when outsiders are poorly informed about the trades among contractants? According to Hölmstrom (1983) and Bull (1986), self-interest will enforce contracts that third parties are not sufficiently informed to implement.

In particular, workers will put in the required amount of effort on the job, not because effort can be ascertained easily by an outside arbitrator but rather because they know that their wages and speed of promotion depend on performance. And employers will be careful not to break even the most implicit of their commitments if doing so will compromise their ability to attract workers in the future. As of this writing, the design of self-enforcing contracts seems to be the central theoretical problem in the field of implicit contracts.

Import Substitution and Export-Led Growth

John Eatwell

In an economy in which expansion is limited by a balance of payments constraint, action must be taken either to boost exports or to limit imports. This truism takes on an added dimension when the trade strategy adopted is part of a general development strategy. In these circumstances the evaluation of any particular trade strategy must include not only the implications for the allocation of resources, but also the consequences for the rate of accumulation and of technological progress.

In the 1950s and early 1960s, the years of the dollar shortage, the balance of payments constrained industrial countries adopted quite different trade and industrial strategies. West Germany pursued a strategy of export expansion by means of an undervalued Deutschmark and subsidies to export industries. With world trade in manufactures growing rapidly, and West Germany's share of that trade growing too, the rapid growth of manufactured exports provided the foundation for domestic expansion (Shonfield 1963). Italy pursued a similar strategy by means of regular devaluation of the lira, devaluations often being associated with a surplus on Italy's current account.

These two examples of export-led growth contrast markedly with the strategies adopted by France and by Japan. Both countries vigorously protected their home markets, using industrial expansion within the home market as a springboard for the capture of export markets. The rationale behind this policy of import substitution was spelt out by Vice-Minister Ojimi, of the Japanese Ministry of International Trade and Industry:

> After the war, Japan's first exports consisted of such things as toys or other miscellaneous merchandise and low-quality textile products. Should Japan have entrusted its future, according to the theory of comparative advantage, to these industries characterized by intensive use of labour? That would perhaps be rational advice for a country with a small population of 5 or 10 million. But Japan has a large population. If the Japanese economy had adopted the simple doctrine of free trade and had chosen to specialise in this kind of industry, it would almost permanently have been unable to break away from the Asian pattern of stagnation and poverty . . .
>
> The Ministry of International Trade and Industry decided to establish in Japan industries which require intensive employment of capital and technology, industries that in consideration of comparative cost should be the most inappropriate for Japan, industries such as steel, oil refining, petrochemicals, automobiles, industrial machinery of all sorts, and electronics, including electronic computers. From a short-run, static viewpoint, encouragement of such industries would seem to be in conflict with economic rationalism. But from a long-range viewpoint, these are precisely in industries where income elasticity of demand is high, technological progress is rapid, and labour productivity rises fast . . . (Ojimi 1970).

Ojimi's argument encapsulates the dispute over import substitution or export-led growth as development strategies. The orthodox theory of international trade suggests that resources are most efficiently allocated in a regime of free trade. Efficient development would therefore require the adoption of free trade, with variation in exchange rates being used as the means of balancing trade.

This argument rests on a number of strong assumptions, in particular the assumptions that all countries have access to the same technologies, that factor markets clear (labour is fully employed), and that all countries have equal access to all markets – including equal access to all financial markets. If these, and other well-known assumptions, are not fulfilled, then the argument for free trade *on these grounds* no longer stands, and is superseded by the uncertainties of the second best.

Rejection of arguments for the efficiency of the price mechanism, for example on Keynesian grounds, also lead to the rejection of the efficiency of free trade. It was Keynesian arguments that underpinned the so-called ECLA strategy for structural change in Latin America. If expansion of domestic demand could be prevented, by protective measures, from leaking abroad then savings and fiscal revenues at home would finance

domestic investment and government expenditure. Moreover, the profitability of protected domestic production would encourage further investment. The process of expansion would be self-sustaining.

The application of import-substitution strategies in Latin America in the 1950s met initially with considerable success. Output of domestically produced manufactured goods grew rapidly, as did industrial employment. Later the policy fell into disrepute. It was argued that import substitution took place primarily in 'soft' consumer goods industries, whereas investment goods continued to be imported. Hence after the early growth associated with import substitution in consumer goods, growth was once again constrained by the necessity of importing machinery. Moreover, it was argued that protected domestic industry was relatively inefficient, and unable to compete on world markets. These matters are the subject of considerable dispute, particularly as they involve not only questions of economic efficiency, but also issues of national sovereignty, since the IMF has responded to the difficulties in which some Latin American countries have found themselves by demanding the removal of the trade protection on which the earlier development strategy was based.

These criticisms of import substitution extend beyond the traditional case for free trade, to consideration of the implication of different trade strategies for structural development and technological change. It was on exactly these grounds that Ojimi sought to justify Japan's strategy of import substitution. The Japanese case suggests that the traditional dichotomy between import substitution and export-led growth is invalid. Whilst Japanese industry was developed within a rapidly growing and protected home market, that growth proved to be springboard for expansion into world markets. Exports were domestic-growth led.

The performance of the successful Japanese (and French) examples of import substitution, and the problems encountered in Latin America, cannot be evaluated using static conceptions of allocative efficiency. Success (and lack of it) have clearly been associated with technological progress and industrial modernization. The case for free trade must be made on the ground that it encourages the most rapid adoption of the new techniques which determine competitive advantage.

Nicholas Kaldor's version of Verdoorn's Law (Kaldor 1966), whereby it is argued that the rate of productivity growth in manufacturing industry is a function of the rate of growth of demand for manufactured products, provides a framework within which trade strategies may be evaluated (see, for example, Brailovsky 1981).

The growth of demand for a country's manufactures is a function of the rate of growth of its home market, the rate of growth of its export markets, and the rate of change of its share of those markets. Changing market shares is a slow and uncertain business. It is growth of markets which is the major determinant of growth of demand. Since all countries are competing for shares of (roughly) the same export market, it is growth of the home market which typically differentiates the growth of demand for the manufactures of one country from those of another. This would suggest that manipulation of growth of the home market, using whatever means are necessary to relax the balance of payments constraint, is the most efficient development strategy.

However, the Verdoorn argument does not encompass the scale of productivity response to any given growth of demand. The implementation of industrial policies which both ensure that the expansion of industrial structure is 'balanced', and hence not overly dependent on imports, and directs demand toward those sectors which have both greatest competitive potential and which have the highest ratio of domestic value-added to import content, are more likely produce a greater response than if these issues are neglected.

The efficiency of any given trade strategy is not independent of the performance of the world economy as a whole. All countries cannot achieve export-led growth at once. Moreover, the success of the West Germany recovery strategy was undoubtedly enhanced by the fact that it was implemented in a period of rapid growth in world trade. In an era in which world trade is expanding relatively slowly, reliance on export

demand is unlikely to prove a successful foundation for rapid growth of demand and hence for rapid technological progress.

Impulse Response Function

Helmut Lütkepohl

Abstract

Impulse response functions are useful for studying the interactions between variables in a vector autoregressive model. They represent the reactions of the variables to shocks hitting the system. It is often not clear, however, which shocks are relevant for studying specific economic problems. Therefore structural information has to be used to specify meaningful shocks. Structural vector autoregressive models and the estimation of impulse responses are discussed and extensions to models with cointegrated variables or nonlinear features are considered.

Sims (1980) questioned the way classical simultaneous equations models were specified and identified. He argued in particular that the exogeneity assumptions for some of the variables are often problematic. As an alternative he advocated the use of vector autoregressive (VAR) models for macroeconometric analysis. These models have the form

$$y_t = A_i y_{t-1} + \cdots + A_p y_{t-p} + u_t,$$

where $y_t = (y_{1t},\ldots,y_{Kt})'$ (the prime denotes the transpose) is a vector of K observed variables of interest, the A_i's are (K × K) parameter matrices, p is the lag order and u_t is an error process which is assumed to be white noise with zero mean, that is, $E(u_t) = 0$, the covariance matrix, $E\left(u_t u_t'\right) = \Sigma_u$ is time invariant and the u_t's are serially uncorrelated or independent. There are usually also deterministic terms such as constants, seasonal dummies or polynomial trends. These terms are neglected here because they are not of interest in what follows. The relations between the variables in a VAR model are difficult to see directly from the parameter matrices. Therefore, *impulse response functions* have been proposed as tools for interpreting VAR models.

AVAR model can be written more compactly as $A(L)y_t = u_t$, where the lag or back-shift

operator L is defined such that $Ly_t = y_{t-1}$ and $A(L) = I_K - A_1L - \cdots - A_pL^p$ is a matrix polynomial in the lag operator. If the polynomial in z defined by $\det A(z)$ has all its roots outside the complex unit circle, the process is stationary and has a Wold moving average (MA) representation

$$y_t = A(L)^{-1}u_t = u_t + \sum_{i=1}^{\infty} \Phi_i u_{t-i}. \qquad (1)$$

In this framework impulse response analysis may be based on the counterfactual experiment of tracing the marginal effect of a shock to one variable through the system by setting one component of u_t to one and all other components to zero and evaluating the responses of the y_t's to such an impulse as time goes by. These impulse responses are just the elements of the Φ_i matrices. Because the u_t's are the one-step ahead forecast errors of the system, the resulting functions are sometimes referred to as *forecast error impulse responses* (for example, Lütkepohl 2005, section 2.3.2).

Such a counterfactual experiment may not properly reflect the actual responses of an economic system of interest because the components of u_t are instantaneously correlated, that is, Σ_u may not be a diagonal matrix. In that case, forecast error impulses are just not the kinds of impulses that occur in practice, because an impulse in one variable is likely to be accompanied by an impulse in another variable and should not be considered in isolation. Therefore, *orthogonalized impulse responses* are often considered in this context. They are obtained from (1) by choosing some matrix B such that $BB' = \Sigma_u$ or such that $B^{-1}\Sigma_u B'^{-1}$ is a diagonal matrix and defining $\varepsilon_t = B^{-1}u_t$. Substituting in (1) gives

$$y_t = B\varepsilon_t + \sum_{i=1}^{\infty} \Theta_i \varepsilon_{t-i}, \qquad (2)$$

where $\Theta i = \Phi_i B$, $i = 1, 2, \ldots$ The ε_t's have a diagonal or even a unit covariance matrix and are hence contemporaneously uncorrelated (orthogonal). Thus, ε_t shocks may give a more realistic picture of the reactions of the system. The problem is, however, that the matrix B is not unique and many different orthogonal shocks exist. Thus, identifying restrictions based on non-sample information are necessary to find the unique impulses of interest which represent the actual responses of the system to shocks that occur in practice. These considerations have led to what is known as *structural VAR (SVAR) models* and *structural impulse responses*.

SVAR Models

Various types of restrictions have been considered for identifying the structural innovations or, equivalently, for finding a unique or at least locally unique B matrix. For example, using a triangular B matrix obtained from a Choleski decomposition of Σ_u is quite popular (for example, Sims 1980; Christiano et al. 1996). Choosing a lower-triangular matrix amounts to setting up a recursive system with a so-called *Wold causal ordering* of the variables. One possible interpretation is that an impulse in the first variable can have an instantaneous impact on all other variables as well, whereas an impulse in the second variable can also have an instantaneous effect on the third to last variables but not on the first one, and so on. Because such a causal ordering is sometimes difficult to defend, other types of restrictions have also been proposed. Examples are:

1. Instantaneous effects of some shocks on certain variables may be ruled out. In other words, zero restrictions are placed on B just as in the Choleski decomposition approach. The zero restrictions do not have to result in a triangular B matrix, however.
2. Identification is achieved by imposing restrictions on the instantaneous relations of the variables. In this case a structural form model of the type $A_0y_t = A_1y_{t-1} + \cdots + A_py_{t-p} + \varepsilon_t$ may be considered and typically linear restrictions are imposed on A_0. Usually the elements on the main diagonal of A_0 will be normalized to unity. The restrictions on A_0 imply restrictions

for $B = A_0^{-1}$. For example, if A_0 is triangular, then so is B.

3. It is also possible to set up a model in the form $A_0 y_t = A_1 y_{t-1} + \cdots + A_p y_{t-p} + B\varepsilon_t$ and impose restrictions on both A_0 and B to identify structural shocks. Combining restrictions on B with those on the instantaneous effects on the observed variables results in the so-called AB-model of Amisano and Giannini (1997).
4. There may be prior information on the long-run effects of some shocks. In this case restrictions may be placed on $B + \sum_{i=1}^{\infty} \Theta_i = A(1)^{-1}B$ (for example, Blanchard and Quah 1989). For instance, demand shocks may be assumed to have no accumulated long-run effects on some variable (in their case output). In fact, distinguishing between shocks with permanent and transitory effects is perhaps done more naturally in models which allow for integrated variables. They will be discussed later.
5. Sign restrictions may be imposed on the impulse responses (for example, Canova and De Nicoló 2003; Uhlig 2005), that is, one may want to require that certain shocks have positive or negative effects on certain variables. For example, a restrictive monetary shock should reduce the inflation rate.

Integrated and Cointegrated Variables

If the VAR operator has unit roots, that is, $\det A(z) = 0$ for $z = 1$, then the variables have stochastic trends. Variables with such trends are called integrated. They can be made stationary by differencing. Moreover, they are called cointegrated if stationary linear combinations exist. If the VAR model contains integrated and cointegrated variables, impulse response analysis can still be performed as for stationary processes. For the latter processes the Φ_i's go to zero for $i \to m$ and, hence, the marginal response to an impulse to a stationary process is transitory, that is, the effect goes to zero as time goes by. In contrast, some impulses have permanent effects in cointegrated systems. In fact, in a K-dimensional system with $r < K$ cointegration relations, at least $K - r$ of the K shocks have permanent effects and at most r shocks have transitory effects (King et al. 1991; Lütkepohl 2005, ch. 9). These facts open up the possibility to find identifying restrictions for the structural innovations by taking into account the cointegration properties of the system.

Estimation of Impulse Responses

Estimation of reduced form and structural form parameters of VAR processes is usually done by least squares, maximum likelihood or Bayesian methods. Estimates of the impulse responses are then obtained from the VAR parameter estimates. Suppose the VAR coefficients are contained in a vector $\boldsymbol{\alpha}$ and denote its estimator by $\hat{\boldsymbol{\alpha}}$. Any specific impulse response coefficient θ is a (nonlinear) function of $\boldsymbol{\alpha}$ and may be estimated as $\widehat{\theta} = \theta(\hat{\boldsymbol{\alpha}})$. If $\hat{\boldsymbol{\alpha}}$ is asymptotically normal, that is, $\sqrt{T}(\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha}) \xrightarrow{d} \mathcal{N}(0, \Sigma_{\hat{\boldsymbol{\alpha}}})$, then, under general conditions, $\hat{\theta}$ is also asymptotically normally distributed, $\sqrt{T}\left(\hat{\theta} - \theta\right) \xrightarrow{d} \mathcal{N}\left(0, \sigma_\theta^2\right)$. The variance of the asymptotic distribution is $\sigma_\theta^2 = \frac{\partial \theta}{\partial \boldsymbol{\alpha}'} \Sigma_{\hat{\boldsymbol{\alpha}}} \frac{\partial \theta}{\partial \boldsymbol{\alpha}}$. Here $\partial\theta/\partial\boldsymbol{\alpha}$ denotes the vector of first order partial derivatives of θ with respect to the elements of $\boldsymbol{\alpha}$ (see Lütkepohl 1990, for the precise expressions). This result can be used for setting up asymptotic confidence intervals for impulse responses in the usual way.

Asymptotic normality of $\widehat{\theta}$ requires that σ_θ^2 is non-zero, which follows if $\Sigma_{\hat{\boldsymbol{\alpha}}}$ is non-singular and $\partial\theta/\partial\alpha \neq 0$. In general the covariance matrix $\Sigma_{\hat{\boldsymbol{\alpha}}}$ will not be nonsingular for cointegrated systems, for example. Moreover, the impulse responses generally consist of sums of products of the VAR coefficients and, therefore, the partial derivatives will also be sums of products of such coefficients. Consequently, the partial derivatives will also usually be zero in parts of the parameter space. Thus, $\sigma_\theta^2 = 0$ may hold and, hence, $\hat{\theta}$ may actually converge at a faster rate than $\sqrt{T}$ in parts of the parameter space (cf. Benkwitz et al. 2000).

Even under ideal conditions where the asymptotic theory holds, it may not provide a good guide for small sample inference. Therefore, bootstrap

methods are often used to construct confidence intervals for impulse responses (for example, Kilian 1998; Benkwitz et al. 2001). If one uses these methods, deriving explicit forms of the analytical expressions for the asymptotic variances of the impulse response coefficients can be avoided. Unfortunately, bootstrap methods generally do not overcome the problems due to zero variances in the asymptotic distributions of the impulse responses. In fact, they may provide confidence intervals which do not have the desired coverage level even asymptotically (Benkwitz et al. 2000).

Confidence bands for impulse response functions can also be constructed with Bayesian methods (for example, Koop 1992). Prior information on the VAR parameters or the impulse responses can in that case be considered. It is not uncommon to report confidence intervals for individual impulse response coefficients and connecting them to get a confidence band around an impulse response function. This approach has been criticized by Sims and Zha (1999), who propose likelihood- characterizing error bands instead.

Extensions

There are a number of extensions to the models and impulse response functions considered so far. For example, all observed variables are treated as endogenous. A main criticism regarding problematic exogeneity assumptions in classical simultaneous equations models is thereby accounted for. On the other hand, this approach often results in heavily parameterized models and imprecise estimates. Therefore, it is occasionally desirable to classify some of the variables as exogenous or consider partial models where we condition on some of the variables which remain unmodelled. In this case one may be interested in tracing the effects of changes in the exogenous or unmodelled variables on the endogenous variables. The resulting impulse response functions are often referred to as dynamic multipliers in the literature on simultaneous equations (see Lütkepohl 2005, for an introductory treatment). The inference problems related to these quantities are similar to those discussed earlier for VAR impulse responses.

It was also acknowledged in the related literature that finite order VAR models are at best good approximations to the actual data generation processes of multiple time series. Therefore, inference for impulse responses was also considered under the assumption that finite order VAR processes are fitted to data generated by infinite order processes (for example, Lütkepohl 1988; Lütkepohl and Saikkonen 1997).

Impulse responses associated with linear VAR models have the property of being time invariant and their shape is invariant to the size and direction of the impulses. These features make it easy to represent the reactions of the variables to impulses hitting the system in a small set of graphs. Such responses are often regarded as unrealistic in practice, where, for instance, a positive shock may have a different effect from a negative shock or the effect of a shock may depend on the state of the system at the time when it is hit. Hence, the linear VAR models are too restrictive for some analyses. These problems can be resolved by considering nonlinear models. Although nonlinear models have their attractive features for describing economic systems or phenomena, their greater flexibility makes them more difficult to interpret properly. In fact, it is not obvious how to define impulse responses of nonlinear models in a meaningful manner. Gallant et al. (1993) proposed so-called *conditional moment profiles* which may give useful information on important features of nonlinear multiple time series models. For example, one may consider quantities of the general form $E[g(y_{t+h})|y_t + \xi, \Omega_{t-1}] - E[g\{y_{t+h}\})|y_t, \Omega_{t-1}]$, $h = 1,2,\ldots$, where $g(\cdot)$ denotes some function of interest, ξ represents the impulses hitting the system at time t, and $\Omega_{t-1} = (y_{t-1}, y_{t-2},\ldots)$ denotes the history of the variables at time t. In other words, the conditional expectation of some quantity of interest, given the history of y_t in period t, is compared to the conditional expectation that is obtained if a shock ξ occurs at time t. For example, defining $g\{y_{t+h}) = [y_{t+h} - E\{y_{t+h}|\Omega_{t+h-1})][y_{t+h} - E\{y_{t+h}|\Omega_{t+h-1})]'$ results in conditional volatility profiles, which may be compared to a baseline

profile obtained for a specific history of the process and a zero impulse. Clearly, in general the conditional moment profiles depend on the history Ω_{t-1} as well as the impulse ξ. Similar quantities were also considered by Koop et al. (1996), who called them *generalized impulse responses* (see also Pesaran and Shin 1998).

Although these quantities may be interesting to look at, they depend on t, h, and ξ. Hence, there is a separate impulse response function for each given t and ξ. In empirical work it will therefore be necessary to summarize the wealth of information in the conditional moment profiles in a meaningful way – for instance, by considering summary statistics. In practice, an additional obstacle is that the actual data generation process is unknown and estimated models are available at best. In that case, the conditional moment profiles or generalized impulse responses will be estimates, and it would be useful to have measures for their sampling variability. It is not clear how this additional information may be computed and presented in the best way in practice.

'Imputation' is a term introduced into economics as *Zurechnung* by the Austrian School economist Friedrich Freiherr von Wieser (1889). The term was a legal one, and the analogy was based on the legal method by which the jurist *imputes* guilt or liability to one or another criminal or tortfeasor. Imputation was a central concern of the Austrian School, since its analysis centred on the nature of the means–ends relationship (Mises 1949) and on the process by which the subjective valuations and value-preferences of individual consumers 'impute' value to the goods being produced. As Carl Menger, founder of the Austrian School, pointed out, the valuations by consumers of their satisfactions, or ends, impute values to the consumer goods, the means, that are expected to satisfy those wants (Menger 1871). And since producers' goods are only means to the production and sale of consumer goods, the values of the factors of production will in turn be determined by and be equal to the expected values of the consumer goods to the consumers. In short, values are 'imputed' back to the prices of the factors of production; the rents of Champagne land are high because the consumers value the champagne highly, and not the other way round. 'Costs' of resources are reflections of the value of products forgone.

While this process was clear in principle, there were considerable difficulties in working out the specifics. Essentially, Menger and his student Böhm-Bawerk stuck close to the realities of the market process, and focused on value imputation as a process of estimating how much of a product would be lost if the producer were deprived of one unit of a factor. Wieser, on the other hand, presumed that the marginal value of each factor could be found with great precision; in doing so, he assumed illegitimately that subjective values can be added and multiplied to arrive at the total value of a quantity of goods. But by its nature subjective value is an expression of ordinal preferences and therefore can neither be added nor measured.

The modern theory of marginal productivity has essentially solved these problems and shown how values of products can be imputed back to productive factors. One exception is the current assumption that the existence of variable proportions solves the problem of pricing factors and leaves no theoretical room for arbitrary bargaining between factor owners. But the more important solution depends on whether factors are purely specific to one line of production or are relatively non-specific, that is, can be employed in the production of more than one good. If two factors are each purely specific to a given product, then, even if their proportions are variable, there is still no principle by which the market can determine their relative prices except by arbitrary bargaining (Mises 1949, p. 336). In the real world, of course, the existence of such purely specific factors, and hence the scope for such bargaining, will be extremely limited.

The other important point is that values cannot be added or divided, and that the imputation process takes place, not automatically or precisely in an abstract realm of 'values', but only concretely and by trial and error, in the realistic market process of changing prices. In other words, although consumers can evaluate consumer goods and determine their prices directly by valuation, the prices of productive factors are only determined indirectly through market prices and entrepreneurial trial and error. There is no direct, abstract or pure process of imputing values.

This problem became strikingly relevant during the well-known debate over the Mises–Hayek demonstration that socialist governments cannot calculate economically. Joseph Schumpeter brusquely dismissed this contention with the statement that economic calculation under socialism follows 'from the elementary proposition that consumers in evaluating ("demanding") consumers' goods *ipso facto* also evaluate the means of production which enter into the production of these goods' (Schumpeter 1942, p. 175). Hayek's perceptive reply points out that the *'ipso facto'* assumes complete knowledge of values, demands, scarcities, and so on, to be 'given' to everyone,

thereby ignoring the reality of the universal lack of complete knowledge, as well as the necessary function of the market economy, and the market price system, in conveying knowledge to all its participants (Hayek 1945).

The analysis of imputation began in a neglected work of Aristotle, the *Topics.* Here, Aristotle analysed the ends–means relationship, and pointed out that the means, or 'instruments of production', necessarily derive their value from the ends, the final products useful to man, 'the instruments of action'. The more desirable the final good, the more valuable will be the means to arrive at the product. Aristotle introduced the theme of marginality by stating that, if the addition of a good *A* to an already desirable good *C* yields a more desirable result than the addition of good *B,* then *A* will be more highly valued than B. Indeed, he also added a pre-Böhm- Bawerkian note by stressing the differential value of the loss rather than the addition of a good. Good *A* will be more valuable than *B* if the loss of *A* is considered to be worse than the loss of B. While critics have noted that Aristotle only slightly applied his analysis to the economic realm, his imputation theory was still an important contribution to the general theory of action of which economic theory is a highly developed part (Spengler 1955).

Incentive Compatibility

John O. Ledyard

I

Abstract

Incentive compatibility – a characteristic of mechanisms whereby each agent knows that his best strategy is to follow the rules, no matter what the other agents will do – is desirable because it promotes the achievement of group goals. But it is elusive because pervasive opportunities exist for misbehaviour, such as by misrepresenting preferences. This article reviews attempts to solve or at least to manage the incentive compatibility problem. Incentive compatibility provides a basic constraint on the possibilities for normative analysis, and so serves as the fundamental interface between what is desirable and what is possible in a theory of organizations.

Allocation mechanisms, organizations, voting procedures, regulatory bodies, and many other institutions are designed to accomplish certain ends such as the Pareto- efficient allocation of resources or the equitable resolution of disputes. In many situations it is relatively easy to conceive of feasible processes; processes which will accomplish the goals if all participants follow the rules and are capable of handling the informational requirements. Examples of such mechanisms include marginal cost pricing, designed to attain efficiency, and equal division, designed to attain equity. Of course once a feasible mechanism is found, the important question then becomes whether such a mechanism is also informationally feasible and compatible with 'natural' incentives of the participants. Incentive compatibility is the concept introduced by Hurwicz (1972, p. 320) to characterize those mechanisms for which participants in the process would not find it advantageous to violate the rules of the process.

The historical roots of the idea of incentive compatibility are many and deep. As was pointed out in one of a number of recent surveys,

> the concept of incentive compatibility may be traced to the 'invisible hand' of Adam Smith who claimed that in following individual self-interest the interests of society might be served. Related issues were a central concern in the 'Socialist Controversy' which arose over the viability of a decentralized socialist society. It was argued by some that such societies would have to rely on individuals to follow the rules of the system. Some believed this reliance was naive; others did not. (Groves and Ledyard 1986, p. 1)

Further, the same issues have arisen in the design of voting procedures. Concepts and problems related to incentives were already identified and documented in the 18th century in discussions of proposals by Borda to provide alternatives to majority rule committee decisions. (See ▶ Strategy-proof Allocation Mechanisms for further information on voting procedures.)

Incentive compatibility is both desirable and elusive. The desirability of incentive compatibility can be easily illustrated by considering public goods, goods such that one consumer's consumption of them does not detract from another consumer's simultaneous consumption of that good. The existence of these collective consumption commodities creates a classic situation of *market failure*; the inability of markets to arrive at a Pareto-optimal allocation. It was commonly believed, prior to Groves and Ledyard (1977), that in economies with public goods it would be impossible to devise a decentralized process that would allocate resources efficiently since agents would have an incentive to 'free ride' on others' provision of those goods in order to reduce their own share of providing them. Of course Lindahl (1919) had proposed a feasible process which mimicked markets by creating a separate price for each individual's consumption of the public good. This designed process was, however, rejected as unrealistic by those who recognized that these 'synthetic markets' would be shallow (essentially monopsonistic) and therefore buyers would have no incentive to treat prices as fixed and invariant to their demands. The classic quotation is '... it is in the selfish interest of each person to give *false* signals, to pretend to have less interest in a given collective consumption activity than he really has...' (Samuelson 1954, pp. 388–9). Allocating public goods efficiently through Lindahl pricing would be feasible and successful if consumers followed the rules; but, it would not be successful since the mechanism is not incentive compatible. If buyers do not follow the rules, efficient resource allocation will not be achieved and the goals of the design will be subverted because of the motivations of the participants. Any institution or rule, designed to accomplish group goals, must be incentive compatible if it is to perform as desired.

The elusiveness of incentive compatibility can be most easily illustrated by considering a situation with only private goods. Economists generally model behaviour in private goods markets by assuming that buyers and sellers 'follow the rules' and take prices as given. It is now known, however, that as long as the number of agents is finite then any one of them can still gain by misbehaving and, furthermore, can do so in a way which can not be detected by anyone else. The explanation is provided in two steps. First, if there are a finite number of traders, and none have a perfectly elastic offer curve (which will be true if preferences are non- linear) then one trader can gain by being able to control prices. For example, a buyer would want to set price where his marginal benefit equalled his marginal outlay and thereby gain monopsonistic benefits. Of course, if the others know that buyer's demand curve (either directly or through inferences based on revealed preference) then they would know that the buyer was not 'taking prices as given' and could respond with a suitable punishment against him. This brings us to our second step. Even though others can monitor and prohibit price setting behaviour, our benefit- seeking monopsonist has another strategy which can circumvent this supervision. He calculates a (false) demand curve which, when added to the others' offer curves, produces an equilibrium price equal to that which he would have set if he had direct control. He then calculates a set of preferences which yields that demand curve and participates in the process *as if he had these (false) preferences*. Usually this involves simply acting as if one has a slightly lower demand curve than one really does. Since preferences are not able to be observed by others, he can follow this behaviour which looks like it is price-taking, and therefore 'legal', and can do individually better. The unfortunate implication of such concealed misbehaviour is that the mechanism performs other than as intended. In this case, resources are artificially limited and too little is traded to attain efficiency.

In 1972 Hurwicz established the validity of the above intuition. His theorem can be precisely stated after the introduction of some notation and a framework for further discussion.

The Impossibility Theorem

The key concepts include economic environments, allocation mechanisms, incentive compatibility, the no-trade option, and Pareto-efficiency. We take up each in turn.

An *economic environment*, those features of an economy which are to be taken as given throughout the analysis, includes a description of the agents, the feasible allocations they have available and their preferences for those allocations. While many variations are possible, I concentrate here on a simple model. Agents (consumers, producers, politicians, etc.) are indexed by $i = 1, \ldots, n$. X is the set of feasible allocations where $x = (x^i, \ldots, x^n)$ is a typical element of X. (An exchange environment is one in which X is the set of all $x = (x^1, \ldots, x^n)$ such that $x^i \geq 0$ and $\sum x^i = \sum w^i$, where w^i is i's initial endowment of commodities.) Each agent has a selfish utility function $u^i(x^i)$. The environment is $e = [I, X, u^1, \ldots, u^n]$. A crucial fact is that initially *information is dispersed* since i, and only i, knows u^i. We identify the specific knowledge i initially has as i's *characteristic,* e^i. In our model, $e^i = u^i$.

Although there are many variations in models of allocation mechanisms, I begin with the one introduced by Hurwicz (1960). An *allocation mechanism* requests information from the agents and then computes a feasible allocation. It requests information in the form of messages m^i from agent i through a *response* function $f^i(m^i, \ldots, m^n)$. Agent i is told to report $f^i(m, e^i)$ if others have reported m and i's characteristic is e^i. An equilibrium of these response rules, for the environment e, is a joint message m such that $m^i = f^i(m, e^i)$ for all i. Let $\mu(e, f)$ be the set of equilibrium messages for the response functions f in the environment e. The allocation mechanism computes a feasible allocation x by using an *outcome* function $g(m)$ on equilibrium messages. The net result of all of this in the environment e is the allocation $g[\mu(e, f)] = x$ *if all i follow the rules*, f. Thus, for example, the *competitive mechanism* requests agents to send their demands as a function of prices which are in turn computed on the basis of the aggregate demands reported by the consumers. In equilibrium, each agent is simply allocated their stated demand. (An alternative mechanism, yielding exactly the

same allocation in one iteration, would request the demand function and then compute the equilibrium price and allocation for the reported demand functions.) It is well known, for exchange economies with only private goods, that if agents report their true demands then the allocations computed by the competitive mechanism will be Pareto-optimal.

It is obviously important to be able to identify those mechanisms, those rules of communication, that have the property that they are self-enforcing. We do that by focusing on a class of mechanisms in which each agent gains nothing, and perhaps even loses, by misbehaving. While a multitude of misbehaviours could be considered it is sufficient for our purposes to consider a slightly restricted range. In particular we can concentrate on undetectable behaviour, behaviour which no outside agent can distinguish from that prescribed by the mechanism. We model this limitation on behaviour by requiring the agent to restrict his misrepresentations to those which are consistent with some characteristic he might have. An allocation mechanism is said to be *incentive compatible* for all environments in the class E if there is no agent i and no environment e in E and no characteristic e^{*i} such that (e/e^{*i}) is in E (where (e/e^{*i}) is the environment derived from e by replacing e^i with e^{*i}) and such that

$$u^i\{g[\mu(e,f)],e^i\} < u^i\{g[\mu(e/e^{*i},f)],e^i\}$$

where $u^i(x^*, e^i)$ is i's utility function in the environment e. That is, no agent can manipulate the mechanism by pretending to have a characteristic different from the true one and do better than acting according to the truth. The agent has an incentive to follow the rules and the rules are compatible with his motivations.

Incentive compatibility is at the foundation of the modern *theory of implementation*. In that theory, one tries to identify conditions under which a particular social choice rule or performance standard, $P : E \to X$, can be recreated by an allocation mechanism under the hypothesis that individuals will follow their self-interest when they participate in the implementation process. In our language, the rule P is implementable if and only if there is an incentive compatible mechanism (f, g) such that $g[\mu(e, f)] = P(e)$ for all e in E. The theory of implementation seeks to answer the question 'which P are implementable?' We will see some of the answers below for P which select from the set of Pareto-efficient allocations. Those interested in more general goals and performance standards should consult Dasgupta et al. (1979) or Postlewaite and Schmeidler (1986).

An allocation mechanism is said to have the *no trade-option* if there is an allocation θ at which each participant may remain. In exchange environments the initial endowment is usually such an allocation. Mechanisms with a no-trade option are non-coercive in a limited sense. If an allocation mechanism possesses the no- trade option then the allocation it computes for an environment e, if agents follow the rules, must leave everyone at least as well off, using the utility functions for e, as they are at θ. That is, for all i and all e in E

$$u^i\{g[\mu(e,f)],e^i\} > u^i(\theta,e^i).$$

An allocation mechanism is said to be *Pareto-efficient in E* if the allocations selected by the mechanism, when agents follow the rules, are Pareto-optimal in e. That is, for each e in E, there is no allocation x^* in X such that, for all i,

$$u^i(x^*,e^i) \geq u^i\{g[\mu(e,f)],e^i\}$$

with strict inequality for some i.

With this language and notation, Hurwicz's theorem on the elusive nature of incentive compatibility in private markets, subsequently expanded by Ledyard and Roberts (1974) to include public goods environments, can now be easily stated. *Theorem*: In classical (public or private) economic environments with a finite number of agents, there is no incentive compatible allocation mechanism which possesses the no-trade option and is Pareto-efficient. (Classical environments include pure exchange environments with Cobb–Douglas utility functions.)

A more general version of this theorem, in the context of social choice theory, has been proven by Gibbard (1973) and Satterthwaite (1975) with

the concept of a 'non-dictatorial social choice function' replacing that of a 'mechanism with the no- trade option'. (See ▶ Strategy-proof Allocation Mechanisms.)

There are a variety of possible reactions to this theorem. One is simply to give up the search for solutions to market failure since the theorem seems to imply that one should not waste any effort trying to create institutions to allocate resources efficiently. A second is to notice that, at least in private markets, if there are a very large number of individuals in each market then efficiency is 'almost' attainable (see Roberts and Postlewaite 1976). A third is to recognize that the behaviour of individuals will generally be different from that implicitly assumed in the definition of incentive compatibility. A fourth is to accept the inevitable, lower one's sights, and look for the 'most efficient' mechanism among those which are incentive compatible and satisfy a voluntary participation constraint. We consider the last two options in more detail.

Other Behaviour: Nash Equilibrium

If a mechanism is incentive compatible, then each agent knows that his best strategy is to follow the rules according to his true characteristic, *no matter what the other agents will do*. Such a strategic structure is referred to as a dominant strategy game and has the property that no agent need know or predict anything about the others' behaviour. In mechanisms which are not incentive compatible, each agent must predict what others are going to do in order to decide what is best. In this situation agents' behaviour will not be as assumed in the definition of incentive compatibility. What it will be continues to be an active research topic and many models have been proposed. Since most of these are covered in Groves and Ledyard (1986), I will concentrate on the two which seem most sensible. Both rely on game-theoretic analyses of the strategic possibilities. The first concentrates on the outcome rule, g, and postulates that agents will not choose messages to follow the specifications of the response functions but to do the best they can against the messages sent by others. Implicitly this assumes that there is some type of iterative process (embodied in the response rules) which allows revision of one's message in light of the responses of others. We can formalize this presumed strategic behaviour in a new concept of incentive compatibility. An allocation mechanism (f, g) is called *Nash incentive compatible* for all environments in E if there is no environment e, no agent i, and no message m^{*i} which i can send such that

$$u^i\left(g\left[\mu(e,f)/m^{*i}, e^i\right]\right) > u^i\left(g\left[\mu(e,f), e^i\right]\right)$$

where $\mu(e, f)$ is the 'equilibrium' message of the response rules f in the environment e, $g(m)$ is the outcome rule, and $[m/m^{*i}]$ is the vector m where m^{*i} replaces m^i. In effect this requires the equilibrium messages of the response rules to be Nash equilibria in the game in which messages are strategies and payoffs are given by $u[g(m)]$. It was shown in a sequence of papers written in the late 1970s, including those by Groves and Ledyard (1977), Hurwicz (1979), Schmeidler (1980), and Walker (1981), that Nash incentive compatibility is not elusive. The effective output of that work was to establish the following. *Theorem*: In classical (public or private) economic environments with a finite number of agents, there are many Nash incentive compatible mechanisms which possess the no-trade option and are Pareto-efficient.

With a change in the predicted behaviour of the participants in the mechanism, in recognition of the fact that in the absence of dominant strategies agents must follow some other self-interested strategies, the pessimism of the Hurwicz theorem is replaced by the optimistic prediction of a plethora of possibilities. (See Dasgupta et al. (1979), Postlewaite and Schmeidler (1986) and Groves and Ledyard (1986) for comprehensive surveys of these results including many for more general social choice environments.) Although it remains an unsettled empirical question whether participants will indeed behave this way, there is a growing body of experimental evidence that seems to me to support the behavioural hypotheses

underpinning Nash incentive compatibility, especially in iterative tâtonnement processes.

Other Behaviour: Bayes' Equilibrium

The second approach to modelling strategic behaviour of agents in mechanisms, when dominant strategies are not available, is based on Bayesian decision theory. These models, called *games of incomplete information* (see Myerson 1985), concentrate on the beliefs of the players about the situation in which they find themselves. In the simplest form, it is postulated that there is a common knowledge (everyone knows that everyone knows that...) probability function, $\pi(e)$, which describes everyone's prior beliefs. Each agent is then assumed to choose that message which is best against the expected behaviour of the other agents. The expected behaviour of the other agents is also constrained to be 'rational' in the sense that it should be best against the behaviour of others. This presumed strategic behaviour is embodied in a third type of incentive compatibility. (It could be argued that the concept of incentive compatibility remains the same, based on non- cooperative behaviour in the game induced by the mechanism, while only the presumed information structure and sequence of moves required to implement the allocation mechanism are changed. Such a view is not inconsistent with that which follows.) An allocation mechanism (f, g) is called *Bayes incentive compatible* for all environments in E given π on E if there is no environment e^*, no agent i, and no message m^{*i} which i can send such that

$$\int u^i\{g[\mu(e,f)/m^{*i}], e^{*i}\}\mathrm{d}\pi(e|e^{*i}\} > \int u^i\{g[\mu(e,f), e^{*i}]\mathrm{d}\pi(e,|e^{*i})\}$$

where, as before, μ is the equilibrium message vector and g is the outcome rule. Further, $\pi(e/e^{*i})$ *is the conditional probability measure on e* given e^{*i}, and u^i is a von Neumann–Morgenstern utility function. In effect, this requires the equilibrium messages of the response rules to be Bayes equilibrium outcomes of the incomplete information game with messages as strategies, payoffs $u[g(m)]$ and common knowledge prior π.

There are two types of results which deal with the possibilities for Bayes incentive compatible design of allocation mechanisms, neither of which is particularly encouraging. The first type deals with the possibilities for incentive compatible design which is independent of the beliefs. The typical theorem is illustrated by the following result proven by Ledyard (1978). *Theorem*: In classical economic environments with a finite number of agents, there is no Bayes incentive compatible mechanism which possesses the no-trade option and is Pareto-efficient *for all* π *on* E. Understanding this result is easy when one realizes that any mechanism (f, g) is Bayes incentive compatible for all π for all e in E if and only if it is (Hurwicz) incentive compatible for all e in E. Thus the Hurwicz impossibility theorem again applies.

The second type of result is directed towards the possibilities for a specific prior π; that is, towards what can be done if the mechanism can depend on the common knowledge beliefs. The most general characterizations of the possibilities for Bayes incentive compatible design can be found in Palfrey and Srivastava (1987) and Postlewaite and Schmeidler (1986). They have shown that two conditions, called monotonicity and self-selection, are necessary and sufficient for a social choice correspondence to be implementable in the sense that there is a Bayes incentive compatible mechanism that reproduces that correspondence. The details of these conditions are not important. What is important is that many correspondences do not satisfy them. In particular, there appear to be many priors π and many sets of environments E for which there is no mechanism which is Bayes incentive compatible, provides a no-trade option and is Pareto-efficient. Thus, impossibility still usually occurs even if one allows the mechanism to depend on the prior.

One recent avenue of research which promises some optimistic counterweight to these negative results can be found in Palfrey and Srivastava (1987). In much the same way that the natural move from Hurwicz incentive compatibility to Nash incentive compatibility created

opportunities for incentive compatible design, these authors have shown that a move back towards dominant strategies may also open up possibilities. Refinements arise by varying the equilibrium concept in a way that reduces the number of (Bayes or Nash) equilibria for a given e or π. Moore and Repullo use subgame perfect Nash equilibria. Palfrey and Srivastava eliminate weakly dominated strategies from the set of Nash equilibria. They have discovered that, in pure exchange environments, virtually all performance correspondences are implementable if behaviour satisfies these refinements. In particular, any selection from the Pareto-correspondence is implementable for these refinements, and so there are many refined-Nash incentive compatible mechanisms which are Pareto-efficient and allow a no-trade option. It is believed that these results will transfer naturally to refinements of Bayes equilibria, but the research remains to be done.

Incentive Compatibility as a Constraint

Another of the reactions to the Hurwicz impossibility result is to accept the inevitable, to view incentive compatibility as a constraint, and to design mechanisms to attain the best level of efficiency one can. If full efficiency is possible, it will occur as the solution. If not, then one will at least find the second-best allocation mechanism. Examples of this rapidly expanding research literature include work on optimal auctions (Harris and Raviv 1981; Matthews 1983; Myerson 1981), the design of optimal contracts for the principle-agent problem, and the theory of optimal regulation (Baron and Myerson 1982). As originally posed by Hurwicz (1972, pp. 299–301), the idea is to adopt a social welfare function $W(x, e)$, a measure of the social welfare attained from the allocation x if the environment is e and then to choose the mechanism (f, g) to maximize the (expected) value of W subject to the 'incentive compatibility constraints', the constraint that the rules (f, g) be consistent with the motivations of the participants. One chooses (f, g) to

$$\text{maximize} \int W\{g[\mu(e,f)], e\}\mathrm{d}\pi(e)$$

subject to, for every i, every e, and every e^{*i},

$$\int u^i\{g[\mu(e/e^{*i},f)], e^i\}\mathrm{d}\pi(e|\,e^i) \leq \int u^i(g[\mu(e,f), e^i])\mathrm{d}\pi(e|\,e^i).$$

As formalized here the incentive compatibility constraints embody the concept of Bayes incentive compatibility. Of course, other behavioural models could be substituted as appropriate.

Sometimes a voluntary participation constraint, related to the no-trade option of Hurwicz, is added to the optimal design problem. One form of this constraint requires that (f, g) also satisfy, for every i and every e,

$$\int u^i\{g[\mu(e)], e^i\}\mathrm{d}\pi(e|\,e^i) \geq \int u^i(\theta[e], e^i)\mathrm{d}\pi(e|\,e^i).$$

In practice this optimization can be a difficult problem since there are a large number of possible mechanisms (f, g). However, an insight due to Gibbard (1973) can be employed to reduce the range of alternatives and simplify the analysis. Now called the *revelation principle*, the observation he made was that, to find the maximum, it is sufficient to consider only mechanisms, called direct revelation mechanisms, in which agents are asked to report their own characteristics. The reason is easy to see. Suppose that (f^*, g^*) solves the maximum problem. Let (F^*, G^*) be a new (direct revelation) mechanism defined by $F^{*i}(m, e^i) = e^i$ and $G^*(m) = g[\mu(m, f)]$. Each i is told to report his characteristic and then G^* computes the allocation by computing that which would have been chosen if the original mechanism (f, G^*) had been used honestly in the reported environment. (F^*, G^*) yields the same allocation as (f^*, g^*), *if each agent reports the truth*. But the incentive compatibility constraints, which (f^*, g^*) satisfied, ensure that each agent will want to report truthfully. Thus, whatever can be done, by any

arbitrary mechanism subject to the Bayes incentive compatibility constraints, can be done with direct revelation mechanisms subject to the constraint that each agent wants to report their true characteristic. One need only choose a function $G : E \to X$ to

$$maximize \int W\{G(e), e\} d\pi(e)$$

subject to, for every *i, e* and e^i,

$$\int u^i\{G(e/e^{*i}), e^i\} \mathrm{d}\pi(e|\, e^i) \leq \int u^i[G(e), e^i] \mathrm{d}\pi(e|\, e^i),$$

and

$$\int u^i[G(e), e^i] \mathrm{d}\pi(e|\, e) \geq \int u^i(\theta[e], e^i) \mathrm{d}\pi(e|\, e^i).$$

There are at least two problems with this approach to organizational design. The first is that the choice of mechanism depends crucially on the prior beliefs, π. This is a direct result of the use of Bayes incentive compatibility in the constraints. Since the debate is still open let me simply summarize some of the arguments. One is that if the mechanism chosen for a given situation does not depend on common knowledge beliefs then we would not be using all the information at our disposal to pursue the desired goals and would do less than is possible. Further, since the beliefs are common knowledge we can all agree as to their validity (misrepresentation is not an issue) and therefore to their legitimate inclusion in the calculations. An argument is made against this on the practical grounds that one need only consider actual situations, such as the introduction of new technology by a regulated utility or the acquisition of a major new weapons system by the government, to understand the difficulties involved in arriving at agreements about the particulars of common knowledge. Another argument against is based on the feeling that mechanisms should be robust. A 'good' mechanism should be able to be described in terms of its mechanics and, while it probably should have the capacity to incorporate the common knowledge relevant to the current situation, it should be capable of being used in many situations. How to capture these criteria in the constraints or the objective function of the designer remains an open research question.

The second problem with the optimal auction approach to organizational design is the reliance on the revelation principle. Restricting attention to direct revelation mechanisms, in which an agent reports his entire characteristic, is an efficient way to prove theorems, but it provides little guidance for those interested in actual organization design. For example it completely ignores the informational requirements of the process and any limitations, if any, in the information processing capabilities of the agents or the mechanism. Writing down one's preferences for all possible consumption patterns is probably harder than writing down one's entire demand surface which is certainly harder than simply reacting to a single price vector and reporting only the quantities demanded at that price. A failure to recognize the information processing constraints in the optimization problem is undoubtedly one of the reasons there has been limited success in using the theory of optimal auctions to explain the existence of pervasive institutions, such as the first- price sealed-bid auction used in competitive contracting or the posted price institution used in retailing.

Summary

Incentive compatibility captures the fundamental positivist notion of self-interested behaviour that underlies almost all economic theory and application. It has proven to be an organizing principle of great scope and power. Combined with the modern theory of mechanism design, it provides a framework in which to analyse such diverse topics as auctions, central planning, regulation of monopoly, transfer pricing, capital budgeting, and public enterprise management. Incentive compatibility provides a basic constraint on the possibilities for normative analysis. As such it serves as the

fundamental interface between what is desirable and what is possible in a theory of organizations.

Incentive Contracts

Edward P. Lazear

Incentives are the essence of economics. The most basic concept, demand, considers how to induce a consumer to buy more of a particular good; that is, how to give him an incentive to purchase. Similarly, supply relationships are descriptions of how agents respond with more output or labour to additional compensation.

Incentive contracts arise because individuals love leisure. In order to induce them to forgo some leisure, or put alternatively, to put forth

effort, some form of compensation must be offered. The theme of this essay is that different forms of incentive contracts deal with some aspects of the problems better than others. The strength of one type of contract is the weakness of another. The labour market trades off these strengths and weaknesses and thereby selects a set of institutions. In what follows, the development of the literature on incentive contracts is briefly discussed. The emphasis is on concepts rather than specific papers or authors, so the bibliography is far from exhaustive.

To discuss incentive contracts, the most general concepts must be narrowed. This essay does that in two ways. First, attention here is restricted to the labour market. At a more general level, incentive contracts can relate to other areas as well. For example, the government may want to have a space satellite built at the lowest possible cost. To do so, incentives must be set appropriately or the producer may charge too much or fail to meet desired quality standards. This problem is analogous to those that arise in the labour context, but for the most part they are ignored, except when isomorphic with the labour market paradigm. Similarly, the law and economics literature is another area where incentive problems are studied, usually in the context of accident liability (see, for example, Green 1976; Polinsky 1980; Shavell 1980). These specific questions are ignored as well, except as they border on the labour market context. Second, the focus is on observability problems. Standard labour supply functions, where hours of work can be observed and paid, are incentive contracts. However, standard labour supply issues are eliminated from consideration since they are dealt with in other essays in *The New Palgrave*.

General Framework

An employer in a competitive environment must induce a worker to perform at the efficient level of effort or face extinction. The reason is simple: if one employer can, through clever use of an incentive contract, get a worker to perform at a more efficient level, that firm's cost will be lower. Lower costs imply that higher wages can be paid to workers and all workers will be stolen from inefficient firms. As a result, the objective function that is taken as standard for the firm is:

$$\underset{F}{\text{Max}}\ F(Q,E) - C(E), \tag{1}$$

where Q is output and E is worker effort. Thus $F(Q, E)$ is the compensation schedule that the firm announces to the worker; $C(E)$ is the worker's cost of effort function, to be thought of as the dollar cost associated with supplying effort level E.

The competitive nature of the firm in factor and product markets implies that the firm must maximize worker net wealth as in (1) subject to the zero profit constraint:

$$Q = F(Q,E). \tag{2}$$

Output is defined so that each unit sells for \$1 (the numeraire). Thus (2) merely says that output, Q, must be paid entirely to the worker otherwise another firm could steal the worker away by paying more.

The incentive problem arises because the worker takes the compensation scheme $F(Q, E)$ as given and chooses effort to maximize expected utility. Once the worker has accepted the job, his problem is:

$$\underset{F}{\text{Max}}\ F(Q,E) - C(E). \tag{3}$$

The worker's effort supply function comes from solving the first-order condition associated with (3) or

$$C'(E) = \frac{\partial F}{\partial Q}\cdot\frac{\partial Q}{\partial E} + \frac{\partial F}{\partial E}, \tag{4}$$

which says that the worker sets the marginal cost of effort equal to its marginal return to him. The transformation of effort into output, (i.e. $\partial Q/\partial E$) depends on the production function. A convenient specification is

$$Q = E + v, \tag{5}$$

so that output is the sum of effort, E, and luck, v.

An incentive contract selects $F(Q, E)$ subject to the zero-profit constraint, (2), taking into account that the worker behaves according to (4). There are an infinite variety of incentive contracts that are subsumed by $F(Q, E)$. To make things clear, we consider two polar extremes – the salary and the piece rate (for a more detailed treatment, see Lazear 1986).

Let us define a salary as compensation that depends only on input so that $F(Q, E)$ takes the form $S(E)$. An hourly wage is an example. Irrespective of the amount that is produced during the hour, the worker receives a fixed amount that depends only on the fact that he supplies E of effort for the hour. (Of course, difficulty in measuring E may be a compelling reason to avoid this form of incentive contract.) At the other extreme is a piece rate where compensation depends only on output so that $F(Q, E)$ takes the form of $R(Q)$. There, no matter how much or how little effort the worker exerts, his compensation depends only on the number of units produced. Both salaries and piece rates are incentive contracts; the first provides incentives by paying workers on the basis of input. The second provides incentives by paying on the basis of output. More sophisticated incentive contracts, which blend the two or use multiperiod approaches are discussed later.

The Principal–Agent Problem

At the centre of the incentive contract literature is the 'principal–agent' problem. The principal, say, an employer, wants to induce its agent, say, a worker, to behave in a way that is beneficial to the employer. The problem is that the principal's knowledge is imperfect; either he cannot see what the agent does (as in the case of a taxi driver who can sleep on the job) or he cannot interpret the actions (as in the case of an auto mechanic who replaces a number of parts to correct a perhaps simple malfunction). The incentive contracts that can be used to address the problem were discussed early by Ross (1973), Mirrlees (1976), Calvo and Wellisz (1978) and by Becker and Stigler (1974). The last in particular, uses a sampling approach. For example, a politician can be required to post a large bond on taking office. If he is caught engaging in some malfeasant behaviour, he forfeits the bond. This contract is based on output, which is observed infrequently or imperfectly. Other kinds of incentive contracts are discussed in the following sections.

Payment by Output

Sharecropping

One of the earliest examples of incentive contracts that is based on output is sharecropping. In sharecropping, the owner contracts to split the output of the land in some proportion with the individual who farms and lives on it. It was also one of the first incentive schemes that was clearly analysed (see Johnson 1950, and later Cheung 1969, and Stiglitz 1974). The original problem as formulated in sharecropping can be seen as follows.

Payment is conditional only on Q and by some fixed proportion so that the worker receives γQ. Using (4) and (5), compensation of this sort implies that the worker's first-order condition is

$$C'(E) = \gamma$$

so that the worker sets the marginal cost of effort equal to γ. But (5) implies that the marginal value of effort is \$1, which exceeds γ so that the worker puts forth too little effort. This is inefficient. Additionally, if the farmer can obtain land without limit, he pushes his sharecropping acreage to the point where the next unit of land has zero marginal product. This is clearly inefficient but can be remedied if landowners can select sharecroppers and terms according to the amount of land each works. Both the owner and worker could be made better off if the worker could be induced, by another incentive contract, to produce where $C'(E) = 1$.

Renting the land to the farmer and allowing the farmer to keep all of the output accomplishes this. Under rental, the worker's compensation is [Q-Rent]. By (4) and (5), the worker is induced to set $C'(E) = 1$; the marginal cost and marginal

value of output are equated. Of course, rental does not solve all of the problems. Absent in the production function in (5) is that maintenance may be required. For example, if the farmer does not fertilize the land, it may not produce as well in the future. A renter, who can move on to the next plot after the soil is drained of minerals, has little incentive to put resources into the land. Thus the solution is to sell the land to the farmer. Then the individual who works the land has the correct incentives, either because he will continue to use it in the future or because the sale price will reflect the quality of the land. But sale of the land begs most of the questions. The sale may not come about because of the farmer's capital constraints, because of his lack of entrepreneurial skill, or because of his distaste for risk. (Note that risk is shifted from owners to farmers even in sharecropping and renting. Only labour contracts based exclusively on effort shift the risk entirely to the owner.)

The sharecropping paradigm applies to industrial production as well. Profit-sharing arrangements are, in many respects, like sharecropping. This is especially true when there is only one worker. Partnerships are similar. The same incentive problems arise. A worker who can quit and move on to another firm without penalty does not have the same desire to maintain the equipment as the firm's owner. Again the solution is to sell the capital to the worker, but this simply redefines the owner. Then there is no principal-agent problem because there is no agent. This can be considered in more detail in the next section.

Piece Rates

Piece-rate compensation is not much different from sharecropping, the latter being a special case of the former (see Stiglitz 1975). The owner allows the worker (or farmer) to use his capital (or land) and pays the worker according to some function of output. In the simplest scheme, a linear piece rate is used and the worker is paid rate R per unit Q so that compensation is RQ. The worker's maximization problem (3) and (4) implies that the worker sets $C'(E) = R$. The firm's zero-profit constraint in (2) implies that $Q = RQ$ or that $R = 1$. Thus the piece rate is efficient because the worker sets the marginal cost of effort equal to its marginal social value, \$1.

The issue is only slightly more complicated if capital is involved. A linear piece rate with an intercept (i.e. compensation equal to $A + RQ$) will do the job. This incentive contract achieves first-best efficiency. The worker's first-order condition, (4), still guarantees that he sets $C'(E) = R$. The intercept drops out. But the zero-profit constraint now becomes:

$$Q - \text{rental cost of capital} = A + RQ.$$

The firm must 'charge' the worker for the cost of using the capital, but how should this be done? R can be reduced below 1 or A can be set to a negative number. The answer is that $A = -$(rental cost of capital) and $R = 1$. Since (4) does not contain A, the worker does not respond to changes in A. However, reducing R below 1 causes the worker to reduce effort. Thus the efficient incentive contract, which also maximizes worker wealth subject to the firm's zero-profit constraint, requires that $R = 1$. Zero profit requires that $A = -$ (rental cost of capital).

A major advantage to the use of piece rates as an incentive contract is that it tolerates heterogeneity of worker ability. More able – that is, lower effort cost – workers choose higher levels of effort but are paid more. There is no inefficiency involved in having workers of both types in the firm. Of course, if capital is important so that the worker is 'charged' A for the right to work on a machine, only workers above some threshold ability level will choose to work. But workers self-sort. There is no need for the firm to do anything other than pay the efficient piece rate, in this case $R = 1$.

Linear piece rates are no longer appropriate incentive contracts if workers are risk-averse. In general, a non-linear scheme will do better but will fail to achieve first-best solutions. As long as asymmetric information exists, so that individual actions cannot be observed and contracted upon, Pareto optimal risk-sharing is precluded (see Hölmstrom 1979; Harris and Raviv 1979).

Payment of Relative Output

The study of relative compensation has become increasingly important. There are two approaches in this literature. The first, from Lazear and Rosen (1981), characterizes the labour market as a tournament, where one worker is pitted against another. The one with the highest level of output receives the winning prize (i.e. the high-wage job) while the other gets the losing prize (i.e. the low-wage job). By increasing the spread between the winning and losing prizes, incentives are provided to work hard. The optimum spread induces workers to move to the point where the marginal cost of effort exactly equals the marginal (social) return to it. The major advantages to payment by tournament method are twofold. First, tournaments require only that relative comparisons be made. It may be cheaper to observe that one worker produces more than another than to determine the actual amount that each produces. Second, compensation by rank 'differences out' common noise. For example, sales may be low because the economy is in a slump, which has nothing to do with worker effort. Risk aversion operates against penalizing or rewarding workers for factors over which they have no control. But since the slump affects both workers equally, relative comparisons are unaffected. The best worker still produces more, even though both produce small amounts.

Tournament-type incentive contracts induce workers to behave efficiently if they are risk neutral. They are easy to use but carry one major disadvantage. Workers increase the probability of winning, not only by doing well themselves but also by causing the opponent to do poorly. Thus tournaments discourage cooperation. This results in wage compression, which works to discourage the aggressive behaviour of workers who are competing for the same job. Other work in the area of tournament-type incentive contracts includes Nalebuff and Stiglitz (1983), Green and Stokey (1983) and Carmichael (1983).

The second approach, from Hölmstrom (1982), suggests that if levels of output can be observed, then payments can be based, at least in part, on a team average. As Hölmstrom points out, a tournament is not a sufficient statistic, so that using a team average allows the firm to better address risk aversion. This incentive device also takes out common noise. A peer average picks up disturbances that are common to the industry and allows the firm to cater to the tastes of risk-averse workers.

Payment by Input

Observability of Effort

It is commonly alleged that payment of a salary or hourly wage does not provide workers with the appropriate incentives. Whether or not this is true depends on the connection between the measurement of time and measurement of effort. To see this, suppose that effort can be observed perfectly, but that output cannot be observed at all. For example, suppose that it is easy to measure the number of calories burned up by a worker during his work day, but it is impossible to separate his output from that of his peers. Payment by effort is a first-best incentive contract. The compensation scheme that pays the worker \$1 per unit of effort exerted induces him to set $C'(E) = 1$, which, as we have seen, is first best. Note further that this is first best even for risk-averse workers since compensation does not vary with random productivity shocks, v (see Hall and Lilien 1979).

The allegation that effort pay does not provide incentives is based on the difference between hours of work and effort. If hours were a perfect proxy for effort, then payment of an hourly wage would be an optimal incentive contract. But because workers can vary work per hour, the connection breaks down. Payment per hour provides appropriate incentives for choice of the number of hours, but does not deal with what is done within the hour.

Payment by Effort and Worker Sorting

Piece rates induce workers to sort appropriately. Above, it was argued that workers who cannot produce a sufficiently high level of output will not come to a firm that 'charges' for use of capital. Salaries (or hourly wages) that pay on the basis of

an imperfect measure of effort encourage the lower-quality workers to come to the firm. Lazear (1986) demonstrates that a separating equilibrium (see, e.g., Rothschild and Stiglitz 1976; Salop and Salop 1976) exists where high-quality workers choose to work at firms that pay piece rates and low-quality ones choose salaries. The difference in quality across firms might lead one to conclude that movement to output-based incentive contracts increases total output. In fact, the reverse may well be true. In the same sense that screening in Spence (1973) is socially unproductive, forcing salary firms to adopt piece-rate incentive contracts wastes resources on a potentially useless signal.

Incentive Contracts and Product Quality

Sometimes quantity is easier to observe than quality. The problem with incentive contracts that are based on output quantity is that they induce the worker to go for speed and to ignore quality. If quality can be observed, then the worker can be compensated appropriately for quantity and quality. The appropriate compensation function is essentially the consumer's demand for the product as it varies with quality and quantity. But if quality cannot be observed, payment by input 'solves' the quantity/quality problem. If the worker is paid, say, by hour, and is merely instructed to produce goods of a given quality, he has no incentive to deviate from that instruction. Compensation is based only on input, so there is no desire to rush the job. Of course, this requires a method of monitoring effort cheaply (see Lazear 1986, for a full discussion of the trade-offs).

Other Issues in Incentive Contracting

Efficient Separation and Long-Term Investments

A properly structured incentive contract must induce the correct amount of long-term investment. The problem is most clearly seen in the context of specific human capital, as in Becker (1962, 1975). Specific human capital is only valuable when the worker is employed at the current firm. As such, workers are reluctant to invest in specific capital because the firm may capriciously fire the worker, in which case the investment is lost. Similarly, firms are reluctant to invest because the worker may capriciously quit. The incentive contract that Becker suggests is a sharing of investment costs and returns by both workers and firms (Hashimoto and Yu 1980, model this more precisely). Kennan (1979) points out that a particular kind of severance pay solves the investment problem. It is akin to the liability rules that are efficient in auto accident problems. But as Hall and Lazear (1984) argue, these rules may actually induce too much investment. Since a worker is compensated for the full investment whether work occurs or not, he has no incentive to account for situations that make a separation optimal. For example, if it were optimal to sever the work relationship 25 per cent of the time, the worker should behave as if a specific investment that yields $1 return only yields $0.75. A full-reimbursement severance pay arrangement ensures a full $1, irrespective of the status of work, and induces too much investment.

More general issues of efficient separation arise in the labour market context, and incentive contracts must be structured to deal with these problems. Hall and Lazear (1984) consider a variety of different incentive contracts and conclude that none generally achieves first best. One that comes close to doing so is Vickrey's (1961) bilateral auction approach. There, compensation and work are separated so that the worker and firm have incentives to reveal the true relevant values. Another scheme is coordinated severance pay, suggested by d'Aspremont and Gerard-Varet (1979). Sufficiently high penalties on the firm associated with a worker's refusal to work induces the firm to behave in a manner that is apparently first best.

Intertemporal Incentive Contracts

Sometimes, the fact that workers live for more than one period allows contracts to be structured in a way that solves incentive problems. This is the subject of Lazear (1979, 1981). The problem is that as a worker approaches the end of his career, he has an incentive to shirk because the costs, even of being fired, are reduced as his retirement date draws near. A way to discourage shirking is to

tilt the age-earnings profile and couple it with a contingent pension. Young workers are paid less than their marginal products; old workers are paid more. In equilibrium, shirking is discouraged and workers receive exactly their lifetime marginal products. The distortion in the timing of the payments implies that workers do not voluntarily choose to work the correct number of hours. Thus hours constraints are required, an extreme form of which is mandatory retirement. Other work that has refined or provided empirical support for that concept is Kuhn (1986) and Hutchens (1986a, b).

There are other papers that focus on the intertemporal aspects of incentive contracts. The first, Fama (1980) argues that the market provides a discipline on workers. In a spot market, the wage that another firm is willing to offer a worker next period depends on how well he did last period. Fama shows that this can act as a perfect incentive device. Of course, no end-game problems are addressed by this mechanism, but it does demonstrate the possibility of incentive provision even without explicit or implicit contracts. The second idea is attributable to Rogerson (1985). The emphasis here is on risk-sharing, but the work has some features in common with Fama (1980). In particular, memory plays a strong role in these incentive contracts, so that an outcome that affects the current wage also affects the future wage.

Intertemporal Strategic Behaviour by Firms

Once intertemporal contracts are considered, it is necessary to examine the issue of opportunistic behaviour by firms. It may be that a firm does not know a worker's cost of effort function, $C(E)$. Actions that the worker takes may reveal information about that function. The firm can use that information in subsequent periods against the worker. As a result, the worker attempts to disguise $C(E)$, leading to inefficiencies. Such is the case of salesmen, whose next period quota depends on this period's performance. In Lazear (1986) it is shown that a properly structured contract in a competitive labour market can undo the effects of this kind of strategic behaviour. This is a specific example of the general theorem on revelation presented in Harris and Townsend (1981). It is also related to the literature on planned economies, since bureaucrats tend to make things look worse than they are to lessen next period's requirements or to increase next period's budget allocation (see, e.g., Weitzman 1976, 1980; Fan 1975).

Insurance

Finally, there is a closely related literature that examines insurance contracts. That literature focuses, for the most part, on the trade-off between insurance and efficiency in the labour market. Some of the more important papers in that literature include Harris and Hölmstrom (1982), Grossman and Hart (1983) and Green and Kahn (1983).

Conclusion

Although incentive problems are pervasive, the market has found a number of solutions. These involve payment by output of the piece rate or sharecropping variety; payment by relative output, exemplified by labour market tournaments; payment by measured input, such as hours of work; and multi-period incentive contracts. The contracts do not always achieve the first best, especially when risk aversion is an issue. Still, the rich variety of institutions that address incentive problems and the large amount of literature devoted to study attest to the problem's importance in the labour market context.

Income

D. Usher

Like 'supply', 'demand', 'rent', 'welfare' and 'utility', the word 'income' is a part of common speech that has entered economics as a technical term. *The Concise Oxford Dictionary* defines income as 'receipts from one's lands, work, investment etc'. That meaning carries over into economic theory, where, for instance, a consumer may be said to maximize utility subject to an income constraint or a firm may be said to maximize income accruing to its stockholders. The meaning of income is somewhat modified in the construction of income statistics. These are employed in two quite distinct contexts: as the basis for income taxation and as generalized to national income.

In each context, the definition of income is governed by the purpose of the statistics. Personal and corporate income are defined to serve as criteria for taxing people and corporations, the main principles behind the definitions being equity or fairness among people with different sources of income and efficiency in the economy as a whole. The purpose of income within the national accounts is less easily defined. The national accounts are an intricate set of statistics intended to describe the economy as a whole, primarily but not exclusively to facilitate counter-cyclical policy. The simple concept of income as applied to a person is extended to the entire nation in several ways: national income is the sum of the earnings of all factors of production; national product is the value of output of all goods and services; national expenditure is the sum of each person's expenditure on goods and services. All three would be equal in a world without depreciation, indirect taxation or subsidies. Income statistics also serve as the basis for comparisons among regions, products and occupations; converted to real income, they become the basis for the measurement of the rate of economic growth.

As a first approximation, we may say that national income is the sum of all personal incomes, but the definition of income for tax purposes differs in several important respects from the definition in the national accounts. The major differences can be classified under the headings of scope, intermediation and timing.

The scope of income is a trade-off between two objectives, to include all benefits to consumers as part of income, even benefits arising from non-market activity, and to construct statistics that are reasonably precise and beyond dispute. The latter consideration is relatively more important for tax purposes. Thus money values of the services of owner-occupied housing, food grown and consumed on farms, and direct provision of food and lodging for the armed services, are usually included in national income but almost never as part of the tax base. Housework, on the other hand, is included in neither definition, giving rise to the old paradox that the national income falls if a man marries his housekeeper. There is an ongoing debate in public finance as to whether the base for personal taxation should be income as a whole (consumption plus investment) or just consumption.

The major issue in the timing of income concerns capital gains which are sometimes included in income for tax purposes but are never part of the national income. They are excluded from the national income so that beneficial changes in technology and other aspects of the economy appear as part of income in the years when they materialize as goods and services rather than when they are first anticipated. Personal income is another matter. A person becomes wealthy in the year his assets appreciate, regardless of the dates of the increases in the marginal products of the corresponding capital goods. The usual justification for including capital gains as part of taxable income is that a person should be taxed when be becomes wealthy, just as he is taxed when he earns ordinary income.

The inclusion of capital gains in the tax base creates several problems: assets may appreciate as part of a general inflation; taxation of capital gains may only be feasible when gains are realized

rather than when they accrue; gain on human capital is automatically exempt from the tax; taxation of capital gain may be double taxation of the return to capital because future tax on the earnings to capital goods is discounted back in the price at which the goods are sold. However, the exclusion of capital gains from the tax base creates an incentive for firms to seek ways to disburse money to people as non-taxable capital gains rather that as taxable income.

Both personal and national income are defined net of the cost of intermediate products. The income of the travelling salesman is net of the cost of his car, and the national income is net of the aggregate cost of transport for business purposes – of the cost of haulage of goods, business travel, and so on. The boundary between final and intermediate products is sometimes problematic. For example, it is not always clear how to classify the business lunch, especially for participants who would rather diet. Current expenditure of government is classified in the national accounts as consumption, yet it is arguable that most such expenditure is either intermediate product (social overhead for the economy as a whole) or intangible investment (the obvious instance being current expenditure on research).

Depreciation is like an intermediate product. An input to production that is used up in the course of the year or incorporated into output is unambiguously intermediate, and its cost is excluded on that account from the measure of income. An input to production that lasts more than a year but depreciates somewhat during the first year is financially equivalent to the sum of an ordinary intermediate product and an input that only becomes available at the end of the first year. To deduct depreciation from income is to treat the intermediate component of investment like an ordinary intermediate good. On the other hand, it is often difficult in practice to determine what depreciation ought to be. The tax code specifies rates of allowable depreciation for each type of capital equipment, for it is more important in this context to be precise and predictable than to be right. There is more flexibility in the national accounts and an attempt is made to measure the true loss over the year in the value of capital goods. Loss of value may be deterioration or obsolescence. Both belong as part of depreciation, especially when obsolescence is anticipated, for it makes no difference at the time a machine is purchased whether it is destined to deteriorate through use or to become worthless as better machines are developed. Unanticipated obsolescence is more problematic, for there is something anomalous in reducing this year's national income for the fall in the value of capital goods brought about by expected technical change next year when the benefit of the change itself is excluded. Income would fall though there would be no reduction of output in the current year and people would be better off in the long run.

Income Mobility

Gary S. Fields

Abstract

Income mobility means different things to different people. This article explains the six different mobility concepts used in the literature, reviews the various indices used in the mobility literature to measure these concepts, summarizes the difference the use of different mobility concepts and measures makes in practice, presents the axiomatic approach to income mobility, and discusses a number of other issues that arise in the mobility literature.

Keywords

Absolute mobility; Exchange mobility; Income mobility; Inequality (measurement); Intergenerational income mobility; Movement studies; Relative mobility; Structural mobility; Time-independence studies; Translation invariance

What is income mobility? Extensive surveys of the income and earnings mobility literatures may be found in Atkinson et al. (1992), Maasoumi (1998), Solon (1999), and Fields and Ok (1999a). ('Income' refers to income from all sources while 'earnings' refers to income earned in the labour market.) Mobility analysts agree on one defining feature: 'income mobility' is about how much income each recipient receives at two or more points in time. In this way, income mobility studies are distinguished from studies of the inequality and poverty aspects of income distribution, both of which are based (typically) on anonymous cross sections or (less frequently) marginal distributions of the joint distributions.

The following notation is used throughout this article. Let $x = (x^1, \ldots, x^n)$ denote a vector of 'incomes' in an initial year. This vector is 'personalized' in the sense that the same recipient units are followed over time. It is conventional to array the recipients in the base year from lowest income to highest. Whether this convention is followed or not, it is essential to keep the same order for subsequent years (or generations). Denote the ordered vector in a subsequent year by $y = (y^1, \ldots, y^n)$. The micro-mobility data, also termed in the literature the pattern of 'distributional change', is summarized by the transformation $x \rightarrow y$ in the two-period case or more generally the transformation $x \rightarrow y \rightarrow z \rightarrow \cdots$ in the T-period case. The extent of mobility associated with the transformation $x \rightarrow y$ will be denoted by $m(x, y)$.

Beyond agreeing that income mobility studies are about transformations of the type $x \rightarrow y$ or $x \rightarrow y \rightarrow z \rightarrow \cdots$, the literature is marked by considerable disagreement. This is because the term 'income mobility' connotes precise but *different* ideas to different researchers. It is for this reason that mobility analysts often have trouble communicating with each other, with other social scientists, or with the general public. Furthermore, these differences in notions of what income mobility is remain even after agreement is reached on a number of other aspects of the mobility under consideration. These other aspects, discussed in the following paragraphs, are whether the context is intergenerational or intragenerational, what the indicator of social or economic status is, and whether the analysis is at the macro-mobility or micro-mobility level.

One issue is whether the aspect of mobility of interest is intergenerational or intragenerational. In the *intergenerational* context, the recipient unit is the family, specifically a parent and a child. In the *intragenerational* context, the recipient unit is the individual or family at two different dates. The issues discussed in this article apply equally to both.

Second, agreement must be reached on an indicator of social or economic status and the

choice of recipient unit. For brevity, I shall talk about mobility of 'income' among 'individuals'.

Third, the mobility questions asked and our knowledge about mobility phenomena may be grouped into two categories, macro and micro. *Macro*-mobility studies start with the question, 'How much economic mobility is there?' Answers are of the type '*a* per cent of the people stay in the same income quintile', '*b* per cent of the people moved up at least $1,000 while *c* per cent of the people moved down at least $1,000', 'the mean absolute value of income change was $*d*,' and 'in a panel of length T, the mean number of years in poverty is t^*.' The macro-mobility studies often go beyond this question to ask, 'Is economic mobility higher here than there and what accounts for the difference?' Answers would be of the type, 'economic mobility has been rising over time', '*A* has more upward mobility than *B* because economic growth was higher in *A* than in *B*', and 'incomes are more stable in *C* than in *D* because *C* has a better social safety net'. *Micro*-mobility studies, on the other hand, start with the question, 'What are the correlates and determinants of the income or positional changes of individual income recipients?' The answers to these questions would be of the type, 'unconditionally, income changes are higher for the better-educated' and 'other things equal, higher initial income is associated with lower subsequent income growth'.

These three issues – intergenerational versus intragenerational, changes in the distribution of what among whom, and macro-mobility versus micro-mobility – help determine which kind of mobility analysis is being undertaken. Yet major differences remain. It is to these that we now turn.

Mobility Concepts and Measures

At least 20 mobility measures have been used in the literature. Many empirical mobility studies divide base- and final-year incomes into quantiles (for example, quintiles or deciles) and calculate immobility ratios, mean upward movements, and the like (Fields 2001). Other studies estimate correlation coefficients between base-year and final-year incomes (Atkinson et al. 1992). In the intergenerational mobility literature, it is common to calculate intergenerational elasticities, that is, the coefficient obtained when the logarithm of the child's income is regressed on the logarithm of the parent's (Solon 1999).

In each case, we may ask, what are the various measures measuring? The essential answer is this: *different indices measure different underlying entities*. Whenever one of these underlying entities is measured, other information contained in the joint distribution of initial and final incomes is lost.

What are the different underlying entities that the various income mobility measures measure? The first distinction to be drawn is between measures of time independence and measures of movement. The question asked by *time-independence* studies is, how dependent is current income on past income? One commonly used measure of time independence is the beta coefficient commonly calculated in the intergenerational mobility literature by regressing the log-income of the child on the log-income of the parent.

Movement studies ask a different question, namely: in comparisons of incomes of the same individuals between one year and another, or of parents and children between one generation and another, how much income movement has taken place? The various movement indices in the literature may usefully be classified into five categories or concepts ('concepts' because they are different underlying entities, not alternative measures of the same underlying entity).

Positional movement (or 'quantile movement') is about the movement of individuals among various positions (quintiles, deciles, centiles, or ranks) in the income distribution. An individual experiences positional movement if and only if he or she changes quintiles, deciles, centiles, or ranks. Positional movement in a population is greater the more such positional changes there are and/or the larger these positional changes are. King (1983) derived a broad class of positional movement indices axiomatically, one member of which is

$$M_K(x,y) = 1 - \exp\left[-\frac{\gamma}{n}\sum_{i=1}^{n}\frac{|z_i - y_i|}{\mu(y)}\right],$$

where γ is the observer's degree of immobility aversion, z_i is the income level agent i would have obtained if his or her rank order did not change during the process $x \rightarrow y$, and $\mu(y)$ is the mean income in distribution y.

Like positional movement, *share movement* is relative but it is relative in a different way. Share movement takes place if and only if an individual's income rises or falls relative to the mean. Thus, an individual can experience upward or downward share movement even if his or her income in dollars is unchanged and/or if he or she does not change position within the income distribution. Share movement in the population reflects the frequency and magnitude of these individual share changes. One attractive index of share movement in a population is the mean absolute value of share changes

$$M_S(x,y) = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{y_i}{\mu_y} - \frac{x_i}{\mu_x}\right|,$$

where $\mu(x)$ and $\mu(y)$ are the means of distributions x and y respectively.

Another concept is *non-directional income movement* (also called '*flux*'), which gauges the extent of fluctuation in individuals' incomes. To illustrate, suppose that in a two-person economy one person's income goes up by $10,000 while another's goes down by $10,000. Those who see an average income change of $10,000 are non-directional income movement adherents. Two indices of non-directional income movement have been suggested by Fields and Ok (1996, 1999b):

$$M_{F-O_1}(x,y) = \frac{1}{n}\sum_{i=1}^{n}|y_i - x_i|$$

and

$$M_{F-O_2}(x,y) = \frac{1}{n}\sum_{i=1}^{n}|\log y_i - \log x_i|.$$

Suppose, however, that, when one person's income goes up by $10,000 and another's goes down by $10,000, the observer cares not only about the amounts of the income changes but also about their direction. *Directional income movement* may be judged using a linear or a concave valuation function. One valuation function which embodies concavity is the mean change in log-incomes (Fields and Ok 1999a, b):

$$M_{F-O_3}(x,y) = \frac{1}{n}\sum_{i=1}^{n}(\log y_i - \log x_i).$$

As a fifth and final notion of income movement, consider how the income changes experienced by individuals cause the inequality of longer-term incomes to differ from the inequality of base-year incomes. *Mobility as an equalizer of longer-term incomes* would judge that a pattern of income change (1, 3) → (1, 5) would *disequalize* longer-term income relative to the base, while a pattern of income change (1,3)→ (5,1) would *equalize* longer-term income relative to the base. This concept is well-established in the literature (Schumpeter 1955; Shorrocks 1978b; Atkinson et al. 1992; Slemrod 1992; Krugman 1992; Jarvis and Jenkins 1998), but only recently has a class of measures of this concept been proposed (Fields 2005). One family within this class is

$$\varepsilon \equiv 1 - (I(a)/I(x)),$$

where x is the vector of base-year incomes, y is the vector of final-year incomes, a is the vector of average incomes, the i'th element of which is $a^i \equiv \frac{x^i + y^i}{2}$, and $I(.)$ is a cross-sectional inequality measure such as the Gini coefficient or the Theil index.

We thus have six mobility concepts and a large number of measures. Because these concepts are fundamentally different from one another, it is important for analysts to choose the concepts that are of greatest interest to them and then measure those concepts. Let us now turn to a brief empirical review of studies that have used two or more of these concepts.

Different Mobility Concepts in Practice

The previous section distinguished between time independence, positional movement, share movement, non-directional income movement, directional income movement, and mobility as an equalizer of longer-term incomes. How do these six concepts and the measures of them compare in empirical work? Specifically, which country has more mobility than another? Has mobility been rising or falling over time within a country? Are some groups in the population more or less mobile than others?

The answers to these questions have been shown empirically to depend on which mobility concept is used. In comparing *OECD countries*, some countries were found to be more mobile than others with the use of measures of some concepts and less mobile than others with the use of measures of other concepts (OECD 1996; 1997). When we looked over time, in the *United States* measures of four concepts (time independence, positional movement, share movement, and income flux) all peaked in 1980–5 but measures of two other concepts did not: directional income movement exhibits a saw-tooth pattern, while mobility as an equalizer of longer-term incomes exhibits a peak followed by a valley (Fields et al. 2002; Fields 2005). In *France*, mobility differences among demographic groups have been explored (Buchinsky et al. 2004). The answers to the questions 'Who has more mobility: women or men? Better-educated or less-educated workers?' were shown to differ depending on which mobility concept was used. By gender, women in France have *more* time independence and positional movement than men, *less* share movement than men, *about the same* non-directional and directional movement in logs, and *about the same* amount of mobility as an equalizer of longer-term incomes. By education, those with the highest educational attainments have *less* time independence and positional movement, and if anything *more* share movement, flux, and directional income movement in logs. In *Argentina*, too, measures of the six different concepts produced qualitatively different results (Sánchez Puerta 2005).

Looking at changes over time, some mobility indices increased, some decreased, and some showed no clear trend. Comparing population subgroups (genders, educational levels, age ranges, regions, initial quintiles, and initial sector), some groups were found to have higher earnings mobility for some concepts and lower earnings mobility for others; no group was found to have higher mobility than others for every mobility concept. Finally, in both *Venezuela* and *Mexico*, the time trend of mobility was found to vary according to the notion of mobility measured (Freije 2001; Duval Hernández 2005).

The conclusion is that at both levels, macro and micro, it makes an important qualitative difference which mobility concept is being gauged. When a layperson asks an economist which of two situations is the more mobile, the answer 'It depends' is not very satisfying. An answer of the type 'Current incomes are more dependent on past incomes in the United Kingdom than in the United States (that is, the UK is *less* mobile in this respect than the USA), but the United Kingdom has more quintile movement than the United States (and therefore is *more* mobile than the USA in this sense)' is more informative, even if less clear-cut than the questioner may have been hoping for.

The Axiomatic Approach to Income Mobility

We have seen that there are different income mobility concepts and that the indices measuring these concepts behave differently from one another. How is the analyst to decide which notion(s) best capture(s) the essence of 'income mobility' for him or her? One approach is to proceed axiomatically, that is, to say that 'for me, mobility is such and such' and then to see which concepts, if any, embody these axioms.

Two broad approaches to axiomatization may be found in the literature. In one approach, mobility is conceptualized in social welfare terms (Atkinson 1980; King 1983; Chakravarty et al. 1985; Dardanoni 1993; Gottschalk and Spolaore 2002; Ruiz-Castillo 2004). In the other, a descriptive approach is used, wherein analysts

specify the properties they wish income mobility concepts and measures to possess, and then proceed to deduce which indices, if any, have these properties (Cowell 1985; Fields and Ok 1996, 1999b; D'Agostino and Dardanoni 2005). The work of Shorrocks (1978a, b) makes use of both of these approaches. This difference between the ethical and the descriptive axiomatizations in the mobility literature parallels the two strands of the inequality literature (Foster and Sen 1997): for Atkinson (1970), inequality is the amount of social welfare lost because incomes are distributed the way they are rather than being distributed perfectly equally, whereas for Sen (1973, p. 2), inequality is objective in the sense that 'one can distinguish between (*a*) "seeing" more or less inequality, and (*b*) "valuing" it more or less in ethical terms'. Note that under both the ethical and the descriptive approaches the amount of mobility recorded has or may have welfare significance. For example, many observers would say that an economy with more directional income movement has performed better than an economy with less directional income movement.

The literature offers a wide variety of axioms, some of which were designed with particular mobility concepts in mind, others of which have been explored to help sharpen what is meant by 'mobility'. Shorrocks (1993) presents 12 axioms for mobility and shows that they are mutually incompatible. In view of their incompatibility, there is a need for judgements as to which ones an analyst wants a measure to embody.

Fields and Ok (1999a) and Fields (2001) have suggested that analysts choose among the axioms by considering their views on simple examples. For example, consider the following three situations:

$$\begin{aligned} \text{I} &: (1,3) \rightarrow (1,3) \\ \text{II} &: (1,3) \rightarrow (2,6) \\ \text{III} &: (2,6) \rightarrow (4,12) \end{aligned}$$

and the corresponding degree of mobility $m(x, y)$. (As above, $\rightarrow$ denotes a change in the ordered (personalized) vector of incomes.) The axiom of strong relativity, if accepted, would maintain that $m(\lambda x, \alpha y) = m(x, y)$ for all $\lambda, \alpha > 0$ and all $x, y \in \mathcal{R}^n_+$. If strong relativity is accepted, it requires that Situations I, II, and III all have the same mobility. In Situation I, the only sensible amount of mobility for there to be is zero, and therefore strong relativity requires that Situations II and III also have zero mobility. An analyst who sees non-zero income mobility in Situations II and III is therefore not a strong relativity adherent.

Similarly, (weak) relativity specifies that $m(\lambda x, \lambda y) = m(x, y)$ for all $\lambda > 0$ and all $x, y \in \mathcal{R}^n_+$. This axiom requires that Situations II and III have the same mobility, though not necessarily the same mobility as Situation I. Therefore, an analyst who sees more mobility in Situation III than in Situation II is not a (weak) relativity adherent either.

The literature offers characterizations of some of the mobility measures that have been used – for example, Fields and Ok's (1996, 1999b) measures of non-directional and directional income movement and Chakravarty et al. (1985) index of mobility as welfare change. More commonly, though, the axioms are used to state a number of desirable properties and then display a measure or a family of measures consistent with these properties.

In summary, a fruitful way for the analyst to choose which mobility concept(s) is (are) most salient for oneself is to consider the axiomatic judgements underlying each of the concepts. To date, some but not all of the income mobility concepts have been so characterized.

Other Issues

The income mobility literature has a number of other issues that remain more or less contentious, not because the different views have not been worked out but because different analysts hold genuinely different positions on a number of important matters.

Is All Distributional Change 'Mobility' or Only Some of It?

Lurking in the background of some writings on income mobility is a fundamental difference of opinion about what income mobility is. For the

majority of analysts, the notion of 'income mobility' has both absolute and relative components. For example, if all incomes double, most would judge there to be more mobility than if all incomes remain unchanged. For some analysts, though, the notion of 'income mobility' is relative only; therefore, the change in the mean needs to be taken out, and 'mobility' applies only to what is left.

Thinking of 'mobility' in this way can lead to some controversial judgements. For example, Chakravarty, Dutta and Weymark (hereafter CDW) (1985) propose the following mobility index:

$$M_{CDW} \equiv \left(E\left(y_{agg}\right)/E(b)\right) - 1,$$

where $E(.)$ is an equality measure, y_{agg} is a vector of aggregate incomes over the observation period, and b is the benchmark vector of incomes under the assumption of complete relative immobility following the first period. In the case in which $E(.)$ is a relative equality measure, the term $E(b)$ is replaced by $E(x)$, where x is the vector of first-period incomes. In the view of these authors (CDW, 1985, p. 8): 'Socially desirable mobility is associated with income structures having positive index values while socially undesirable mobility is associated with income structures having negative index values.' Thus, given their index, CDW judge that mobility contributes positively to social welfare if and only if y_{agg} is distributed more equally than x. Thus, if all incomes rise but the percentage gains are larger at the top end of the income distribution than they are at the bottom, mobility would be judged by CDW to have been socially *undesirable*, in direct contradiction to the quasi-Paretian welfare judgement that an increase in some incomes with no decline in others *raises* social welfare. This difference of views – whether 'income mobility' includes the growth aspect of distributional change or whether 'mobility' is what remains after growth has been taken out – underlies much of the mobility literature, but rarely is it made explicit.

What Is 'Relative Mobility'?

As already noted, the term 'relative mobility' is used ambiguously, sometimes to refer to mobility notions characterized by strong relativity $m(\lambda x; \alpha y) = m(x; y)$ for all λ; $\alpha > 0$ and all $x, y \in \mathcal{R}^n_+$ and sometimes to refer to those characterized by weak relativity $m(\lambda x, \lambda y) = m(x, y)$ for all $\lambda > 0$ and all $x, y \in \mathcal{R}^n_+$. Note that for both of these relativity notions the basis for determining whether a given individual is experiencing upward or downward relative mobility is that individual's change in *income* relative to the *income* changes of others.

However, the term 'relative mobility' is used in yet another sense, namely, to refer to *positional* movements. On this view, an individual experiences relative mobility if and only if he or she changes position (quintile, decile, centile, or rank) from base year to final year. For example, Jenkins and Van Kerm (2003) break down trends in income inequality into a 'pro-poor income growth' component and an 'income mobility' component. The 'income mobility' component involves re-rankings and only re-rankings. Thus, for them as for some others, mobility *is* positional movement and nothing more.

Finally, D'Agostino and Dardanoni (2005) have yet a different definition of relative mobility. For them, relative mobility involves a change in an individual's relative standing with respect to all others, whereas absolute status is something that can be derived by looking at data regarding the individual taken in isolation.

This last point raises the issue of what is meant by 'absolute mobility,' to which we now turn.

What Is 'Absolute Mobility'?

The term 'absolute mobility' is used in at least three different ways in the income mobility literature. One way is to express a concern with gains and losses of *income* rather than *income shares* or *positions*. In this sense, the concept of directional income movement and the various measures of that concept are about absolute mobility. Second, 'absolute mobility' is sometimes used to mean that the analyst is concerned with the *absolute value* of income changes, as would be the case

in studies of non-directional income movement, or flux. Third, the term is used in the sense of *translation invariance*, in the sense that, if all initial and final incomes are increased by the same amount, the new situation has the same absolute mobility as the original one, that is, $m(x + \alpha, y + \alpha) = m(x, y)$.

As is the case elsewhere in economics, when a term has more than one meaning within the same literature, it is probably best to drop the term altogether. Henceforth, researchers would do better to speak of dollar-based, absolute-value-based, or translation-invariant income mobility measures in preference to 'absolute mobility'.

Is 'Income Mobility' Decomposable, and If So, How?

Consider the total income mobility recorded in a population. Under what circumstances can the total be broken down into component parts?

Of the six income mobility concepts considered above, one involves the time-independence aspect of mobility and the other five involve the movement aspect of mobility. The time-independence aspect of mobility is not decomposable. However, there have been decompositions of various movement measures.

One type of decomposition is subgroup decomposability, that is, if the population is divided into J subgroups, the total income mobility in the population as a whole equals a (possibly) weighted average of the mobility in each of the subgroups:

$$m(x, y) = \sum_{j=1}^{J} w_j m_j(x, y).$$

A number of income mobility measures are subgroup decomposable; examples are Fields and Ok's (1996, 1999b) non-directional income movement measures

$$m_1(x, y) \equiv \frac{1}{n} \sum_{i=1}^{n} |y_i - x_i|$$

$$\text{and } m_2(x, y) \equiv \frac{1}{n} \sum_{i=1}^{n} |\log y_i - \log x_i|$$

and their directional income movement measure

$$m_3(x, y) \equiv \frac{1}{n} \sum_{i=1}^{n} (\log y_i - \log x_i).$$

A second kind of decomposition is into substantively meaningful components. There is a long tradition in the sociology literature (for example, Bartholomew 1982) of breaking down the movement of individuals among occupations or social classes into two component parts: (*a*) changes that can be attributed to the increased availability of positions in the better occupations and social classes ('structural mobility') and (*b*) changes that can be attributed to increased movement of individuals among occupations and social classes for a given distribution of positions among these classes ('exchange mobility'). Bridging the economics and sociology literatures, Markandya (1982, 1984) proposes two alternative decompositions of income mobility along these lines. The first defines exchange mobility as the proportion of the change in welfare that could have been obtained if the income distribution had stayed constant through time, in which case structural mobility is defined as the residual welfare change. The second defines structural mobility as the change in welfare that would have taken place if the two-period or two-generation transition matrix had exhibited complete immobility, in which case exchange mobility is defined as the residual. Along similar lines, Ruiz-Castillo (2004) shows how the CDW (1985) index of welfare due to mobility could be decomposed into either (*a*) a precisely defined structural component and a residual representing exchange mobility or (*b*) a precisely defined exchange component and a residual representing structural mobility. In all these cases, the residual component makes the decomposition exact but in a rather unexciting way.

The results just cited do *not* mean that an exact additive decomposition of income mobility is impossible. Fields and Ok (1996) show that their mobility index $m_1(x, y)_n \equiv \frac{1}{n} \sum_{i=1}^{n} |y_i - x_i|$ is decomposable into the sum of appropriately

defined structural and exchange components. In the case of a growing economy, the decomposition equation is $m_1(x,y) = \left(\sum_{i=1}^{n} y_i - \sum_{i=1}^{n} x_i\right) + 2\sum_{\{i:y<x_i\}}(x_i - y_i)$. An analogous decomposition holds for a contracting economy. Along similar lines, Fields and Ok (1999b) show that their directional movement measure $m_3(x,y)_n \equiv \frac{1}{n}\sum_{i=1}^{n}(\log y_i - \log x_i)$ is decomposable into social utility growth and social utility transfer components. In all of these cases, the weakness of Markandya's and Ruíz-Castillo's residual approaches is averted.

What Other Empirical Issues Arise?

Empirical researchers should bear in mind two additional issues. One is that, as an empirical matter, the longer the observation period, the greater is the amount of mobility registered (Atkinson et al. 1992). Therefore, care should be taken not to compare, for example, two-year mobility in one context with, for example, five-year mobility in another.

Second, measurement error is a serious issue. There is an ample literature on mismeasurement of earnings *levels* but, as yet, only a very limited literature on mismeasurement of earnings *changes* (Deaton 1997; Bound et al. 2001). A task for the future is to estimate empirically the effect of measurement error on estimates of both macro-mobility and micro-mobility.

Conclusions

The income mobility literature is fundamentally unsettled. This is because the very term 'income mobility' connotes different things to different people. This article has reviewed a number of dimensions in which differences arise: which of six notions most accurately captures the fundamental idea of 'income mobility', which indices best measure each of the concepts, which axioms best characterize the essence of 'income mobility', how income mobility has been evolving over time in different countries, which demographic groups have more mobility than others in different settings, and which theoretical refinements to the notion of 'income mobility' hold the greatest promise.

Given the unsettled state of the field, before researchers 'do a mobility study', it is important that we specify which concept or concepts of mobility we are considering, which measures of these concepts we are using, and which questions we are answering. More than once, when I have given seminars, a member of the audience has raised his or her hand and said, 'But that's not what mobility *is*'. Let us do all that we can to clarify what we are talking about so that we do not talk past one another any more than we have to.

Income Taxation and Optimal Policies

Louis Kaplow

Abstract

Various economic literatures address the question whether first-best prescriptions for government policy require modification because redistributive income taxation distorts labour supply and cannot achieve the distributive ideal. Perhaps second-best rules for public goods provision, corrective taxation, public sector pricing, and other government activity should reflect concerns about distribution and labour supply distortion. Recent work demonstrates, however, that in basic cases first-best principles remain applicable. Demonstrations make use of income tax adjustments that preserve not only budget balance but also the pre-reform distribution of utility.

Optimal policy analysis is complicated by problems of the second best. Two of the most important problems – non-ideal distribution and labour supply distortion – are intimately connected with limitations of income taxation. In a first-best world, individualized lump-sum taxes can be used to achieve any desired distribution without causing distortion. Accordingly, the optimal design of other government policies is dictated by familiar first-best rules: the Samuelson cost-benefit test for public goods, the Pigouvian prescription for externalities to equate the full marginal social costs and benefits, marginal cost pricing for publicly provided goods and services and for regulated utilities, and so forth.

In practice, however, informational limitations require the use of distortionary instruments, notably labour income taxation, so even at the optimum (Mirrlees 1971) the distributive ideal is not achieved. Due to the second-best nature of the optimal income taxation problem, it is natural to consider whether first-best prescriptions for other government policies should be modified in order to assist the redistributive function. In addition, such other policies – most obviously but not exclusively those that raise or expend revenue – may affect labour supply, which also may require modification of standard policy rules. Particularly since the explosion of interest in optimal taxation in the 1970s, extensive literatures have developed to address these issues in each particular context. Much work focuses on distortion, some on distribution, and a portion considers both simultaneously. A range of adjustments to first-best formulas have been proposed, revisions that in general depend on the initially prevailing income tax and on the modification thereof that is assumed to accompany the underlying policy reform.

Another strand of research offers a new view of the second-best problem in each of these areas and allows a substantial synthesis across these seemingly different contexts. To analyse these issues, this literature employs a construction under which the income tax modification hypothesized to accompany any policy change is one that, in combination with the altered policy, holds the distribution of utility constant. In a simple standard model, it turns out that first-best policy principles are applicable without refinements: there is no need for distributive adjustments since distribution is unaffected; and, as it happens, holding distribution constant also leaves labour supply unchanged, rendering unnecessary any adjustments on account of labour supply distortion.

The analysis of income taxation and optimal government policy is best introduced in the most fundamental setting, in which the only question is whether a labour income tax should be supplemented by differential commodity taxes. As will be elaborated in the first section below, the answer is negative in simple cases regardless of whether the initial income tax is optimal, a result that in an important sense displaces principles of Ramsey taxation (and, as will subsequently be noted, other applications of Ramsey principles as well). The next section explains how a range of government policies – including public goods provision, regulation of externalities, and public sector pricing – are all formally analogous to differential commodity taxation. Hence, the results (and qualifications) can readily be extended, which allows for the understanding of second-best problems in these disparate fields to be unified substantially. Two final sections relate the analysis to classical and contemporary work and explore further implications of this approach for second-best policy analysis.

Commodity Taxation

The problem of optimal commodity taxation with labour income taxation can be stated as follows. Individuals choose commodity vectors x and labour effort l to maximize the utility function $u(v(\mathrm{x}), l)$, where v is a subutility function. This form of the utility function entails what is referred to as weak separability of labour: for a given level of after-income-tax income, individuals will allocate their disposable income among commodities in the same manner regardless of the level of labour effort required to earn that level of income.

An individual's budget constraint requires that expenditures, $\boldsymbol{\rho x}(wl)$, not exceed before-tax income, wl, minus income taxes, $T(wl)$, which can be negative, thereby allowing for net transfers; $\boldsymbol{\rho}$ is the consumer price vector, w is an individual's wage, and $\mathrm{x}(wl)$ denotes the consumption vector chosen by an individual who earns wl. Individuals' wages w have density $f(w)$, and the government is assumed to know this density but not each individual's wage, which renders individualized lump-sum taxes infeasible. The consumer price vector $\boldsymbol{\rho}$ is understood as the sum of a producer price vector (taken to be constant and equal to production costs) and a vector of commodity taxes (which, if negative, are subsidies).

The government's maximization problem is to select commodity taxes (equivalently, $\boldsymbol{\rho}$) and an income tax schedule $T(wl)$ to maximize a standard concave social welfare function, subject to meeting a given revenue requirement and to incentive compatibility constraints deriving from individuals' maximization problems. If commodity taxes are taken to be zero, we have the optimal nonlinear income tax problem of Mirrlees (1971).

Atkinson and Stiglitz (1976) demonstrated that, when the income tax is set optimally, commodity taxes should be undifferentiated (i.e., uniform) in this basic setting. The derivation to follow is taken from Kaplow (2006), who does not require that the income tax be optimal and provides a more intuitively accessible approach.

For any commodity tax reform, which changes the consumer price vector from ρ to ρ^*, suppose that the income tax schedule is initially adjusted from $T(wl)$ to $T^{\mathrm{o}}(wl)$ such that $V(\boldsymbol{\rho}^*, T^{\mathrm{o}}, wl) = V(\boldsymbol{\rho}, T, wl)$ for all wl, where V is an indirect subutility function indicating the maximized value of $v(\mathrm{x})$, subject to the budget constraint, where $\boldsymbol{\rho}$, T, and wl are taken as given. That is, one adjusts the income tax schedule to the $T^{\mathrm{o}}(wl)$ that restores the original level of subutility achieved at each level of disposable income; hence, $T^{\mathrm{o}}(wl) - T(wl)$ is the schedule of utility-compensating changes in disposable income.

This income tax schedule adjustment has a number of properties. First, if individuals do not change their level of labour supply, they achieve the same utility, for u depends only on v (which is held fixed, given l) and l.

Second, faced with this income tax adjustment, individuals will not in fact change their level of labour supply: each individual's (each type w's) total utility u for any choice of l after this combined reform of commodity taxes and the income tax precisely equals the total utility for that choice of l before the reform; therefore, whatever l previously maximized utility must continue to do so.

Third, the hypothetical reform will in general affect government revenue. Specifically, it can be shown that there will be a surplus if and only if the reform increases efficiency in the narrow sense – by reducing aggregate distortion among commodities – a condition that will prevail, for example, if all commodity taxes (and subsidies) are moved proportionally toward zero, including the case of complete abolition of differential commodity taxation. The reason is that reducing consumption distortion, *ceteris paribus*, raises individuals' utilities; because the income tax adjustment is set to hold utility constant, it must therefore reduce individuals' disposable income to offset what would otherwise be a utility increase. Accordingly, net tax collections must rise.

Finally, to complete the analysis, budget balance can be restored by further adjusting T to rebate the surplus pro rata: $T^*(wl) = T^{\mathrm{o}}(wl) - c$, where c is some positive constant. The result is a Pareto improvement, for utility was unchanged until this final stage of the reform. To summarize, if any commodity tax reform is

accompanied by an income tax adjustment that, when combined with the underlying reform, holds utility constant (until the rebate stage), there is no effect on distribution, labour supply is unchanged, and there is a surplus, allowing a Pareto improvement, if and only if the underlying commodity tax reform is efficient in a narrow, conventional sense.

It is useful to consider the intuition behind this result. It is familiar from the general theory of second-best analysis (Lipsey and Lancaster 1956) that first-best conditions do not generally govern once some distortion is introduced. However, in the present setting the only unavoidable distortion is of the labour–leisure choice, and differential commodity taxation does not help to alleviate it. Thus, differential taxes involve the cost of distorting consumption without any offsetting benefit. The reason that differential commodity taxes cannot help offset the labour–leisure distortion is the assumption of weak separability. Just as different levels of labour supply do not change preferences among commodities, so different consumption allocations do not change the disutility of labour.

This result on the inefficiency of differential commodity taxation provides an important benchmark for understanding and analysis. The conclusion is subject to many qualifications, each of which is best appreciated by reference to this basic starting point. First, as follows immediately from the preceding remarks, weak separability may be violated. This is the point, first elaborated by Corlett and Hague (1953), that it tends to be efficient to tax leisure complements (perhaps beach attendance or reading) and subsidize complements to labour (possibly central city transit or amenities). Second, preferences were taken to be homogeneous, but if preferences depend on unobservable ability it would be optimal to tax commodities preferred by the more able (independent of income per se), perhaps highbrow art, and to subsidize those preferred by the less able. Additional qualifications have been offered, including, importantly, concerns with administration and tax avoidance that may affect income taxation, especially in developing countries.

The foregoing analysis is usefully contrasted with that of Ramsey (1927) taxation, which involves a substantial, widely known literature that itself provides the foundation for much economic analysis of myriad other policy applications (including all those examined in the following section). Most familiar is the rule that commodity taxes should be inversely proportional to the elasticity of demand, with refinements for demand interdependencies. Also well known are modifications due to distributive concerns, which favour taxing luxuries and subsidizing necessities, commands that often conflict with the inverse elasticity rule and thus require tradeoffs (Feldstein 1972; Diamond 1975). As initially emphasized in Atkinson and Stiglitz (1976), however, neither prescription is apt if there is an income tax. In the original Ramsey model in which all individuals are identical and thus there are no distributive concerns, the optimal tax is a uniform lump-sum extraction (a limiting case of an income tax), which, it should be noted, neither requires information about individuals' types nor is distributively objectionable in this setting. When differences in earning ability are admitted, the optimal tax is a nonlinear income tax, and in typical cases the lump-sum component involves a uniform lump-sum subsidy. Nevertheless, optimal commodity taxation still is not guided either by the familiar inverse-elasticity rule or by the general preference for harsher treatment of luxuries than of necessities; as noted, in the basic case, optimal differentiation is nil regardless of the demand elasticity or how demand changes with income.

Paradoxically, the literatures that build upon Ramsey's path-breaking contribution are motivated by second-best concerns, yet it turns out that a more complete second-best analysis – notably, incorporating the income tax, the primary distributive tool and also a central cause of unavoidable distortion that calls for second-best inquiry – returns us to a simple, first-best rule in the benchmark case. Here, that prescription is against differential commodity taxes on account of the resulting distortion of consumption. As will now be explained, this pattern of analysis is replicated with regard to a broad range of government policies.

Government Policies Generally

The foregoing framework can be employed to address the optimal provision of public goods, the optimal control of externalities, and other government actions, as developed by Kaplow (1996, 2004, 2008). The reason is that departures from firstbest rules in these contexts are formally analogous to differential commodity taxation and hence are inefficient in the basic case (a conclusion that also is subject to similar qualifications).

To see this, suppose now that individuals have the utility function $u(v(\mathrm{x}, \mathrm{e}, \mathrm{g}), l)$. Here, e is a vector of externalities (suppose, for example, that each element of e is the population's total consumption of the corresponding commodity in the vector x), and g is a vector of public goods. This functional form maintains the assumption that labour is weakly separable from other sources of individuals' utility.

We can again consider reforms, here of commodity taxes (and subsidies) $\boldsymbol{\rho}$, but now with the thought of internalizing externalities, or of g. Again, we can construct $T^{\circ}(wl)$ such that individuals' subutility v is kept constant if they choose to supply the same level of labour. As before, this reform is distribution neutral and in fact induces all individuals to supply the same labour effort. (A review of the foregoing analysis will confirm that nothing depended on the fact that the reform was only of commodity taxes or that there were no externalities or public goods involved.)

The question, then, is whether the intermediate adjustment of the income tax schedule, from $T(wl)$ to $T^{\circ}(wl)$, will produce a surplus or a deficit. With externalities, if, for example, one sets all commodity taxes equal to the marginal external effect of consumption on individuals' utilities – the traditional Pigouvian prescription (Pigou 1920) – there will be a surplus: individuals may be better or worse off because of being subject to a different vector of commodity prices, and they may be better or worse off on account of changes in the levels of externalities; however, it can be demonstrated that the net effect on revenue is positive, essentially because of traditional efficiency considerations. (Note that the income tax adjustment from $T(wl)$ to $T^{\circ}(wl)$ taxes away all sources of surplus and compensates for any disutility; hence, the sign of the net revenue effect is given by the sign of the total of all changes in individuals' surplus from the underlying reform.) Observe that this result is very similar in spirit to that on commodity taxation without externalities. There, the optimum involves setting consumer prices equal to true marginal resource costs of commodities; with externalities, the same principle holds, but true resource costs now include not only production costs but also effects on others' utilities.

For public goods, the total revenue effect has two components. The first (which is negative) is the production cost of the public goods, and the second is (by the method of construction of $T^{\circ}(wl)$) the integral of individuals' surplus from changes in the levels of the public goods. Hence, there is a surplus (deficit) if and only if the reform passes (fails) the Samuelson (1954) cost–benefit test, which asks whether the integral of individuals' benefits exceeds the cost of producing the public goods. The essence of the argument is again similar to that for the basic case with commodity taxation. For example, supplying less of a public good than dictated by the Samuelson test corresponds to imposing a differential tax on a private good. To push the analogy further, consider a hypothetically decentralized regime in which consumer prices for private goods correspond to Lindahl prices for public goods, and commodity taxes on public goods are defined as the difference between the price charged to a consumer in the imaginary regime and that consumer's marginal rate of substitution. The source of the allocative inefficiency is again a failure of the prices faced by consumers to equal true marginal resource costs.

In the present setting, therefore, moving to the first best – now regarding internalization of externalities or provision of public goods rather than setting commodity taxes in a simpler world – makes possible a Pareto improvement. Concerns about distribution and labour supply effects caused by the income tax can be ignored because they are moot.

Similar logic can be employed to address other areas of government policy, most obviously regulations that mimic corrective taxation but also seemingly unrelated fields like public sector pricing and utility regulation. Thus, marginal cost pricing will be optimal in spite of distributive concerns or the distortionary cost of raising funds to meet deficits because, if the income tax is adjusted in the manner described, distribution will be unaffected and there will be a net surplus if the reform is (narrowly) efficient in the basic case.

Historical Development of Second-Best Policy Rules

First-best principles have a long and familiar lineage. The command to internalize externalities is inspired by Pigou's (1920) classical treatment, and the cost-benefit test for public goods is due to Samuelson's (1954) elegant formulation. It is notable that Samuelson (1954) explicitly said that he was considering a first-best setting in which individualized lump-sum taxes permitted any social welfare optimum to be implemented.

Second-best qualifications start with another of Pigou's (1928) books, in which he observed that, on account of the resource cost of raising revenue, public goods probably should have to meet a higher standard. Refinements appeared in Atkinson and Stern (1974), Diamond and Mirrlees (1971), and Stiglitz and Dasgupta (1971), with subsequent research crystallized by Ballard and Fullerton (1992). Analogous work on environmental taxation – addressed to the possibility of a 'double dividend' (a tax might both internalize an externality and raise revenue distortion-free) and qualifications implying a more negative view of corrective policies – became intense in the 1990s (see Bovenberg and Goulder 2002; Goulder 2002). Largely separate literatures proposed second-best adjustments to account for distributive effects (Weisbrod 1968; Drèze and Stern 1987). See also Bös (1985) on public sector pricing.

Much of this work builds on Ramsey's (1927) model of taxation and extensions thereof. Often, such analyses employ the original representative-individual model in which distribution is immaterial; yet, at the same time, the possibility of income taxation is ignored (specifically, the possible use of a uniform grant that, as noted above, makes commodity taxation unnecessary) or the income tax adjustments that are stipulated turn out not to be distribution-neutral. Literature focusing on distribution also often ignores the availability of the income tax.

The lessons presented in the prior sections arise from another line of work that developed intermittently and largely independently of the foregoing literatures. Hylland and Zeckhauser (1979) used a distribution-neutral income tax adjustment with a special case of individuals' utility functions to show that distributive weights are inappropriate in cost–benefit analysis. Shavell (1981) offers a similar demonstration for legal rules. Christiansen (1981) and Boadway and Keen (1993) show that, with an optimal income tax, the basic cost–benefit test for public goods is appropriate. Kaplow (1996, 2004, 2006, 2008) considers both distribution and labour supply distortion, does not require the income tax to be optimal, and examines a broad range of government policies.

Implications

Ever since Lipsey and Lancaster (1956), economists have sought to develop principles to provide guidance in a second-best world; indeed, in the area of taxation, the search had already begun. The inability to achieve an ideal distribution without distortion is one of the most important unavoidable deviations from the first best. Thus, not surprisingly, substantial research addresses second-best concerns regarding income taxation and commodity taxation as well as all manner of government policies that may have distributive effects or influence government revenue.

Perhaps surprisingly, a number of first-best principles prove to be rather robust in basic, benchmark cases. Important caveats were noted,

but, importantly, they are largely orthogonal to the original second-best concerns that motivate most research in these fields.

One further qualification deserves attention. The present analysis assumes that the income tax will be adjusted in a distribution-neutral manner. This is hardly an unnatural assumption. For example, if the initial income tax does not optimally trade off distribution and distortion, the divergence may arise from political forces that dictate some other degree of redistribution. If so, particular reforms might be expected to leave that distributive balance unaltered.

Nevertheless, consider the possibility of non-distribution-neutral adjustments of the income tax. As suggested in Kaplow (1996, 2004, 2008), a simple two-step decomposition is illuminating in this case:

1. Assume that, initially, the underlying policy is implemented in the previously hypothesized distribution-neutral fashion.
2. Assume also that, a moment later, a further income tax adjustment transforms the policy in step 1 into the actually imagined policy.

Analysis of step 1 can proceed as before. Step 2, observe, is a purely redistributive reform. Accordingly, the analysis is in the province of optimal income taxation and involves the familiar distribution-distortion trade-off. Significantly, the analysis of step 2 is generic – that is, it is the same regardless of whether step 1 involves changing commodity taxes, one or another regulation, the level of some public good, or indeed nothing at all (a purely redistributive overall reform). For economists, this allows substantial specialization. Step 2 analysis must be undertaken anyway and, as noted, tends to be independent of step 1. Step 1 analysis can be undertaken by experts on gasoline taxes, health care, electric utilities, and so forth, who need not concern themselves with redistribution. Policymakers can combine analyses as appropriate.

Specialization has an additional virtue in this context: it facilitates communication, both among researchers and to policymakers. For example, a study of a highway project that does not focus on step 1 will need to include analysis of (*a*) direct effects of the highway project (such as on pollution or congestion), (*b*) what other, budget-accommodating tax adjustment will in fact be made in the long run (an exercise in political economy), (*c*) an analysis of the effects of the resulting change in the extent of redistribution, and (*d*) a social welfare assessment, requiring choice of a social welfare function. Relatedly, when studies of a highway project reach different conclusions, the discrepancies may arise from any combination of these four components, making it difficult to compare and synthesize research.

A particular concern arises with much work in these literatures, both abstract and highly applied, because step 1 is often combined with an incomplete analysis of step 2. For example, work might identify a redistributive benefit from a policy; yet, if there is not a complete analysis of redistributive taxation, the likely associated increase in labour supply distortion may be overlooked. Contrariwise, much work identifies increases in distortion, failing to recognize that the increases are due to effects on labour supply that accompany an implicit increase in redistribution, the benefit of which is omitted. Because of the original second-best problem, involving redistribution through distortionary taxation, redistribution is not an unambiguous good because (usually) it comes at a cost, and distortion – particularly of labour supply – is not an unmitigated evil because (frequently) it is symptomatic of an underlying benefit. Analysis that incorporates one side of the balance while excluding the other may be the worst approach of all.

To summarize, Ramsey principles are widely acknowledged and broadly employed as a foundation for second-best policy analysis. However, at least in developed economies in which an income tax is feasible, the model's most familiar implications for differential commodity taxation are inapt and, by extension, so are its applications to public goods provision, regulation of externalities, public sector pricing, and other policy areas. In the basic case, the problem of optimal

redistribution – involving the trade-off of distribution and labour supply distortion – is separable from these other realms. Accordingly, traditional first-best principles that focus on efficiency in the area under consideration provide a useful benchmark. Complications abound, but for the most part they do not replicate the adjustments called for by the original Ramsey model or typical applications thereof. Instead, they are best understood by direct reference to the problem of redistributive income taxation.

Income–Expenditure Analysis

Michael Artis

The term 'income–expenditure analysis' serves as a short-hand expression for the dominant type of conceptual framework for macroeconomic analysis to emerge from the debate which crystallized around Keynes's *General Theory* (Keynes 1936). As Coddington (1976) notes, income-expenditure analysis was not the only thing to be learned from the *General Theory*, but it has certainly been the dominant one, forming the central message of Keynesian economics as generally understood. Although the term does not appear to have been used by Keynes himself it is to be found, freely used, in the early works of exposition of the *General Theory* and the Keynesian Revolution. At the formal and simplest level it can be taken to refer to the 45° 'Keynesian Cross' diagram, at a more sophisticated level to the IS/LM analysis.

At the outset of the *General Theory*, Keynes noted the inability of traditional theory to explain the Great Depression. His analysis was evolved to make good this deficiency and does so by sidestepping the concerns of that theory, in that the power of the price system to ensure the equilibration of the economy is simply denied. Relative prices being set on one side, the analysis focuses on the interaction of flows of expenditure to explain economic fluctuations and the determination of output. In the more familiar embodiments of income-expenditure analysis, the abstraction is clearer and proceeds further than it does in the *General Theory* itself. In particular, both wages and prices are taken as fixed, whilst the stock of productive capital, wealth and the 'state of expectations' are also taken as given. Capital markets are imperfect. Keynes's concept of the propensity to consume is central and leads to the key result of the multiplier. Because expenditures are cash-constrained and output is demand-constrained, an autonomous increment in demand relaxes the constraint on spending and so on output, raising incomes and so stimulating further 'rounds' of expenditures. The ultimate increase in demand may exceed the initial stimulus. In the simplest version of this analysis, exemplified in the 'Keynesian Cross' diagram, asset prices are taken as fixed along with wages and commodity prices. In the IS/LM version this restriction is relaxed and demand increases may then spend themselves at least partly in changes in asset prices which in turn affect the desire to acquire capital goods. In this way the multiplier process may be attenuated if monetary conditions are tight rather than passive.

The framework readily accommodates policy, inviting the tools of fiscal and monetary policy to be used in the management of demand with the objective of output stabilization. Further, the analysis lends itself to quantification; with the addition of a modelling of the wage-price sector and of the foreign exchanges (or capital flows), income–expenditure analysis was the initial basis for the construction of macroeconometric models of the kind used by Finance Ministries and Central Banks and indeed remains the basic foundation for such models today.

The abstraction from relative prices of this approach, its highly aggregative and often heavily quantified nature has exposed income-expenditure analysis to the criticism that it is excessively mechanical (Coddington 1976) describes it as 'hydraulic' Keynesianism in reference to this criticism and perhaps to the fact that some early teaching machines of this model were literally hydraulic); it was said to 'lack microfoundations'. Modern temporary equilibrium theory of the kind pioneered by, for example, Barro and Grossman (1976) has supplied such foundations – or, to be more accurate, has shown how a general equilibrium model with fixed prices generates properties which are very similar to those to be found in income–expenditure analysis – involuntary unemployment may exist, the multiplier process is replicated, and fiscal and monetary policy can be given a demand management rationale, for example. The condition on which these results are generated is that wages and prices fail to equilibrate the model and this condition is imposed as a stylized fact rather than explained by the model itself, a weakness in the

eyes of critics who would argue that the existence of such rigidities implies unexploited opportunities for profitable trade to (well-informed) rational agents. On the other hand, there appear to be a number of reasons why wages and prices are in fact sticky, supporting the principal strategic simplification of income-expenditure analysis, whilst modern exploration of the properties of rational expectations models has confirmed the wisdom of Keynes's tactic of treating expectations as parametric in view of the problem of multiple equilibria. Certainly, the resultant mode of analysis has been very successful and still retains a dominant place in macroeconomics, despite the flourishing new classical school.

Incomes Policies

Rupert Pennant-Rea

Keynes's *General Theory* attacked the foundation of the quantity theory of money – the proposition that the level of activity is determined by real forces. But though Keynes provided a new theory of output, he offered no systematic explanation of the price level. He simply took money wages as given, and argued that their level was the key determinant of all nominal magnitudes.

In *How to Pay for the War* Keynes took the analysis further, presenting two complementary theories of the determination of the *rate of change* of money wages and prices. The rate of inflation was affected on the one hand, by the pressure of demand; on the other, by the attempt of workers to maintain the real value of their incomes in a recession or when the terms of trade deteriorated.

These two explanations reinforce one another in Keynes's exposition, but they are formally distinct. The pressure of demand may explain the rate of change of wages independently of any predetermined real wage; this was one central implication of Phillips's (1958) study of the relationship between money wage inflation and the level of unemployment, and of later refinements of the Phillips curve. However, the efforts of workers to maintain real incomes may determine the rate of change of money wages and prices relatively *independently* of the pressure of demand (though they may be affected by rapid changes in the pressure of demand).

If the two processes are combined, the result may be formulated as a relationship between the pressure of demand and the rate of change of the rate of inflation. In some writers' view, the pressure of demand leads to real wage bids which cannot be satisfied and hence to cumulative rises in wages and prices, as workers and employers bid for shares of real income which total more than one (Rowthorn 1977).

When the Phillips curve analysis was presented, it appeared to carry an important message for macroeconomic policy: that there is a trade-off between unemployment and the rate of inflation (or between unemployment and the rate of change of the rate of inflation). The inflation which was believed to be associated with macroeconomic expansion provided a constraint on such expansion. If inflationary pressures could be reduced, it was argued, economies could produce more. From that perspective, the purpose of an incomes

policy was to reduce the inflationary pressure associated with any given level of demand.

Discussion of incomes policy often fails to make it clear whether the policy is intended to operate solely on nominal wages, or on real wages. In fact, the distinction is important for both analytical and practical reasons. If the level of money wages is given and unrelated to real variables (as Keynes appeared to suggest in the *General Theory*), then it may be argued that the role of incomes policy is to moderate the rate of change of nominal magnitudes, with no particular implications for real wages, or for the distribution of income between wages and profits. In which case, the pressure to disrupt an income policy will logically come from groups intent on changing the distribution of real income in their favour.

But if the level of money wages is the outcome of bargaining over real incomes, then the purpose of an incomes policy will usually be to persuade workers to achieve lower real wages and thus change the distribution of income. In which case, the policy must either deal directly with the forces which determine real incomes in the first place; or it will be placed under considerable strain – perhaps breaking down as those forces reassert themselves (Tarling and Wilkinson 1977).

In reality, incomes policies have often been justified as a way of reducing inflation in nominal magnitudes; but they have also changed the distribution of income, usually by squeezing real wages.

In the view of those who favour incomes policy, successful policies – those that have lasted the longest and been associated with relatively low rates of inflation – have been those which (a) recognize explicitly that the distribution of real income is at stake, and plan the rate of change of money wages as part of a socio-political 'deal' (war-time policies are good examples); and/or (b) are implemented when real national income is growing rapidly, so that all real wages can increase even as the distribution of real income is changed.

Although labelled 'incomes policy', most such policies are concerned only with wages. They may sometimes be linked to controls on dividends to provide an aura of 'fairness'; or to a prices policy, in which case they are overtly a policy for real incomes.

In the OECD countries five main types of incomes policies have been tried. One version relies on *exhortatory guidelines*. It does little more than encourage employers and employees to settle for lower increases in nominal wages and salaries. As one author sympathetic to incomes policy has argued, 'a principal objective of incomes policy must be to inform public opinion and develop a consensus on the appropriate rate of increase for most wages and salaries . . .' (Braun 1986). To this end, a government may set an example itself in the sectors in which it is the direct employer (such as the civil service) or the indirect financier (as may be the case in some nationalized industries). And the government may also argue that monetary and fiscal expansion will be restrained if inflation is 'too high'.

If exhortation fails, a government may resort to *temporary measures*, such as a wage freeze. For example, it may be argued that a freeze is a temporary measure designed to adjust inflationary expectations in such a way as to minimize the consequences of deflationary policies. The most dramatic examples of the use of temporary measures have occurred in countries suffering from very rapid inflation (Argentina, Bolivia and Israel in 1985, and Brazil in 1986), and have often been accompanied by price freezes and currency reform.

A *statutory norm* involves a government laying down limits for the increase of nominal wages allowed in any one year. The increase has usually been couched in percentage terms, though sometimes this has been combined with an absolute limit. The rate is set for the economy as a whole, with increases beyond the norm being sanctioned by some form of arbitration tribunal – usually on the grounds of exceptional productivity growth. This approach has been widely used in Britain, and, from time to time, in the United States. The relative success or failure of the statutory norm has been determined by its consequences for the rate of increase of real wages, and by the impact on wage differentials of productivity-based 'exceptions'.

Recognition that incomes policies are concerned with the distribution of real income

has led to the suggestion that nominal magnitudes should be *indexed*. This usually means that wage agreements contain automatic escalator clauses. Such agreements are undermined when the increase in real incomes implicit in nominal wage negotiations cannot be sustained – as, for example, when the quadrupling of oil prices in 1973–4 resulted in a transfer of real income from the OECD countries to the oil producers. In such circumstances, indexation can become a source of explosive inflation, at least in the short term.

Milton Friedman has claimed (1974) that

> widespread escalator clauses would make it easier for the public to recognize changes in the rate of inflation, would thereby reduce the time-lag in adapting to such changes, and thus make the nominal price level more sensitive and variable . . ..But, if so, the real variables would be less sensitive and more stable – a highly beneficial trade-off.

In short, indexation would allow governments to disinflate (by appropriate monetary measures) with the least harmful consequences for the real economy. Wage earners would find that their wages adjusted quickly to disinflationary policies. Without that prompt adjustment, they would have obtained unjustifiably large increases, which would cause bankruptcies and unemployment. Indexation may be favoured on other grounds. For example, it may give confidence to particular bargaining groups, who will therefore have no incentive to bid for large increases in nominal wages as a means of protecting real wages.

As a policy device, indexation was adopted by several countries in the late 1940s, among them Belgium, Luxembourg, Italy, Denmark and Norway. During the 1970s indexation was introduced in Britain, the Netherlands, Ireland, Switzerland and Australia. Indexation had been common in France until 1958, when it was abolished at the same time as the franc was devalued. This proved a pointer to the subsequent abandonment of indexation in many other countries. Governments found that indexation prevented them from making desired changes in relative prices (such as changes in exchange rates) which had implications for the distribution of income. In such circumstances indexation is a device for institutionalizing inflation.

A different automatic device for regulating wage increases is the *tax-based incomes policy* (TIP).

In this scheme the government sets a norm for wage increases. Firms that pay less than the norm receive a reward, typically in the form of lower corporate taxes. Those that pay more face a tax penalty. A variant would provide employees with tax incentives to settle for wage increases below the norm.

Schemes of this type have been tried only in the most general form. In Britain in 1977–8, for example, the Labour government promised to reduce income tax if the national increase in wages was moderated. In Austria in 1967–8, the government achieved a wage-tax bargain. When it tried again, in 1974, its proposal was rejected by the unions.

In practice, incomes policies have tended to follow a sequence of initial acceptance and effectiveness, followed by growing opposition and circumvention, and then breakdown. Explanations of this phenomenon vary according to each author's view of the price mechanism. For example, some economists argue that incomes policies fail because they seek to over-ride market forces. An incomes policy unsupported by suitably anti-inflationary macroeconomic policies is bound to fail; but one that is so supported is superfluous. Indeed it may do microeconomic harm because it slows down and distorts market adjustments: 'the theory of incomes policy, as opposed to the desperate "ad-hocery" of practice, has not come to grips with resolving some form of wage, dividend and price control with the resource-allocating function that both goods and factor prices are held to play' (Ball and Doyle 1969; see also Paish 1986).

A different explanation of the failure of incomes policy comes from those who take a somewhat jaundiced view of the efficiency of markets, particularly of the labour market. They attribute failure to inefficient implementation – imposing an incomes policy as part of a deflationary package, rather than using it as part of an expansionary programme. Other analysts point to particular groups of workers who break norms. Still others single out the impact of external shocks, which destroy the assumptions on which the policy had been framed.

Incomplete Contracts

Oliver Hart

The past decade has witnessed a growing interest in contract theories of various kinds. This development is partly a reaction to our rather thorough understanding of the standard theory of perfect competition under complete markets, but more importantly to the resulting realization that this paradigm is insufficient to accommodate a number of important economic phenomena. Studying in more detail the process of contracting – particularly its hazards and imperfections – is a natural way to enrich and amend the idealized competitive model in an attempt to fit the evidence better.

In one sense, contracts provide the foundation for a large part of economic analysis. Any trade – as a quid pro quo – must be mediated by some form of contract, whether it be explicit or implicit. In the case of spot trades, however, where the two sides of the transaction occur almost simultaneously, the contractual element is usually down-played, presumably because it is regarded as trivial (although we will argue below that this need not be the case). In recent years, economists have become much more interested in long-term relationships where a considerable amount of time may elapse between the quid and the quo. In these circumstances, a contract becomes an essential part of the trading relationship.

Research on contracts has progressed along several different lines. Two prominent areas of work are principal-agent theory and implicit labour contract theory. In these literatures, the focus is on risk-sharing or income-smoothing as the motivation for a contract; that is, on the gains the parties receive from transferring income from one state of the world or one period to another. For example, in implicit contract theory, it is supposed that workers are constrained in their ability to get insurance or to borrow on the open market and that employers therefore offer these services as part of an employment contract.

While 'income-smoothing' is undoubtedly important, there are arguably more fundamental factors underlying the existence of long-term contracts. A basic reason for long-term relationships is the existence of investments which are to some extent party specific; that is, once made, they have a higher value inside the relationship than outside. Given this 'lock-in' effect, each party will have some monopoly power *ex-post*, although there may be plenty of competition *ex-ante*, before investments are sunk. Since the parties cannot rely on the market once their relationship is underway, a long-term contract is an important way for them to regulate, and divide up

the gains from, their trade. This will be the case even if the parties are risk neutral and have access to perfect capital markets, that is, even if the income-smoothing role is completely inessential. Moreover, in the case, say, of supply contracts involving large firms, risk neutrality and perfect capital markets may be reasonable approximations in view of the many outside insurance and borrowing/lending opportunities available to such parties.

In spite of their importance, contracts whose *raison d'être* is the regulation of specific relationships have been the subject of little analysis. A notable early reference is Becker's (1964) analysis of worker training. More recently, Williamson (1985) and Klein et al. (1978) have emphasized the difficulty of writing contracts which induce efficient relationship-specific investments as an important factor in explaining vertical integration.

In this entry I will try to summarize what is known theoretically about contracts of this type. I will focus particularly on the problems which arise when the parties write a contract which is incomplete in some respects. Given the rudimentary state of our knowledge of the area, the entry is inevitably quite speculative in nature. The reader who is interested in an elaboration of some of the ideas presented here, and how they fit into the rest of contract theory, might want to consult Hart and Holmstrom (1987).

The Benefits of Writing Long-Term Contracts Given Relationship-Specific Investments

The role of a long-term contract when there are relationship-specific investments can be seen from the following example (based on Grout 1984). Let B, S be, respectively, the buyer and seller of (one unit of) an input. Suppose that in order to realize the benefits of the input, B must make an investment, a, which is specific to S; for example, B might have to build a plant next to S. Assume that there are just two periods; the investment is made at date 0, while the input is supplied and the benefits are received at date 1. S's supply cost at date 1 is c, while B's benefit function is $b(a)$ (all costs and benefits are measured in date 1 dollars).

If no long-term contract is written at date 0, the parties will determine the terms of trade from scratch at date 1. If we assume that neither party has alternative trading partners at date 1, there is, given B's sunk investment cost a, a surplus of $b(a) - c$ to be divided up. A simple assumption to make is that the parties split this 50:50 (this is the Nash bargaining solution). That is, the input price p will satisfy $b(a) - p = p - c$. This means that the buyer's overall payoff, net of his investment cost, is

$$b(a) - p - a = \frac{b(a) - c}{2} - a \qquad (1)$$

The buyer, anticipating this payoff, will choose a to maximize (1), i.e. to maximize $1/2\ b(a) - a$.

This is to be contrasted with the efficient outcome, where a is chosen to maximize total surplus, $b(a) - c - a$. Maximizing (1) will lead to underinvestment; in fact, in extreme cases, a will equal zero and trade will not occur at all. The inefficiency arises because the buyer does not receive the full return from his investment – some of this return is appropriated by the seller in the date 1 bargaining. Note that an upfront payment from S to B at date 0 (to compensate for the share of the surplus S will later receive) will not help here, since it will only change B's objective function by a constant (it is like a lump-sum transfer). That is, it redistributes income without affecting real decisions.

Efficiency can be achieved if a long-term contract is written at date 0 specifying the input price p^* in advance. Then B will maximize $b(a) - p^* - a$, yielding the efficient investment level, a^* An alternative method is to specify that the buyer must choose $a = a^*$ (if not he pays large damages to S) – the choice of p can then be left until date I, with an upfront payment by S being used to compensate B for his investment. The second method presupposes that investment decisions are publicly observable, and so in practice may be more complicated than the first (see below).

We see then that a long-term contract can be useful in encouraging relationship- specific investments. The word 'investment' should be interpreted broadly here; the same factors will apply whenever one party is forced to pass up an opportunity as a result of a relationship with another party (e.g., A's 'investment' in the relationship with B may be not to lock into C). That is, the crucial element is a sunk cost (direct or opportunity) of some sort (an effort decision is one example of a sunk cost). Note that the income-transfer motive for a long-term contract is completely absent here; there is no uncertainty and everything is in present value terms.

Given the advantages of long-term contracts in specific relationships, the question that obviously arises is why we do not see more of them, and why those we do see seem often to be limited in scope. To this question we now turn.

The Costs of Writing Long-Term Contracts

Contract theory is sometimes dismissed because 'we don't see the long-term contingent contracts that the theory predicts'. In fact, there is no shortage of complex long-term contracts in the world. Joskow (1985), for example, in his recent study of transactions between electricity generating plants and mine-mouth coal suppliers finds that some contracts between the parties extend for fifty years, and a large majority for over ten years. The contractual terms include quality provisions, formulae linking coal prices to costs and prices of substitutes, indexation clauses, and so on. The contracts are both complicated and sophisticated. Similar findings are contained in Goldberg and Erickson's (1982) study of petroleum coke.

At a much more basic level, a typical contract for personal insurance, with its many conditions and exemption clauses, is not exactly a simple document. Nor for that matter is a typical house rental agreement. On the other hand, labour contracts are often surprisingly rudimentary, at least in certain respects (for example, there is little indexation of wages to retail prices or to firm employment or sales; layoff pay is limited, etc.).

Given that complex long-term contracts are found in some situations but not others, it is natural to explain any observed contract as an outcome of an optimization process in which the relative benefits and costs of additional length and complexity are traded off at the margin. In the last section, we indicated some of the benefits of a long-term contract. (The example considered was sufficiently straightforward that the ideal long-term contract was a simple noncontingent one; however, with the inclusion of such factors as uncertainty about payoffs and variable quality of the input, the optimal contract would be a (possibly much more complex) contingent one.) But what about the costs? These are much harder to pin down since they fall under the general heading of 'transaction costs', a notoriously vague and slippery category. Of these, the following seem to be important: (1) the cost to each party of anticipating the various eventualities that may occur during the life of the relationship: (2) the cost of deciding, and reaching an agreement about, how to deal with such eventualities; (3) the cost of writing the contract in a sufficiently clear and unambiguous way that the terms of the contract can be enforced; and (4) the legal cost of enforcement.

One point to note is that *all* these costs are present also in the case of *short- term* contracts, although presumably they are usually smaller. In particular, since the short-term future is more predictable, the first cost is likely to be much reduced, and so possibly is the third. However, it certainly is not the case that there is a sharp division between short-term contracts and long-term contracts, with, as is sometimes supposed, the former being costless and the latter being infinitely costly.

It is also worth emphasizing that, when we talk about the cost of a long-term contract, we are presumably referring to the cost of a 'good' long-term contract. There is rarely significant cost or difficulty in writing *some* long-term contract. For example, the parties to an input supply contract could agree on a fixed price and level of supply for the next fifty years. They do not presumably because such a rigid arrangement would be very inefficient. (In some cases the courts will not enforce such an agreement, taking the point of

view that the parties could not really have intended it to apply unchanged for such a long time. A clause to the effect that the parties really do mean what they say should be enough to overcome this difficulty, however. In other cases, it may be impossible to write a binding long-term contract because the identities of some of the parties involved may change. For example, one party may be a government that is in office for a fixed period, and it may be impossible for it to bind its successors. This latter idea underlies the work of Kydland and Prescott (1977) and Freixas et al. (1985)).

Due to the presence of transaction costs, the contracts people write will be *incomplete* in important respects. The parties will quite rationally leave out many contingencies, taking the point of view that it is better to 'wait and see what happens' than to try to cover a large number of individually unlikely eventualities. Less rationally, the parties will leave out other contingencies that they simply do not anticipate. Instead of writing very long-term contracts the parties will write limited term contracts, with the intention of renegotiating these when they come to an end. (A paper which explores the implications of this is Crawford 1986). Contracts will often contain clauses which are vague or ambiguous, sometimes fatally so.

Anyone familiar with the legal literature on contracts will be aware that almost every contractual dispute that comes before the courts concerns a matter of incompleteness. In fact, incompleteness is probably at least as important empirically as asymmetric information as an explanation for departures from 'ideal' Arrow–Debreu contingent contracts. In spite of this, relatively little work has been done on this topic, the reason presumably being that an analysis of transaction costs is so complicated. One problem is that the first two transaction costs referred to above are intimately connected to the idea of bounded rationality (as in Simon 1982), a successful formalization of which does not yet exist. As a result, perhaps, the few attempts that have been made to analyse incompleteness have concentrated on the third cost, the cost of writing the contract.

One approach, due to Dye (1985), can be described as follows. Suppose that the amount of input, q, traded between a buyer and seller should be a function of the product price, p, faced by the buyer: $q = f(p)$. Writing down this function is likely to be costly. Dye measures the costs in terms of how many different values q takes on as p varies; in particular, if $\#\ \{q|q = f(p)$ for some $p\} = n$, the cost of the contract is $(n - 1)c$, where $c > 0$. This means that a noncontingent statement '$q = 5$ for all p' has zero cost, the statement '$q = 5$ for $p \leq 8$, $q = 10$ for $p > 8$' has cost c, and so on.

The costs Dye is trying to capture are real enough, but the measure used has some drawbacks. It implies for example, that the statement '$q = p^{1/2}$ for all p' has infinite cost if p has infinite domain, and does not distinguish between the cost of a simple function like this and the cost of a much more complicated function. As another example, a simple indexation clause to the effect that the real wage should be constant (i.e. the money wage $= \lambda p$ for some λ) would never be observed since, according to Dye's measure, it too has infinite cost. In addition, the approach does not tell us how to assess the cost of indirect ways of making q contingent; for example, the contract could specify that the buyer, having observed p, can choose any amount of input q he likes, subject to paying the seller σ for each unit.

There is another way of getting at the cost of including contingent statements. This is to suppose that what is costly is describing the state of the world ω rather than writing a statement per se. That is, suppose that ω cannot be represented simply by a product price, but is very complex and of high dimension – e.g., it includes the state of demand, what other firms in the industry are doing, the state of technology, etc. Many of these components may be quite nebulous. To describe the state *ex-ante* in sufficient detail that an outsider, e.g. The courts, can verify whether a particular state $\omega = \hat{\omega}$ has occurred, and so enforce the contract, may be prohibitively costly. Under these conditions, the contract will have to omit some (in extreme cases, all) references to the underlying state.

Similar to this is the case where what is costly is describing the *characteristics* of what is traded or the *actions* (e.g. investments) the parties must take. For example, suppose that there is only one

state of the world, but that q now represents the quality of the item traded rather than the quantity. An ideal contract would give a precise description of q. However, quality may be multidimensional and very difficult to describe unambiguously (and vague statements to the effect that quality should be 'good' may be almost meaningless). The result may be that the contract will have to be silent on many aspects of quality and/or actions.

Models of this sort of incompleteness have been investigated by Grossman and Hart (1987) and Hart and Moore (1985) for the case where the state of the world cannot be described and by Bull (1985) and Grossman and Hart (1986, 1987) for the case where quality and/or actions cannot be specified. These models do not rely on any asymmetry of information between the parties. Both parties may recognize that the state of the world is such that the buyer's benefit is high or the seller's cost is low, or that the quality of an item is good or bad or that an investment decision is appropriate or not. The difficulty is conveying this information to others. *That is, it is the asymmetry of information between the parties on the one hand, and outsiders, such as the courts, on the other, which is the root of the problem*.

To use the jargon, incompleteness arises because states of the world, quality and actions are *observable* (to the contractual parties) but not *verifiable* (to outsiders).

We describe an example of an incomplete contract along these lines in the next section.

Incomplete Contracts: An Example

We will give an example of an incomplete contract for the case where it is prohibitively costly to specify the quality characteristics of the item to be exchanged or the parties' investment decisions. Similar problems arise when the state of the world cannot be described. The example is a variant of the models in Grossman and Hart (1986, 1987), Hart and Moore (1985).

Consider a buyer B who wishes to purchase a unit of input from a seller S. B and S each make a (simultaneous) specific investment at date 0 and trade occurs at date 1. Let I_B, I_S denote, respectively, the investments of B and S, and to simplify assume that each can take on only two values, H or L (high or low). These investments are observable to B and S, but are not verifiable (they are complex and multidimensional, or represent effort decisions) and hence are non-contractible. We assume that at date 1 the seller can supply either 'satisfactory' input or 'unsatisfactory' input. 'Unsatisfactory' input has zero benefit for the buyer and zero cost for the seller (so it is like not supplying at all). 'Satisfactory' input yields benefits and costs which depend on *ex-ante* investments. These are indicated in Fig. 1.

The first component refers to the buyer's benefit, v, and the second to the seller's cost, c. So when $I_S = H$, $I_B = H$, $v = 10$ and $c = 6$ (if input is 'satisfactory'). From these gross benefits and costs must be subtracted investment costs, which we assume to be 1.9 if investment is high and zero if it is low (for each party). (All benefits and costs are in date 1 dollars.) Note that there is no uncertainty and so attitudes to risk are irrelevant.

Our assumption is that the characteristics of the input (e.g. whether it is 'satisfactory') are observable to both parties, but are too complicated to be specified in a contract. The fact that they are observable means that the buyer can be given the option to reject the input at date 1 if he does not like it. This will be important in what follows.

An important feature of the example is that the seller's investment affects not only the seller's costs but also the buyer's benefit and the buyer's investment affects not only the buyer's benefit but also the seller's costs. The idea here is that a better investment by the seller increases the quality of 'satisfactory' input; and a better investment by the buyer reduces the cost of producing 'satisfactory' input, that is input that can be used by the buyer.

For instance, one can imagine that B is an electricity generating plant and S a coal mine that the plant is sited next to. I_B might refer to the type of coal-burning boiler that the plant installs and I_S to the way the coal supplier develops the mine. By investing in a better boiler, the power plant may be able to burn lower quality coal, thus reducing the seller's costs, while still increasing its gross (of investment) profit. On the other hand, by developing a good seam, the coal

supplier may raise the quality of coal supplied while reducing its variable cost.

The first-best has $I_B = I_S = H$, with total surplus equal to $(10 - 6) - 3.8 = 0.2$ (if $I_B = H$ and $I_S = L$, or vice versa, surplus $= 0.1$ and if $I_B = I_S = L$, no trade occurs and surplus is zero). This could be achieved if *either* investment *or* quality were contractible as follows. If investment is contractible, an optimal contract would specify that the buyer must set $I_B = H$ and the seller $I_S = H$ and give the buyer the right to accept the input at date 1 at price p_1 or reject it at price p_0. If $10 > p_1 - p_0 > 6$, the seller will be induced to supply satisfactory input (the gain, $p_1 - p_0$, from having the input accepted exceeds the seller's supply cost) and the buyer to accept it (the buyer's benefit exceeds the increment price $p_1 - p_0$. If, on the other hand, quality is contractible, the contract could specify that the seller must supply input with the precise characteristics which make it satisfactory when $I_B = I_S = H$. Each party would then have the socially correct investment incentives since, with specific performance, neither party's investment affects the other's payoff (there is no externality).

We now show that the first-best cannot be achieved if investment and quality are both noncontractible. A second-best contract can make price a function of any variable that is verifiable. Investment and quality are not verifiable (nor is v or c), but we shall suppose that whether the item is accepted or rejected by the buyer is, so the contract can specify an acceptance price, p_1, and a rejection price, p_0. In fact, p_0, p_1 can also be made functions of (verifiable) messages that the buyer and seller send each other, reflecting the investment decisions that both have made (as in Hart and Moore 1985). The following argument is unaffected by such messages and so, for simplicity, we ignore them (the interested reader is referred to Hart and Holmstrom 1987).

Can we sustain the first-best by an appropriate choice of p_0, p_1? The seller always has the option of choosing $I_S = L$ and producing an item of unsatisfactory quality, which yields him a net payoff of p_0. In order to induce him not to do this, we must have

$$p_1 - 6 - 1.9 \geq p_0, \quad \text{i.e. } p_1 - p_0 \geq 7.9. \quad (2)$$

Similarly the buyer's net payoff must be no less than $-p_0$ since he always has the option of choosing $I_B = L$ and rejecting the input. That is,

$$10 - p_1 - 1.9 \geq -p_0, \quad \text{i.e. } p_1 - p_0 \leq 8.1. \quad (3)$$

So $(p - p_0)$ must lie between 7.9 and 8.1.

Now the seller has an additional option. If he expects the buyer to set $I_B = H$, he can choose $I_S = L$ and, given that $8.1 \geq p_1 - p_0 \geq 7.9$, still be confident that trade of 'satisfactory' input will occur under the original contract at date 1 (the buyer will accept satisfactory input since $v = 9 > p_1 - p_0$, while the seller will supply it since $p_1 - p_0 > 7 = c$). But if the seller deviates, his payoff rises from $p_1 - 6 - 1.9$ to $p_1 - 7$. (The example is symmetric and so a similar deviation is also profitable for the buyer.) Hence the $I_B = I_S = H$ equilibrium will be disrupted.

We see, then, that the first-best cannot be sustained if investment and quality are both noncontractible. The reason is that it will be in the interest of the seller (or the buyer) to reduce investment since, although this reduces social benefit by lowering the buyer's (or seller's) benefit, it increases the seller's (or buyer's) own profit. The optimal second-best contract will instead have $I_B = H$, $I_S = L$ (or vice versa), which will be sustained by a pair of prices p_0, p_1 such that $9 > p_1 - p_0 > 7$. Total surplus will be 0.1 instead of the first-best level of 0.2. (Note the importance of the assumption that both the buyer and seller can choose $I = H$ or L. If only the buyer (or the seller) can choose $I = L$, the first-best can be achieved by choosing $p_1 - p_0$ between 6 and 7 (or 9 and 10): any deviation by the buyer (or the seller) will then be unprofitable since it will lead to no trade.)

The conclusion is that inefficiencies can arise in incomplete contracts even though the parties have common information (both observe investments and both observe quality). The particular inefficiency that occurs in the model analysed is in *ex-ante* investments. *Ex-post* trade is always efficient relative to these investments since p_1, p_0 can and will be chosen such that $v > p_1 - p_0 > c$,

i.e. the seller wants to supply and the buyer to receive satisfactory input. The example can be regarded as formalizing the intuition of Williamson (1985) and Klein et al. (1978) that relationship-specific investments will be distorted due to the impossibility of writing complete contingent contracts – note that this result is achieved without imposing arbitrary restrictions on the form of the permissible contract (e.g. we have not ruled out the existence of long-term contracts from the start). (There is one exception to this statement – we have excluded the participation of a third party to the contract; for a discussion and justification of this, see Hart and Holmstrom 1987.)

The example may be used to illustrate a theory of ownership presented in Grossman and Hart (1986, 1987). It is sometimes suggested that when transaction costs prevent the writing of a complete contract, there may be a reason for firm integration (see Williamson 1985). Consider the payoffs of Fig. 1 and suppose that B takes over S. The control that B thereby gains over S's assets may allow B to affect S's costs in various ways, and this may reduce the possibility of opportunistic behaviour by S. To take a very simple (and contrived) example, suppose that if S chooses $I_S = L$, B can take some action, α with respect to S's assets at date 1 so as to make S's cost of supplying either satisfactory or unsatisfactory input equal to 9 (in the coal-electricity example, α might refer to the part of the mine's seam the coal is taken out of; note that we now drop the assumption that the cost of supplying unsatisfactory input is zero). Imagine furthermore that this action increases B's benefit, so that B will indeed take it at date 1 if S chooses L. Then with this extra degree of freedom, the first-best can be achieved. In particular, if $p_1 = p_0 + 6.1$, $I_S = I_L = H$ is a Nash equilibrium since, by the above reasoning, any deviation by the seller will be punished, while if the buyer deviates, the seller will supply unsatisfactory input given that $p_1 < p_0 + 7$.

	$I_B = H$	$I_B = L$
$I_s = H$	(10, 6)	(9, 7)
$I_s = L$	(9, 7)	(6, 10)

Incomplete Contracts, Fig. 1

Note that if action α could be specified in the initial contract, there would be no need for integration: the initial contract would simply say that B has the right to choose α at date 1. Ownership becomes important, however, if (i) α is too complicated to be specified in the date 0 contract and therefore qualifies as a residual right of control; and (ii) residual rights of control over an asset are in the hands of whomever owns that asset. The point is that under incompleteness the allocation of residual decision rights matters since the contract cannot specify precisely what each party's obligations are in every state of the world. To the extent that ownership of an asset guarantees residual rights of control over that asset, vertical and lateral integration can be seen as ways of ensuring particular – and presumably efficient – allocations of residual decision rights. (While in the above example, integration increases efficiency, this is in no way a general conclusion. In Grossman and Hart (1986, 1987), examples are presented where integration reduces efficiency.)

Before concluding this section, we should emphasize that for reasons of tractability we have confined our attention to incompleteness due to a very particular sort of transaction cost. In practice, some of the other transactions costs we have alluded to are likely to be at least as important, if not more so. For example, in the type of model we have analysed, although the parties cannot describe the state of the world or quality characteristics, they are still supposed to be able to write a contract which is unambiguous and which anticipates all eventualities. This is very unrealistic. In practice, a contract might, say, have B agreeing to rent S's concert hall for a particular price. But suppose S's hall then burns down. The contract will usually be silent about what is meant to happen under these conditions (there is no hall to rent, but should S pay B damages and if so how much?), and so, in the event of a dispute, the courts will have to fill in the 'missing provision'. (A situation where it becomes impossible or extremely costly to supply a contracted for good is known as one of

'impossibility' or 'frustration' in the legal literature.) An analysis of this sort of incompleteness, although extremely hard, is a very important topic for future research. It is likely to yield a much richer and more realistic view of the way contracts are written and throw light on how courts should assess damages (this latter issue has begun to be analysed in the law and economics literature; see, e.g., Shavell 1980).

Self-Enforcing Contracts

The previous discussion has been concerned with explicit binding contracts that are enforced by outsiders, such as the courts. Even the most casual empiricism tells us that many agreements are not of this type. Although the courts may be there as a last resort (the shadow of the law may therefore be important), these agreements are enforced on a day to day basis by custom, good faith, reputation, etc. Even in the case of a serious dispute, the parties may take great pains to resolve matters themselves rather than go to court. This leads to the notion of a self-enforcing or implicit contract (the importance of informal arrangements like this in business has been stressed by Macaulay (1963) and Ben-Porath (1980) among others).

People often by-pass the legal process presumably because of the transaction costs of using it. The costs of writing a 'good' long-term contract discussed in section "The Costs of Writing Long-Term Contracts" are relevant here. So also is the skill with which the courts resolve contractual disputes. If contracts are incomplete and contain missing provisions as well as vague and ambiguous statements, appropriate enforcement may require abilities and knowledge (what was in the parties' minds?) that many judges and juries do not possess. This means that going to court may be a considerable gamble – and an expensive one at that. (This is an example of the fourth transaction cost noted in section "The Costs of Writing Long-Term Contracts".)

Although the notion of implicit or self-enforcing contracts is often invoked, a formal study of such agreements has begun only recently (see, e.g. Bull 1985), with a considerable stimulus coming from the theory of repeated games. This literature has stressed the role of *reputation* in 'completing' a contract. That is, the idea is that a party may behave 'reasonably' even if he is not obliged to do so in order to develop a reputation as a decent and reliable trader. In some instances such reputational effects will operate only within the group of contractual parties – this is sometimes called *internal* enforcement of the contract – while in others the effects will be more pervasive. The latter will be the case when some outsiders to the contract, for example other firms in the industry or potential workers for a firm, observe unreasonable behaviour by one party, and as a result are more reluctant to deal with it in the future. In this case the enforcement is said to be *external* or *market-based*. Note that there may be a tension between this external enforcement and the reasons for the absence of a legally binding contract in the first place – the more people can observe the behaviour, the more likely it is to be verifiable.

The distinction between an incomplete contract and a standard asymmetric information contract should be emphasized here. It is the former that allows reputation to operate since the parties have the same information and can observe whether reasonable behaviour is being maintained. In the latter case, it is unclear how reputation can overcome the asymmetry of information between the parties that is the reason for the departure from an Arrow–Debreu contract.

The role of reputation in sustaining a contract can be illustrated using the following model (based on Bull (1985) and Kreps (1984); this is an even simpler model of incomplete contracts than that of the last section). Assume that a buyer, B, and a seller, S, wish to trade an item at date 1 which has value v to the buyer and cost c to the seller, where $v > c$. There are no *ex-ante* investments and the good is homogeneous, so quality is not an issue. Suppose, however, that it is not verifiable whether trade actually occurs. Then a legally binding contract which specifies that the seller must deliver the item and the buyer must pay p, where $v > p > c$, cannot be enforced. The reason is that, assuming (as we shall) that simultaneous delivery and payment are infeasible,

if the seller has to deliver first, the buyer can always deny that delivery occurred and refuse payment, while if the buyer has to pay first, the seller can always claim later that he did deliver even though he did not. As a result, if the parties must rely on the courts, a gainful trading opportunity will be missed.

The idea that not even the level of trade is verifiable is extreme, and Bull (1985) in fact makes the more defensible assumption that it is the quality of the good that cannot be verified (in Bull's model, S is a worker and quality refers to his performance). Bull supposes that quality is observable to the buyer only with a lag, so that take it or leave it offers of the type considered in the last section are not feasible. As a result the seller always has an incentive to produce minimum quality (which corresponds in the above model to zero output). Making quantity nonverifiable is a cruder but simpler way of capturing the same idea (this is the approach taken in Kreps 1984).

Note that in the above model incompleteness of the contract arises entirely from transaction cost (3), the difficulty of writing and enforcing the contract.

To introduce reputational effects one supposes that this trading relationship is repeated. Bull (1985) and Kreps (1984) follow the supergame literature and assume infinite repetition in order to avoid unravelling problems. This approach, as is well known, suffers from a number of difficulties. First, the assumption of infinite (or in some versions, *potentially* infinite) life is hard to swallow. Secondly, 'reasonable' behaviour, i.e. trade, is sustained by the threat that if one party behaves unreasonably so will the other party from then on. While this threat is 'credible' (more precisely, subgame perfect), it is unclear why the parties could not decide to continue to trade after a deviation, i.e. to 'let bygones be bygones' (see Farrell 1984.)

It would seem that a preferable approach is to assume that the relationship has finite length, but introduce asymmetric information, as in Kreps and Wilson (1982) and Milgrom and Roberts (1982). The following is based on some very preliminary work that Bengt Holmstrom and I have undertaken along these lines.

Suppose that there are two types of buyers in the population, honest and dishonest. Honest buyers will always honour any agreement or promise that they have made while dishonest ones will do so only if this is profitable. A buyer knows his own type, but others do not. It is common knowledge that the fraction of honest buyers in the population is π, $0 < \pi < 1$. In contrast, all sellers are known to be dishonest. All agents are risk neutral.

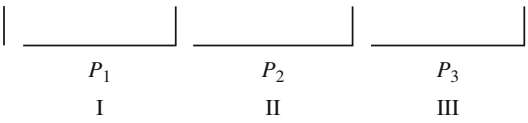
Assume for simplicity that a single buyer and seller are matched at date 0 with neither having any alternative trading partners at this date or in the future. Consider first the one-period case. Then a date 0 agreement can be represented as follows. The interpretation is that the buyer promises to pay the seller p_1 before date 1 (stage I); in return, the seller promises to supply the item at date 1 (stage II); and in return for this, the buyer promises to make a further payment of p_2 (stage III).

We should mention one further assumption. Honest buyers, although they never breach an agreement first, are supposed to feel under no obligation to fulfil the terms of an agreement that has already been broken by a seller (interestingly, although this is a theory of buyer psychology, it has parallels in the common law). Note that if a buyer ever breaks an agreement first, he reveals himself to be dishonest, with the consequence that no further self-enforcing agreement with the seller is possible and hence trade ceases.

What is an optimal agreement? Consider Fig. 2. The seller knows that he will receive p_2 only with probability π since a dishonest buyer will default at the last stage. Since the seller is himself dishonest, he will supply at Stage II only if it is profitable for him to do so, i.e. only if

$$\pi p_2 - c \geq 0. \tag{4}$$

Assume for simplicity that the seller has all the bargaining power at date 0 (nothing that follows



Incomplete Contracts, Fig. 2

depends on this). Then the seller will wish to maximize his overall payoff

$$p_1 + \pi p_2 - c, \tag{5}$$

subject to (4) which makes it credible that he will supply at stage II and also the constraint that he does not discourage an honest buyer from participating in the agreement at date 0. Since with (4) satisfied, buyers know that they will receive the item for sure, this last condition is

$$v - p_1 - p_2 \geq \quad 0. \tag{6}$$

Note that a dishonest buyer's payoff $v - p_1$ is always higher than an honest buyer's payoff given in (6), so there is no way to screen out dishonest buyers. In the language of asymmetric information models, the equilibrium is a pooling one.

Since the seller's payoff is increasing in p_1, (6) will hold with equality (the buyer gets no surplus). (More generally, changes in p_1 simply redistribute surplus between the two parties without changing either's incentive to breach.) If we substitute for p_1 in (5), the seller's payoff becomes $v - p_2(1 - \pi) - c$, which, when maximized subject to (4), yields the solution $p_2 = c/\pi$. The maximized net payoff is

$$v - c/\pi, \tag{7}$$

which is less than the first-best level, $v - c$.

We see then that the conditions for trade are more stringent in the absence of a binding contract. If $c/(\pi) > v > c$, there are gains from trade which would not be realized in a one-period relationship.

Suppose now that the relationship is repeated. Consider a two-period version of the above and assume no discounting. Now the diagram shown in Fig. 3 applies. That is, the agreement says that the buyer pays, the seller supplies the first time, the buyer pays more, the seller supplies a second time, and the buyer makes a final payment. Rather than solving for the optimal arrangement, we shall simply show that the seller can do better than in the one period case. Let $p_3 = c/\pi$, $p_2 = c$ and $p_1 = 2v - c - (c)/\pi$. Then (i) the seller will supply at Stage IV (if matters have got that far), knowing that he will receive $p3$ with probability π (ii) both honest and dishonest buyers will pay p_2 at Stage III, the latter because, at a cost of c, they thereby ensure supply worth $v > c$ at Stage IV; (iii) the seller will supply at stage II because this gives him a net payoff of $p_2 + \pi p_3 - 2c \geq 0$, while if he does not the arrangement is over and his payoff is zero; (iv) an honest buyer is prepared to participate since his surplus is non-negative (actually zero).

The seller's overall expected net payoff is

$$p_1 + \pi_2 + \pi p_3 - 2c = 2v - c - c/\pi, \tag{8}$$

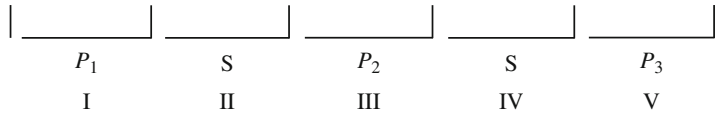
which *exceeds* twice the one-period payoff. Hence trade is more likely to take place in a two-period relationship than in a one-period one. In fact it can be shown that the above is an *optimal* two-period agreement.

Repetition improves things by allowing the honest buyer to pay less second time round (Stage III) than third time round (Stage V). That is, the arrangement *back-loads* payments. This is acceptable to the seller because he knows that even a dishonest buyer will not default at Stage III since he has a large stake in the arrangement continuing. To put it another way, the dishonest buyer does not want to reveal his dishonesty at too early a stage.

The same arrangement can be used when there are more than two periods: the buyer promises to pay c at every stage except the last, when he pays (c/π). In fact the per period surplus of the seller from such an arrangement converges to the first-best level $(v - c)$ as the number of periods tends to ∞ (assuming no discounting, of course).

Although the above analysis is extremely provisional and sketchy, we can draw some tentative

Incomplete Contracts, Fig. 3



conclusions about the role of reputation and indicate some directions for further research. First, the notion of a psychic cost of breaking an agreement seems to be a useful – as well as a not unrealistic – basis for a theory of self- enforcing contracts. It is obviously desirable to drop the assumption that some agents are completely honest and others completely dishonest, and assume instead that the typical trader has a finite psychic cost of breaking an agreement, where this cost is distributed in the population in a known way. In other words, everybody 'has their price', but this price varies. Preliminary work along these lines suggests that the above results generalize; in particular, repetition makes it easier to sustain a self-enforcing agreement.

Of course, asymmetries of information about psychic costs are not the only possible basis for a theory of reputation. For example, the buyer and seller could have private information about v and c, and might choose their trading strategies to influence perceptions about the values of these variables (the role of uncertainty about v and c in determining reputation has been investigated by Thomas and Worrall 1984). A theory of self-enforcing contracts should ideally generate results which are not that sensitive to where the asymmetry of information is placed. The work of Fudenberg and Maskin (1986) in a related context, however, suggests that this may be a difficult goal to achieve.

There are a number of other natural directions in which to take the model. One is to introduce trade with other parties. For example, the seller may trade with a succession of buyers rather than a single one. The extent to which repetition increases per period surplus in this case depends on whether new buyers observe the past broken promises of the seller. (This determines the degree to which external enforcement operates; more generally, 'a new buyer may observe that default occurred in the past, but be unsure about who was responsible for it.) If new buyers do not observe past broken promises, repetition achieves nothing, which gives a very strong prediction of the possible benefits of a long-term relationship between a fixed buyer and seller. Even if past broken promises are observed perfectly, it appears that, *ceteris paribus*, a single long-term agreement may be superior to a succession of short-term ones. The reason is that in the latter case the constraint is imposed that each party must receive non-negative surplus over *their* term of the relationship whereas in the former case there is only the single constraint that surplus must be non-negative over the whole term (see Bull 1985; Kreps 1984).

Probably the most important extension is to introduce incompleteness due to other sorts of transaction costs, e.g. the 'bounded rationality' costs (1) and (2) discussed in section "The Costs of Writing Long-Term Contracts". The problem is that the same factors which make it difficult to anticipate and plan for eventualities in a formal contract apply also to informal arrangements. That is, an informal arrangement is also likely to contain many 'missing provisions'. But then the question arises, what constitutes 'reasonable' or 'desirable' behaviour (in terms of building a reputation) with regard to states or actions that were not discussed *ex-ante*? Custom, among other things, is likely to be important under these conditions: behaviour will be 'reasonable' or 'desirable' to the extent that it is generally regarded as such (for a good discussion of this, see Kreps 1984). This raises many new and interesting (as well as extremely difficult) questions.

Summary and Conclusions

The vast majority of the theoretical work on contracts to date has been concerned with what might be called 'complete' contracts. In this context, a complete contract means one that specifies each party's obligations in every conceivable eventuality, rather than a contract that is fully contingent in the Arrow–Debreu sense. In particular, according to this terminology, the typical asymmetric information contract found in the principal-agent or implicit contract literatures (see Hart and Holmstrom 1987) is complete.

In reality it is usually impossible to lay down each party's obligations completely and unambiguously in advance, and so most actual contracts are seriously incomplete. In this entry, we have

tried to indicate some of the implications of such incompleteness. Among other things, we have seen that incompleteness can lead to departures from the first-best even when there are no asymmetries of information among the contracting parties (and, moreover, the parties are risk neutral).

More important perhaps than this is the fact that incompleteness raises new and difficult questions about how the behaviour of the contracting parties is determined. To the extent that incomplete contracts do not specify the parties' actions fully, i.e. they contain 'gaps', additional theories are required to tell us how these gaps are filled in. Among other things, outside influences such as custom or reputation may become important under these conditions. In addition, outsiders, such as the courts (or arbitrators), may have a role to play in filling in missing provisions of the contract and resolving ambiguities rather than in simply enforcing an existing agreement. Incompleteness can also throw light on the importance of the allocation of decision rights or rights of control. If it is too costly to state precisely how a particular asset is to be used in every state of the world, it may be efficient simply to give one party 'control' of the asset, in the sense that he is entitled to do what he likes with it, subject perhaps to some explicit (contractible) limitations.

While the importance of incompleteness is very well recognized by lawyers, as well as by those working in law and economics, it is only beginning to be appreciated by economic theorists. It is to be hoped that work in the next few years will lead to significant advances in our formal understanding of this phenomenon. Unfortunately, progress is unlikely to be easy since many aspects of incompleteness are intimately connected to the notion of bounded rationality, a satisfactory formalization of which does not yet exist.

As a final illustration of the importance of incompleteness, consider the following question. Why do parties frequently write a limited term contract, with the intention of renegotiating this when it comes to an end, rather than writing a single contract that extends over the whole length of their relationship? In a complete contract framework such behaviour cannot be advantageous since the parties could just as well calculate what will happen when the contract expires and include this as part of the original contract. It is to be hoped that future work on incomplete contracts will allow this very basic question to be answered.

Incomplete Markets

Charles Wilson

Abstract

'Incomplete markets' describes a market structure in which there are effective constraints on which bundles of goods may be exchanged with each other. When incompleteness arises from markets that are sequentially segmented, some of the basic properties of general equilibrium are affected. First, equilibrium may not exist even under the usual regularity assumptions. Second, allocations may not be Pareto optimal, even after the limitations imposed by the market structure are taken into account. Third, if securities are denominated in nominal values, the equilibrium allocation is generally not locally unique.

Incomplete markets arise when agents are unable to exchange every good either directly or indirectly with every other agent. In the case of a single market with no limitations on the exchange of goods, relatively mild assumptions guarantee the existence, Pareto optimality, and local uniqueness of a competitive equilibrium. However, once we impose restrictions on the trade of goods and introduce sequential markets so that not all trade take place in a single market, any one of these properties may fail to be satisfied. A large literature has evolved that examines the conditions under which different sets of securities generate a complete set of markets and the properties of the equilibrium allocations when they do not. In this article I illustrate a few of the main ideas in this literature.

A good starting point is the work of Arrow (1973), who demonstrated that static competitive analysis can be extended to deal with the case of uncertainty, but only by expanding the set of markets to include a separate price for each commodity in each state of the world. With a complete set of markets in state contingent commodities, it follows immediately that, under the usual conditions on preferences, the competitive allocation exists, is *ex-ante* Pareto efficient and locally unique. Although this approach solves the problem of extending general equilibrium analysis to deal with uncertainty, it strains the credibility of the model by requiring an unrealistic number of goods to be simultaneously exchanged. It is important, therefore, to examine the extent to

which the same allocation can be attained with a different market structure requiring a smaller number of instruments.

Consider an economy with S possible realizations of an uncertain state of the world with N goods in each state. We will refer to the state contingent good i in state s as good is. To allow for more general market structures, we suppose that all trading takes place in securities, which are claims on the vector of state contingent goods. A *simple* security promises delivery of one unit of only one state contingent good. Observe that any security may be represented as a linear combination of simple securities. The *span* of any set of securities is the set of state-contingent goods that can be obtained by some linear combination of those securities. A *market* is a set of securities and a price vector at which they may be exchanged. An Arrow–Debreu market is a market consisting of the complete set of simple securities, and an Arrow–Debreu allocation is the competitive equilibrium for an Arrow–Debreu market. A *spot* market for state s is a market in which only the simple securities for s goods are traded. We will always assume that the spot market for each state s is 'complete' in the sense that the set of feasible trades spans the set of all simple securities for state s.

To reduce the number of securities traded in any market, Arrow considers a two-stage market structure. In the first stage, before the state is realized, all agents have access to a 'securities' market. In this market, there is one security f^s for each state s, which represents a claim of one unit of each good in that state. In the second stage, after the state is realized and the claims of the first-stage securities are realized, the corresponding spot market opens and the final allocation is determined by the spot market equilibrium. Arrow demonstrates that, when agents have perfect foresight of the future spot market prices, any Arrow–Debreu allocation can be attained as a competitive equilibrium for this two-stage market structure. Since spot markets operate only when the actual state is realized, the total number of securities that are required to obtain the Arrow–Debreu allocation is reduced from NS to N + S.

To demonstrate the logic of Arrow's result, let p(s) denote the vector of spot prices in state s and let qs denote the first-stage price of security fs. Then, defining pis = qspi(s) for each good is, we obtain an NS vector (p_{is}) that defines the relative prices for all state contingent goods. For example, to exchange good is for good js', an agent exchanges security $f^{s'}$ for security f^s in the first-stage securities market and then uses the spot markets to obtain the desired net exchange. Alternatively, given a vector (p_{is}) of state-contingent prices, we may obtain the equivalent prices for the two-stage market by defining each $q_s = \Sigma_i p_{is}$ and each $p_i(s) = p_{is}/q_s$. Then, since each agent effectively faces the same budget constraint in both market structures, it follows that both market structures generate the same equilibrium allocation of goods.

Notice that the only role of the first-stage securities market is to transfer purchasing power across states. For instance, the set of simple securities of good 1 would work just as well. The essential requirement is that the set of securities spans the set of all possible transfers of purchasing power across states. Furthermore, so long as there is an 'insurance' security for each state s that delivers only state s contingent goods, the spanning condition is necessarily satisfied (at least if the vectors of all spot prices are strictly positive). Other sets of securities may also satisfy the spanning condition. However, the consideration of a more general set of securities also introduces some complications that may impact on the existence of equilibrium and the welfare analysis of the market structure.

The problem is not just that the set of available securities might not span the entire commodity space. In fact, as long as all trade takes place in a single market so that any feasible security can be traded with another, the span of the market is fixed. So if we simply redefine the commodity space as the market span and restrict preferences accordingly, the existence, Pareto optimality, and local uniqueness of equilibria (for any basis of securities) follow from the standard arguments. With multi-stage markets, however, the security markets are essentially segmented. Consequently, a change in relative spot market prices may translate into changes in the space of feasible transfers

of purchasing power that may be obtained by exchanging any given set of securities.

To illustrate, suppose there are only two goods in each state and the first-stage securities market consists of just two 'forward' securities, which respectively represent the claim of one unit of good X or one unit of good Y regardless of the state. Now fix the spot market prices in each state. Then since there are only two securities, it follows immediately that the dimension of the space of income transfers (measured, say, in terms of good X in each state) that can be obtained using the first- stage securities is at most two. Furthermore, if there are more than two states, the space of transfers that are spanned by the securities market depends on the relative prices in the different spot markets. For instance, suppose that the relative spot prices are the identical in states 1 and 2. Then any transfer of income to state 1 must be accompanied by the same transfer of income to state 2. However, if $p_x(1)/p_y(1) < 1 < p_x(2)/p_y(2)$, income can be transferred from state 1 to state 2 by exchanging one of forward security X for one unit of forward security Y. For the general case with N goods and S states, Townsend (1978) shows that when all first- stage securities are forward securities, the income transfers of these securities span R^S, the space of income transfers, if and only if there are at least S securities and the set of spot market price vectors are linearly independent.

The Existence of Equilibrium

When the dimension of the span of the transfers of a set of securities depend on the prices in the spot markets, the usual regularity assumptions on preferences no longer guarantee the existence of an equilibrium. Consider the following example based on Hart (1975). There are two agents, a and b, and two states. In each state there are two goods, labelled X and Y which must be consumed in non-negative amounts by each agent. The preferences and endowments of the agents are given in Table 1, where x_{as} and y_{as} are the respective amounts of good X and Y consumed by agent α in state s.

Incomplete Markets, Table 1

Agent	Endowments		Utility
	(X_1, Y_1)	(X_2, Y_2)	
a	(2, 2)	(1, 1)	$3x_{a1} + y_{a1} + 3x_{a2} + y_{a2}$
b	(1, 1)	(2, 2)	$x_{b1} + 3y_{b1} + x_{b2} + 3y_{b2}$

Agent a is endowed with two units of each good in state 1 and one unit of each good in state 2. His marginal rate of substitution between X and Y in either state is 3, and his marginal rate of substitution between goods across states is 1. Agent b is endowed with one unit of each good in state 1 and two units of each good in state 2. His preferences are the same as those of agent a except that the role of X and Y is reversed. It is easy to check that in the unique Arrow–Debreu equilibrium, the price of all state contingent goods must be equal.

Consider next the case in which the first-stage market consists of the two forward securities. We will show that a competitive equilibrium does not exist. As above, let $p_x(s)$ and $p_y(s)$ denote the equilibrium prices of goods X and Y in the state s spot market, and let q_x and q_y denote the equilibrium prices of the two forward securities. Now suppose some agent α exchanges q_x units of security Y for q_y units of security X. Then his income in state s changes by the amount $p_{xs}q_y - p_{ys}q_x$. Therefore, in equilibrium either (a) q_x/q_y lies between $p_x(1)/p_y(1)$ and px(2)/py(2), or (b) qx/qy = px1/py1 = px2/py2. Otherwise, one security dominates the other in the sense that an exchange of securities raises or lowers purchasing power in both states.

We show first that case (b) in which the relative spot prices are equal is not consistent with equilibrium. In this case, an exchange of securities leaves the income in both spot markets unchanged. Consequently, the equilibrium allocation and prices in the spot market must be the same as if no securities market existed. But the solution to either spot market then yields the allocation in which agent a obtains all three units of good X and agent b all three units of good Y. However, to clear the spot markets, the spot prices in the two states must differ, with $p_{x1}/p_{y1} = 2$ and

$p_{x2}/p_{y2} = 1/2$. We conclude that the relative spot prices cannot be equal in equilibrium.

Now suppose the relative spot prices are different. Then, using both the securities market and the spot markets, an agent may exchange good X in state 1 for good X in state 2 at the relative price $(p_x(1)/p_y(1))([p_x(2)q_y - p_y(2)q_x]/[p_y(1)q_x - p_x(1)q_y])$. Since markets are now effectively complete, the equilibrium prices in the market structure with forward securities must generate an Arrow–Debreu allocation. But we have already observed that the prices of state contingent goods must all be equal in an Arrow–Debreu equilibrium. It then follows that the relative spot prices in the two states must also be equal, which contradicts our conclusion above. We conclude that there is no competitive equilibrium for the forward security market structure.

In this example, an equilibrium fails to exist for the market structure with forward securities because the dimension of the resulting space of feasible net trades in state contingent goods abruptly shrinks at certain prices. As the relative prices of future securities and spot prices converge to the same ratio, the volume of trade in future securities that is required for a given transfer of purchasing power across states goes to infinity. Consequently, the demand functions for securities may be unbounded even in regions where all relative prices are bounded away from zero. To avoid this problem, Radner (1972) imposes an exogenous lower bound on short sales of securities and shows that this is sufficient to guarantee the existence of equilibrium under standard assumptions. Another approach is to assume that the set of securities is sufficiently rich to guarantee that the dimensionality of net trades does not vary with the price as in Geanokoplos and Polemarchakis (1986). Under these conditions, the demand functions remain bounded and continuous, so there is no need for an exogenous lower bound on excess demand. Kreps (1979) also notes that the set of transfers for any set of securities has full rank for almost all spot prices and therefore that the existence problem is not generic. A general theorem for the generic existence of equilibrium is established by Duffie and Shafer (1985).

Pareto Efficiency

As observed above, whenever the two-stage market structure generates a complete set of markets, the equilibrium allocation is an Arrow–Debreu allocation and is therefore Pareto optimal. However, if the first-stage market does not span the space of income transfers, then markets are not complete and the equilibrium allocation is generally not Pareto optimal. In this case, it may be of more use to restrict attention to a more limited set of allocations that reflect the restrictions imposed by the market structure. With the segmentation of markets, however, it is not immediately obvious how we should redefine the set of feasible allocations. For instance, if we permit a central planner to reallocate securities in each spot market, then any technologically feasible allocation can be obtained. To capture the restrictions implied by the market structure, therefore, we must impose some restrictions on how the spot market securities may be allocated.

One possibility is to permit the central planner to arbitrarily allocate securities in the first-stage market, but leave the allocation of securities in the spot markets to be determined by market clearing prices. This approach leads to the following definition suggested by Hart (1975). Let F denote the set of securities in the first- stage market. An allocation of state contingent goods is *constrained Pareto efficient* if (*a*) it is attained as an equilibrium in the spot markets for some feasible distribution of securities in F, and (*b*) there is no Pareto superior allocation of state contingent goods attained as an equilibrium in the spot markets for some other feasible distribution of securities in F.

We will show that when the number of securities in F is less than S, an equilibrium need not be even constrained Pareto efficient. The reason is that a redistribution of the ownership of securities generally leads to a change in the spot market prices and hence to a change in the vector of income transfers associated with each security. As we observed above, when the set of securities in F does not span R^S, the space of transfer vectors that are spanned by the securities in F generally depends on the spot market prices. Consequently, the transfer of real income generated by the

Incomplete Markets, Table 2 Caption missing

Agent	Endowments		Utility
	(X_1, Y_1)	(X_2, Y_2)	
a	(0, 2)	(2, 0)	$x_{a1} + \varepsilon \min \{x_{a2}, y_{a2}\}$
b	(2, 0)	(0, 2)	$\varepsilon \min \{x_{b1}, y_{b1}\} + x_{b2}$
c	(1, 1)	(1, 1)	$y_{c1} + y_{c2}$

redistribution of securities following the adjustment of prices in the spot markets typically lies outside the span of the transfers generated by the set of securities at the competitive equilibrium prices. By redistributing existing securities, therefore, it may be possible to increase the welfare of every agent in the economy.

To illustrate, consider an economy with three agents, *a, b* and *c*, and two states of the world, 1 and 2. In each state *s* there are two goods, labelled *X* and *Y*. Suppose the preferences and endowments of the agents are given by Table 2, where $x_{\alpha s}$ and $y_{\alpha s}$ are the respective consumption of goods *X* and *Y* by agent α in state *s*.

In this economy, agent *a* is endowed with two units of good *Y* in state 1 and two units of good *X* in state 2. He consumes only good *X* in state 1 and always consumes an equal amount of both goods in state 2. For each pair of units of the two goods he consumes in state 2 he is willing to give up ε units of his consumption of good *X* in state 1. The endowment and preferences of agent *b* are the same except that the role of the two states is reversed. Agent *c* is endowed with one unit of good *X* in both states but consumes only good *Y*. His marginal rate of substitution between consumption in the two states is one.

Suppose there is a single security that promises to deliver one unit of good *X* in each state. Since there is nothing for which to exchange this security, the equilibrium income and spot prices in each state will be determined solely by the endowments of the agents in that state. It is easy to check that the relative price of the two goods is one in both states. Agent *a* consumes two units of good *X* in state 1 and one unit of each good in state 2. Agent *b* consumes one unit of each good in state 1 and one unit of good *X* in state 2. Agent *c* consumes two units of good *Y* in both states.

Incomplete Markets, Table 3 Caption missing

Agent	Endowments	
	(X_1, Y_1)	(X_2, Y_2)
a	(−2, 2)	(0, 0)
b	(0, 0)	(−2, 2)
c	(5, 1)	(5, 1)

Although the security will never be traded in the market, it can still be used by the government to redistribute purchasing power in the two states and thereby change the spot prices. Suppose, for instance, that agents *a* and *b* must each supply agent *c* with two units of the security. Then the effect is the same as if the endowments were changed as to the endowments listed in Table 3.

For this economy the equilibrium price of good *Y* in terms of good *X* in each state is 5/2. Agent *a* consumes the three units of good *X* in state 1 and nothing in state 2. Agent *b* consumes nothing in state 1 and all three units of good *X* in state 2. Agent *c* consumes the three units of good *Y* in both states.

Now compare the welfare of the two agents in the two economies. Without the transfer payments, agents *a* and *b* attain an expected utility of $2 + \varepsilon$ while agent c attains an expected utility of 4. With the transfer payments, agent *a* and *b* both attain an expected utility of 3 while agent c attains a utility of 6. Consequently, for $0 < \varepsilon < 1$, the equilibrium with transfer payments Pareto dominates the equilibrium without transfer payments. By transferring purchasing power to agent *c* in both states, the economy has made the price of the goods demanded by agents *a* and *b* cheaper in those states where they value their increased welfare the most.

The possibility that securities can be reallocated to attain a Pareto superior allocation when markets are incomplete was first illustrated

by Hart (1975). He provided an example in which removing securities and hence decreasing the possibilities for trade actually resulted in a Pareto superior allocation. The intuition is similar to that provided in the example above. If markets are not compete, the introduction of a new security may change the spot market prices in such a way that utilities of all agents decrease unless they can make trades that are not available with the existing set of securities.

Geanokoplos and Polemarchakis (1986) consider a model with two periods and enlarge the commodity space to include consumption before the state of nature is realized. With a complete set of spot markets in the second period and a combined spot and securities market in the first period, they establish that the competitive equilibrium is almost never constrained Pareto optimal whenever the number of securities in F is less than S and there are at least two goods in each state. Geanokoplos et al. (1990) establish a similar result for a general equilibrium model of the stock market.

Nominal Securities and the Indeterminacy of Equilibrium

Cass (1985) investigates the implications for equilibrium when some of the securities are 'nominal'. These are securities in which the returns in any state are denominated in some unit of account. When all securities are nominal an equilibrium always exists. However, if the dimension of the span of these securities is less than S, the equilibrium is generally not locally unique. In fact, the dimension of indeterminacy is generally equal to $S - 1$.

This result derives from the fact that the real income actually transferred to any state by a nominal security depends on the price level in that state. Suppose the prices in each spot market s are normalized so that they sum to q_s. Then for each vector, $q = (q_1, \ldots q_S)$, any given nominal security f that promises delivery of f_s units of income in each state s corresponds to a unique 'real' security which pays f_s/q_s units of each good in each state s. Let $g_{f(q)}$ denote the real security $(f_1/q_1, \ldots, f_S/q_S)$, and let $F(q)$ denote the set of all such securities generated by the initial set of nominal securities. Then, for any security in $F(q)$, the relative prices in each state do not affect the amount of real income that is transferred by any given exchange of securities. Consequently, there will generally be a locally unique equilibrium associated with each vector q.

Suppose that the set of nominal securities does not span R^S. Then, any non-proportional change in q (generically) changes the span of $F(q)$. Consequently, when we replace the market of nominal securities with a market of real securities $F(q)$, each (normalized) vector q generally produces a distinct equilibrium allocation. Observe, however, that each of these allocations can be realized as an equilibrium with the same set of nominal securities. Therefore, since the dimension of normalized vectors q is $S - 1$, it follows that the dimension of equilibrium allocations associated with any incomplete set of nominal securities is generically $S - 1$.

Notice that this argument only works when the set of nominal securities does not span RS. When the span is complete, the possibilities for distributing real income using the artificial real securities no longer depend on q. Consequently, any equilibrium must yield an Arrow–Debreu allocation.

Increasing Returns to Scale

Spyros Vassilakis

The focus of this essay is the set of positive propositions that can be obtained when technology exhibits increasing returns to scale. The basic incompatibility of perfect competition and increasing returns to scale is examined separately in a section on existence of equilibria, in which we discuss how one should model economies exhibiting such technologies, i.e. essentially how to modify the Walrasian equilibrium concept in order to guarantee existence of equilibria. Welfare and purely empirical problems are not considered.
Definitions: A technology exhibits increasing returns to scale if a proportionate increase in all inputs allows for a more than proportionate increase in outputs; in the single-output case, this implies a decreasing average cost curve.

Division of Labour and Increasing Returns to Scale

Adam Smith (1776), Babbage (1832), Marshall (1890, 1919) and Young (1928) considered the process of division of labour as the main reason why we observe technologies that exhibit increasing returns to scale. A version of their arguments runs as follows: Let A be the set of tasks to be executed in order to produce good x; a partition $A_1,\ldots, A_n$ is called a first-stage division of labour. Each sub-task A_i, $i = 1,\ldots, n$ is executed by (potentially but not necessarily) different kinds of machinery and primary factors, to be called first-stage intermediate goods. The set of tasks to be executed in order to produce each first-stage intermediate good is also subject to division of labour, to be called second-stage division of labour. Each subtask generated by a second-stage division of labour is executed by intermediate goods, to be called second-stage intermediate goods. Clearly, this process can go on indefinitely. We say that the process of division of labour stops at the nth stage if the n-stage intermediate products are all primary factors; a process is feasible if it stops after a finite number of stages and if the demand for primary factors that it generates does not exceed supply. Suppose, now, that production processes are indivisible, i.e. that when an intermediate good is utilized in the production of some other good, its quantity cannot fall short of a minimum irreducible amount, to be called a fixed cost. An increase in the degree of division of labour is defined as either a finer partition of the set of tasks to be executed in order to produce some good, with the number of stages fixed; or an increase in the number of stages. Clearly, then, an increase in the degree of division of labour implies an increase in fixed costs; discarding inferior divisions of labour, therefore, means that an increase in the degree of division of labour has to imply a decrease in variable cost coefficients.

Smith (1776, p. 7) gave three reasons for such a decrease:

> first, … the increase of dexterity in every particular workman; secondly …, the saving of the time which is commonly lost in passing from one species of work to another; and lastly … the invention of a great number of machines which facilitate and abridge labour, and enable one man to do the work of many.

(See also Babbage 1832, ch. xix.) From now on, the (degree of) division of labour and the degree of increasing returns are used as synonyms.

Adam Smith

Adam Smith formulated the following propositions:

(1) The division of labour is limited by the extent of the market (Book 1, ch. 3).
(2) The extent of the market is positively related to population size and density, the amount of natural resources and accumulated capital available, and the ease of transportation (Book 1, ch. 3; Book 2, pp. 259–61).
(3) Small economies devote most of their resources to agriculture, while large economies specialize in industry, because the latter affords a greater degree of division of labour. For exactly the same reason, increases in market size decrease the price of industrial products relative to primary products, and as a consequence the profit rate in industry declines (Book I, ch. XI, pp. 242–7; Book III, ch. I).
(4) Trade increases market size and allows each trader (country, region, individual) to specialize and reap the benefits of increased division of labour. Trade is therefore beneficial to all parties involved, it increases real income of all classes, and therefore should not be restricted by governments (Book IV, ch. II; Book I, ch. II).
(5) Economic activity is located in areas in which transportation is least costly, and therefore in areas with the largest potential for division of labour and trade (Book I, pp. 18–21).
(6) The division of labour is limited by the stability of the market (this is not explicitly stated by Smith, but a number of passages indicated that he was aware of it: Book I, p. 21; Book IV, p. 430).

Notice that (1), (2) and (6) are general propositions, while (3), (4) and (5) are applications.

Proposition (1) has generated many important subsidiary propositions, to be described below. Smith used it to derive (3), (4) and (5) without paying attention to the fact that he never demonstrated how the division of labour is determined (as opposed to limited) by the extent of the market.

Marx (1867, Vol. I, Part IV, section 4), Young (1928), Coase (1937) and Stigler (1951) utilized Proposition (1), often unwittingly, to provide the rudiments of a theory of vertical integration and production roundaboutness. Marx (1867, Vol. I) considered the two as different aspects of the same problem, i.e. vertical (dis)integration is 'division of labour in the society' and production roundaboutness is 'division of labour in the workshop'. The following quotation is from Book I, ch. XIV, section 4, p. 355:

> But what is it that forms the bond between the independent labours of the cattle-breeder, the tanner, and the shoemaker? It is the fact that their respective products are commodities. What, on the other hand, characterizes division of labour in manufactures? The fact that the detail labourer produces no commodities. It is only the common product of all the detail labourers that becomes a commodity. Division of labour in society is brought about by the purchase and sale of the products of different branches of industry, while the connexion between the detail operations in a workshop is due to the sale of labour-power of several workmen in one capitalist, who applies it as combined labour-power. The division of labour in the workshop implies concentration of the means of production in the hands of one capitalist; the division of labour in society implies their dispersion among many independent producers of commodities. While within the workshop, the iron law of proportionality subjects definite numbers of workers to definite functions, in the society outside the workshop, chance and caprice have full play in distributing the producers and their means of production among the various branches of industry.

Marx also saw that the degree of vertical integration is higher the higher the degree of market imperfection:

> the distinction between division of labour in society and in manufacture was practically illustrated to the Yankees. One of the new taxes devised at Washington during the Civil War, was the duty of 6% 'on all industrial products'. Question: What is an industrial product? Answer of the legislature: A thing is produced 'when it is made', and it is made when it is ready for sale . . ..The New York and Philadelphia manufacturers had previously been in the habit of 'making' umbrellas with all their belongings. But since an umbrella is a mixtum compositum of very heterogeneous parts, by degrees these parts became the products of various separate industries, carried on independently in different places. They entered as separate commodities into the umbrella

> manufactory, where they were fitted together. The Yankees have given to articles thus fitted together the name of 'assembled articles', a name they deserve, for being an assemblage of taxes. Thus the umbrella 'assembles' first, 6% on the price of each of its elements, and a further 6% on its own total price' (ibid., p. 355, footnote 2).

Coase (1937) rediscovered and generalized these observations of Marx and constructed a theory of the firm out of them: price-mediated transactions are costly, and firms exist in order to economize on these costs by organizing transactions in a different, non-price mediated way. At this level of generality, the theory is tautological. Stigler (1951) was the first to try to make it operational: he assumes that a single-output firm executes a set of functions, some of them subject to diminishing and others to increasing average cost. The reason why the firm does not become a monopoly is that the increasing cost functions eventually prevail over the decreasing cost ones, so that the firm's average cost curve is U-shaped. (This is clearly not in the spirit of the classical economists, who assumed global increasing returns.) The reason why with small market size, a firm performs the increasing returns functions itself, instead of abandoning them to specialized firms and so sharing fixed costs with other buyers, is that the fixed cost of these functions is too high relative to market size to allow for the survival of even one specialized firm. This argument is based on the implicit assumption that it is profitable for an integrated firm to perform the increasing returns to scale function, while a specialized firm would make a loss because it would not be able to capture all the surplus of the downstream firms, i.e. it would be able to practise only a sufficiently imperfect degree of price discrimination. As market size increases, though, the position of the specialized firm is strengthened, and eventually it can extract enough surplus from the downstream firms to make positive profit; at this point integrated firms abandon the increasing returns function and become downstream firms (buyers) as far as this function is concerned. Spence and Porter (1977) have provided a formal, partial-equilibrium model along these lines.

The nature of the trade-off is different in Vassilakis (1986b): there are global increasing returns to scale, and firms can choose both the degree of division of labour in the production of the final good (i.e. production roundaboutness) and the extert to which they will make their own intermediate goods (vertical integration). Integrated firms do not buy their intermediate goods, and so they avoid monopolistic exploitation associated with the non-price taking behaviour of intermediate goods sellers; on the other hand, they have to pay the fixed cost of producing intermediate goods. For specialist firms the trade-off is reversed. Also, a firm that adopts a high degree of division of labour has to pay higher fixed cost, but lower variable cost, than a firm that produces the same product with a lower degree of division of labour. In equilibrium, the ratio of specialist to integrated firms (the degree of vertical disintegration), and the degree of division of labour within each firm (production roundaboutness), are such that the costs and benefits of marginal changes cancel out. Increases in market size (the number of agents) increase vertical disintegration and production roundaboutness for the same reason: it pays to exploit economies of scale more fully now both by sharing fixed costs with other buyers instead of bearing them unilaterally, and by reducing variable cost through increases in fixed cost. In this sense, market size determines the degree of division of labour. Very clear anticipations of these views on vertical integration are to be found in Austin Robinson (1931, pp. 19, 65, 96, 110).

Proposition (3), another application of Proposition (1), has not been subject to equally intensive theoretical investigation. Kaldar (1978, Essay 9) and Negishi (1986, ch. 3) provide some clarifications. Proposition (4) reappears in Ohlin (1933, ch. 3). For the empirical puzzles that led to the reintroduction of increasing returns to scale in formal trade theory, see Helpman and Krugman (1985, pp. 2–4).

Proposition (5) can be found in Ohlin (1933, pp. 200–211), who generalizes it considerably; increasing returns to scale in production and transportation favour concentration of economic activity in as few points as possible, while the

I

dispersion of natural resources and the fact that certain economics activities are resource-intensive favour decentralization. It is also important whether raw materials for final products are cheaper to transport, with the obvious implications for localization of activities. The result of these consicierations is a generalization of Proposition (5).

> [5] Districts with good transport relations tend to attract pierty of labour and capital and become important market; consequently they tend to specialize in industries which (1) are market-localized and show important advantages from large-scale production; and (2) produce goods which are difficult to transport. On the other hand, districts with poor transport relations become scantily populated and tend to specialize in goods which are easy to transport and can be advantageously produced on a small scale (Ohlin 1933, p. 208).

Implience in Ohlin et al. (1976, pp. 48–50) is the proposition that increases in market size increase geographical concentration of economic activity; the reason seems to be that with increased size there is more to be gained by fuller exploitation of scale economies, i.e. by higher concentration of economic activity, and this gain more than compensates for loss due to increased transportation costs.

Proposition (6) has been exploited by Piore and Sabel (1984). Given that a reduction in demand uncertainty is equivalent to an increase in market size, reductions in uncertainty will increase the degree of division of labour. Piore and Sabel view the coexistence of large and small firms, inventory holding, long-term contracts tying buyers to sellers and vertical integration as uncertainty-reducing devices that allow for a higher degree of division of labour. Also, collective wage bargaining and government stabilization policies are attempts to control that part of uncertainty that cannot be affected by individual firms. Weitzman (1982) and then Kaldor (1983) went even further and argued that a necessary condition for involuntary unemployment, and therefore for Keynesian economics, is the presence of increasing returns to scale, otherwise the unemployed can 'produce themselves out of unemployment', since non-increasing returns to scale imply that small-scale production is at least as efficient as large-scale. (see also the Symposium on Increasing Returns and Unemployment Theory 1985).

Mill and Marx

Mill and Marx gave two closely interrelated propositions:

(7) Increases in market size result in increased concentration of economic activity, in the sense that a higher percentage of the population earn income by selling labour (and not by producing). See Mill (1848, Book I, ch. IX, p. 3) and Marx (1867, ch. XXXII).

(8a) Increases in market size, and the resulting concentration and increase in the scale of production of each firm, is an unqualified benefit from the efficiency point of view, but not necessarily from the equity point of view (Mill ibid.; Marx ibid. and ch. XXV).

Both (7) and (8a) are derived as a consequence of the fact that concentration allows for fuller exploitation of scale economies; Marx added another reason, i.e. that the skills of small-scale producers are 'rendered worthless' by division of labour, which subdivides and simplifies the tasks to be executed in order to produce a commodity (Marx 1848, in McLellan 1977, p. 227).

Another proposition of Marx on the same subject is:

(8b) Increases in market size increase the distance between the economy's actual and potential performance (Marx 1867, ch. XXXII); Elster (1985, ch. 5), provides a rather exhaustive discussion of the exact meaning of this proposition.

We now make (8b) more precise by thinking of increases in market size as generating two contradictory forces: on the one hand, efficiency increases because the increase in market size and the resulting increase in concentration (Proposition 7) allow for fuller exploitation of scale economies; on the other hand, this very

increase in concentration that results in fuller exploitation of scale economies, hampers efficiency by increasing the distortionary effects associated with non-price taking behaviour. In other words, economies of scale are created faster than they are exploited. Finally, we can safely attribute to Marx the following proposition, a variant of his law of the falling rate of profit (Marx 1894, Vol. III, Part III).

(9) Increases in market size reduce the profit rate.

Proposition (9) differs from Proposition (3) of Smith (and Ricardo), because it does not rely on the law of diminishing returns due to land scarcity. (In Marx's words, Ricardo 'fled from economics to seek refuge in organic chemistry' in order to generate a falling profit rate). It is formulated in this particular way, because it has been shown that under constant returns to scale and a constant real wage, the law does not hold, while with a rising real wage it holds only under very restrictive assumptions that turn the law into an improbable special case (Roemer 1981, chs 4, 5 and 6). On the other hand, Negishi (1985, ch. 4) has provided some textual evidence to support the view that Marx had in mind an economy with increasing returns to scale technology and producers facing downward sloping demand, so that (9) is the only version of the law that might be sustainable. Indeed, increasing concentration and a falling profit rate have been obtained in Vassilakis (1986a) as a result of increases in market size; the profit rate, though, falls because both the real wage and the proportion of workers in the population rise in a full employment model, so this version of the law is not entirely in the Marxian spirit. As for Proposition (8a), the formal literature supports the view that with increasing returns to scale only in the neighbourhood of the origin, increases in market size reduce Pareto inefficiency and in the limit they eliminate it (Novshek and Sonnenschein 1978; Hart 1979). On the other hand, Hart and Guesnerie (1985) have found that with global increasing returns, Pareto inefficiency does not disappear in the limit, although per capita inefficiency does; Vassilakis (1986a) finds that even per capita welfare loss can be positive in the limit, for a particular choice of technology; the difference in the result is due to the fact that the latter reference assumes that the alternative to producing is being a worker and earning wage income, while Hart and Guesnerie assume the opportunity cost of a producer to be zero. So, it is fair to say that there is some support for Proposition (8a), while Proposition (8b) remains untested.

Marshall

Marshall (1890, p. 318, 1919, pp. 186–9) believed that all industries exhibit global increasing returns to scale, checked only by short-run fixities or land scarcities; in this case he agreed with the classical economists. As Stigler (1941, p. 78) remarked, though, 'if the economies of large scale production are so important . . ., how do small concerns manage to exist at all?' and 'either the division of labour is limited by the extent of the market, and, characteristically, industries are monopolized; or industries are characteristically competitive, and the theorem is false or of little significance' (Stigler 1951). Marshall tried to reconcile economies of scale and perfect competition in three different ways, namely:

(a) (Some) economies of scale are external to the firm.
(b) Increasing returns to scale is a dynamic phenomenon, and its full effects take so long to manifest themselves that 'the guidance of the business falls into the hands of people with less energy and less creative genius' (Marshall 1890, p. 316).
(c) Transportation costs rise so fast in some industries as to restrict the market area of each firm.

Clearly, (a) assumes the problem away; in Marshall's own words,

> . . . with the growth of capital, the development of machinery, and the improvement of the means of communication the importance of internal economies has increased steadily and fast, while some of the old external economies have declined in importance (Marshall 1919, p. 167).

But even if we assume that most economies of scale are external to the firm, competition is not the most likely outcome; one still has to explain why firms do not merge to internalize external economies, in which case oligopoly is the most likely outcome, or why markets for external effects do not emerge, in which case again, external economies become internal, and we are back to square one. (Starret and Heller (1976) analyse external effects as absence of markets; Makowski (1980) analyses mergers as a way to internalize external effects.)

Explanation (b) is at best of limited importance, unless one can show that expansion by merger is impossible or that the market for managers is so imperfect that a long-lived firm is doomed to fall in the hands of the inept. Also, in Stigler's words, 'if Marshall's discussion of economies is correct and approximately complete, it would not require an extraordinarily high calibre of entrepreneurship to secure a monopoly, or at least a dominant position, in almost any industry' (Stigler 1941, p. 81). Finally, explanation (c) is of limited applicability because it ignores increasing returns to scale in transportation. Marshall himself thought that it cannot be elevated to a general explanation of the coexistence of competition and increasing returns, so he had to invent explanation (b); (Marshall 1919, pp. 315–16). We have to conclude that (not only) in 'competitive, stationary economies, Marshall clearly fails to provide the conditions of stable equilibrium' (Stigler 1941, p. 81). Downward sloping demand and non-price taking behaviour cannot be avoided, therefore; based on Marshall's cues (Marshall 1890, pp. 286–7, 453–8), Sraffa (1926), Robinson (1933) and Chamberlin (1933) reintroduced downward sloping demand almost one hundred years after Cournot.

Despite the fact that Marshall did not have a formal theory of increasing returns economies, he relentlessly applied 'the principle of Increasing Return' to generate propositions. He is the only one after Smith, Marx and Mill to propose a new general proposition (not an application), namely:

(10) '... almost every kind of horizontal extension tends to increase the internal economies of production on a large scale, but as rule, an increase in the variety of output lessens the gain in this direction' (Marshall 1919, p. 216).

In other words, increasing variety reduces efficiency. Proposition (10) is then utilized by Marshall to explain the coexistence of large and small firms, and to determine the range of products of a multiproduct firm. Large firms produce those goods that are most in demand and/or afford the greatest degree of division of labour; their product range is determined by the condition that the addition of one more product would increase cost (due to lost scale economies) by more than it would increase revenue (due to increased market area). Small firms produce goods whose demand is so low, and/or afford so small a degree of division of labour, that large firms do not want to produce, because they can be better off devoting their resources to increase production of the commodities they already produce. As market size increases, there is more to be gained by concentration, so firm size tends to increase. On the other hand, though, small firms will survive at all market sizes, because of three factors (Marshall 1919, ch. III and IV).

(a) The increased income generated by increased market size allows consumers to demand goods closer to their ideal specifications, so the variety of goods demanded increases.
(b) Increased market size increases household specialization, i.e. goods previously produced within the household become commodities.
(c) Increased size increases vertical disintegration.

An obvious implication of this theory is that increases in market size will have different effects, depending on the degree of demand homogeneity and on whether demand is concentrated on goods that afford considerable division of labour. Marshall (1919, Book I) attributes the different growth patterns of industrial economies to differences in

the size stability and perfection of their respective markets.

Existence of Equilibrium

The incompatibility of pricetaking behaviour and increasing returns to scale was first noticed by Cournot (1838, pp. 59–60), but rigorous examination of the issue has been taken up only very recently.

No general existence theorems are available because there is no generally accepted model to imperfect competition. What is available, though, points to the importance of the following three factors: (i) downward sloping demand; (ii) a variable number of firms; (iii) a large number of agents relative to the degree of increasing returns. Downward sloping demand is clearly a necessary condition for existence in economies with global increasing returns to scale, for otherwise firms would have an incentive to produce an unlimited amount of some output. The number of firms should be variable for three reasons: first, because of fixed costs, the number of firms cannot be too large for otherwise profit would be negative; secondly, the number of firms should be sufficiently large to ensure that the demand price faced by each firm is lower than average costs for large enough output levels, otherwise firms would produce arbitrarily large amounts; thirdly, the number of firms should be sufficiently large to discourage entry, so as to ensure that if one more agent sets up a firm, he will earn less than his earnings in the best alternative occupation. Finally, one needs a large number of agents relative to the degree of increasing returns to ensure that the number of firms is large enough to satisfy the conditions above, and in order to convexify reaction correspondences, so that fixed-point theorems can be applied (see Roberts and Sonnenschein 1977, and Novshek and Sonnenschein 1978). All models in the literature on increasing returns to scale base their existence results on (i), (ii) and (iii) above, although they differ in specifics. Thus, we have Bertrand models, in which the agents' strategic variable is price, and Cournot models, in which agents compete in quantities. Also, we have symmetric models, in which all agents are allowed the same strategic possibilities; and non-symmetric models, in which the set of agents is, *a priori* and once and for all, divided into two disjoint sets: the set of consumers–factor suppliers–price takers, and the set of producers–factor demanders–price makers (or quantity setters).

Existence in non-symmetric Cournot models with increasing returns only in a small neighbourhood of the origin is proved in Novshek and Sonnenschein (1978), and with global increasing returns in Hart and Guesnerie (1985); existence in symmetric Cournot models with global increasing returns is proved in Vassilakis (1986a). All proofs with global increasing returns refer to a single-input, single-output economy. For non-symmetric Bertrand games, with a single input, see Hart (1985) and Economides (1982, 1983); for the single-output many-inputs case see Sharkey (1982, ch. 8).

Indentured servants were workers – mostly unmarried young adult males – who voluntarily entered alienable forward-labour contracts typically lasting between three and five years in exchange for passage to an overseas destination.

Indentured servitude was important to European overseas expansion and labour migration from the 17th into the 20th century. It was initially prominent among English, Scots, and Irish workers moving to colonies in British America. French and German servants joined this trade in the 18th century, going primarily to Canada and Pennsylvania, respectively (Emmer 1986).

The servant trade had disappeared among British, Irish, and French migrants by the Napoleonic era and among Germans by 1820 (Grubb 1994). Approximately half of the transatlantic migrants in this period were indentured. Servants dominated the colonial labour force early on but, by 1700, African slaves south of Pennsylvania and colonial-born free workers north of Virginia eclipsed them in importance (Galenson 1981; Grubb and Stitt 1994).

After 1830, the repression of the African slave trade and the abolition of slavery in many European colonies led to the revival of the servant trade, especially to tropical sugar-plantation colonies. Between 1834 and 1918 around 1,500,000 indentured servants from India, 250,000 from China, 80,000 from Japan, 50,000 from Portuguese Atlantic islands, and 100,000 from Melanesia were sent to British, French, Dutch, Spanish, German, and US colonies in the Caribbean, Indian Ocean, South and West Africa, Malaya, Australia, Peru, Hawaii, Fiji, and Samoa (Emmer 1986; Northrup 1995).

Servant contracts in the transatlantic trade were typically preprinted single-page forms with blank spaces where negotiated terms were handwritten in. Contracts specified the destination, length of servitude, transferability rights, and 'freedom dues' to be paid at the contract's completion – typically two suits of clothing. In the post-1830 trade freedom dues typically were return-passage tickets. The work to be performed and the maintenance to be received by servants during their contracts were incompletely specified, with contracts typically stating only that servants were to perform customary labour and masters were to provide food, apparel, and lodging (Grubb 2000).

Because passage was provided first, servants had an incentive after arrival to run away or not work hard. Running away was criminalized and runaways were harshly penalized with whippings and forced contract extensions. The disincentive to work was remedied through the contract's incompleteness. With the servants' daily provisions incompletely specified contractually, masters could adjust daily provisions to elicit the optimal daily diligence from servants. Freedom dues compensated servants for their masters' incentive to withhold semi-durable provisions (clothing) from servants near the end of the contract (Grubb 2000).

In the transatlantic trade, markets were largely unregulated and competitive. Servants bargained with shippers over the length of servitude and fixed contract terms before sailing. At debarkation shippers sold these contracts to the highest bidders, thereby recouping their shipping expenses. Competition led to servants signing the shortest contracts necessary to secure passage and to shippers earning zero economic profits on servant cargo. Passage costs were relatively constant across servants but labour productivity was not. Less productive servants had to sign longer contracts for the same passage cost. Contract lengths were inversely related to, whereas auction prices in America were unrelated to, servant productivity known at embarkation (Galenson 1981; Grubb 1985). Servants were also charged about 15 per cent more than free passengers (who paid cash in advance) to compensate shippers for forgoing other investment opportunities and to cover expected servant defaults through mortality, morbidity, and escape.

In the mid-18th century a new variant – redemption – came into use primarily among German immigrants. Under redemption passengers entered fixed-debt passage contracts before sailing that required them to enter servitude at debarkation, if necessary, to clear the debt. Redemption shifted the voyage risk and forecast error in the market from shipper to migrant. With passage debts, but not contract lengths, fixed before sailing, shippers no longer had to forecast at embarkation the amount of labour needed in a servant contract for it to sell at debarkation for enough to cover shipping costs. Instead, at debarkation migrants had to offer however much labour was needed to clear the passage debt contractually guaranteed to the shipper before sailing (Galenson 1981). Migrants accepted this risk because it gave them greater flexibility over selecting their American masters, negotiating contingency clauses into their contracts, and using a single labour contract to pay both the passage debt and any pre-voyage debts transferred to the shipper.

In the post-1830 trade, markets were more highly regulated. For example, in the Melanesian trade to Queensland, Australia, the British government fixed the length of labour contracts at three years and servant wages at six pounds sterling per year, did not allow unrestricted recruiting, and did not allow servants to be auctioned upon arrival. Shippers were licensed to recruit only the number of servants requested by planters and were paid a set fee per recruit. Officials assigned arriving servants to planters according to the number requested. This perversely induced shippers to recruit low-quality labour.

The transatlantic servant trade ended because the supply of servants collapsed, not because American demand declined. Prospective servants found better jobs elsewhere, such as military service during the Napoleonic Wars, or better ways to pay for passage, such as borrowing from already emigrated family members (Grubb 1994). Many post-1830 servant trades were ended by government action or the changing fortunes of the global sugar industry (Emmer 1986; Northrup 1995).

Index Numbers

W. Erwin Diewert

Abstract

Index numbers are used to aggregate detailed information on prices and quantities into scalar measures of price and quantity levels or their growth. The article reviews four main approaches to bilateral index number theory where two price and quantity vectors are to be aggregated: fixed basket and average of fixed baskets, stochastic, test or axiomatic and economic approaches. The article also considers multilateral index number theory where it is necessary to construct price and quantity aggregates for more than two value aggregates. A final section notes some of the recent literature on related aspects of index number theory.

Introduction

Each individual consumes the services of thousands of commodities over a year and most producers utilize and produce thousands of individual products and services.

Index numbers are used to reduce and summarize this overwhelming abundance of microeconomic information. Hence index numbers impinge on virtually every empirical investigation in economics.

The index number problem may be stated as follows. Suppose we have price data $p^t \equiv (p_1^t, \ldots, p_N^t)$ and quantity data $q^t \equiv (q_1^t, \ldots, q_N^t)$ on N commodities that pertain to the same economic unit at time period t (or to comparable economic units) for $t = 0, 1, 2, \ldots, T$. The *index number problem* is to find $T+1$ numbers P^t and $T+1$ numbers Q^t such that

$$p^t Q^t = p^t \cdot q^t \equiv \sum_{n=1}^{N} p_n^t q_n^t \text{ for } t = 0, 1, \ldots, T. \tag{1}$$

P^t is the *price index* for period t (or unit t) and Q^t is the corresponding *quantity index*. P^t is supposed to be representative of all of the prices $p_n^t, n = 1, \ldots, N$ in some sense, while Q^t is to be similarly representative of the quantities q_n^t, $n = 1, \ldots, N$. In what precise sense P^t and Q^t represent the individual prices and quantities is not immediately evident, and it is this ambiguity that leads to different approaches to index number theory. Note that we require that the product of the price and quantity indexes, $P^t Q^t$, equals the actual period (or unit) t expenditures on the N commodities, $p^t \cdot q^t$. Thus if the P^t are determined, then the Q^t may be implicitly determined using eq. (1), or vice versa.

The number P^t is interpreted as an aggregate period t price level while the number Q^t is interpreted as an aggregate period t quantity level. The *levels* approach to index number theory works as follows. The aggregate price level P^t is assumed to be a function of the components in the period t price vector, p^t while the aggregate period t quantity level Q^t is assumed to be a function of the period t quantity vector components, q^t; that is, it is assumed that

$$P^t = c(p^t) \text{ and } Q^t = f(q^t); \; t = 0, 1, \ldots, T. \tag{2}$$

The functions c and f are to be determined somehow. Note that we are requiring that the functional forms for the price aggregation function c and for the quantity aggregation function f be independent of time. This is a reasonable requirement since there is no reason to change the method of aggregation as time changes.

Substituting (2) into (1) and dropping the superscripts t means that c and f must satisfy the following functional equation for all strictly positive price and quantity vectors:

$$c(p)f(q) = p \cdot q \equiv \sum_{n=1}^{N} p_n q_n \text{ for all } p >> 0_N \text{ and for all } q >> 0_N. \tag{3}$$

Note that $p >> 0_N$ means that each component of p is positive, $p \geq 0_N$ means each component is non-negative and $p > 0_N$ means each component is non-negative and at least one component is positive. We now could ask what properties the price aggregation function c and the quantity aggregation function f should have. We could assume that c and f satisfied various 'reasonable' properties and hope that these properties would determine the functional form for c and f. However, it turns out that we have only to make the following very weak *positivity* assumptions on f and c in order to obtain an impossibility result:

I

$$c(p) > 0 \text{ for all } p >> 0_N; \quad f(q) > 0 \text{ for all } q >> 0_N. \tag{4}$$

Eichhorn (1978, p. 144) proved the following result: if the number of commodities N is greater than 1, then there do not exist any functions c and f that satisfy (3) and (4). Thus this *levels approach* to index number theory comes to an abrupt halt. As we shall see later, when the economic approach to index number theory is studied, this is not quite the end of the story: in (3) and (4), we allowed p and q to vary independently from each other, and this is what leads to the impossibility result. If instead we allow p to vary independently but assume that q is determined as the result of an optimizing model, then eq. (3) can be satisfied.

If we change the question that we are trying to answer slightly, then there are practical solutions to the index number problem. The change is that instead of trying to decompose the value of the aggregate into price and quantity components for a single period, we instead attempt to decompose a *value ratio* pertaining to two periods, say periods 0 and 1, into a *price change component* P times a *quantity change component* Q. Thus we now look for two functions of $4N$ variables, $P(p^0, p^1, q^0, q^1)$ and $Q(p^0, p^1, q^0, q^1)$ so that:

$$p^1.q^1/p^0.q^0 = P\left(p^0,p^1,q^0,q^1\right)\ Q\left(p^0,p^1,q^0,q^1\right). \tag{5}$$

Note that if some approach to index number theory determines the 'best' functional form for the price index $P(p^0, p^1, q^0, q^1)$, then the *product test* (5) can be used to determine the functional form for the corresponding quantity index, $Q(p^0, p^1, q^0, q^1)$.

If we take the *test or axiomatic approach* to index number theory, then we want eq. (5) to hold for all positive price and quantity vectors pertaining to the two periods under consideration, p^0, p^1, q^0, q^1. If we take the *economic approach*, then only the price vectors p^0 and p^1 are regarded as independent variables while the quantity vectors, q^0 and q^1, are regarded as dependent variables. In section "The Test Approach to Index Number Theory" below, we will pursue the test approach and in sections "The Economic Approach to Price Indexes," "Economic Approaches to Quantity Indexes," and "Exact and Superlative Indexes," we will take the economic approach. In sections "Fixed Basket Approaches," "The Stochastic Approach to Index Number Theory," "The Test Approach to Index Number Theory," "The Economic Approach to Price Indexes," "Economic Approaches to Quantity Indexes," and "Exact and Superlative Indexes," we take a *bilateral approach to index number theory*; that is, in making price and quantity comparisons between any two time periods, the relevant indexes use *only* price and quantity information that pertains to the two periods under consideration. It is also possible to take a *multilateral approach*; that is, we look for functions, P^t and Q^t, that are functions of *all* of the price and quantity vectors, $p^0, p^1, \ldots, p^T, q^0, q^1, \ldots, q^T$. Thus we look for $2(T+1)$ functions, $P^t(p^0, p^1, \ldots, p^T, q^0, q^1, \ldots, q^T)$ and $Q^t(p^0, p^1, \ldots, p^T, q^0, q^1, \ldots, q^T)$, $t = 0, 1, \ldots, T$, so that

$$p^t \cdot q^t = P^t\left(p^0,p^1,\ldots,p^T,q^0,q^1,\ldots;q^T\right) \times Q^t\left(p^0,p^1,\ldots,p^T,q^0,q^1,\ldots,q^T\right) \quad \text{for } t = 0, 1, \ldots, T. \tag{6}$$

We briefly pursue the multilateral approach to index number theory in section "Multilateral Indexes".

The four main approaches to bilateral index number theory will be covered in this review: (i) the *fixed basket approach* (section "Fixed Basket Approaches"), (ii) the *stochastic approach* (section "The Stochastic Approach to Index Number Theory"), (iii) the *test approach* (section "The Test Approach to Index Number Theory") and (iv) the *economic approach*, which relies on the assumption of maximizing or minimizing behaviour (sections "The Economic Approach to Price Indexes," "Economic Approaches to Quantity Indexes," and "Exact and Superlative Indexes").

Section "The Fixed Base Versus the Chain Principle" discusses fixed base versus chained index numbers, and section "Other Aspects of Index Number Theory" concludes by mentioning some recent areas of active research in the index number literature.

Fixed Basket Approaches

The English economist Joseph Lowe (1823) developed the theory of the consumer price index in some detail. His approach to measuring the price change between periods 0 and 1 was to specify an approximate representative commodity basket quantity vector, $q \equiv (q_1, \ldots, q_N)$, which was to be updated every 5 years, and then calculate the level of prices in period 1 relative to period 0 as

$$P_{Lo}(p^0,p^1,q)\ p^1 \cdot q/p^0 \cdot q \tag{7}$$

where p^0 and p^1 are the commodity price vectors that the consumer (or group of consumers) face in periods 0 and 1 respectively. The fixed basket approach to measuring price change is intuitively very simple: we simply specify the commodity 'list' q and calculate the price index as the ratio of the costs of buying this same list of goods in periods 1 and 0.

As time passed, economists and price statisticians demanded more precision with respect to the specification of the basket vector q. There are two natural choices for the reference basket: the period 0 commodity vector q^0 or the period 1 commodity vector q^1. These two choices lead to the Laspeyres (1871) price index P_L defined by (8) and the Paasche (1874) price index P_P defined by (9):

$$P_L(p^0,p^1,q^0,q^1) \equiv p^1 \cdot q^0/p^0 \cdot q^0; \tag{8}$$

$$P_p(p^0,p^1,q^0,q^1) \equiv p^1 \cdot q^1/p^0 \cdot q^1. \tag{9}$$

The above formulae can be rewritten in an alternative manner that is very useful for statistical agencies. Define the period t expenditure share on commodity n as follows:

$$s_n^t \equiv p_n^t q_n^t/p^t.q^t \text{ for } n = 1, \ldots, N \text{ and } t = 0, 1. \tag{10}$$

Following Fisher (1911), the Laspeyres index (8) can be rewritten as follows:

$$\begin{aligned} P_L(p^0,p^1,q^0,q^1) &= \sum_{n=1}^{N} p_n^1\ q_n^0/p^0 \cdot q^0 \\ &= \sum_{n=1}^{N} (p_n^1/p_n^0) p_n^0\ q_n^0/p^0 \cdot q^0 \\ &= \sum_{n=1}^{N} (p_n^1/p_n^0) \\ &\quad \times s_n^0 \text{ using definitions (10).} \end{aligned} \tag{11}$$

Thus the Laspeyres price index P_L can be written as a base period expenditure share weighted average of the N price ratios (or price relatives using index number terminology), p_n^1/p_n^0. The Laspeyres formula (until the very recent past when in 2003 the US Bureau of Labor Statistics introduced its chained consumer price index) has been widely used as the intellectual basis for country consumer price indexes (CPIs) around the world. To implement the formula, the country statistical agency collects information on expenditure shares s_n^0 for the index domain of definition for the base period 0 and then collects information on *prices* alone on an ongoing basis. Thus a Laspeyres-type CPI can be produced on a timely basis without one having to know current period quantity information. In fact, the situation is more complicated than this: in actual CPI programmes, prices are collected on a monthly or quarterly frequency and with base month 0 say, but the quantity vector q^0 is typically *not* the quantity vector that pertains to the price base month 0; rather, it is actually equal to a *base year quantity vector*, q^b say, which is typically prior to the base month 0. Thus the typical CPI, although loosely based on the Laspeyres index, is actually a form of Lowe index; see (7) above. Instead of using the Lowe formula for their CPI, some statistical agencies use the following Young (1812) index:

$$P_Y(p^0,p^1,s^b) \equiv \sum_{n=1}^{N} (p_n^1/p_n^0) s_n^b \tag{12}$$

where the s_n^b are base year expenditure shares on the N commodities in the index. For additional

material on Lowe and Young indexes and their use in CPI and producer price index (PPI) programmes, see the ILO (2004) and the IMF (2004).

The Paasche index can also be written in expenditure share and price ratio form as follows:

$$\begin{aligned} P_p(p^0,p^1,q^0,q^1) &= 1/\left[\sum_{n=1}^{N} p_n^0 q_n^1/p^1.q^1\right] \\ &= 1/\left[\sum_{n=1}^{N} (p_n^0/p_n^1) p_n^1 q_n^1/p^1.q^1\right] \\ &= 1/\left[\sum_{n=1}^{N} (p_n^1/p_n^0)^{-1} s_n^1\right] \text{ using definitions} \\ (10) &= \left[\sum_{n=1}^{N} (p_n^1/p_n^0)^{-1} s_n^1\right]^{-1}. \end{aligned} \tag{13}$$

Thus the Paasche price index P_P can be written as a period 1 (or current period) expenditure share weighted *harmonic* average of the N price ratios.

The problem with the Paasche and Laspeyres index number formulae is that they are equally plausible but, in general, they will give different answers. This suggests that, if we require a single estimate for the price change between the two periods, then we need to take some sort of evenly weighted average of the two indexes as our final estimate of price change between periods 0 and 1. Examples of such symmetric averages are the arithmetic mean, which leads to the Sidgwick (1883, p. 68) and Bowley (1901, p. 227) index, $(1/2)P_L + (1/2)P_P$, and the geometric mean, which leads to the Fisher (1922) ideal index, P_F, which was actually first suggested by Bowley (1899, p. 641), defined as

$$\begin{aligned} &P_F(p^0,p^1,q^0,q^1) \\ &\equiv [P_L(p^0,p^1,q^0,q^1) P_P(p^0,p^1,q^0,q^1)]^{1/2}. \end{aligned} \tag{14}$$

At this point, the fixed basket approach to index number theory is transformed into the *test approach* to index number theory; that is, in order to determine which of these fixed basket indexes or which averages of them might be best, we need *criteria* or *tests* or *properties* that we would like our indexes to satisfy. We will pursue this topic in more detail in section "The Test Approach to Index Number Theory," but we give the reader an introduction to this topic in the present section because some of these tests or properties are useful to evaluate other approaches to index number theory.

Let a and b be two positive numbers. Diewert (1993b, p. 361) defined a *symmetric mean* of a and b as a function $m(a, b)$ that has the following properties: (i) $m(a, a) = a$ for all $a > 0$ (mean property); (ii) $m(a, b) = m(b, a)$ for all $a > 0, b > 0$ (symmetry property); (iii) $m(a, b)$ is a continuous function for $a > 0, b > 0$ (continuity property) and (iv) $m(a, b)$ is a strictly increasing function in each of its variables (increasingness property). Eichhorn and Voeller (1976, p. 10) showed that, if $m(a, b)$ satisfies the above properties, then it also satisfies the following property: (v) $\min\{a, b\} \leq m\{a, b\} \leq \max\{a, b\}$ (min-max property); that is, the mean of a and b, $m(a, b)$, lies between the maximum and minimum of the numbers a and b. Since we have restricted the domain of definition of a and b to be positive numbers, it can be seen that an implication of the last property is that m also satisfies the following property: (vi) $m(a, b) > 0$ for all $a > 0$, $b > 0$ (positivity property). If in addition, m satisfies the following property, then we say that m is a *homogeneous symmetric mean*: (vii) $m(\lambda a, \lambda b) = \lambda m(a, b)$ for all $\lambda > 0$, $a > 0$, $b > 0$.

What is the best symmetric average of P_L and P_P to use as a point estimate for the theoretical cost of living index? It is very desirable for a price index formula that depends on the price and quantity vectors pertaining to the two periods under consideration to satisfy the *time reversal test*. We say that the index number formula $P(p^0, p^1, q^0, q^1)$ satisfies this test if

$$P(p^1,p^0,q^1,q^0) = 1/P(p^0,p^1,q^0,q^1); \tag{15}$$

that is, if we interchange the period 0 and period 1 price and quantity data and evaluate the index, then this new index $P(p^1, p^0, q^1, q^0)$ is equal to the reciprocal of the original index $P(p^0, p^1, q^0, q^1)$. For the history of this test (and other tests), see Diewert (1992a, p. 218, 1993a).

Diewert (1997, p. 138) proved the following result: the Fisher ideal price index defined by (14)

above is the *only* index that is a homogeneous symmetric average of the Laspeyres and Paasche price indexes, P_L and P_P, that also satisfies the time reversal test (15) above.

Thus the symmetric basket approach to index number theory leads to the Fisher ideal index as the best formula. It is interesting to note that this symmetric basket approach to index number theory dates back to Bowley, one of the early pioneers of index number theory, as the following quotations indicate:

> If [the Paasche index] and [the Laspeyres index] lie close together there is no further difficulty; if they differ by much they may be regarded as inferior and superior limits of the index number, which may be estimated as their arithmetic mean ... as a first approximation. (Bowley 1901, p. 227)

> When estimating the factor necessary for the correction of a change found in money wages to obtain the change in real wages, statisticians have not been content to follow Method II only [to calculate a Laspeyres price index], but have worked the problem backwards [to calculate a Paasche price index] as well as forwards. ... They have then taken the arithmetic, geometric or harmonic mean of the two numbers so found. (Bowley 1919, p. 348)

Instead of taking a symmetric average of the Paasche and Laspeyres indexes, an alternative average basket approach takes a symmetric average of the baskets that prevail in the two periods under consideration. For example, the average basket could be the arithmetic or geometric mean of the two baskets, leading the Marshall (1887) and Edgeworth (1925) index P_{ME} or the Walsh (1901, p. 398, 1921a, pp. 97–101) index P_W:

$$P_{ME}\left(P^0,P^1,q^0,q^1\right) \equiv \sum_{n=1}^{N} p_n^1 (1/2)\left(q_n^0+q_n^1\right) / \sum_{m=1}^{N} P_j^0 (1/2)\left(q_m^0+q_m^1\right); \tag{16}$$

$$P_W\left(P^0,P^1,q^0,q^1\right) \equiv \sum_{n=1}^{N} p_n^1 \left(q_n^0 q_n^1\right)^{1/2} / \sum_{m=1}^{N} P_m^0 \left(q_m^0,q_m^1\right)^{1/2}. \tag{17}$$

Diewert (2002b, pp. 569–71) showed that the Walsh index P_W emerged as being best in this average basket framework; see also ILO (2004, chs 15 and 16).

We turn now to the second major approach to bilateral index number theory.

The Stochastic Approach to Index Number Theory

> In drawing our averages the independent fluctuations will more or less destroy each other; the one required variation of gold will remain undiminished. (Jevons 1884, p. 26)

The stochastic approach to the determination of the price index can be traced back to the work of Jevons (1865, 1884) and Edgeworth (1888, 1923, 1925) over 100 years ago. For additional discussion on the early history of this approach, see Diewert (1993a, pp. 37–8, 1995b).

The basic idea behind the stochastic approach is that each price relative, p_n^1/p_n^0 for $n = 1,2,\ldots,N$ can be regarded as an estimate of a common inflation rate α between periods 0 and 1; that is, it is assumed that

$$p_n^1/p_n^0 = \alpha + \varepsilon_n; n = 1,2,\ldots,N \tag{18}$$

where α is the common inflation rate and the ε_n are random variables with mean 0 and variance σ^2. The least squares estimator for α is the Carli (1764) price index P_C defined as

$$P_C\left(p^0,p^1\right) \equiv \sum_{n=1}^{N} (1/N)\left(p_n^1/p_n^0\right). \tag{19}$$

Unfortunately, P_C does not satisfy the time reversal test, namely, $P_C(p^1, p^0) \neq 1/P_C(p^0, p^1)$. In fact, Fisher (1922, p. 66) noted that $P_C(p^0, p^1)$ $P_C(p^1, p^0) \geq 1$ unless the period 1 price vector p^1 is proportional to the period 0 price vector $p0$; that is, Fisher showed that the Carli (and the Young) index has a definite upward bias. He urged statistical agencies not to use these formulae.

Now assume that the logarithm of each price relative, $\ln\left(p_n^1/p_n^0\right)$, is an unbiased estimate of the logarithm of the inflation rate between periods 0 and 1, β say. Thus we have:

$$\ln\left(p_n^1/p_n^0\right), = \beta + \varepsilon_n; n = 1, 2, \ldots, N \qquad (20)$$

where $\beta \equiv \ln \alpha$ and the ε_n are independently distributed random variables with mean 0 and variance σ^2. The least squares estimator for β is the logarithm of the geometric mean of the price relatives. Hence the corresponding estimate for the common inflation rate α is the Jevons (1865) price index P_J defined as:

$$P_J\left(p^0, p^1\right) \equiv \prod_{n=1}^{N} \left(p_n^1/p_n^0\right)^{1/N}. \qquad (21)$$

The Jevons price index P_J satisfies the time reversal test and hence is much more satisfactory than the Carli index P_C.

Bowley (1928) attacked the use of both (19) and (21) on two grounds. First, from an empirical point of view, he showed that price ratios were not symmetrically distributed about a common mean and their logarithms also failed to be symmetrically distributed. Second, from a theoretical point of view, he argued that it was unlikely that prices or price ratios were independently distributed. Keynes (1930) developed Bowley's second objection in more detail; he argued that changes in the money supply would not affect all prices at the same time. Moreover, real disturbances in the economy could cause one set of prices to differ in a systematic way from other prices, depending on various elasticities of substitution and complementarity. In other words, prices are not randomly distributed, but are systematically related to each other through the general equilibrium of the economy. Keynes (1930, pp. 76–7) had other criticisms of this *unweighted stochastic approach* to index number theory, including the point that that there is no such thing as *the* inflation rate; there are only price changes that pertain to well-specified sets of commodities or transactions; that is, the domain of definition of the price index must be carefully specified. Keynes also followed Walsh in insisting that price movements must be weighted by their economic importance, that is, by quantities or expenditures:

> It might seem at first sight as if simply every price quotation were a single item, and since every commodity (any kind of commodity) has one price-quotation attached to it, it would seem as if price-variations of every kind of commodity were the single item in question. This is the way the question struck the first inquirers into price-variations, wherefore they used simple averaging with even weighting. But a price-quotation is the quotation of the price of a generic name for many articles; and one such generic name covers a few articles, and another covers many. ... A single price-quotation, therefore, may be the quotation of the price of a hundred, a thousand, or a million dollar's worth, of the articles that make up the commodity named. Its weight in the averaging, therefore, ought to be according to these money-unit's worth. (Walsh 1921a, pp. 82–3)

Theil (1967, pp. 136–7) proposed a solution to the lack of weighting in (21). He argued as follows. Suppose we draw price relatives at random in such a way that each dollar of expenditure in the base period has an equal chance of being selected. Then the probability that we will draw the nth price relative is equal to $s_n^0 \equiv p_n^0 q_n^0 / p^0 . q^0$, the period 0 expenditure share for commodity n. Then the overall mean (period 0 weighted) logarithmic price change is $\sum_{n=1}^{N} s_n^0 \ln \left(p_n^1/p_n^0\right)$. Now repeat the above mental experiment and draw price relatives at random in such a way that each dollar of expenditure in period 1 has an equal probability of being selected. This leads to the overall mean (period 1 weighted) logarithmic price change of $\sum_{n=1}^{N} s_n^1 \ln \left(p_n^1/p_n^0\right)$. Each of these measures of overall logarithmic price change seems equally valid so we could argue for taking a symmetric average of the two measures in order to obtain a final single measure of overall logarithmic price change. Theil (1967, p. 138) argued that a nice symmetric index number formula can be obtained if we make the probability of selection for the nth price relative equal to the arithmetic average of the period 0 and 1 expenditure shares for commodity n. Using these probabilities of selection, Theil's final measure of overall logarithmic price change was

$$\ln P_T(p^0, p^1, q^0, q^1) \equiv \sum_{n=1}^{N} (1/2)\left(s_n^0 + s_n^1\right) \times \ln\left(p_n^1/p_n^0\right). \qquad (22)$$

We can give the following *descriptive statistics* interpretation of the right hand side of (22). Define the *n*th logarithmic price ratio *rn* by:

$$r^n \equiv \ln\left(p_n^1/p_n^0\right) \quad \text{for } n = 1, \ldots, N. \tag{23}$$

Now define the discrete random variable, R say, as the random variable which can take on the values r_n with probabilities $\rho_n \equiv (1/2)\left[s_n^0 + s_n^1\right]$ for $n = 1, \ldots, N$. Note that, since each set of expenditure shares, s_n^0 and s_n^1, sums to one, the probabilities ρ_n will also sum to one. It can be seen that the expected value of the discrete random variable R is

$$\begin{aligned} E[R] &\equiv \sum_{n=1}^{N} \rho_n r_n \\ &= \sum_{n=1}^{N} (1/2)\left(s_n^0 + s_n^1\right) \ln\left(p_n^1/p_n^0\right) \\ &= \ln P_T\left(p^0, p^1, q^0, q^1\right) \end{aligned} \tag{24}$$

using (22) and (23). Thus the logarithm of the index P_T can be interpreted as *the expected value of the distribution of the logarithmic price ratios* in the domain of definition under consideration, where the N discrete price ratios in this domain of definition are weighted according to Theil's probability weights $\rho_n \equiv (1/2)\left[s_n^0 + s_n^1\right]$ for $n = 1, \ldots, N$.

If we take antilogs of both sides of (24), we obtain the Törnqvist (1936) and Törnqvist and Törnqvist (1937). Theil price index, P_T. This index number formula has a number of good properties. Thus the second major approach to bilateral index number theory has led to the Törnqvist-Theil price index P_T as being best from this perspective.

Additional material on stochastic approaches to index number theory and references to the literature can be found in Selvanathan and Rao (1994), Diewert (1995b), Wynne (1997), ILO (2004), IMF (2004), and Clements et al. (2006).

Formulae (8), (9), (14) and (22) (the Laspeyres, Paasche, Fisher and Törnqvist-Theil formulae) are the most widely used formulae for a bilateral price index. But Walsh (1901) and Fisher (1922) presented hundreds of functional forms for bilateral price indexes – on what basis are we to choose one as being better than the other? Perhaps the next approach to index number theory will narrow the choices.

The Test Approach to Index Number Theory

In this section, we will take the perspective outlined in section "Introduction" above; that is, along with the price index $P(p^0, p^1, q^0, q^1)$, there is a companion quantity index $Q(p^0, p^1, q^0, q^1)$ such that the product of these two indexes equals the value ratio between the two periods. Thus, throughout this section, we assume that P and Q satisfy the product test (5) above.

If we assume that the product test holds means that as soon as the functional form for the price index P is determined, then (5) can be used to determine the functional form for the quantity index Q. However, as Fisher (1911, pp. 400–6) and Vogt (1980) observed, a further advantage of assuming that the product test holds is that we can assume that the quantity index Q satisfies a 'reasonable' property and then use (5) to translate this test on the quantity index into a corresponding test on the price index P.

If $N = 1$, so that there is only one price and quantity to be aggregated, then a natural candidate for P is p_1^1/p_1^0, the single price ratio, and a natural candidate for Q Is q_1^1/q_1^0, the single quantity ratio. When the number of commodities or items to be aggregated is greater than 1, then what index number theorists have done over the years is to propose properties or tests that the price index P should satisfy. These properties are generally multidimensional analogues to the one good price index formula, p_1^1/p_1^0. Below, following Diewert (1992a), we list 20 tests that characterize the Fisher ideal price index.

We shall assume that every component of each price and quantity vector is positive; that is, $p^t >> 0_N$ and $q^t >> 0_N$ for $t = 0,1$. If we want to set $q^0 = q^1$, we call the common quantity vector q; if we want to set $p^0 = p^1$, we call the common price vector p.

Our first two tests, due to Eichhorn and Voeller (1976, p. 23) and Fisher (1922, pp. 207–15), are not very controversial and so we will not discuss them.

T1: *Positivity*: $P(p^0, p^1, q^0, q^1) > 0$.
T2: *Continuity*: $P(p^0, p^1, q^0, q^1)$ is a continuous function of its arguments.

Our next two tests, due to Laspeyres (1871, p. 308), Walsh (1901, p. 308), and Eichhorn and Voeller (1976, p. 24), are somewhat more controversial.

T3: *Identity or constant prices test*: $P(p, p, q^0, q^1) = 1$.

That is, if the price of every good is identical during the two periods, then the price index should equal unity, no matter what the quantity vectors are. The controversial part of this test is that the two quantity vectors are allowed to be different in the above test.

T4: *Fixed basket or constant quantities test*: $P(p^0, p^1, q, q) = \sum_{i=1}^{N} p_j^1 q_i / \sum_{i=1}^{N} p_i^0 qi$.

That is, if quantities are constant during the two periods so that $q^0 = q^1 \equiv q$, then the price index should equal the expenditure on the constant basket in period 1, $\sum_{i=1}^{N} p_i^1 qi$, divided by the expenditure on the basket in period 0, $\sum_{i=1}^{N} p_i^0 qi$. The origins of this test go back at least 200 years to the Massachusetts legislature which used a constant basket of goods to index the pay of Massachusetts soldiers fighting in the American Revolution: see Willard Fisher (1913). Other researchers who have suggested the test over the years include Lowe (1823, Appendix, p. 95), Scrope (1833, p. 406), Jevons (1865), Sidgwick (1883, pp. 67–8), Edgeworth (1887, p. 215), Marshall (1887, p. 363), Pierson (1895, p. 332), Walsh (1901, p. 540, 1921b, p. 544), and Bowley (1901, p. 227). Vogt and Barta (1997, p. 49) also observed that this test is a special case of Fisher's (1911, p. 411) proportionality test for quantity indexes which Fisher (1911, p. 405) translated into a test for the price index using the product test (5).

The following four tests restrict the behaviour of the price index P as the scale of any one of the four vectors p^0, p^1, q^0, q^1 changes. The following test was proposed by Walsh (1901, p. 385), Eichhorn and Voeller (1976, p. 24), and Vogt (1980, p. 68).

T5: *Proportionality in Current Prices*: $P(p^0, \lambda p^1, q^0, q^1) = \lambda P(p^0, p^1, q^0, q^1)$ for $\lambda > 0$.

That is, if all period 1 prices are multiplied by the positive number λ, then the new price index is λ times the old price index. Put another way, the price index function $P(p^0, p^1, q^0, q^0)$ is (positively) homogeneous of degree one in the components of the period 1 price vector $p1$. Most index number theorists regard this property as a very fundamental one that the index number formula should satisfy.

Walsh (1901) and Fisher (1911, p. 418, 1922, p. 420) proposed the related proportionality test $P(p, \lambda p, q^0, q^1) = \lambda$. This last test is a combination of T3 and T5; in fact Walsh (1901, p. 385) noted that this last test implies the identity test, T3.

In the next test, due to Eichhorn and Voeller (1976, p. 28), instead of multiplying all period 1 prices by the same number, we multiply all period 0 prices by the number λ.

T6: *Inverse proportionality in base period prices*: $P(\lambda p^0, p^1, q^0, q^1) = \lambda^{-1} P.\ (p^0, p^1, q^0, q^1)$ for $\lambda > 0$.

That is, if all period 0 prices are multiplied by the positive number λ, then the new price index is $1/\lambda$ times the old price index. Put another way, the price index function $P(p^0, p^1, q^0, q^1)$ is (positively) homogeneous of degree minus one in the components of the period 0 price vector p^0.

The following two homogeneity tests can also be regarded as invariance tests.

T7: *Invariance to proportional changes in current quantities*: $P(p^0, p^1, q^0, \lambda q^1) = P(p^0, p^1, q^0, q^1)$ for all $\lambda > 0$.

That is, if current period quantities are all multiplied by the number λ, then the price index

remains unchanged. Put another way, the price index function $P(p^0, p^1, q^0, q^1)$ is (positively) homogeneous of degree zero in the components of the period 1 quantity vector q^1. Vogt (1980, p. 70) was the first to propose this test and his derivation of the test is of some interest. Suppose the quantity index Q satisfies the quantity analogue to the price test T5, that is, suppose Q satisfies $Q(p^0, p^1, q^0, \lambda q^1) = \lambda Q(p^0, p^1, q^0, q^1)$ for $\lambda > 0$. Then using the product test (5), we see that P must satisfy T7.

T8: *Invariance to proportional changes in base quantities*: $P(p^0, p^1, \lambda q^0, q^1) = P(p^0, p^1, q^0, q^1)$ for all $\lambda > 0$.

That is, if base period quantities are all multiplied by the number λ, then the price index remains unchanged. Put another way, the price index function $P(p^0, p^1, q^0, q^1)$ is (positively) homogeneous of degree zero in the components of the period 0 quantity vector q^0. If the quantity index Q satisfies the following counterpart to T8: $Q(p^0, p^1, \lambda q^0, q^1) = \lambda^{-1} Q(p^0, p^1, q^0, q^1)$ for all $\lambda > 0$, then, using (5), the corresponding price index P must satisfy T8. This argument provides some additional justification for assuming the validity of T8 for the price index function P. This test was proposed by Diewert (1992a, p. 216).

T7 and T8 together impose the property that the price index P does not depend on the *absolute* magnitudes of the quantity vectors q^0 and q^1.

The next five tests are invariance or symmetry tests. Fisher (1922, pp. 62–3, 458–60) and Walsh (1921b, p. 542) seem to have been the first researchers to appreciate the significance of these kinds of tests. Fisher (1922, pp. 62–3) spoke of fairness but it is clear that he had symmetry properties in mind. It is perhaps unfortunate that he did not realize that there were more symmetry and invariance properties than the ones he proposed; if he had realized this, it is likely that he would have been able to provide an axiomatic characterization for his ideal price index, as will be done shortly. Our first invariance test is that the price index should remain unchanged if the *ordering* of the commodities is changed:

T9: *Commodity reversal test* (or invariance to changes in the ordering of commodities):

$$P(p^{0*}, p^{1*}, q^{0*}, q^{1*}) = P(p^0, p^1, q^0, q^1)$$

where p^{t*} denotes a permutation of the components of the vector p^t and q^{t*} denotes the same permutation of the components of q^t for $t = 0, 1$. This test is due to Fisher (1922), and it is one of his three famous reversal tests. The other two are the time reversal test and the factor reversal test which will be considered below.

T10: *Invariance to changes in the units of measurement* (commensurability test):

$$P(\alpha_1 p_1^0, \ldots, \alpha_N p_N^0; \alpha_1 p_1^1, \ldots, \alpha_N p_N^1; \alpha_1^{-1} q_1^0, \ldots, \alpha_N^{-1} q_N^0; \alpha_1^{-1} q_1^1, \ldots, \alpha_N^{-1} q_N^1)$$
$$= p(p_1^0, \ldots, p_N^0; p_1^1, \ldots p_N^1; q_1^0, \ldots, q_N^0; q_1^1, \ldots, q_N^1) \text{ for all } \alpha_1 > 0, \ldots, \alpha_N > 0.$$

That is, the price index does not change if the units of measurement for each commodity are changed. The concept of this test was due to Jevons (1884, p. 23) and the Dutch economist Pierson (1896, p. 131), who criticized several index number formula for not satisfying this fundamental test. Fisher (1911, p. 411) first called this test *the change of units test* and later, Fisher (1922, p. 420) called it the *commensurability test*.

T11: *Time reversal test*: $P(p^0, p^1, q^0, q^1) = 1/P(p^1, p^0, q^1, q^0)$.

That is, if the data for periods 0 and 1 are interchanged, then the resulting price index should equal the reciprocal of the original price index. We have already encountered this test: see (15) above. Obviously, in the one good case when the price index is simply the single price ratio, this test is satisfied (as are all of the other tests listed in this section). When the number of goods is greater than one, many commonly used price indexes fail this test; for example, the Laspeyres and Paasche price indexes, P_L and P_P defined earlier by (8) and (9) above, both *fail* this fundamental test. The concept of the test was due to Pierson (1896, p. 128), who was so upset by the fact that many of the commonly used index number formulae did not satisfy this test that he proposed that the entire concept of an index number should be abandoned. More formal statements of the test were made by Walsh (1901, p. 368; 1921b, p. 541) and Fisher (1911, p. 534; 1922, p. 64).

Our next two tests are more controversial, since they are not necessarily consistent with the economic approach to index number theory. However, these tests are quite consistent with the weighted stochastic approach to index number theory discussed in section "The Stochastic Approach to Index Number Theory" above.

T12: *Quantity reversal test* (quantity weights symmetry test): $P(p^0, p^1, q^0, q^1) = P(p^0, p^1, q^1, q^0)$.

That is, if the quantity vectors for the two periods are interchanged, then the price index remains invariant. This property means that if quantities are used to weight the prices in the index number formula, then the period 0 quantities q^0 and the period 1 quantities q^1 must enter the formula in a symmetric or even-handed manner. Funke and Voeller (1978, p. 3) introduced this test; they called it the *weight property*.

The next test proposed by Diewert (1992a, p. 218) is the analogue to T12 applied to quantity indexes:

T13: *Price reversal test* (price weights symmetry test):

$$\left\{\sum_{n=1}^{N} p_i^1 q_i^1 / \sum_{i=1}^{N} p_j^0 q_i^0\right\} / P\left(p^0, p^1, q^0, q^1\right) = \left\{\sum_{i-1}^{N} p_i^0 q_i^1\right\} / P\left(p^1, p^0, q^0, q^1\right)$$

Thus, if we use (5) to define the quantity index Q in terms of the price index P, then it can be seen that T13 is equivalent to the following property for the associated quantity index Q:

$$Q\left(p^0, p^1, q^0, q^1\right) = Q\left(p^1, p^0, q^0, q^1\right). \tag{25}$$

That is, if the price vectors for the two periods are interchanged, then the quantity index remains invariant. Thus if prices for the same good in the two periods are used to weight quantities in the construction of the quantity index, then property T13 implies that these prices enter the quantity index in a symmetric manner.

The next three tests are mean value tests. The following test was proposed by Eichhorn and Voeller (1976, p. 10):

T14: *Mean value test for prices*:

$$\min_i\left(p_i^1/p_i^0 : i = 1, \ldots, N\right) \leq P\left(p^0, p^1, q^0, q^1\right) \leq \max_i\left(p_i^1/p_i^0 : i = 1, \ldots, N\right).$$

That is, the price index lies between the minimum price ratio and the maximum price ratio. Since the price index is supposed to be some sort of an average of the N price ratios, p_i^1/p_i^0, it seems essential that the price index P satisfy this test.

The next test proposed by Diewert (1992a, p. 219) is the analogue to T14 applied to quantity indexes:

T15: *Mean value test for quantities*:

$$\min_i\left(q_i^1/q_i^0 : i = 1, \ldots, n\right) \leq \left\{V^1/V^0\right\} / P\left(p^0, p^1, q^0, q^1\right) \leq \max_i\left(q_i^1/q_i^0 : i = 1, \ldots, n\right)$$

where V^t is the period t value aggregate $V^t \equiv \sum_{n=1}^{N} p_n^t q_n^t$ for $t = 0, 1$. Using (5) to define the quantity index Q in terms of the price index P, we see that T15 is equivalent to the following property for the associated quantity index Q:

$$\begin{aligned} &\min_i \left(q_i^1/q_i^0 : i = 1, \ldots, N\right) \\ &\quad \leq Q\left(p^0, p^1, q^0, q^1\right) \\ &\quad \leq \max_i \left(q_i^1/q_i^0 : i = 1, \ldots, N\right). \end{aligned} \tag{26}$$

That is, the implicit quantity index Q defined by P lies between the minimum and maximum rates of growth q_i^1/q_i^0 of the individual quantities.

In section "Fixed Basket Approaches," it was argued that it was very reasonable to take an average of the Laspeyres and Paasche price indexes as a single best measure of overall price change. This point of view can be turned into a test:

T16: *Paasche and Laspeyres bounding test*: The price index P lies between the Laspeyres and Paasche indexes, PL and PP, defined by (8) and (9) above.

Bowley (1901, p. 227) and Fisher (1922, p. 403) both endorsed this property for a price index.

Our final four tests are monotonicity tests; that is, how should the price index $P(p^0, p^1, q^0, q^1)$ change as any component of the two price vectors p^0 and p^1 increases or as any component of the two quantity vectors q^0 and q^1 increases.

T17: *Monotonicity in current prices*: $P(p^0, p^1, q^0, q^1) < P(p^0, p^2, q^0, q^1)$ if $p^1 < p^2$.

That is, if some period 1 price increases, then the price index must increase, so that $P(p^0, p^1, q^0, q^1)$ is increasing in the components of p^1. This property was proposed by Eichhorn and Voeller (1976, p. 23) and it is a very reasonable property for a price index to satisfy.

T18: *Monotonicity in base prices*: $P(p^0, p^1, q^0, q^1) > P(p^2, p^1, q^0, q^1)$ if $p^0 < p^2$.

That is, if any period 0 price increases, then the price index must decrease, so that $P(p^0, p^1, q^0, q^1)$ is decreasing in the components of p^0. This very reasonable property was also proposed by Eichhorn and Voeller (1976, p. 23).

T19: *Monotonicity in current quantities*: *if* $q^1 < q^2$, *then*

$$\left\{\sum_{i=1}^{N} p_i^1 q_i^1 / \sum_{i=1}^{N} p_i^0 q_i^0\right\} / P\left(p^0, p^1, q^0, q^1\right) < \left\{\sum_{i=1}^{N} p_i^1 q_i^2 / \sum_{i=1}^{N} p_i^0 q_i^0\right\} / P\left(p^0, p^1, q^0, q^2\right).$$

T20: *Monotonicity in base quantities: if* $q^0 < q^2$, *then*

$$\left\{\sum_{i=1}^{N} p_i^1 q_i^1 / \sum_{i=1}^{N} p_i^0 q_i^0\right\} / P\left(p^0, p^1, q^0, q^1\right) > \left\{\sum_{i=1}^{N} p_i^1 q_i^1 / \sum_{i=1}^{N} p_i^0 q_i^2\right\} / P\left(p^0, p^1, q^2, q^1\right).$$

If we define the implicit quantity index Q that corresponds to P using (1), we find that T19 translates into the following inequality involving Q:

$$Q\left(p^0, p^1, q^0, q^1\right) < Q\left(p^0, p^1, q^0, q^2\right) \text{if } q^1 < q^2. \tag{27}$$

That is, if any period 1 quantity increases, then the implicit quantity index Q that corresponds to the price index P must increase. Similarly, we find that T20 translates into:

$$Q\left(p^0, p^1, q^0, q^1\right) > Q\left(p^0, p^1, q^2, q^1\right) \text{if } q^0 < q^2. \tag{28}$$

That is, if any period 0 quantity increases, then the implicit quantity index Q must decrease. Tests T19 and T20 are due to Vogt (1980, p. 70).

Diewert (1992a, p. 221) showed that the only index number formula $P(p^0, p^1, q^0, q^1)$ which satisfies tests T1–T20 is the Fisher ideal price

index P_F defined earlier by (14), as the geometric mean of the Laspeyres and Paasche price indexes.

P_F satisfies yet another test, T21, which was Fisher's (1921, p. 534, 1922, pp. 72–81) third reversal test (the other two being T9 and T11):

T21: *Factor reversal test* (functional form symmetry test):

$$P(p^0,p^1,q^0,q^1)P(q^0,q^1,p^0,p^1) = \sum_{i=1}^{N} p_i^1 q_i^1 / \sum_{i=1}^{N} p_i^0 q_i^0.$$

A justification for this test is the following one: if $P(p^0, p^1, q^0, q^1)$ is a good functional form for the price index, then if we reverse the roles of prices and quantities, $P(q^0, q^1, p^0, p^1)$ ought to be a good functional form for a quantity index (which seems to be a correct argument) and thus the product of the price index $P(p^0, p^1, q^0, q^1)$ and the quantity index $Q(p^0, p^1, q^0, q^1) = P(q^0, q^1, p^0, p^1)$ ought to equal the value ratio, V^1/V^0. The second part of this argument does not seem to be valid and thus many researchers over the years have objected to the factor reversal test. However, if one is willing to embrace T21 as a basic test, Funke and Voeller (1978, p. 180) showed that the only index number function $P(p^0, p^1, q^0, q^1)$ which satisfies T1 (positivity), T11 (time reversal test), T12 (quantity reversal test) and T21 (factor reversal test) is the Fisher ideal index P_F defined by (14).

Other characterizations of the Fisher price index can be found in Funke and Voeller (1978) and Balk (1985; p. 1995).

The Fisher price index P_F satisfies all 20 of the tests listed above. Which tests do other commonly used price indexes satisfy? Recall the Laspeyres index P_L defined by (8), the Paasche index P_P defined by (9) and the Törnqvist-Theil index P_T defined by (22). Straightforward computations show that the Paasche and Laspeyres price indexes fail only the three reversal tests, T11, T12 and T13. Since the quantity and price reversal tests, T12 and T13, are somewhat controversial and hence can be discounted, the test performance of P_L and P_P seems at first sight to be quite good. However, the failure of the time reversal test, T11, is a severe limitation associated with the use of these indexes.

The Törnqvist-Theil price index P_T fails nine tests: T4 (the fixed basket test), the quantity and price reversal tests T12 and T13, T15 (the mean value test for quantities), T16 (the Paasche and Laspeyres bounding test) and the four monotonicity tests T17–T20. Thus the Törnqvist-Theil index is subject to a rather high failure rate from the perspective of this particular axiomatic approach to index number theory.

However, it could be argued that the list of tests or axioms that was used to establish the superiority of the Fisher ideal index might have been chosen to favour this index. Thus Diewert (2004), following the example of Walsh (1901, pp. 104–05) and Vartia (1976), developed a set of axioms for price indexes of the form $P(p^0, p^1, v^0, v^1)$ where v^0 and v^1 are vectors of expenditures on the N commodities in the index and these vectors replace the quantity vectors q^0 and q^1 as weighting vectors for the prices. In this new axiomatic framework, the Törnqvist-Theil index P_T emerged as the best.

The consistency and independence of various bilateral index number tests was studied in some detail by Eichhorn and Voeller (1976). Our conclusion at this point echoes that of Frisch (1936): the test approach to index number theory, while extremely useful, does not lead to a single unique index number formula. However, two test approaches that take alternative approaches to the methods for weighting prices do lead to the Fisher and Törnqvist-Theil indexes as the best in their respective axiomatic frameworks.

For additional material on the test approach to bilateral index number theory, see Balk (1995), Reinsdorf and Dorfman (1999), Balk and Diewert (2001), Vogt and Barta (1997), and Reinsdorf (2007).

In the following three sections, we consider various economic approaches to index number theory. In the economic approach to price index theory, quantity vectors are no longer regarded as being exogenous variables; rather, they are regarded as solutions to various economic optimization problems.

The Economic Approach to Price Indexes

Before a definition of a microeconomic price index is presented, it is necessary to make a few preliminary definitions.

Let $F(q)$ be a function of N variables, $q \equiv (q_1, \ldots, q_N)$. In the consumer context, F represents a consumer's preferences; i.e. if $F(q^2) > F(q^1)$, then the consumer prefers the commodity vector q^2 over q^1. In this context, F is called a *utility function*. In the producer context, $F(q)$ might represent the output that could be produced using the input vector q. In this context, F is called a *production function*. In order to cover both contexts, we follow the example of Diewert (1976) and call F an *aggregator function*.

Suppose the consumer or producer faces prices $p \equiv (p_1, \ldots, p_N)$ for the N commodities. Then the economic agent will generally find it is useful to minimize the cost of achieving at least a given utility or output level u; we define the *cost function* or *expenditure function* C as the solution to this minimization problem:

$$C(u,p) \equiv \min_q \{p.q : F(q) \geq u\} \tag{29}$$

where $p.q \equiv \sum_{n-1}^{N} p_n q_n$ is the inner product of the price vector p and quantity vector q.

Note that the cost function depends on $1+N$ variables; the utility or output level u and the N commodity prices in the vector p. Moreover, the functional form for the aggregator function F completely determines the functional form for C.

We say that an aggregator function is *neoclassical* if F is: (i) continuous, (ii) positive; i.e. $F(q) > 0$ if $q >> 0_N$ and (iii) linearly homogeneous; that is, $F(\lambda q) = \lambda F(q)$ if $\lambda > 0$. If F is neoclassical, then the corresponding cost function $C(u, p)$ equals u times the unit cost function, $c(p) \equiv C(1, p)$, where $c(p)$ is the minimum cost of producing one unit of utility or output; that is,

$$C(u,p) = uC(1,p) = uc(p). \tag{30}$$

Shephard (1953) formally defined an aggregator function F to be *homothetic* if there exists an increasing continuous function of one variable g such that $g[F(q)]$ is neoclassical. However, the concept of homotheticity was well known to Frisch (1936) who termed it expenditure proportionality. If F is homothetic, then its cost function C has the following decomposition:

$$\begin{aligned} C(u,p) &\equiv \min_q \{p \cdot q : F(q) \geq u\} \\ &= \min_q \{p \cdot q : g[F(q)] \geq g(u)\} \\ &= g(u)c(p) \end{aligned} \tag{31}$$

where $c(p)$ is the unit cost function that corresponds to $g[F(q)]$.

Let $p^0 >> 0_N$ and $p^1 >> 0_N$ be positive price vectors pertaining to periods or observations 0 and 1. Let $q > 0_N$ be a non-negative, non-zero reference quantity vector. Then the Konüs (1924) *price index* or *cost of living index* is defined as:

$$P_K(p^0, p^1, q) \equiv C[F(q), p^1] / C[F(q), p^0]. \tag{32}$$

In the consumer (producer) context, P_K may be interpreted as follows. Pick a reference utility (output) level $u \equiv F(q)$. Then $P_K(p^0, p^1, q)$ is the minimum cost of achieving the utility (output) level u when the economic agent faces prices p^1 relative to the minimum cost of achieving the same u when the agent faces prices p^0. If $N = 1$ so that there is only one consumer good (or input), then it is easy to show that $P_K(p_1^0, p_1^1, q_1) = p_1^1 q_1 / p_1^0 q_1 = p_1^1 / p_1^0$.

Using the fact that a cost function is linearly homogeneous in its price arguments, it can be shown that P_K has the following homogeneity property: $P_K(p^0, \lambda p^1, q) = \lambda P_K(p^0, p^1, q)$ for $\lambda > 0$ which is analogous to the proportionality test T5 in the previous section. P_K also satisfies $P_K(p^1, p^0, q) = 1/P_K(p^0, p^1, q)$ which is analogous to the time reversal test, T11.

Note that the functional form for P_K is completely determined by the functional form for the aggregator function F, which determines the functional form for the cost function C.

In general, P_K depends not only on the two price vectors p^0 and p^1, but also on the reference vector q. Malmquist (1953), Pollak (1983), and Samuelson and Swamy (1974) have shown that P_K is independent of q and is equal to a ratio of unit cost functions, $c(p^1)/c(p^0)$, if and only if the aggregator function F is homothetic.

If we knew the consumer's preferences or the producer's technology, then we would know F and we could construct the cost function C and the Konüs price index P_k. However, we generally do not know F or C and thus it is useful to develop *bounds* that depend on observable price and quantity data but do not depend on the specific functional form for F or C.

Samuelson (1947) and Pollak (1983) established the following bounds on P_K.

Let $p^0 >> 0_N$ and $p^1 >> 0_N$. Then for every reference quantity vector $q > 0_N$, we have

$$\min_n\{p_n^1/p_n^0\} \leq P_K(p^0,p^1,q) \leq \max_n\{p_n^1/p_n^0\}; \quad (33)$$

that is, P_K lies between the smallest and largest price ratios. Unfortunately, these bounds are usually too wide to be of much practical use.

To obtain closer bounds, we now assume that the observed quantity vectors for the two periods, $q^i \equiv (q_1^i,\ldots,q_N^i), i = 0, 1,$ are solutions to the producer's or consumer's cost minimization problems; that is, we assume:

$$p^i \cdot q^i = C[F(q^i),p^i], p^i >> 0_N, q^i > 0_N, i = 0, 1. \quad (34)$$

Given the above assumptions, we now have two natural choices for the reference quantity vector q that occurs in the definition of $P_K(p^0, p^1, q)$: q^0 or q^1. The *Laspeyres–Konüs price index* is defined as $P_K(p^0, p^1, q^0)$ and the *Paasche–Konüs price index* is defined as $P_K(p^0, p^1, q^1)$.

Under the assumption of cost minimizing behaviour (34), Konüs (1924) established the following bounds:

$$P_K(p^0,p^1,q^0) \leq p^1 \cdot q^0/p^0 \cdot q^0 \equiv P_L(p^0,p^1,q^0,q^1); \quad (35)$$

$$P_K(p^0,p^1,q^1) \geq p^1 \cdot q^1/p^0 \cdot q^1 \equiv P_P(p^0,p^1,q^0,q^1), \quad (36)$$

where P_L and P_P are the Laspeyres and Paasche price indexes defined earlier by (8) and (9). If in addition, the aggregator function is homothetic, then Frisch (1936) showed that for any reference vector $q > 0_N$,

$$P_P \equiv p^1 \cdot q^1/p^0 \cdot q^1 \leq P_K(p^0,p^1,q) \leq p^1 \cdot q^0/p^0 \cdot q^0 \equiv P_L. \quad (37)$$

In the consumer context, it is unlikely that preferences will be homothetic; hence the bounds (37) cannot be justified in general. However, Konüs (1924) showed that bounds similar to (37) would hold even in the general non-homothetic case, provided that we choose a reference vector $q \equiv \lambda q^0 + (1 - \lambda)q^1$ which is a λ, $(1 - \lambda)$ weighted average of the two observed quantity points. Specifically, Konüs showed that there exists a λ between 0 and 1 such that if $P_P \leq P_L$, then

$$P_P \leq P_K[p^0,p^1,\lambda q^0 + (1-\lambda)q^1] \leq P_L \quad (38)$$

or if $P_p > P_L$, then

$$P_L \leq P_K[p^0,p^1,\lambda q^0 + (1-\lambda)q^1] \leq P_P. \quad (39)$$

The bounds on the microeconomic price index P_K given by (37) in the homothetic case and (38)–(39) in the non-homothetic case are the best bounds that we can obtain without making further assumptions on F. In the time series context, the bounds given by (38) or (39) are usually quite satisfactory: the Paasche and Laspeyres price indexes for consecutive time periods will usually differ by less than one per cent (and hence taking the Fisher geometric average will generally suffice for most practical purposes). However, in the cross-section context where the observations represent, for example, production data for two producers in the same industry but in different regions, the bounds are often not very useful since P_L and P_P can differ by 50 per cent or more in the cross-sectional context: see Ruggles (1967) and Hill (2006a).

For generalizations of the above single household theory to many households, see Pollak (1980, p. 276, 1981, p. 328), Diewert (1983a, 2001) and in ILO (2004, ch. 18).

In section "Exact and Superlative Indexes," we will make additional assumptions on the aggregator function F or its cost function dual C that will enable us to determine P_K exactly. Before we do this, in the next section we will define various quantity indexes that have their origins in microeconomic theory.

Economic Approaches to Quantity Indexes

In the one commodity case, a natural definition for a quantity index is q_1^1/q_1^0, the ratio of the single quantity in period 1 to the corresponding quantity in period 0. This ratio is also equal to the expenditure ratio, $p_1^1 q_1^1/p_1^0 q_1^0$, divided by the price ratio, $p_1^1 p_1^0$. This suggests that in the N commodity case a reasonable definition for a quantity index would be the expenditure ratio divided by the Konüs price index, P_K. This type of index was suggested by Pollak (1983). Thus the *Konüs-Pollak quantity index*, Q_K, is defined by:

$$\begin{aligned} &Q_K(p^0,p^1,q^0,q^1,q) \\ &\quad \equiv p^1.q^1/p^0.q^0 P_K(p^0,p^1,q) \\ &\quad = \{C[F(q^1),p^1]/C[F(q),p^1]\}/ \\ &\quad \{C[C(q^0),p^0]/C[F(q),p^0]\} \end{aligned} \tag{40}$$

where the second line follows from the definition of P_K, (32), and the assumption of cost minimizing behaviour in the two periods, (34).

The definition of Q_K depends on the reference vector q which appears in the definition of P_K. The general definition of Q_K simplifies considerably if we choose the reference q to be q^0 or q^1. Thus define the *Laspeyres-Konüs* quantity index as

$$\begin{aligned} &Q_K(p^0,p^1,q^0,q^1,q^0) \\ &\quad \equiv C[F(q^1),p^1]/C[F(q^0),p^1] \end{aligned} \tag{41}$$

and the *Paasche-Konüs* quantity index as

$$\begin{aligned} &Q_K(p^0,p^1,q^0,q^1,q^0) \\ &\quad \equiv C[F(q^1),p^0]/C[F(q^0),p^0]. \end{aligned} \tag{42}$$

The indexes defined by (41) and (42) are special cases of another class of quantity indexes. For any reference price vector $p >> 0_N$, define the *Allen* (1949) *quantity index* by

$$Q_A(q^0,q^1,p) \equiv C[F(q^1),p]/C[F(q^0),p]. \tag{43}$$

If p is chosen to be p^0, (43) becomes (42) and if $p = p^1$, then (43) becomes (41). Using the properties of cost functions, it can be shown that if $F(q^1) \geq F(q^0)$, then $Q_A(q^0, q^1, p) \geq 1$, while if $F(q^1) \leq F(q^0)$, then $Q_A(q^0, q^1, p) \leq 1$. Thus the Allen quantity index correctly indicates whether the commodity vector q^1 is larger or smaller than q^0. It can also be seen that Q_A satisfies a counterpart to the time reversal test; that is, $Q_A(q^1, q^0, p) = 1/Q_A(q^0, q^1, p)$.

Just as the price index P_K depended on the unobservable aggregator function, so also do the quantity indexes Q_K and Q_A. Thus it is useful to develop bounds for the quantity indexes that do not depend on the particular functional form for F.

Samuelson (1947) and Allen (1949) established the following bounds for (41) and (42):

$$\begin{aligned} Q_A(q^0,q^1,p^0) &= Q_K(p^0,p^1,q^0,q^1,q^1) \\ &\leq p^0 \cdot q^1/p^0 \cdot q^0 \equiv Q_L; \end{aligned} \tag{44}$$

$$\begin{aligned} Q_A(q^0,q^1,p^0) &= Q_K(p^0,p^1,q^0,q^1,q^0) \\ &\leq p^1.q^1/p^1.q^0 \equiv Q_P. \end{aligned} \tag{45}$$

Note that the observable *Laspeyres* and *Paasche quantity indexes*, Q_L and Q_P, appear on the right hand sides of (44) and (45).

Diewert (1981), utilizing some results of Pollak (1983) and Samuelson and Swamy (1974), established the following results: if the

underlying aggregator function F is neoclassical and (32) holds, then for all $P >> 0_N$ and $q >> 0_N$,

$$\begin{aligned} Q_P &\leq Q_A(q^0, q^1, p) \\ &= Q_K(p^0, p^1, q^0, q^1, q) \\ &\leq F(q^1)/F(q^0) \leq Q_L \end{aligned} \tag{46}$$

Thus if the aggregator function F is neoclassical, then the Allen quantity index for all reference vectors p equals the Konüs quantity index for all reference quantity vectors q, which in turn equals the ratio of aggregates, $F(q^1)/F(q^0)$. Moreover, Q_A and Q_K are bounded from below by the Paasche quantity index Q_P, and bounded from above by the Laspeyres quantity index Q_L in the neoclassical case.

In the general non-homothetic case, Diewert (1981) showed that there exists a λ between 0 and 1 such that $Q_K(p^0, p^1, q^0, q^1, \lambda q^0 + (1 - \lambda)q^1]$ lies between QP and QL and there exists a λ^* between 0 and 1 such that $Q_A(q^0, q^1, \lambda^* p^0 + (1 - \lambda^*)p^1)$ also lies between Q_P and Q_L. Thus the observable Paasche and Laspeyres quantity indexes bound both the Konüs quantity index and the Allen quantity index, provided that we choose appropriate reference vectors between q^0 and q^1 and p^0 and p^1 respectively.

Using the linear homogeneity property of the cost function in its price arguments, we can show that the Konüs price index has the desirable homogeneity property, $P_K(p^0, \lambda p^0, q) = \lambda$ for all $\lambda > 0$; that is, if period 1 prices are proportional to period 0 prices, then P_K equals this common proportionality factor. It would be desirable for an analogous homogeneity property to hold for quantity indexes.

Unfortunately, it is not in general true that $Q_K(q^0, \lambda q^0, p^0, p^1, q) = \lambda$ or that $Q_A(q^0, \lambda q^0, p) = \lambda$. Thus we turn to a third economic approach to defining a quantity index which has the desirable quantity proportionality property.

Let q^1 and q^2 be the observable quantity vectors in the two situations as usual, let $F(q)$ be an increasing, continuous aggregator function, and let $q >> 0$ be a reference quantity vector. Then the *Malmquist* (1953) *quantity index QM* is defined as:

$$Q_M(q^0, q^1, q) \equiv D[F(q), q^1]/D[F(q), q^0] \tag{47}$$

where $D(u, q^t) \equiv \max_k\{k : F(q^t/k) \geq u, \quad k > 0\}$ is the *deflation* or *distance function* which corresponds to F. Thus $D[F(q), q^1]$ is the biggest number which will just deflate the quantity vector q^1 onto the boundary of the utility (or production) possibilities set $\{z: F(z) \geq F(q)\}$ indexed by the reference quantity vector q while $D[F(q), q^0]$ is the biggest number which will just deflate the quantity vector q^0 onto the set $\{z: F(z) \geq F(q)\}$ and QM is the ratio of these two deflation factors. Note that there is no optimization problem involving prices in the definition of the Malmquist quantity index, but the definition of the distance function involves certain deflation problems that can be interpreted as technical efficiency optimization problems.

Q_M depends on the unobservable aggregator function F and as usual, we are interested in bounds for Q_M.

Diewert (1981) showed that Q_M satisfied bounds analogous to (33); that is,

$$\begin{aligned} \min_n\{q_n^1/q_n^0\} &\leq Q_M(q^0, q^1, q) \\ &\leq \max_n\{q_n^1/q_n^0\} \end{aligned} \tag{48}$$

As noted above, the assumption of cost minimizing behaviour is not required in order to define the Malmquist quantity index or to establish the bounds (46).

However, in order to establish the following bounds due to Malmquist (1953) for Q_M, we do need the assumption of cost-minimizing behaviour (32) for the two periods under consideration, and we require the reference vector q to be q^0 or q^1:

$$Q_M(q^0, q^1, q^0) \leq p^0 \cdot q^1 / p^0 \cdot q^0 \equiv Q_L; \tag{49}$$

$$Q_M(q^0, q^1, q^1) \leq p^1 \cdot q^1 / p^1 \cdot q^0 \equiv Q_P. \tag{50}$$

Diewert (1981) showed that, under the hypothesis of cost-minimizing behaviour, there exists a λ between 0 and 1 such that $Q_M(q^0, q^1, \lambda q^0 + (1 - \lambda)q^1)$ lies between Q_P and Q_L. Thus the Paasche and Laspeyres quantity indexes provide bounds for a Malmquist quantity index for some reference

indifference or product surface indexed by a quantity vector which is a λ, $(1-\lambda)$ weighted average of the two observable quantity vectors, q^0 and q^1.

Pollak (1983) showed that, if F is neoclassical, then we can extend the string of equalities in (46) to include the Malmquist quantity index $Q_M(q^0, q^1, q)$, for any reference quantity vector q. Thus, in the case of a linearly homogeneous aggregator function, all three theoretical quantity indexes coincide and this common theoretical index is bounded from below by the Paasche quantity index Q_P and bounded from above by the Laspeyres quantity index Q_L.

In the general case of a non-homothetic aggregator function, our best theoretical quantity index, the Malmquist index, is also bounded by the Paasche and Laspeyres indexes, provided that we choose a suitable reference quantity vector. In order to improve upon the bounding approach, Caves et al. (1982b) show that, if one is willing to assume optimizing behaviour and make certain functional form assumptions about the underlying technology, then it is possible to obtain exact expressions for the Malmquist quantity index.

We noted in the price index context that the Paasche and Laspeyres price indexes were usually quite close in the time series context. A similar remark also applies to the Paasche and Laspeyres quantity indexes. Thus taking an average of the Paasche and Laspeyres indexes, such as the Fisher price and quantity indexes, will generally approximate underlying microeconomic price and quantity indexes sufficiently accurately for most practical purposes. However, this observation does not apply to the cross-sectional context, where the Paasche and Laspeyres indexes can differ widely. In the following section, we offer another microeconomic justification for using the Fisher indexes that also applies in the context of making interregional and cross-country comparisons.

Exact and Superlative Indexes

Assume that the producer or consumer is maximizing a neoclassical aggregator function f subject to a budget constraint during the two periods. Under these conditions, it can be shown that the economic agent is also minimizing cost subject to a utility or output constraint. Moreover, the cost function C that corresponds to f can be written as $C[f(q), p] = f(q)c(p)$ where c is the unit cost function (see (28) above).

Suppose a bilateral price index $P(p^0, p^1, q^0, q^1)$ and the corresponding quantity index $Q(p^0, p^1, q^0, q^1)$ that satisfy (5) are given. The quantity index Q is defined to be *exact* for a neoclassical aggregator function f with unit cost dual c if for every $P^0 >> 0_N$, $P^1 >> 0_N$ and $q^i >> 0_N$ which is a solution to the aggregator maximization problem $\max_q\{f(q) : p^i.\ q \leq p^i.\ q^i\} = f(q^i) > 0$ for $i = 0, 1$, we have

$$Q(p^0, p^1, q^0, q^1) = f(q^1)/f(q^0). \tag{51}$$

Under the same hypothesis, the price index P is *exact* for f and c if we have

$$P(p^0, p^1, q^0, q^1) = c(p^1)/c(p^0). \tag{52}$$

In (51) and (52), the price and quantity vectors are not regarded as being independent. The *pi* can be independent, but the *qi* are solutions to the corresponding aggregator maximization problem involving p^i, for $i = 0,1$. Note that, if Q is exact for a neoclassical f, then Q can be interpreted as a Konüs, Allen or Malmquist quantity index and the corresponding P defined implicitly by (5) can be interpreted as a Konüs price index.

The concept of exactness is due to Konüs and Byushgens (1926). Below, we shall give some examples of exact index number formulae. Additional examples may be found in Afriat (1972), Pollak (1983), Samuelson and Swamy (1974), and Diewert (1976, 1992b).

Konüs and Byushgens (1926) showed that Irving Fisher's ideal price index P_F defined by (14) and the corresponding quantity index Q_F defined implicitly by (5) are exact for the homogeneous quadratic aggregator function f defined by

$$f(q_1, \ldots, q_N) \equiv \left(\sum_{n-1}^{N}\sum_{m-1}^{N} a_{nm} q_n q_m\right)^{1/2} \equiv (q\ .\ Aq)^{1/2} \tag{53}$$

where $A \equiv [a_{nm}]$ is a symmetric $N \times N$ matrix of constants. Thus, under the assumption of maximizing behaviour, we can show that $f(q^1)/f(q^0) = Q_F$ and $c(p^1)/c(p^0) = P_F$ where f is defined by (51) and c is the unit cost function that corresponds to f. The important point to note is that f depends on $N(N+1)/2$ unknown a_{nm} parameters but we do not need to know these parameters in order to be able to calculate $f(q^1)/f(q^0)$and $c(p^1)/c(p^0)$.

Diewert (1976) showed that the Törnqvist–Theil price index P_T defined by (22) is exact for the unit cost function $c(p)$ defined by:

$$\ln c(p) \equiv \alpha_0 + \sum_{n=1}^{N} \alpha_n \ln p_n + (1/2) \sum_{m=1}^{N} \sum_{n=1}^{N} \alpha_{mn} \ln p_m \ln p_n \tag{54}$$

where the parameters α_n and α_{mn} satisfy the following restrictions:

$$\sum_{n=1}^{N} \alpha_n = 1, \sum_{n=1}^{N} \alpha_{mn} = 0 \text{ for } m = 1, \ldots, N \text{ and } \alpha_{mn} = \alpha_{mn} \text{ for all } m, n. \tag{55}$$

Thus we may calculate $c(p^1)/c(p^0) = P_T$ and $f(q^1)/f(q^0) = p^1 \cdot q^1 = p^0 \cdot q^0 P_T \equiv Q_T$ where c is the unit cost function defined by (54), f is the aggregator function which corresponds to this c, and QT is the implicit Törnqvist-Theil quantity index. Note that we do not have to know the parameters αn and αmn in order to evaluate $c(p^1)/c(p^0)$ and $f(q^1)/f(q^0)$.

The unit cost function defined by (54) is the *translog* unit cost function defined by Christensen et al. (1971). Since PT is exact for this translog functional form, P_T is sometimes called the *translog price index*.

Define the following family of quantity indexes Qr that depend on a number, $r \neq 0$:

$$Q_r(p^0, p^1, q^0, q^1) \equiv \left[\sum_{n=1}^{N} s_n^0 (q_n^1/q_n^0)^{r/2}\right]^{1/r} \left[\sum_{m=1}^{N} s_m^1 (q_m^1/q_m^0)^{-r/2}\right]^{-1/r} \tag{56}$$

where $s_n^i \equiv p_n^i q_n^i / p^i \cdot q^i$ is the period i expenditure share for good n. For each $r \neq 0$, define the corresponding implicit price index by:

$$P_r^*(p^0, p^1, q^0, q^1) \equiv p^1 \cdot q^1 / p^0 \cdot q^0 \, Q_r(p^0, p^1, q^0, q^1). \tag{57}$$

A quick algebraic calculation will show that when $r = 2$, $P_2^* = P_F$, the Fisher price index defined by (14) and when r equals 1, P_1^*equals:

$$P_1^* = \sum_{n=1}^{N} p_n^1 (q_n^0 q_n^1)^{1/2} / \sum_{m=1}^{N} p_m^0 (q_m^0 q_m^1)^{1/2} = P_W \tag{58}$$

Where P_W is the Walsh price index defined earlier by (17).

Diewert (1976) showed that Q_r and P_r^* are exact for the *quadratic mean* of *order r aggregator function fr* defined as follows:

$$f_r(q_1, \ldots, q_N) \equiv \left(\sum_{m=1}^{N} \sum_{n=1}^{N} a_{mn} q^{r/2} q^{r/2}\right)^{1/r} \tag{59}$$

Where $A = [amn]$ is a symmetric matrix of constants. Thus the Walsh and Fisher price indexes, PW and PF, are exact for $f1(q)$ and $f2(q)$ respectively, defined by (59) when $r = 1$ and 2.

Diewert (1974) defined a linearly homogeneous function f of N variables to be *flexible* if it could provide a second-order approximation to an arbitrary twice continuously differentiable linearly homogeneous function. It can be shown that f defined by (53), c defined by (54) and (55) and fr

defined by (59) for each $r \neq 0$ are all examples of flexible functional forms.

Let the price and quantity indexes P and Q satisfy the product test equality, (5). Then Diewert (1976) defined P and Q to be *superlative indexes* if either P is exact for a flexible unit cost function c or Q is exact for a flexible aggregator function f.

Thus P_F, P_W, P_T and P_r^* are all superlative price indexes. Thus from the viewpoint of the economic approach to index number theory, all of these indexes can be judged to be equally good.

At this point, it is useful to review the various approaches to bilateral index number theory discussed in the previous sections. In section "Fixed Basket Approaches," it was found that the best average basket approaches led to the Fisher or Walsh price indexes. In section "The Stochastic Approach to Index Number Theory," the index from the viewpoint of the stochastic approach was the Törnqvist-Theil index. In section "The Test Approach to Index Number Theory," the test approach led to the Fisher or the Törnqvist-Theil indexes as being best. Finally, in this section, the economic approach led to the Fisher, Walsh and Fisher or the Törnqvist-Theil indexes as being equally good. *Thus all four major approaches to index number theory led to the same three indexes as being best*. But which one of these three formulae, P_F, P_W and P_T, should we choose? Fortunately, it does not matter very much which of these formulae we choose to use in applications; they will all give the same answer to a reasonably high degree of approximation. Diewert (1978, p. 889) showed that all known superlative index number formulae approximate each other to the second order when each index is evaluated at an equal price and quantity point. This means the P_F, P_W, P_T and each P_r^* have the same first and second order partial derivatives with respect to all 4 N arguments when the derivatives are evaluated at a point where $p^0 = p^1$ and $q^0 = q^1$. A similar string of equalities also holds for the corresponding implicit quantity indexes defined using the product test (5). In fact, these derivative equalities are still true provided that $p^1 = \lambda p^0$ and $q^1 = \mu q^0$ for any numbers $\lambda > 0$ and $\mu > 0$. However, although Diewert's approximation result is mathematically true, Hill (2006) has shown that superlative indexes of the form P_r^* for r very large in magnitude do not necessarily empirically approximate the standard superlative indexes P_F, P_W and P_T very closely. But these standard superlative indexes typically approximate each other to something less than 0.2 per cent in the time series context and to about two per cent in the cross-section context; see Fisher (1922), Ruggles (1967), Diewert (1978, pp. 894–5) and Hill (2006) for empirical evidence on this point.

Diewert (1978) also showed that the Paasche and Laspeyres indexes approximate the superlative indexes to the first order at an equal price and quantity point. In the time series context, for adjacent periods, the Paasche and Laspeyres price indexes typically differ by less than 0.5 per cent; hence these indexes may provide acceptable approximations to a superlative index.

After consideration of the case of two observations at length, the many- observation case is considered in the following two sections.

The Fixed Base Versus the Chain Principle

In this section, the merits of using the chain system for constructing price indexes in the time series context versus using the fixed base system are discussed.

The chain system, introduced independently into the economics literature by Lehr (1885, pp. 45–6) and Marshall (1887, p. 373), measures the change in prices going from one period to a subsequent period using a bilateral index number formula involving the prices and quantities pertaining to the two adjacent periods. These one period rates of change (the links in the chain) are then cumulated to yield the relative levels of prices over the entire period under consideration. Thus, if the bilateral price index is P, the chain

system generates the following pattern of price levels for the first three periods:

$$1, P(p^0, p^1, q^0, q^1), \quad P(p^0, p^1, q^0, q^1) \quad P(p^1, p^2, q^1, q^2). \tag{60}$$

On the other hand, the fixed base system of price levels using the same bilateral index number formula P simply computes the level of prices in period t relative to the base period 0 as $P(p^0, p^t, q^0, q^t)$. Thus the fixed base pattern of price levels for periods 0,1 and 2 is:

$$1, P(p^0, p^1, q^0, q^1) \quad P(p^0, p^2, q^0, q^2). \tag{61}$$

Due to the difficulties involved in obtaining current period information on quantities (or equivalently, on expenditures), as was indicated in section "Fixed Basket Approaches," many statistical agencies loosely base their consumer price index on the use of the Laspeyres formula and the fixed base system. Therefore, it is of some interest to look at some of the possible problems associated with the use of fixed base Laspeyres indexes.

The main problem with the use of the fixed base Laspeyres index is that the period 0 fixed basket of commodities that is being priced out in period t can often be quite different from the period t basket. Thus, if there are systematic *trends* in at least some of the prices and quantities in the index basket, the fixed base Laspeyres price index $P_L(p^0, p^t, q^0, q^t)$ can be quite different from the corresponding fixed base Paasche price index, $P_P(p^0, p^t, q^0, q^t)$. This means that both indexes are likely to be an inadequate representation of the movement in average prices over the time period under consideration.

As Hill (1988) noted, the fixed base Laspeyres quantity index cannot be usedfor ever: eventually, the base period quantities q^0 are so far removed from the current period quantities q^t that the base must be changed. Chaining is merely the limiting case where the base is changed each period.

The main advantage of the chain system is that under normal conditions, chaining will reduce the spread between the Paasche and Laspeyres indexes; see Diewert (1978, p. 895) and Hill (1988, 1993, pp. 387–8). These two indexes each provide an asymmetric perspective on the amount of price change that has occurred between the two periods under consideration, and it could be expected that a single point estimate of the aggregate price change should lie between these two estimates. Thus the use of either a chained Paasche or Laspeyres index will usually lead to a smaller difference between the two and hence to estimates that are closer to the 'truth'.

Hill (1993, p. 388), drawing on the earlier research of Szulc (1983) and Hill (1988, pp. 136–7), noted that it is not appropriate to use the chain system when prices oscillate or 'bounce', to use Szulc's (1983, p. 548) term. This phenomenon can occur in the context of regular seasonal fluctuations or in the context of price wars. However, in the context of roughly monotonically changing prices and quantities, Hill (1993, p. 389) recommended the use of chained symmetrically weighted indexes. The Fisher, Walsh and Törnqvist-Theil indexes are examples of symmetrically weighted indexes.

It is possible to be more precise about the conditions under which one should chain or not chain. Following arguments due to Walsh (1901, p. 206, 1921a, pp. 84–5) and Fisher (1911, pp. 204 and 423–4), one should chain if the prices and quantities pertaining to adjacent periods are *more similar* than the prices and quantities of more distant periods, since this strategy will lead to a narrowing of the spread between the Paasche and Laspeyres indexes at each link. Of course, one needs a measure of how similar the prices and quantities pertaining to two periods are. The similarity measures could be *relative* ones or *absolute* ones. In the case of absolute comparisons, two vectors of the same dimension are similar if they are identical and dissimilar otherwise. In the case of relative comparisons, two vectors are similar if they are proportional and dissimilar if they are non-proportional. Once a similarity measure has been defined, the prices and quantities of each period can be compared with each other using this measure, and a 'tree' or path that links all the observations can be constructed where the most similar observations are compared with each other using a bilateral index number formula.

Fisher (1922, pp. 271–6) informally suggested this strategy. However, the more recent literature on this approach is due to Robert Hill. Initially, Hill (1999a, b, 2001) defined the price structures between the two countries to be more dissimilar the bigger is the spread between P_L and P_P, that is, the bigger is $\max\{P_L/P_P, P_P/P_L\}$. The problem with this measure of dissimilarity in the price structures of the two countries is that it could be the case that $P_L = P_P$ (so that the Hill measure would register a maximal degree of similarity) but p^0 could be very different from p^t. Thus there is a need for a more systematic study of similarity (or dissimilarity) measures in order to pick the best one that could be used as an input into Hill's (1999a, b, 2001, 2004, 2006b, 2007) spanning tree algorithm for linking observations, see Diewert (2007a).

The method of linking observations explained in the previous paragraph based on the similarity of the price and quantity structures of any two observations may not be practical in a statistical agency context since the addition of a new period may lead to a reordering of the previous links. However, the above 'scientific' method for linking observations may be useful in deciding whether chaining is preferable or whether fixed base indexes should be used while making month-to-month comparisons within a year.

Some index number theorists have objected to the chain principle on the grounds that it has no counterpart in the spatial context:

> They [chain indexes] only apply to intertemporal comparisons, and in contrast to direct indices they are not applicable to cases in which no natural order or sequence exists. Thus the idea of a chain index for example has no counterpart in interregional or international price comparisons, because countries cannot be sequenced in a 'logical' or 'natural' way (there is no $k+1$ nor $k-1$ country to be compared with country k). (von der Lippe 2001, p. 12)

This is of course correct but the approach of Robert Hill leads to a 'natural' set of spatial links. Applying the same approach to the time series context will lead to a set of links between periods which may not be month-to-month but it will in many cases justify year-over-year linking of the data pertaining to the same month.

It is of some interest to determine if there are index number formulae that give the same answer when either the fixed base or chain system is used. If we compare the sequence of chain indexes defined by (60) above with the corresponding fixed base indexes defined by (61), it can be seen that we will obtain the same answer in all three periods if the index number formula P satisfies the following functional equation for all price and quantity vectors:

$$P(p^0,p^2,q^0,q^2) = P(p^0,p^1,q^0,q^1)P(p^1,p^2,q^1,q^2). \tag{62}$$

If a bilateral index number formula P satisfies (62), then P satisfies the *circularity test*, see Westergaard (1890, pp. 218–19) and Fisher (1922, p. 413).

If it is assumed that the index number formula P satisfies certain properties or tests in addition to the circularity test above, then Funke et al. (1979) showed that P must have the following functional form due originally to Konüs and Byushgens (1926, pp. 163–6):

$$\ln P_{KB}(p^0,p^1,q^0,q^1) \equiv \sum_{i=1}^{N} \alpha_i \ln (p_i^1/p_i^0) \tag{63}$$

where the N constants α_i satisfy the following restrictions:

$$\sum_{i=1}^{N} \alpha_i = 1 \text{ and } \alpha_i > 0 \text{ for } i = 1,\ldots,N. \tag{64}$$

Thus, under very weak regularity conditions, the only price index satisfying the circularity test is a weighted geometric average of all the individual price ratios, the weights being constant through time. This result vindicates Irving Fisher's (1922, p. 274) intuition when he asserted that 'the only formulae which conform perfectly to the circular test are index numbers which have *constant weights*.. .'.

The problem with the indexes defined by Konüs and Byushgens is that the individual price

ratios, p_n^1/p_n^0 have weights that are *independent* of the economic importance of commodity n in the two periods under consideration. Put another way, these price weights are independent of the quantities of commodity n consumed or the expenditures on commodity n during the two periods. Hence, these indexes are not really suitable for use by statistical agencies at higher levels of aggregation when expenditure share information is available.

The above results indicate that it is not useful to ask that the price index P satisfy the circularity test *exactly*. However, it is of some interest to find index number formulae that satisfy the circularity test to some degree of *approximation* since the use of such an index number formula will lead to measures of aggregate price change that are more or less the same no matter whether we use the chain or fixed base systems. Irving Fisher (1922, p. 284) found that deviations from circularity using his data-set and the Fisher ideal price index P_F were quite small. This relatively high degree of correspondence between fixed base and chain indexes has been found to hold for other symmetrically weighted formulae like the Walsh index P_W defined earlier. It is possible to give a theoretical explanation for the approximate satisfaction of the circularity test in the time series context for symmetrically weighted index number formulae, such as P_F and P_W. Another symmetrically weighted formula is the Törnqvist-Theil index P_T. Alterman et al. (1999, p. 61) showed that if the logarithmic price ratios $\ln\left(p_n^t/p_n^{t-1}\right)$ trend linearly with time t and the expenditure shares s_n^t also trend linearly with time, then the Törnqvist index P_T will satisfy the circularity test exactly. Since many economic time series on prices and quantities satisfy these assumptions approximately, then the Törnqvist index P_T will satisfy the circularity test approximately. As was noted earlier, the Törnqvist index generally closely approximates the symmetrically weighted Fisher and Walsh indexes, so that for many economic time series (with smooth trends) all three of these symmetrically weighted indexes will satisfy the circularity test to a high enough degree of approximation so that it will not matter whether we use the fixed base or chain principle.

Walsh (1901, p. 401, 1921a, p. 98, 1921b, p. 540) introduced the following useful variant of the circularity test:

$$1 = P\left(p^0,p^1,q^0,q^1\right)\ P\left(p^1,p^2,q^1,q^2\right)\ldots P\left(p^{T-1},p^T,q^{T-1},q^T\right)\ P\left(p^T,p^0,q^T,q^0\right). \quad (65)$$

The motivation for this test is the following. Use the bilateral index formula $P(p^0, p^1, q^0, q^1)$ to calculate the change in prices going from period 0 to 1, use the same formula evaluated at the data corresponding to periods 1 and 2, $P(p^1, p^2, q^1, q^2)$, to calculate the change in prices going from period 1 to 2, …, use $P(p^{T-1}, p^T, q^{T-1}, q^T)$ to calculate the change in prices going from period $T-1$ to T, introduce an artificial period $T+1$ that has exactly the price and quantity of the initial period 0 and use $P(p^0, p^1, q^0, q^1)$ to calculate the change in prices going from period T to 0. Finally, multiply all these indexes together, and since we end up where we started the product of all of these indexes should ideally be 1. Diewert (1993a, p. 40) called this test a *multiperiod identity test*. Note that, if $T = 2$ (so that the number of periods is 3 in total), then Walsh's test reduces to Fisher's (1921, p. 534, 1922, p. 64) *time reversal test*.

Walsh (1901, pp. 423–33) showed how his circularity test could be used in order to evaluate how 'good' any bilateral index number formula was. What he did was invent artificial price and quantity data for five periods, and he added a sixth period that had the data of the first period. He then evaluated the right-hand side of (65) for various bilateral formula, $P(p^0, p^1, q^0, q^1)$, and determined how far from unity the results were. His best formulae had products that were close to 1. Fisher (1922, p. 284) later used this methodology as well.

This same framework is often used to evaluate the efficacy of chained indexes versus their direct counterparts. Thus if the right hand side of (65) turns out to be different from unity, the chained indexes are said to suffer from 'chain drift'. If a formula suffers from chain drift, it is sometimes recommended that fixed base indexes be used in place of chained ones. However, this advice, if accepted, would *always* lead to the adoption of fixed base indexes, provided that the bilateral

index formula satisfies the identity test, $P(p^0, p^0, q^0, q^0) = 1$. Thus it is not recommended that Walsh's circularity test be used to decide whether fixed base or chained indexes should be calculated. However, it is fair to use Walsh's circularity test as he originally used it, namely, as an approximate method for deciding how good a particular index number formula is. In order to decide whether to chain or use fixed base indexes, one should decide on the basis of how similar the observations being compared are, and choose the method which will best link up the most similar observations.

Robert Hill's method for linking observations can be regarded as a multilateral index number method, one which is based on a suitable bilateral formula, a measure of the similarity of any two price and quantity vectors and an algorithm for linking the observations via a path that links the most similar observations. In the following section, we review some other multilateral methods.

Multilateral Indexes

Assume that there are I positive price vectors $p^i \equiv (p_1^i, \ldots, p_N^i)$ and I quantity vectors $q^i \equiv (q_1^i, \ldots, q_N^i)$ with $p^i\, q^i > 0$ for $i = 1,\ldots,I$. We wish to find $2I$ positive numbers P^i (price indexes) and Q^i (quantity indexes) such that $PiQi = pi \cdot qi$ for $i = 1, \ldots,I$. The I data points (p^i, q^i) will typically be observations on production or consumption units that are separated spatially but yet are still comparable. For the sake of definiteness, we shall refer to the I data points as countries. Each commodity n is supposed to be the same across all countries. This can always be done by a suitable extension of the list of commodities.

Our first approach to the construction of a system of multilateral price and quantity indexes is based on the use of a bilateral quantity index Q. In this method, the first step is to pick the best bilateral index number formula, for example, the Fisher quantity index Q_F defined by (14) and (5) or the implicit Törnqvist-Theil quantity index QT defined by (22) and (5). Secondly, pick a numeraire country, say country 1, and then calculate the aggregate quantity for each country i relative to country 1 by evaluating the quantity index $Q(p^1, p^i, q^1, q^i)$. In order to put these relative quantity measures on a symmetric footing, we convert each relative to country 1 quantity measure into a share of world quantity by dividing through by $\sum_{k=1}^{I} Q(p^1, p^k, q^1, q^k)$. For a general numeraire country j, define the *share of world quantity for country i, using country j as the numeraire country*, by:

$$\sigma_i^j(p,q) \equiv Q(p^j, p^i, q^j, q^i) \Big/ \sum_{k=1}^{I} Q(p^j, p^k, q^j, q^k); \quad i = 1, \ldots, I, \tag{66}$$

where $p \equiv (p^1, \ldots, p^I)$ is the N by I matrix of price data and $q \equiv (q^1, \ldots, q^I)$ is the N by I matrix of quantity data. Once the numeraire country j has been chosen and the country i shares σ_i^j calculated, we may set $Q^i = \sigma_i^j$ and $p^i \equiv p^i \,.\, q^i/Q^i$ for $i = 1,\ldots, I$. Thus we have provided a solution to the multilateral index number problem (1). Of course, one is free to enormalize the resulting P^i and Q^i if desired: all Q^i can be multiplied by a number provided all P^i are divided by this same number. Kravis (1984) called this method the *star system*, since the numeraire country plays a starring role: all countries are compared with it and it alone.

Of course, the problem with the star system for making multilateral comparisons is its lack of invariance to the choice of the numeraire or star country. Different choices for the base country will in general give rise to different indexes P^i and Q^i. This problem can be traced to the lack of circularity of the bilateral formula Q: if Q satisfies the time reversal test and the circular test for quantity indexes, then $\sigma_i^j = \sigma_i^k$ for all i, j and k, that is, the shares σ_i^j defined by (66) do not depend on the choice of the numeraire country j. However, given that the chosen best bilateral formula does not satisfy the circularity test (as is the case with Q_F and Q_T), how can we generate multilateral indexes that treat each country symmetrically?

Fisher (1922, p. 305) recognized that the simplest way of achieving symmetry was to average base specific index numbers over all possible bases. Thus define country i's share of world output $S_i(p, q)$ by

$$S_j(p,q) \equiv \sum_{j=1}^{I} \sigma_i^j(p,q)/I, i = 1, \ldots, I \quad (67)$$

where the σ_i^j are defined by (66). We can now define country i quantities and prices by

$$Q^i \equiv S_i(p,q); P^i \equiv p^i \cdot q^i/Q^i, i = 1, \ldots, I \quad (68)$$

Fisher (1922, p. 305) called this method of constructing multilateral indexes the *blend method* while Diewert (1986) called it the *democratic weights method*, since each share of world output using each country as the base is given an equal weight in the formation of the average.

Of course, there is no need to use an arithmetic average of the σ_i^j as in (67); one can use a geometric average:

$$\sigma_i(p,q) \equiv \left[\prod_{j=1}^{I} \sigma_i^j(p,q)\right]^{1/I}, i = 1, \ldots, I. \quad (69)$$

Using (69), the resulting shares no longer sum to one in general, so country i's share of world output is now defined as:

$$S_i(p,q) \equiv \sigma_i(p,q)/\sum_{k=1}^{I} \sigma_k(p,q), i = 1, ..., I. \quad (70)$$

If the Fisher index Q_F is used in the definition of the σ_i^j, then

$$S_i(p,q)/S_j(p,q) = \left[\prod_{k=1}^{I} Q_F(p^k,p^i,q^k,q^i)/\prod_{m=1}^{I} Q_F(p^m,p^j,q^m,q^j)\right]^{1/I} \quad (71)$$

and in this case the multilateral method defined by (71) reduces to a method recommended by Gini (1924, 1931), Eltetö and Köves (1964) and Szulc (1964), the *GEKS method*. Instead of using the Fisher formula in (71), Caves et al. (1982a) advocated the use of the (direct) Törnqvist-Theil quantity index while Diewert (1986) suggested the use of the implicit translog quantity index Q_T defined by (5) when P is P_T defined by (22), since Q_T is well defined even in the case where some quantities q_n^i are negative. We call the indexes generated by (69) and (70) for a general bilateral index Q *generalized GEKS* indexes.

When forming averages of the σ_i^j as in (67) or (69), there is no necessity to use equal weights: one can define country j's value share of world output as $\beta_j \equiv p^j \cdot q^j/\sum_{k=1}^{I} p^k \cdot q^k$ (this requires all prices to be measured in units of a common currency) and then we may define a plutocratic share weighted average of the σ_i^j:

$$S_i(p,q) \equiv \sum_{j=1}^{I} \beta_j(p,q)\, \sigma_i^j(p,q). \quad (72)$$

Diewert (1986) called this method of constructing multilateral indexes the *plutocratic weights method*.

Another multilateral method that is based on a bilateral index Q may be described as follows. Define

$$\sigma_i(p,q) \equiv \sum_{j=1}^{I} \left[Q\left(p^j,p^i,q^j,q^i\right)^{-1}\right]^{-1}; \quad i = 1, \ldots, I. \quad (73)$$

If there is only one commodity so that $N = 1$ and the bilateral index Q satisfies quantity counterparts to tests T3 and T5, then $\alpha_i = \left[\sum_{j=1}^{I} (q_i/q^j)^{-1}\right]^{-1} = \left[\sum_{j=1}^{I} q^j/q^j\right]^{-1} = q^j/\sum_{j=1}^{I} q^j$ which is country i's share of world product. In the general case where $N > 1$, the 'shares' α_i do not necessarily sum up to unity, so it is necessary to normalize them:

$$S_i(p,q) \equiv \alpha_i(p,q)/\sum_{k=1}^{I} \alpha_k(p,q); \quad i = 1, \ldots, I. \quad (74)$$

Diewert (1986, 1988, 1999b) called this the *own share method* for making multilateral comparisons.

The above methods for achieving consistency and symmetry rely on averaging over various bilateral index number comparisons. Fisher (1922, p. 307) realized that symmetry could be achieved by making comparisons with an average, he called this broadening the base. Thus the *average basket method* (see Walsh 1901, p. 431; Gini 1931, p. 8; Fisher 1922, p. 307; Ruggles 1967; Diewert 1999b, pp. 24–5) may be described as follows. The price level of country I relative to country j is set equal to $p^i \cdot \left(\sum_{k=1}^{J} q^k/I\right)/p^j \cdot \left(\sum_{k=1}^{J} q^k/I\right)$. Now define $Q^{ji} \equiv [p^i \cdot q^i/p^j \cdot q^j]/[p^i \cdot (\sum_k q^k)/p^j \cdot (\sum_k q^k)]$ to be the implicit output of country i relative to j. Choose a j as a numeraire country and calculate country i's share of world output as:

$$S_i(p,q) \equiv Q^{ji} / \sum_{k=1}^{I} Q^{jk} = \left(p^i \cdot q^i / p^i \cdot \sum_k q^k\right) / \sum_{m=1}^{I} \left(p^m \cdot q^m / p^m \cdot \sum_k q^k\right); \quad i = 1, \ldots, I. \tag{75}$$

Note that the final expression for S_i does not depend on the choice of the numeraire country j. As usual, once the share functions, S_i, have been defined, the aggregate Q_i and P_i may be defined by (68).

A variation on the basket method due to Geary (1958) and Khamis (1972) is defined by (76–78) below:

$$\pi_n \equiv \sum_{i=1}^{I} p_n^i q_n^i / P^i \sum_{k=1}^{I} q_n^k, n = 1, \ldots, N; \tag{76}$$

$$p^i \equiv \sum_{n=1}^{N} p_n^i q_n^i / \sum_{m=1}^{N} \pi_m q_m^i, \; i = 1, \ldots, I; \tag{77}$$

$$Q_i \equiv p^i \cdot q^i / P^i, \; i = 1, \ldots, I. \tag{78}$$

π_n is interpreted as an average international price for good n. From (77), it can be seen that P^i, the price level or purchasing power parity for country i, is a Paasche- like price index for country i except that the base prices are chosen to be the international prices π_n. The π_n and $(P^i) - 1$ can be solved for as a system of simultaneous linear equations (up to a scalar normalization) or the $(P^i)^{-1}$ may be determined as the components of the eigenvector that corresponds to the maximal positive eigenvalue of a certain matrix. The P^i can be normalized so that the quantities Qi defined by (78) sum up to unity. This GK *method* for making multilateral comparisons has been widely used in empirical applications, for example, see Kravis et al. (1975).

We have defined seven methods for making multilateral comparisons: the star method (66), the democratic (67) and plutocratic (72) weights methods, the GEKS method (71), the own share method (74), the average basket method (75) and the GK method (78). Many additional methods have been suggested, for example, see Hill (1997), Diewert (1986, 1988, 1999b), Rao (1990), and Balk (1996). How can we discriminate among them? One helpful approach would be to define a system of *multilateral tests* and then evaluate how the above methods satisfy these tests. Space does not permit the development of this approach in this short survey, for applications of this approach, see Diewert (1988, 1999b) and Balk (1996). A clear consensus on the best multilateral method has not yet emerged.

We conclude this section by looking at a stochastic or descriptive statistics approach to making multilateral comparisons: namely, Summer's (1973) country product dummy (CPD) method for making multilateral comparisons. If there are I countries in the comparison and N products, the relationship of the prices between the various countries using the CPD model is given (approximately) by the following model:

$$p_n^c \approx \alpha_c \beta_n; \quad c = 1, \ldots, I; \quad n = 1, \ldots, N; \tag{79}$$

$$\alpha_1 = 1 \tag{80}$$

where p_n^c is the price (in domestic currency) of commodity n in country c. Quantities for each

commodity in each country are assumed to be measured in the same units. Equation 80 above is an identifying normalization, that is, we measure the price level of each country relative to the price level in country 1. Note that there are *IN* prices in the model and there are $I - 1 + N$ parameters to 'explain' these prices. Note also that the basic hypothesis that is implied by (79) is that commodity prices are approximately proportional between the two countries. Taking logarithms of both sides of (79) and adding error terms leads to the following CPD regression model:

$$\ln p_n^c = \ln \alpha_c + \ln \beta_n + \varepsilon_n^c; \quad c = 1, \ldots, I; \; n = 1, \ldots, N. \tag{81}$$

The main advantage of the CPD method for comparing prices across countries over traditional index number methods is that we can obtain *standard errors* for the country price levels $\alpha_2, \alpha_3, \ldots, \alpha_I$. This advantage of the stochastic approach to index number theory was stressed by Summers (1973) and more recently by Selvanathan and Rao (1994).

The recent literature on the CPD method notes that it is a special case of a hedonic regression model and this recent literature makes connections between weighted hedonic regressions and traditional index number formulae, see Triplett and McDonald (1977), Diewert (2003, 2005b, c, 2007b), de Haan (2004a, b), Silver (2003), and Silver and Heravi (2005).

Other Aspects of Index Number Theory

There are many important recent developments in index number theory that we cannot cover in any depth in this brief survey. Some of these developments are:

- Sampling problems and the construction of indexes at the first stage of aggregation: see Dalén (1992), Diewert (1995a), ILO (2004), and IMF (2004).
- *The treatment of seasonality*: see Turvey (1979), Balk (1980), (2005), Diewert (1983c), (1998b), (1999a), Hill (1996), Alterman et al. (1999), ILO (2004), and Armknecht and Diewert (2004).
- *The analysis of sources of bias in consumer price indexes*. This topic was greatly stimulated by the Boskin Commission Report, see Boskin et al. (1996). For additional contributions to this subject, see Diewert (1987, 1998a), Reinsdorf (1993), Schultze and Mackie (2002), Lebow and Rudd (2003), Balk and Diewert (2004), and ILO (2004).
- *Productivity indexes*. As more and more countries start programmes to measure sectoral and economy wide productivity, this topic has become more important. The original methodology for measuring productivity using index number techniques is due to Jorgenson and Griliches (1967, 1972) and it was first adopted by the U.S. Bureau of Labor Statistics (1983) and subsequently by Canada, Australia and more recently by New Zealand and Switzerland. Diewert (1976, 1983b), Caves et al. (1982b), Diewert and Morrison (1986), Kohli (1990), Morrison and Diewert (1990), Balk (1998, 2003), Schreyer (2001), Diewert and Fox (2004), Diewert and Nakamura (2003), and Diewert and Lawrence (2006) all made contributions connecting productivity measurement with index number theory.
- *Contribution analysis*. Suppose an aggregate price or quantity index shows a certain change over a certain period. Many analysts want to be able to compute the contribution of price or quantity change of specific components of the overall index and the problem of precisely defining such contributions has given rise to a fairly substantial recent literature. Contributors to this literature include Diewert (1983b, 2002a), Diewert and Morrison (1986), van IJzeren (1957, 1983, 1987), Kohli (1990, 2003, 2004, 2007), Morrison and Diewert (1990), Fox and Kohli (1998), and Reinsdorf et al. (2002).
- *Quality change*. The analysis thus far has assumed that the list of commodities in the aggregate is fixed and is unchanging and thus it is not able to deal with the problem of quality

change. For extensive discussions of this problem, see Triplett (2004) and the chapters on quality change in ILO (2004) and IMF (2004).

- *Index number theory in terms of differences rather than ratios*. Hicks (1941–42) noticed the similarities between measuring welfare change (difference measures) and index numbers of quantity change (ratio measures). The early literature on the difference approach dates back to Bennet (1920) and Montgomery (1929, 1937). More recent contributions to this subject may be found in Diewert (1992b, 2005a).

Since the mid-1980s interest in index number theory and economic measurement problems in general has increased. Perhaps influenced by Hill (1993), who in turn was influenced by Diewert (1976) and (1978), national statistical agencies are moving towards using chained superlative indexes as their target indexes: see Moulton and Seskin (1999) and Cage et al. (2003) for US developments. International agencies have also endorsed the use of superlative indexes as target indexes: see the manuals produced by the ILO (2004) and the IMF (2004). These manuals are a useful development since they help disseminate best practices and they help to harmonize statistics across countries, leading to a higher degree of accuracy and comparability. One hopes that these positive developments will continue.

Indexed Securities

Alicia H. Munnell and Joseph B. Grolnic

Conventional securities are generally offered at a fixed coupon rate that incorporates the underlying expected real rate of return in the economy, the market's expectation at the time the security is issued of inflation over the duration of the instrument, a premium to compensate for the fact that future rates of inflation are uncertain, and an adjustment reflecting the tax treatment of interest on behalf of both the lender and the borrower. For simplicity, it is useful to abstract temporarily from the inflation risk premium and taxes, although both these factors will be discussed later.

With these simplifying assumptions, if the real rate of return in the economy is 3 per cent, and inflation is expected to remain constant at 4 per cent annually, the nominal return will be 7 per cent. If expectations should prove incorrect and inflation turns out to be lower than anticipated, say 2 per cent, investors will receive more income in present value terms than they expected and experience an increase in their real rate of return, reflecting the unanticipated decline in the inflation rate. On the other hand, if inflation turns out to be 6 per cent, then investors will receive less in real terms than expected and their real return will fall below the rate initially negotiated. If they attempt to sell the security in the higher inflationary environment, they will experience a capital loss.

Index bonds are financial instruments designed to protect investors fully against the

erosion of principal and interest due to inflation. This protection is accomplished in one of two ways. Under the first option, the bond is issued at a specified real coupon rate and both coupon payment and repayment of principal are scaled up or down by the change in prices that occurs between the time that the money is borrowed and the time the payments are made. For example, if inflation is 4 per cent annually, the coupon on a five-year $1000 bond issued at a real interest rate of 3 per cent would increase from $30 in the first year to $35.10 in the fifth year. At maturity, the government then would adjust the principal for inflation over the life of the bond; thus, in the above example, the government would repay $1217 at the end of the five-year period. This approach is similar to the index bonds that have been sold in Great Britain.

Under the second approach the entire inflation adjustment is made through the coupon payment and the bondholder is repaid his original principal at maturity. For example, if the real rate is set at 3 per cent and inflation averages 4 per cent, the total annual interest cost would be 7 per cent. This approach mimics the current method of compensating the lender for inflation, except that instead of trying to predict inflation at the time of the loan and incorporating this expectation into the stated nominal interest rate, actual observations on price are used to determine annual interest payments.

Either of these two approaches will protect the investor against the risks associated with unanticipated price changes if the index bond is held to maturity; however, it is important to emphasize that neither produces a risk-free investment. As with any long-term security, bondholders selling an index bond before maturity would take a capital loss if the underlying expected real rates have increased since the date of purchase. The result is that these bonds would probably not be the ideal assets for individuals to purchase directly unless they were certain that they could hold them to maturity. For index bonds to serve as risk-free inflationprotected investments, financial intermediaries are required which will hold the bonds to maturity and offer repackaged investments free of the real-return risk.

Impact on the Government Budget

Arguments about the potential impact of index bonds on the government budget have figured prominently in debates about this form of financing and the range of opinion has been extraordinary. In Great Britain, some opponents argued that index bonds would cost the government more than fixed-interest securities to service, since they would have to be issued at positive real interest rates as opposed to the negative real returns received by investors on nominal debt during the period 1973–8 (Rutherford 1983). On the other hand, in hearings before the Joint Economic Committee in May 1985, a major proponent of index bonds projected that, because excessive inflation premiums were incorporated in current yields, the US government could save $9 billion in the first year and $135 billion over a five-year period by issuing indexed rather than conventional long-term debt (Joint Economic Committee 1985).

These conflicting statements are based on opposite assumptions about people's ability to project future inflation. The contention that index bonds will cost money assumes that individuals will continually underestimate future inflation and always end up with lower than anticipated or negative returns; the argument that the Treasury can reduce costs with indexed debt assumes individuals will consistently overestimate inflation and demand excessive inflation premiums. It is unclear why, over the long run, individuals should systematically err on one side or another in their inflation projections.

In the last 15 years, the relationship between expected and actual inflation has varied over time; during the 1970s average expectations about near-term inflation tended to prove too low, while since 1981 inflation has generally fallen one or two percentage points below projections. Although no evidence is available on investors' ability to forecast inflation over longer periods, of say 20 or 30 years, the same pattern is likely to emerge as swings in short-run expectations affect the longer-run outlook. Hence, the most reasonable conclusion is that in the long run forecasting errors will cancel out, and have little impact on the relative costs of indexed versus unindexed debt.

On the other hand, the uncertainty surrounding future rates of inflation means that investors demand an inflation-risk premium before they are willing to take on fixed-coupon debt. In this case, the guarantee of a real return provided by indexed securities, which eliminates the risk of reduced real returns and capital losses caused by unanticipated inflation, would lower the yield that lenders will require in order to provide their funds. In other words, the lender would be willing to accept a somewhat lower rate in return for the privilege of having the government guarantee the real return on the loan.

Little evidence exists about the size of the inflation risk premium (an exception is Bodie et al. 1986). As long as the outlook for price increases is moderate, the premium is probably relatively small; at higher and more volatile rates of inflation, the importance of risk protection would increase. Even if this premium proved to be quite small, however, its elimination could produce substantial savings in view of the enormous magnitude of government debt. The problem is that, in the short run at least, the risk premium effect is likely to be dominated by the difference between expected and actual real returns caused by errors in investors' expectations. Hence, for any defined period of time, it would be impossible to predict whether substituting index bonds for traditional government securities would cost or save the Treasury money. In the long run, however, if errors in inflation forecasts cancel out, index bonds should save the government the inflation-risk premium on long-term securities.

While the net interest saving to the government is difficult to predict, the pattern of government borrowing would certainly be altered if the British indexing option were adopted. Even in an environment where inflationary expectations always prove correct and the inflation premium is zero, an index bond that defers the principal adjustment for inflation until maturity reduces the Treasury's borrowing in the intervening years.

Tax Policy and Index Bonds

Uncertainty about how index bonds would be taxed has been viewed as a major impediment to their introduction. The tax questions are indeed critical, because they determine not only how index bonds would affect revenues but also who might be the likely buyers of these securities and the potential yields.

If the tax code does not distinguish between real and inflationary returns, then the most likely results would be to tax both the real component of interest and the inflation adjustment as ordinary income. This would be quite straightforward in the case of the indexing method that incorporates the inflation adjustment in the interest rate, but some complexities arise in the case of the British approach. In order to make the treatment of bonds indexed in this fashion analogous to that accorded conventional and zero-coupon bonds, the annual appreciation of principal due to inflation would have to be taxed as it accrued.

Taxing the principal adjustment as if it were received each year would make index bonds less attractive than their unindexed counterparts. Not only would owners of securities have to pay taxes on illusory gains, which they do in the case of conventional bonds, but they would also have to pay the tax before they received their inflation compensation. On the other hand, deferring the tax on the adjustment of principal until the bond is redeemed at maturity would favour the indexed over the unindexed security and result in a loss of revenue for the Treasury.

The second problem with applying current tax law to index bonds is that it would no longer be possible to guarantee a constant real after-tax rate of return. Under the current system, taxes would rise with inflation and the real after-tax return would decline. For example, if the tax rate were 30 per cent, the real return on a bond with a 3 per cent coupon would be 2.1 per cent in an environment of no inflation. If inflation should rise to 4 per cent and the nominal coupon rises to only 7 per cent, the after-tax yield is 4.9 per cent or 0.9 per cent real. The only way to avoid this problem is to exempt the nominal adjustments for inflation from taxation. This approach, however, would introduce a type of inflation indexing not found elsewhere in the tax system.

Private Issues of Index Bonds

Some sceptics charge that if index bonds were such a great idea, they would have been offered by the private sector. Indeed, theoretical work by Stanley Fischer leads to the conclusion that firms should be equally willing to issue index bonds as conventional nominal bonds (Fischer 1982). Fischer offers two possible reasons for the lack of the private sector innovation: the relatively stable rates of inflation traditionally experienced in the United States and the possibility that borrowers' expectations about inflation have been systematically higher than those of lenders. Others contend that the issuance of index-linked debt may actually have been illegal in the United States until 1977 (McCulloch 1980). Another problem is that an aggregate price index may not correlate with prices received by an individual firm. The most persuasive reason, however, relates to the lack of indexation in the corporate income tax, which causes the effective tax rate to increase with inflation. If firms were to issue index bonds, this inverse relation between inflation and profitability would worsen, since corporations would forfeit the mitigating effect of the decline in the value of outstanding liabilities as inflation increased. Hence, the non-issuance of index bonds by the corporate sector may be one of the major casualties of an unindexed tax structure.

The only serious objection ever levelled against index bonds is that protecting bondholders from inflation might reduce public pressure to maintain price stability. If part of the pain of inflation is removed, this reasoning goes, the public's resolve to control inflation will weaken, and inflation will ultimately get worse. On the other hand, one could argue in economic terms that index bonds might help in the fight against inflation by providing an attractive investment vehicle that would encourage saving and, as argued by Tobin, by offering the monetary authorities a tool that would strengthen their control of the economy (Tobin 1971). In political terms, it would seem that the issuance of index bonds would eliminate one of the main incentives for the government to inflate the economy. With indexed debt the government can no longer reduce the real value of its outstanding liabilities by allowing prices to rise; instead, inflation will produce an immediate increase in required expenditures. Finally, index bonds do not appear to have encouraged inflation in Great Britain; the inflation rate has declined from 15 to 5 per cent since 1981, the year the bonds were introduced.

India, Economics in

Deepak Lal

Abstract

This article outlines the debates amongst Indian economists on planning, transforming agriculture, poverty and income distribution, and political economy and institutions. It

shows that much of this work pioneered many analyses which have come to define the sub-discipline of 'development economics'.

Economics in India has been mainly concerned with finding means to alleviate its ancient and pervasive poverty. In this article I will concentrate on the debates amongst Indian economists, highlighting the contributions they have made in the process to the new discipline of 'development economics'.

The Indian economic debate began in the early twentieth century when after nearly a century of British colonial rule there were few signs of poverty alleviation, with only a modest rise in per capita income over the period (Sivasubramonian 2000). A nationalist and Marxist literature evolved, which laid the blame for this economic stagnation on alien rule and the implementation – since the 1850s – of the twin classical liberal principles (dominant in the metropolitan centre) of laissez-faire and 'free trade'. Alien rule was epitomized by the fiscal drain of resources from India to Britain (Naoroji 1901; Dutt 1904). Free trade was held responsible for India's failure to industrialize and the destruction of its extensive pre-colonial handloom textile industry.

By the 1930s, the Great Depression and Stalinist Russia's success in rapidly industrializing a large, poor and mainly agrarian economy coloured the thinking of Indian economists and political leaders like Nehru. A series of economic plans were drawn up by various groups and individuals, including the National Planning Committee of the Indian National Congress (Visveswarya 1934; Nehru 1946; Banerjee et al. 1944; Thakurdas et al. 1944; Agarwal 1960), that anticipated most post-war debates and ideas on development objectives, strategy and policy in academia and international organizations. The plans saw poverty alleviation as the basic development objective, outlined a 'basic needs' strategy and covered 'redistribution with growth', the development of agriculture versus industry, heavy industry-based industrialization and import substitution, the respective roles of large- and small-scale industries and of the state versus the market (see Srinivasan 2001).

The Rise and Fall of the Planning Syndrome

With the setting up of the Planning Commission in the 1950s India embarked on a public sector dominated by heavy industry and an import-substituting industrialization strategy as the answer to alleviate its ancient poverty. Professor P.C. Mahalanobis (1953, 1955), a distinguished statistician and the father of Indian planning, provided its rationale in a formal model, taken largely from the model that the Soviet economist Fel'dman had developed for Stalin's industrialization strategy. This showed that, with a binding foreign exchange constraint (which, on the basis of the export pessimism generated by the experience of the Great Depression, was assumed to confront India) independent of a savings

constraint to limit the growth rate of the economy, a higher sustainable development path could be attained by using limited foreign exchange to import (and so support the industrial structure vertically) machines to make machines, until India was producing everything she needed, except for the raw materials that could not be obtained domestically (see Bhagwati and Chakravarty 1969; Lal 1972a).

The Perspective Planning Division of the Planning Commission, headed by its intellectually curious and energetic head, Pitamber Pant, and the branch of Mahalanobis' Indian Statistical Institute (ISI) attached to it, then became the centre of intense intellectual debate. In the 1960s it employed a growing number of Indian economists trained in Western universities (Bhagwati, Bardhan, Minhas, Parikh, Srinivasan, Tendulkar among others), and in association with a programme set up by Rosenstein Rodan at Massachusetts Institute of Technology (MIT) became host to a galaxy of foreign economists (Swan, Reddaway, Lewis, Little and Harberger). The Delhi School of Economics, under the leadership of K.N. Raj, engaged Chakravarty and Sen, and at the Finance Ministry I.G. Patel invigorated the newly established Indian Economic Service by engaging V.K. Ramaswami and Manmohan Singh as economic advisors. Meanwhile, the USAID mission was headed by J.P. Lewis, and the number of foreign economists visiting and participating in the economic debates of the time expanded to include Milton Friedman and Peter Bauer.

The Mahalanobis model was to form the analytical basis for India's second Five Year Plan. The Planning Commission had convened a panel of economists to discuss its framework, and most of them endorsed the broad objectives and strategy of the plan. The only dissenting voice was that of B.R. Shenoy, who questioned, amongst other issues, the massive deficit financing on which the plan depended. In this he was supported by two of the visiting foreign economists, Peter Bauer and Milton Friedman. Whilst Komiya (1959) and Bronfrenbrenner (1960) provided explicit critiques of the Mahalanobis model. But most of these criticisms were disregarded by the prevailing intellectual consensus in favour of dirigiste, state-led planning, though the technocratic basis of the planning models on which it was based was increasingly questioned by Indian economists (see Rudra 1975).

With the emergence of what J.P. Lewis (1963) accurately described as a 'quiet crisis' in India, engendered by the foreign exchange crisis caused by the fiscal expansion the dissenters had predicted (which had led to draconian foreign tradecum- exchange and price controls), new voices arose in the 1960s providing the intellectual basis for the subsequent neoclassical resurgence in development economics. Developing ideas presaged in the writings of James Meade and Harry Johnson, two Indian economists, Jagdish Bhagwati (who was at the ISI) and V.K. Ramaswami, economic advisor at the Ministry of Finance, produced a path-breaking paper that began the process of separating the case for free trade from that for laissez-faire (Bhagwati and Ramaswami 1963). In a series of papers with T.N. Srinivasan (also at the ISI), they established the modern theory of trade and welfare which shows that most of the arguments for protection are second best as they depend upon 'domestic distortions' in the working of the price mechanism, which are best dealt with by direct domestic taxes and subsidies rather than the indirect method of protection.

Two major books, by Bhagwati and Desai (1970) and Bhagwati and Srinivasan (1975), written as part of two large-scale multi-country comparative studies of trade and industrialization directed by I.M.D. Little, T. Scitovsky and M. Fg. Scott for the Organization for Economic Cooperation and Development (OECD), and by J. Bhagwati and A. Krueger for the National Bureau of Economic Research (NBER), provided a detailed empirical analysis of the relevance of this newly developed theory, besides documenting the immense inefficiency and corruption that the dirigiste planning system had engendered. This marked the beginning of the end of the planning syndrome that had held Indian economists in thrall for nearly a century. Furthering this disenchantment was the disappointing performance of Indian industry where the net

effect of the control system was shown to be a capital-intensive bias and low or negative growth of total factor productivity in post-Independence industrial performance (I.J. Ahluwalia 1985).

Moreover, Manmohan Singh (1964), in a detailed study of Indian exports, had shown that the export pessimism underlying the assumption of a foreign-exchange constraint in the Mahalanobis model was unjustified, as it was not lack of external demand but the consequences of India's domestic economic policies that had led to the disappointing Indian export performance.

Nor was the panacea offered by the Gandhians – which was promulgated with reservations for various small-scale industries (particularly cotton textiles) on the grounds that they promoted employment growth – found to be valid. Dhar and Lydall (1961) in an empirical study of these industries showed that these smallscale industries were technically inefficient than their larger modern brethren because they used both more labour and capital per unit of output produced.

The planners' belief that the public sector, given monopoly production rights in the 'commanding heights' of the economy, would be dynamic and through rising profits augment domestic savings was discredited. Numerous official empirical studies documented the growing inefficiency of the public sector and its growing drain on the nation's savings. As part of the debate on their reform which came to the fore in the 1970s, two major manuals of project evaluation were developed to improve the efficiency of the public sector. One was produced for the UN's Industrial Development Organization by P. Dasgupta, A.K. Sen and S. Marglin the other for the OECD by I.M.D. Little and J.A. Mirrlees. With the implicit adoption of the latter by a newly set up Project Appraisal Division in the Planning Commission, Lal (1980) produced the first comprehensive set of 'shadow prices' based on the 'world price rule' for use in the evaluation of public projects in India. But the social cost–benefit analysis they were meant to support soon descended into social cosmetic analysis, as politicians continued to choose and run public projects for rent-seeking reasons rather than social profitability. It was not until the fiscal-cum-foreign exchange crisis of 1991 that planning, and the system of controls on industry and foreign trade it had engendered, finally came to a *de facto* if not *de jure* end. The market increasingly came to replace the plan, and a programme of privatization was slowly and fitfully begun.

Transforming Agriculture

An implicit assumption of the Mahalanobis framework was that agriculture could be left alone, merely being a source of 'surplus labour' and of the limited savings and foreign exchange for the heavy industrialization strategy. By the mid-1960s this neglect had led to a severe food crisis. The transformation of agriculture, which until then had been seen largely as a means of promoting equity through land reforms, then became a matter of debate.

Nationalist and Marxist literature in India, basing itself on the perceived outcomes of the laissez-faire period of colonial rule, had maintained that the commercialization of agriculture through the creation, definition and enforcement of saleable and mortgageable land rights, and the integration of the internal economy through the railways had led to an increased concentration of land, the proletarianization of the peasantry and the growth of landless labour and a shift to cash crops from foodgrains, which in turn had led to famine. Subsequent research (summarized in Kumar and Desai 1983, and Lal 1988), has questioned the empirical bases of these beliefs, whilst Sen (1981a) has argued that the periodic famines that have blighted the subcontinent over the millennia were not due to a shortage of food but to 'exchange entitlement failures'. Whenever the monsoon failed there was a drastic fall in the demand for landless labour and thence wages, leading to a reduction in 'exchange entitlement' in terms of food, which in extremity would lead to a famine. The British had already realized this at the end of the nineteenth century, when they set up a famine code whereby, when the rains failed, local District Commissioners were empowered to fund food-for-work public works to provide

the necessary exchange entitlements. As a result, apart from the 1944 famine in Bengal, which was caused by disruptive wartime conditions, India did not see serious famines in the twentieth century.

One of the implicit assumptions underlying the neglect of agriculture in the early plans was that peasants were not subject to economic incentives. Detailed empirical studies by Dharm Narain (1965) and Raj Krishna (1963) of peasant response to the changing relative prices of crops shows that they behaved like *homo economicus* by shifting cropping patterns to crops with higher expected relative prices.

A second tenet (following the famous Arthur Lewis model of a dual economy) was the existence of vast pools of 'surplus labour' in agriculture which could be removed for industrialization without affecting agricultural output. Mehra (1966) provided empirical content by using farm management studies to estimate the surplus labour time available in various states in India. But these and other studies estimating surplus labour did not take account of the wage at which people are willing to work, or the leisure–income choice facing rural workers. They assumed that they would continue to work for an unchanged wage up to a normal number of working hours per day. But, as Sen (1966) showed, even in an overpopulated country, 'surplus labour' – in the sense of a perfectly elastic supply of labour at a constant wage – would imply that leisure was an inferior good. Empirical studies estimating wage elasticities for rural labour in India soon showed that this assumption was invalid (Bardhan 1979, 1984a; Binswanger and Rosenzweig 1984; Lal 1989).

The means to transform Indian agriculture have not changed since the 1893 report by J. Volcker (1893), consultant chemist to the Royal Agricultural Society. His remedies were: irrigation, fertilizers, better seeds and improvements in land tenure. This has been the conventional wisdom on raising Indian agricultural productivity ever since.

An empirical finding from the Indian farm management studies that there was an inverse relationship between the size of farm and productivity per hectare (Sen 1975, Appendix C) was used to argue for land reforms that would break up large farms and create small, family-labour based and family-owned peasant farms, which would promote both equity and efficiency (Rudra and Sen 1980). However, Bhalla and Roy (1988) showed that, once appropriate adjustments were made for differences in land quality, the inverse relationship between farm size and productivity disappears. This undermined the case for land reform in India.

Lal (1988, 2005, 2006) argued that the Malthusian view that population pressure would lead to a stagnation of rural and industrial wages was invalid, as the alternative Boserupian perspective (Boserup 1965) provided a better description of the changing fortunes of Indian agriculture. Boserup argued that population pressure both induces and facilitates the adoption of more intensive forms of agriculture. She identifies the differing input-per-hectare requirements of different agrarian systems by the frequency with which a particular piece of land is cropped. Thus settled agriculture is more labour- and capital- intensive than nomadic pastoralism, which is in turn more intensive in these inputs than hunting and gathering or the slash-andburn agriculture practised until recently in parts of Africa and the tribal regions of India. Contrary to Malthusian presumptions, population growth leads to the adoption of more advanced techniques that raise yield per acre. Because these new techniques require increased labour effort, they will not be adopted until rising population reduces the per capita food output that can be produced with existing techniques and forces a change. Lal marshals empirical evidence to show that Indian agriculture's long trajectory fits this Boserupian framework, with the population expansion beginning from the early 1900s leading in the post-Independence period to an intensification of agriculture, and with the availability of the new high-yielding varieties (HYV) of seeds, to the Green Revolution in the late 1960s and 1970s.

Many of those adhering to the Marxist canon believed and hoped that the bulk of the income

gains arising from the massive increases in output brought about by the Green Revolution would accrue to landowners, and that rural real wages would stagnate, leading to the revolution turning red. But the evidence showed that with the massive shift in the labour-demand curve that resulted from the new technology there was a marked rise in rural real wages (Ahluwalia 1978; Lal 1976, 1989).

As the new HYV technology required an assured water supply along with high dosages of fertilizers, Volcker's other major means of transforming Indian agriculture, namely irrigation, came to the fore. Surface irrigation was expanded during the Raj (the period of British rule in India), particularly in the drier regions where the marginal social returns from irrigation were likely to be the highest. But these schemes were devised by engineers and their direct and indirect economic effects were not estimated, leading in many cases to long-term losses through salination, waterlogging and the creation of malarial swamps (see Whitcombe 1971). In the 1970s two studies of irrigation – of a major surface water scheme, the Bhakra dam, by Minhas et al. (1972) and of groundwater (well) irrigation in the Deccan plateau by Lal (1972b) – provided economic analyses of irrigation and their optimal design.

One of the deleterious effects of the system of protection set up during the Permit Raj was the heavy implicit tax on agriculture. From 1965 efforts were made to correct this by price supports to farmers, which led to an improvement in the terms of trade. But this changed again in the 1980s with growing but inefficient input subsidies becoming the main form of supporting agriculture. With the post- 1991 liberalization of trade largely affecting industrial products, part of the bias against agriculture was removed. The debate then moved to removing the remaining agricultural protection (particularly for cereals), with proponents (Gulati 1998) arguing for domestic prices of agricultural products to be aligned with world prices to allow agriculture to develop in line with its revealed comparative advantage, and opponents (Patnaik 1996) arguing against, on grounds of food security.

Poverty and Income Distribution

A continuing debate concerns the effects on income distribution and poverty of rapid capitalist growth. Indian economists have been in the forefront in both setting out the conceptual basis as well as the measurement of poverty (see Sen 1976, 1981a, b; Dandekar and Rath 1971; Bardhan and Srinivasan 1974; Srinivasan 1983). The internationally adopted headcount ratio (HCR) of the poor below a nutritionally based poverty line of 15 rupees per capita (at 1960–1961 prices) was based on this efflorescence of research in the 1970s (but see Sukhatme 1978; Srinivasan and Bardhan 1988). The continuing debate has centred on whether rapid (capitalist) growth would alleviate poverty without adverse effects on income distribution, or whether more direct methods of redistribution would be needed to alleviate poverty and prevent any worsening of income distribution. A summary of the evidence from these numerous studies based on two large national surveys undertaken by the official National Sample Survey and those undertaken by the unofficial National Council of Applied Economic Research (NCAER) is provided in Lal et al. (2001a, b). There seems to be no clear trend in the Gini coefficient during the 50 years since Independence in 1947, whilst the fluctuating HCR for poverty shows no marked change until the acceleration of the growth rate after the economic liberalization of the 1990s, since when there has been a fall of varying magnitudes, depending upon which study one trusts.

The nationalist-cum-Marxist School unsurprisingly has argued that 'trickle down' would not alleviate poverty. Given the abysmally poor growth record during the planning period, which was characterized as the Hindu rate of growth (of about 1.5% a year in per capita income from the 1950s to early 1980s) it would six have been surprising if there had been any marked alleviation of India's mass structural poverty. Nevertheless, influential voices on the Left articulated a critique of the capitalist growth process. This critique, purportedly supported by Indian data, was soon shown to be false. Thus it was argued that the

alleviation of poverty and equitable growth within the 'existing institutional framework' would not occur because of an increased concentration of land (Raj 1976; refuted by Sanyal 1977a, b); the increasing proletarianization of the countryside (Raj 1976; refuted by Visaria 1977); increasing rural indebtedness and usury (disputed by Ghatak 1976); a continual improvement in the agricultural terms of trade which damaged industrial development (Bagchi 1970; Chakravarty 1974; Sau 1981; Vaidyanathan 1977; and Mitra 1977), which were critiqued by Desai (1981); and the inimical effects of foreign investment (Sau 1981) which is countered in Lal et al. (1975). These are now seen as shibboleths, particularly after the death of the countries of 'really existing socialism' and the economic liberalizations of the 1990s. The intemperate debate this provoked between the left-wing radicals and neoclassical liberalizers showed up the ideological nature of this debate, with Rudra (1991) stating: 'I put my ideological cards on the table. I hate capitalism', and Srinivasan (1992) rightly responding: 'In Rudra's value system competition, without which the market economy cannot efficiently function, is an instrument with a negative value connotation. In this he would be in the good company of monopolists and oligopolists and state capitalists of the world who would also dearly love to eliminate competition!'

While growth is being increasingly accepted as necessary for the sustainable alleviation of mass structural poverty (see Tendulkar 1998), Lal and Myint (1996) argue that two other forms of poverty, destitution and conjunctural poverty, require income transfers, though not necessarily public ones. Though Dasgupta (1993) claims to be about destitution, it is more about mass structural poverty and income distribution (Srinivasan 1994). The only study of destitution (Lipton 1983) based on village studies found no obvious correlates to identify an extremely heterogenous group. Thus Dasgupta's reasonable assertion that widows become destitute was belied by the evidence in Drèze and Srinivasan (1995).

Public policy has thus sought to deal with the third triad of poverty, conjunctural poverty, which is largely associated with climatic variations through a continuation of the Raj's famine code to prevent famine and by rural employment guarantee schemes to offset seasonal unemployment by offering jobs on public works at a wage only the needy will accept, which because of self-targeting have been shown to be efficacious (Ravallion 1991).

The major advocate of the direct route for poverty alleviation (where the three categories distinguished above are amalgamated) remains Sen (1981a, b), whose earlier empirical evidence on the superiority of this route in low-growth economies (Sri Lanka) and regions (Kerala in India) was questioned by Bhalla and Glewwe (1986). The debates in Drèze and Sen (1989) concentrate on the public provision of food for the malnourished and the merit goods of health and education. But empirical studies of the nearly 50-year-old public programmes to deal with these aspects do not provide much hope for success (Parikh 1993; World Bank 2000; PROBE Team 1999). Similarly, the dismal state of publicly owned and operated infrastructure (Ahluwalia 1998; Ahluwalia and Little 1998) has led to a search for decentralized private solutions to provide these 'public goods' with public funding (Mitra 2006; Bardhan and Mookherjee 2006).

Political Economy and Institutions

With the growing corruption engendered by the Permit Raj, there have been attempts to measure what Krueger (1974) has designated as the 'rent-seeking society'. Her attempts at measuring the rents created by the Permit Raj in India has been supplemented by other studies (see Acharya 1985; Mohammad and Whalley 1984), whilst her rent-seeking model has been expanded by Bhagwati and Srinivasan to encompass a whole host of what they term 'directly unproductive activities' (Bhagwati and Srinivasan 1980).

A large political economy literature has arisen to explain the economic outcomes in India's democratic polity. Much of this has a Marxist lineage (Raj 1973; Jha 1980; Bardhan 1984b). Lal (1984, 1988, 2005) on the other hand has developed a model of 'the predatory state' which maximizes

net revenue and has argued that the successive empires in north India were predatory states that fell when they attempted to extract more than the natural 'rent' the economic system could provide. Lal (1987) and Lal and Myint (1996) also provide a theory which seeks to explain the role of crises in generating economic reforms in previously repressed economies. This is borne out by the liberalization undertaken in the face of a serious fiscal, foreign exchange and inflationary crisis in 1991 caused by the cumulative effects of the dirigisme of the Permit Raj.

There have also been attempts to explain various institutions that have shaped economic outcomes: the caste system (Lal 1988, 2005) as a means of tying scarce labour down to abundant land, and a theory of interrelated factor markets which seeks to explain seemingly inefficient institutions like sharecropping, attached labour, and usurious interest rates as second-best adaptations to problems of risk and the uncertainty to which tropical agriculture is subject (Bardhan 1980; Bardhan and Rudra 1978; Srinivasan et al. 1997; Basu 1983).

The Macroeconomy

Post-Independence India followed an orthodox monetary policy based on the system of fiscal and monetary accounting left by the Raj. In the 1980s, however, in order to push up the growth rate it began to undertake risky macroeconomic policies, and, with the crisis of 1991, macroeconomic issues came to the fore. The best account of India's macroeconomy since Independence was provided by Joshi and Little (1994), whilst Bhagwati and Srinivasan (1993) and Virmani (2001) provide analyses of the genesis of the crises and the lineaments of the partial and still incomplete economic liberalization that occurred in the wake of the crisis.

With the opening of the economy and (by the standards of the planning era) large inflows of foreign capital, India faced the prospect of Dutch disease – with a rise in the real exchange rate reducing the profitability of tradable relative to nontraded goods. The authorities responded by sterilizing these inflows and building up large foreign-exchange reserves, thus stalling an appreciation of the nominal exchange rate, to maintain the competitiveness of Indian exports (which, after their post-Independence stagnation, in the 1990s began to take off with the gradual integration of India into the world economy). Because of the continuing large fiscal deficits, particularly of the states in the Indian federation (Lal et al. 2001a, b), the government was also reluctant to open the capital account for fear of these deficits spilling over and causing another foreign debt crisis. A lively debate began in the early part of the twenty-first century on the correct monetary and exchange-rate policy for India to follow in the light of the continuing build-up in foreign exchange reserves. Lal et al. (2003) argued for liberalizing the capital account and floating the rupee. Joshi and S. Sanyal (2004) demurred, arguing for capital account controls and a managed exchange rate, largely on grounds of exchange-rate protection. The debate is still ongoing as of 2007, and the government has reconstituted an official committee which in the late 1990s had cautioned on opening the capital account.

The economic debates in India have thus moved on to what are no longer distinctively Indian issues, and local contributions are now less likely to be groundbreaking or to deal uniquely with issues in the current debates on development in the subcontinent.

Indian Economic Development

Arvind Panagariya

Abstract

Four or arguably five phases can be identified in India's post-independence economic experience. The first phase in which institutions were put in place and policies were relatively liberal saw moderate growth, but this was stifled by command and control policies in the second phase. More recent liberalization has seen renewed increased in the growth levels, and it is argued that this should continue beyond the 2008–9 economic crisis. However manufacturing, especially labour-intensive sectors, continue to grow slowly, growth is heavily reliant on the service sector, and a disproportionately large workforce remains engaged in inefficient agricultural production.

Post-independence India is one of the most fascinating case studies in economic development. During the six decades since independence in 1947, it has experimented with a diverse set of economic policies within a parliamentary democracy and an institutional framework that has remained unchanged except in details to accommodate the policy changes undertaken. Panagariya (2008), on which this article draws heavily, offers a comprehensive discussion of the twists and turns of the policy and the accompanying ups and downs in the economy.

Four Phases of Growth

India became independent in 1947 and formally launched its economic development programme

in the financial year 1951–2. (Data on India usually relate to its fiscal year, which begins on 1 April and ends on 31 March. Therefore, 1951–2 refers to the period from 1 April 1951 to 31 March 1952.) From the beginning, the overarching objective of the government was the eradication of poverty. Rapid growth was seen as a means to achieving that objective, although it was sometimes stated as an objective in itself in view of the close link between it and poverty alleviation, which Indian analysts in the government saw at an early stage.

The overall economic performance and its link to policies during the six decades are best explained by dividing the period between 1951–52 and 2007–08 into four distinct phases. (Throughout, a period such as 1951–65 refers to the years from 1951–2 to 1964–5 with end-point years included.)

- Phase I (1951–65) with an average annual growth rate of 4.1 per cent.
- Phase II (1965–81) with an average annual growth rate of 3.2 per cent.
- Phase III (1981–8) with an average annual growth rate of 4.6 per cent.
- Phase IV (1988–2008) with an average annual growth rate of 6.6 per cent.

Phase IV can be further subdivided into 15 years spanning 1988–2003 and five years spanning 2003–08, with average annual growth rates of 5.8 and 8.8 per cent respectively.

Phase I (1951–65): Take-Off Under a Liberal Regime

The preservation of India's independence was one of the foremost goals of Pundit Jawaharlal Nehru, the first prime minister of India. He also saw economic independence from the world markets as essential for preserving political independence. While this thinking did not necessarily imply a protectionist import policy, it did required progressive realignment of the production basket with the consumption basket so as to eliminate the need for trade. In Nehru's own words, 'The objective for the country as a whole was the attainment, as far as possible, of national self-sufficiency. International trade was certainly not excluded, but we were anxious to avoid being drawn into the whirlpool of economic imperialism' (1946, p. 403). Nehru reasoned that since private entrepreneurs lacked resources to invest in machinery, metals and other heavy industry, the public sector had to play an active role in these sectors. In addition, he considered it necessary to direct larger privatesector enterprises through investment licensing towards sectors of greater social value than just private profitability. The experience of the Soviet Union, considered a success at the time, also led Nehru to adopt a similar system of planning, with the First Five Year Plan launched in 1951–2.

Although the public sector entered manufacturing activity as a major player in heavy industry, and investment licensing was put in place for enterprises investing 10 million rupees or more, the policy regime remained relatively liberal during the 1950s. Applicants obtained licences with relative ease, with few of them complaining during this period. Import licensing had existed since the Second World War but imports were permitted relatively freely, with significant quantities of foreign consumer goods entering the country. Nehru resisted the demands by the left parties for the nationalization of foreign companies, and maintained a liberal foreign investment policy throughout his rule.

This period also saw the major institutions of the country put in place or revamped. A democratic constitution with parliamentary form of government came into force. Bureaucracy took shape, with officers and employees placed at various levels of administration. The police force was expanded. Schools, colleges and universities multiplied, with the government itself becoming a major employer of scientists and researchers.

A major turning point during this period came in 1958 when, reacting to a foreign exchange shortage, the Finance Ministry adopted centralized foreign exchange budgeting. Under this system the ministry estimated the available foreign exchange for each forthcoming six-month period and allocated it administratively across various claimants. This single policy change considerably tightened not only the import policy but also investment licensing: unless foreign exchange was available for imports of machinery and raw material, a

licence could not be issued. By the mid-1960s, the impact of tightening came to be widely recognized, as was reflected in the large number of government committees that were set up to suggest ways in which the licensing procedures could be improved to eliminate the delays.

With relatively free foreign investment and import policy during the 1950s, an expansionary fiscal policy in the early to mid-1960s, rising savings rates, increased population growth and an overall policy regime geared to the national economic interest, India was able to accelerate its growth rate from less than one per cent during the first half of the 20th century to 4.1 per cent during this phase. This was a source of some satisfaction. Nevertheless, as Maddison (1971) rightly notes, when we consider that much of the rest of the world had grown more rapidly during this period, 'India's post-war performance is well below the average for the developing countries.' After systematic examination, Maddison concluded that India had performed below its potential.

Phase II (1965–81): Socialism Triumphs

Nehru died in 1964 and was succeeded by Lal Bahadur Shastri as prime minister. Shastri did not share Nehru's enthusiasm for heavy industry and was keener on agriculture. Although he passed away within 19 months of assuming the reins, he laid down the foundation of the Green Revolution, perhaps the most important achievement of Phase II.

Indira Gandhi, Nehru's daughter, succeeded Shastri. Political compulsions led her to adopt policies that were highly detrimental to growth and poverty alleviation. Her major policy initiatives included:

- nationalization of the major banks, insurance companies, oil companies and mines
- reservation of the most labour-intensive products for exclusive production by small-scale enterprises (SSE), defined as enterprises with approximately $100,000 or less in assets
- a ban on large firms and business houses, defined as entities with approximately $27 million in investment, investing outside a list of 19 core industries, all of them highly capital intensive
- a 40 per cent ceiling on foreign investment in any firm, with a small number of exceptions
- expansion of price and distribution controls which had been introduced in Phase I
- progressively tighter control on imports through licensing
- a virtual ban on the termination of workers under any circumstances in firms with 300 (later revised to 100) or more workers
- a virtual ban on the acquisition and retention of urban land beyond a tight ceiling varying from 500 square metres (in major cities) to 2,000 square metres.

In effect, these command and control policies, reinforced by a series of external shocks (two wars with Pakistan, two episodes of back-to-back droughts and two oil price shocks) resulted in the growth rate plummeting to an average 3.2 per cent in Phase II, from 4.1 per cent in Phase I. Some observers like to attribute the decline in the growth rate entirely to external shocks, but the importance of policies cannot be underestimated. For one thing, the world economy had grown rapidly from 1965 to 1975, when industrial growth in India fell to just 3.3 per cent from more than six per cent from 1951 to 1964. More importantly, the economy of the South Korea, which adopted an aggressively outward-oriented policy regime beginning in the early 1960s and had none of the command and control machinery of India, shot up like a meteor. It annually grew by 9.5 per cent from1963 to 1973 and by 7.2 per cent from 1974 to 1982.

Phase III (1981–8): Liberalization by Stealth

By 1975, Mrs Gandhi had pushed the command and control policies as far as she could. With industrial growth plummeting and industrialists complaining about unused capacity because of the unavailability of raw materials, or unsatisfied demand because of an inability to expand beyond licensed capacity, pressures began to build up to backtrack. Because no one was willing openly to admit that the system had gone too far, the response was gradual, quiet and within the existing policy framework as if by stealth.

The piecemeal liberalization took place in three phases spanning 1975–9, 1979–84 and 1985–9, with each successive phase being more significant than the preceding one. Measures in the first two phases involved some liberalization of imports by exempting selected products from licensing requirements, allowance for capacity expansion, investment delicensing of selected industries, an increase in the investment level below which a licence was not required, expansion of the list of products in which large firms and big business houses were allowed to invest, and broad-bending of licensed capacity, whereby existing capacity could be used to produce products related to those initially authorized. The last phase, implemented under prime minister Rajiv Gandhi, who succeeded his mother after the latter's Sikh guards had assassinated her in October 1984, went further. In addition to measures similar to those just listed, it included significant measures to promote exports, substantial depreciation of the rupee, tax reform and an end to price and distribution controls on a selected set of important commodities. These reforms, accompanied by an expansionary fiscal policy, returned India to more or less the growth rate it had achieved in Phase I.

Phase IV (1988–2008): The Triumph of Reforms

The last three years of the 1980s saw the growth rate accelerate to 7.2 per cent. This acceleration was achieved partly through expansionary fiscal policy. Fiscal deficits, foreign borrowing, external debt-to-GDP ratio and debt–service ratio (interest and principal payments on external debt as a proportion of export earnings) particularly deteriorated in the second half of the 1980s. For example, the debt–service ratio shot up from 18 per cent in 1984–5 to 27 per cent in 1989–90. The hike in the oil price in the wake of the first Iraq war administered the final blow to a deteriorating balance of payments situation. A balance of payments crisis ensued, paving the way for systematic and systemic reforms this time around.

A Tamil terrorist assassinated Rajiv Gandhi while he was campaigning for the 1991 parliamentary elections. This brought prime minister Narasimha Rao to the helm. Taking advantage of the crisis, Rao decided to set India's house in order. He appointed a technocrat, Dr Manmohan Singh, as his finance minister and provided him with the necessary political support to carry out systematic reforms. In one stroke, the new government abolished import licensing on capital goods and raw materials, ended investment licensing on all but a handful of products and initiated the process of opening the country to foreign investors. The highest industrial tariff rate, which was 355 per cent in 1990–1, was steadily brought down, reaching 50 per cent in 1995–6. The government also took steps to reduce the degree of financial repression, open telecommunications to the private sector and grant entry to private carriers in the airline industry.

The Rao government undertook its most significant reforms in the first three years of its tenure. After that, the reforms became piecemeal once again until the National Democratic Alliance (NDA) was given a clear mandate for five years in 1999. Rao lost his mandate in the 1996 elections and was followed by three fragile coalition governments in as many years.

Finally in 1999, under its determined leader Atal Bihari Vajpayee as prime minister, the NDA government returned to systematic reforms. This second wave of reforms, like the first one during the first three years of the Rao government, touched virtually all sectors of the economy except perhaps labour markets. Trade liberalization was accelerated, doors to foreign investors were opened wider in almost all sectors, genuine privatization of public sector enterprises was introduced, interest rates were liberalized, the insurance sector was opened to the private sector with foreign participation permitted, a key reform of the electricity system was introduced, and above all, a major reform of the telecommunications sector through the New Telecom Policy (1999) revolutionized the communications landscape of India. In my view, while the Rao reforms placed India firmly on the six per cent growth path, the Vajpayee reforms paved the way to the current eight to nine per cent growth.

In a surprise result the NDA government lost the 2004 election, paving the way for the current United Progressive Alliance (UPA) led by the Congress Party. Although Dr Manmohan Singh came to the helm as prime minister raising hopes for continued reforms, internal tensions and opposition from the left parties, which provided critical balancing votes for the survival of the government, held the government's hand back. Indeed, sadly, the government has performed quite poorly, failing to implement policies effectively even in areas of agreement. For instance, from the beginning, the UPA had singled out infrastructure building as its top priority. Yet it ended up considerably slowing down the progress in such critical areas as road building and electricity, where the NDA government had built up substantial momentum. And of course in the critical area of labour regulation, the government pre-committed itself to not undertaking reforms. Even in international trade, a largely non-controversial area, liberalization has come to a standstill.

Has India Moved into Phase V?

A plausible case can be made that starting in 2003–04, India has entered a new phase. Growth during the five-year period spanning 2003–08 averaged 8.8 per cent. This is a full three percentage points higher than the 5.8 per cent rate achieved from 1988–89 to 2002–03. As we shall see below, the economic transformation during the last five years has been unprecedented.

Sceptics argue that the current acceleration is a temporary aberration from the steady-state growth of six per cent. The likely decline in the growth rate in the financial year 2008–09, almost entirely as a result of the global economic crisis, has strengthened this argument. Yet my own view is that over the longer run, say the next ten to 15 years, India will sustain a growth rate of eight to nine per cent, which could be even higher if it were to introduce some key reforms. In terms of growth in the factors of production, gross investment in India has risen from 25 per cent of the GDP in 2002–03 to 36 per cent in 2006–07, and India's population is predicted to become on average younger, implying faster growth in the workforce. The higher proportion of the workforce in the population also promises to raise savings and investment further. As for productivity growth, the competitive pressures on entrepreneurs brought about by the external and internal opening up are here to stay. The changes in the initial conditions brought about by the structural changes in the post-reform era offer yet another reason to take an optimistic view.

Reforms and Growth

That the command and control policies served India rather poorly is not very much in dispute. It is generally agreed that the country's economic performance in Phase II was quite poor. Those who spent time in India during this period would testify to very little change in the country. Poor performance was reflected most visibly in scarcities and poor product quality. People who wanted a scooter, automobile or telephone had to wait for a year or longer. Phone service was so poor that half the time people did not get a dial tone, and when they did, they were frequently connected to a wrong number. Bicycles in the 1970s were hardly any different from those in the 1950s. The same held true of automobiles.

There is less agreement on the 1980s and beyond, however. DeLong (2003) initially raised the question by arguing that growth in India had accelerated in the 1980s prior to the reforms of the 1990s. Building on this argument, Rodrik (2003) raised the stakes, asserting that the 'change in official attitudes in the 1980s' may have had a bigger impact than any specific policy reforms. Panagariya (2004) questioned this assertion, arguing that:

- piecemeal liberalizing reforms had already begun in the late 1970s and continued through the 1980s
- but for the super-high growth during 1988–91, the last three years of the decade, the growth rate in the 1980s was significantly lower than in the 1990s
- this super-high growth rate was partially fuelled by fiscal expansion which could not

be sustained, as evidenced by the 1991 financial crisis
- regardless of the trigger, the higher growth rate could not have been sustained without liberalizing reforms.

Panagariya (2008) also argues that the recent acceleration of the growth rate to nearly nine per cent further strengthened the argument that reforms were critical to accelerating and sustaining high growth rates.

Three examples may help to buttress the argument that without the liberalizing reforms of the 1990s and beyond, India could not have achieved its transformation. First, India's exports of goods and services as a proportion of GDP rose from 7.3 per cent in 1990–1 to 13.6 per cent in 2002–03 and 21 per cent in 2007–08. If India had kept blanket licensing on virtually all imports, and the high tariffs which averaged 113 per cent and peaked at 355 percent in 1990–1, it is inconceivable that this tripling of the ratio could have happened. Second, in 1990–1, foreign investment inflow into India was a paltry US$6 million. It rose to $6 billion in 2002–03 and $61.8 billion in 2007–08. Without liberalization, this change would have been impossible. Finally, tele-density (phones per 100 population) rose from less than three in 1998 to 31 in October 2008. The total number of phones was less than 6 million in 1990–1. It rose to 76.3 million in 2002–03 and to 364 million at the end of October 2008. Even rural India could boast of 109 million phones by October 2008. Without the telecoms sector reforms of the 1990s and 2000s, this expansion would also have been impossible. These examples lead to the conclusion that had India heeded those who recommended a move away from a command and control regime, including an end to import licensing (as in the pioneering work of Bhagwati and Desai 1970), it would have reached a higher growth path much sooner.

Poverty and Inequality

There has been a vibrant debate on whether the reforms and accompanying growth have led to poverty reduction in India. In part, this debate was fuelled by a change in sample design of the large sample survey in 1999–2000, which made it noncomparable to the preceding large survey done in 1993–4. This debate was resolved by another large survey in 2004–05. There is now general agreement that while the precise decline in poverty depends on where one draws the poverty line and which price index is used to convert the poverty line from one year to another, significant reduction in the poverty ratio, measured as the percentage of poor people to the total population, did take place between 1993–4 and 2004–05. Significant reduction in the poverty ratio also took place between 1983 and 1993–4. According to the official calculations by the Planning Commission, the poverty ratio fell from 44.5 per cent in 1983 to 36 per cent in 1993–4 and 27.5 per cent in 2004–05. In contrast, there was no change in the trend poverty ratio between 1951–2 and 1973–4.

Reform critics also argue that post-reform growth has led to massive inequalities in the country. If we use the conventional Gini coefficient as the measure, there is no perceptible increase in its value between 1983 and 2004–05. But regional inequality, as measured by state-level per-capita incomes, and urban–rural inequality, has gone up. This should not be surprising. Rapid growth often creates urban agglomerations which concentrate in a few regions, and therefore leads to both regional and urban–rural inequality. A little-appreciated fact is that even South Korea, which is often cited as an example of rapid growth with equity, actually experienced both regional and urban–rural inequality during its rapid-growth phase (Ho 1979).

A danger of excessive focus on inequality is that it can lead to policies that undermine wealth creation, growth and ultimately poverty alleviation. India's own experience in the second half of the 1960s and 1970s demonstrates the dangers of this approach. Concerns with 'concentration of wealth' largely motivated Mrs Gandhi to impose severe controls on investments by large firms and big business houses, marginal income-tax rates that exceeded 95 per cent, and the reservation of labour-intensive products for SSEs. These

policies scuttled growth and any hope of helping the poor.

A more effective way to combat regional and urban–rural poverty is to concentrate government efforts on anti-poverty programmes. In so far as the poor are concentrated in low per-capita-income states such as Bihar, Orissa and Uttar Pradesh, and in rural areas, efforts to fight poverty will automatically help reduce regional and urban–rural inequalities.

India's Challenge

A key feature of India's growth, different from almost all other countries at a similar stage of development, is the disappointing performance of manufacturing. Whereas a rapidly rising share of industry in the GDP accompanied growth in South Korea and Taiwan in the 1960s and 1970s and in China more recently, the same has not happened in India. The share of industry (including manufacturing; mining and quarrying; and electricity, gas and water) in India's GDP has remained remarkably steady at around 21 per cent since 1990–1. The decline in the share of agriculture and allied activities during these years, from 29.3 per cent in 1990–91 to 17.8 per cent in 2007–08, has been entirely absorbed by services, whose share has grown from 49.2 per cent to 61.4 per cent over the same period.

Although formal sectors such as information technology, telecommunications and finance have shown rapid growth, services largely consist of informal sector services. Within industry, labour-intensive products such as apparel, footwear, toys and other light manufactures that generate well-paid jobs have done poorly. This has meant that the creation of well-paid jobs in the economy has lagged despite rapid growth.

To put it differently, approximately three-fifths of the workforce currently derive their income from agriculture and allied activities, while these sectors generate less than one-fifth of the total income. Given that agricultural growth rarely exceeds four per cent, this means that an extremely large part of the population is not sharing in India's rapid growth. In part, this calls for reforms in agriculture to accelerate growth in that sector. But more importantly, India needs to create well-paid jobs in industry and services far more rapidly in order to pull a large chunk of the labour force out of agriculture. In a modern economy, agriculture can be the primary source of income for only a small proportion of the population. If a substantial proportion of the agricultural workforce migrated to different sectors, this would will also reduce the pressure on land and raise agricultural productivity.

A key reform necessary to accelerate job creation in the formal industrial sector relates to the labour market. Firms must have the right to terminate workers upon payment of appropriate severance pay. The current regulations have worked as a serious barrier to the entry of large-scale firms in the labour-intensive sectors in India. Apparel factories in India have tended to be much smaller than even in Bangladesh and Sri Lanka. With labour accounting for the bulk of the costs in the labour-intensive sectors, firms are reluctant to enter these sectors on a large scale in the absence of the right to terminate workers.

What Can We Learn from the Indian Experience?

India's rich experience offers several lessons. First and foremost, it shows that democracy is not a barrier to rapid growth. Until recently, analysts argued that democracy might be consistent with growth rates of from four to six per cent, but not much higher rates. Even Chile, which is a democracy, has not been able to break the six per cent barrier on a sustained basis. India has now grown at almost nine per cent for five years, and despite the current hiccups, it promises to maintain that rate in the second decade of the 21st century.

Second, reforming a highly distorted economy is a long-drawn-out process. Some analysts have recently argued that countries should look for one or two policies that most constrain growth, and concentrate on changing them. India's experience demonstrates otherwise: the reform process extends to decades. Relaxing constraints on growth in one area only expose the constraints in

other areas. Success on a sustained basis requires sustained action over several decades.

Third, low or declining barriers to trade are extremely critical to rapid growth. Side-by-side, it is necessary to give entrepreneurs space in which they may freely operate. Reforms necessary to give entrepreneurs the necessary space may vary from country to country, but at the end of the day, each country must find ways to free up entrepreneurs to seek profits without undue restraints.

Finally, the country must own its own policies. Forced policy reform by the World Bank and the International Monetary Fund (IMF) in the 1980s in many countries was destined to fail. When governments themselves do not own a reform, they will sabotage it at the implementation level or reverse it once the loan has been disbursed. India's reform was fully owned by its successive governments. At worst, we could argue that the first set of reforms in 1991–2 were carried out under the terms and conditions of the IMF and the World Bank loans. But even this is contestable, as is pointed out in chapter 5 of Panagariya (2008). Everything else that followed was initiated and executed by India. After India's 1991–92 programme, the IMF became irrelevant to the country. Likewise, following the first structural adjustment loan by the World Bank, India was firmly in the driving seat. The World Bank remained engaged only because it wanted to loan money to India, and did so by selling the loans internally to its board based on the policy actions India had been taking. Without ownership, reforms would not have been sustained. Nor would they have been credible to the entrepreneurs.

Indian Economy: Yesterday, Today and Tomorrow

Arvind Panagariya

Abstract

This article offers an analytic overview of India's achievements to date, what its future prospects are, what its rise means to the global economy in the next fifteen years and what challenges India faces in terms of future reforms. The article begins by presenting a summary of the country's growth experience during the last sixty years and relating it to the policies and political economy factors behind the adoption of those policies. It then discusses medium-term prospects of the country. Based on a set of key factors relevant to growth, it argues that India is likely to become the third largest economy in the world and an even bigger contributor to the global workforce than it is today. The article then turns to the study of the impact the growth has had on poverty alleviation during India's sixty-year history. The remainder of the article outlines the key challenge India faces today and the reforms it needs to undertake to sustain and accelerate both growth and poverty alleviation. The article argues that India needs to walk on

two legs – manufacturing and services – and requires reforms that would help strengthen both.

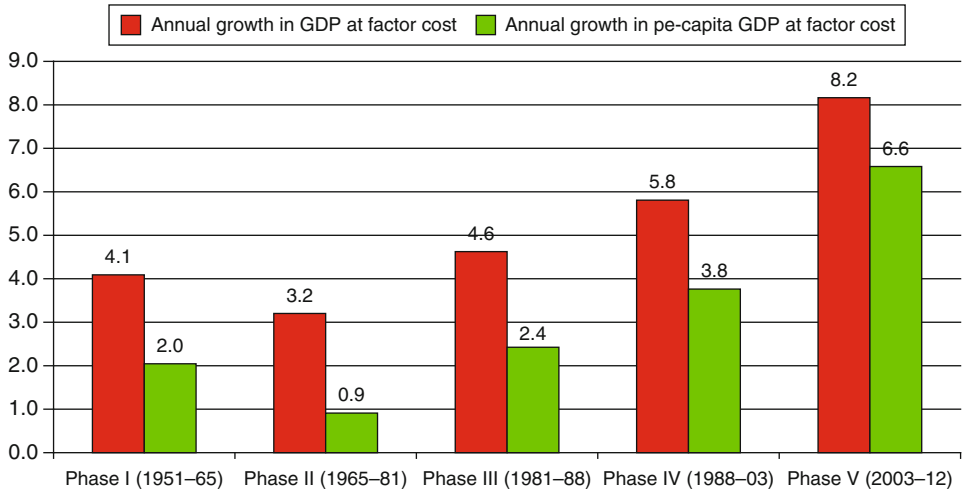
The Indian economy grew an impressive 8.5% per year between the financial years 2003–04 (1 April 2003 to 31 March 2004) and 2010–11. This period included the global-financial crisis year of 2008–09. Unlike most other economies around the world, the Indian economy was barely dented by the crisis. It experienced a small and temporary decline in the growth rate to 6.8% during 2008–09 and bounced back to the 8% plus rate in the following two financial years. This makes the compelling point that the economy has shifted onto a tiger-like growth trajectory for some years to come.

Yet, with surprising speed, pessimism bordering on the gloom of the 1970s and 1980s has returned to the Indian economic scene. The growth rate during the last three-quarters of the financial year 2011–12 fell progressively to 6.7%, 6.1% and 5.3% and has recovered only marginally to 5.5% in the first quarter of 2012–13. The growth rate in 2011–12 as a whole was the lowest, at 6.5%, since the economy began growing at an 8% plus rate in 2003–04. The decline has been accompanied by high inflation, large and rising fiscal deficit and a depreciated rupee against the dollar. The result has been a certain degree of panic among commentators on the Indian economy, with some predicting that the 'I' is about to drop out of the acronym BRIC, others suggesting that the only vowel in the acronym now stands for Indonesia and still others pronouncing an end to India's growth story (see, for example, the article by Mukherji and Ogawa (2012) of Standard and Poor entitled 'Will India be the first fallen BRIC angel?'. The article goes so far as to raise the possibility that India may revert to the pre-reform growth rate of 4–5%. To quote from its concluding section, 'Some observers in India possibly assume that the economy could sustain 6%–7% GDP growth in the coming years without active reforms or more effective economic management. However, we should not exclude the possibility of a more significant drop in trend GDP growth (perhaps to 4%–5%) if weak economic management coincides with a bad external shock or with bad luck, such as a poor monsoon'.).

Against this background, the present article offers an analytic overview of what India has achieved to date, what its future prospects are, what its rise means to the global economy in the next fifteen years and what the challenges are that India faces in terms of future reforms. The first section begins with a summary of the growth experienced during the last sixty years, the role of economic policies in determining this growth trajectory and the political economy factors that led to the adoption of the policies. The second section discusses the medium-term prospects of the country. Based on a set of key factors relevant to growth, it is argued that India is likely to become the third largest economy in the world and an even bigger contributor to the global workforce in the next fifteen years. The third section turns to the impact that growth, or lack thereof, has had on poverty alleviation during the sixty-year history. The fourth section outlines the key challenge that India faces today. The fifth section turns to the reforms that India needs to sustain and accelerate both growth and poverty alleviation. It is argued that India needs to walk on the two legs of manufacturing and services, and requires reforms that would help strengthen both.

Growth: An Overview

It is useful to divide approximately sixty years worth of modern economic history of India into five separate phases, as done in Fig. 1. (The rationale for the phases chosen in Fig. 1 is provided in Panagariya (2008, Chapter 1), which also offers a detailed account of the twists and turns in India's economic policies.) After independence, India



Indian Economy: Yesterday, Today and Tomorrow, Fig. 1 Annual growth rates during five phases, 1951–52 to 2011–12 (Source: based on the author's calculations using the data in the *Handbook of Statistics on Indian Economy, 2012* by the Reserve Bank of India at http://www.rbi.org.in/)

launched its development programme, with the First Five-Year Plan beginning in 1951–52. (Although planning as the principal tool of development has now been largely abandoned, India continues to use the five-year plans as a major medium-term policy statement. Because of breaks between the end of one five-year plan and the launch of the next several on several occasions, India will be launching its Twelfth Five-Year Plan in 2012–13.) In conformity with the prevailing conventional wisdom among all economists, western and Indian, the state was given a key role in the development process. Two objectives guided the policy: self-reliance, interpreted as the absence of dependence on imports to satisfy domestic demand and on exports for the sale of goods produced at home, and therefore a coincidence of production and consumption baskets; and a steady increase in the share of the public sector in investment and output. With the national interest rather than that of a colonial power placed at the centre of the development effort, institutions of a vibrant and durable democracy were put in place: a British-style parliament to legislate, a fiercely independent judiciary, a free press and a substantial bureaucracy headed by the country's brightest men and women. The result was satisfactory though not spectacular economic growth: during the first 14 years of planned development, ending with the year 1964–65, GDP at factor prices grew at the annual rate of 4.1%. Allowing for population growth of 2.1% per year, per capita GDP growth during the period was 2% per annum.

The first 14 years, or Phase 1, largely coincided with the rule of Prime Minister Jawaharlal Nehru. Two key instruments were deployed during this period to catalyse growth while promoting self-reliance by progressively realigning the production basket to the one domestically consumed and expanding the public sector. First, the public sector entered production activity in heavy industry sectors, such as steel and machinery, on the premise that the private sector lacked the resources required for investment in them. Second, larger investment projects in the private sector were subjected to licensing to ensure that private investments were channelled into highpriority sectors rather than being guided purely by profitability. The system worked relatively smoothly through the 1950s. During that decade, barriers to trade were also low, with many consumer goods imports permitted.

A balance of payments crisis in 1957–58 led the government to adopt foreign exchange budgeting under which the finance ministry would predict the expected foreign exchange revenues in the following six-month period and

allocate it across its competing uses. This naturally created an extra layer of bureaucracy in the investment licensing system, since a licence could not be issued unless foreign exchange for the machinery and raw materials necessary for the project was available. This factor, complemented by a rising volume of private investment, which translated into progressively larger number of applications for licences, began to create serious bottlenecks in the administration of the licensing system as the Nehru era ended. Beginning in 1964, several committees were set up to recommend changes that would help streamline the licensing procedures, but the efforts were largely unsuccessful.

Nehru died in 1964 and was succeeded by Prime Minister Lal Bahadur Shastri, who was more sympathetic to agriculture and unenthusiastic about heavy industry. His administration oversaw the launch of the Green Revolution and the creation of much of the infrastructure of public distribution system of food grains, including the Food Corporation of India (FCI) and Agricultural Prices Commission which still exist today. Unfortunately, however, Shastri died unexpectedly in early January 1966 and was succeeded by Prime Minister Indira Gandhi, daughter of Nehru.

Political compulsions led Gandhi to turn to a far more extreme form of socialism than under Nehru. Investment by a large firm or business house, formally defined as a firm or interconnected groups of firms with 350 million rupees or more in assets, was confined to 19 highly capital-intensive core industrial sectors. Alongside, most of the labour-intensive sectors, such as apparel, footwear and light consumer goods of all kinds, were reserved for exclusive manufacture by small-scale enterprises. Imports were subjected to such tight controls that they fell to just 4.1% of GDP in 1969–70. Foreign investment rules, which had been relatively liberal under Nehru, were tightened dramatically. With some exceptions, foreign companies were told either to register as Indian companies or to leave the country. Two major American companies, IBM and Coca-Cola, left India in the second half of the 1970s. The largest 14 domestic banks, insurance companies, coal mines and oil companies were nationalised. A ceiling was placed on urban land holdings. Land held above the specified ceiling was to be put for sale, with the government having the right to buy it at a throwaway price. The result was the disappearance of much urban land from the market. Finally, labour laws were changed to further favour workers, with manufacturing firms employing 100 or more workers denied the right to lay off workers under any circumstances.

These draconian measures had a chilling impact on the economy. While industrial countries boomed during the 1960s and early 1970s (until the oil-price crisis put the brakes on that growth), and countries such as South Korea and Taiwan that had chosen an outward-oriented path to development went on to achieve growth rates ranging from 8% to 10%, the growth rate in India dipped. The decade from 1965–66 to 1974–75 produced GDP growth of just 2.6% per year, with per capita GDP rising just 0.3% annually. This was a lost decade for the country.

By the second half of the 1970s, at least some in the government began to recognise that the controls had gone too far for the good of the economy. Although this was not publicly acknowledged and no policy change was actually announced, some piecemeal liberalisation involving the expansion of production capacity under the existing licenses and freer imports of machinery and raw materials was introduced. This process accelerated in the 1980s, especially in the second half of the decade under Prime Minister Rajiv Gandhi, who succeeded his mother following her assassination in 1984. Growth recovered to 4.2% during 1975–81 (1975–76 to 1980–81) and to 4.6% during 1981–88.

Although the small acceleration in growth during the 1980s was partially stimulated by the piecemeal reforms, it was also fuelled by an expansionary fiscal policy that relied on substantial overseas borrowing. As the 1980s closed, this borrowing had led to an accumulation of substantial external debt. Moreover, despite an acceleration of export earnings in the second half of the 1980s, due to significant depreciation of the rupee and the introduction of some export incentives, their level remained low. As a result, debt

servicing came to absorb nearly 30% of the meagre export earnings by the end of the 1980s. In turn, foreign exchange available for imports progressively dwindled and a balance of payments crisis followed in 1991.

This crisis coincided with an election campaign during which Rajiv Gandhi was assassinated, paving the way for Prime Minister Narasimha Rao to take the helm. Contrary to his reputation, Rao proved to be a decisive prime minister who used the occasion of the crisis to introduce major reforms. He abolished licensing on investment and imports of capital goods and raw materials (though not on consumer goods). He also opened the economy to foreign investment. In the subsequent years, he extended the reforms to telecommunications, civil aviation and the financial sector, while continuing to liberalise trade through tariff reductions.

Rao lost the election in 1996 and was followed by three short-lived coalition governments. Eventually, in 1998, Prime Minister Atal Bihari Vajpayee came to head the Bharatiya Janata Party (BJP) led National Democratic Alliance (NDA) government. Though Vajpayee lost a crucial vote in his first year, leading to the fall of his government, the electorate returned him with a stronger mandate in 1999. He ruled until May 2004, when the NDA lost a crucial election.

The reform process not only continued but also accelerated considerably under Vajpayee. Import licensing on consumer goods imports was ended and tariffs were systematically brought down, with the highest tariff on industrial goods dropping to just 10% (with some exceptions) in the last budget presented under this government. A major reform of the telecommunications sector paved the way for fierce competition among private and public providers. The result was an explosion in the growth of mobile phones in India. Major initiatives were also undertaken in the area of infrastructure, including the building of highways and rural roads and modernisation of ports. Other reforms included the liberalisation of interest rates, freer entry to domestic private and foreign banks, freeing up of markets in agricultural produce, entry of the private sector to insurance, steady trimming of the list of sectors subject to small-scale industries reservation, privatisation of several public-sector enterprises and the repeal of the central urban land ceilings act, which paved the way for state governments to drop the ceiling on urban land holdings. These changes went a long way towards intensifying competition in various markets.

The reforms under the Rao and Vajpayee governments went a long way towards accelerating growth. Although growth had crossed the 7% mark during the three years preceding the 1991 crisis, it could not be sustained due to its partial origins in the expansionary fiscal policies. But the higher growth during the 1990s followed fiscal consolidation and pro-market reforms. As a result, it was not only sustained but accelerated. India grew 5.8% per annum during 1988–89 to 2002–03 and then, in 2003–04, shifted to the higher growth path of 8–9%. Although the growth rate fell to 6.8% in 2008–09 following the global financial crisis, it quickly returned to the 8% plus range in 2009–10 and 2010–11.

The Congress returned to power in May 2004, heading a coalition that came to be known as the United Progressive Alliance (UPA) and consisted of approximately a dozen large and small parties. Dr Manmohan Singh, an economist who had served as the Finance Minister in the Rao government and had guided the reforms in the first half of the 1990s, was appointed Prime Minister. Unfortunately, however, this government interpreted the defeat of the NDA as a vote against reforms. It proclaimed its intention to promote reforms with a 'human face'. In effect, this rhetoric translated into an end to pro-growth reforms and to attention being focused nearly exclusively on redistributive programs. Even progress on building the country's infrastructure slowed down. Perhaps the most visible policy initiative of the government was the introduction of a large-scale National Rural Employment Guarantee Scheme under which one member of each rural household is guaranteed employment for 100 days at a wage significantly above the equilibrium rate.

While the UPA government did not follow up on the Rao–Vajpayee reforms, it generally did not do anything significant to impede their effects from being realised. As a result, the growth

acceleration that had taken place in 2003–04 was sustained during its rule. This steady growth of 8–9%, in turn, helped the government return to power in 2009. (Gupta and Panagariya (2012) provide an empirical analysis of the 2009 election and show that growth is the key to explaining the outcome in this election.) But the policy environment began to deteriorate during the second term of the UPA.

Two factors, in particular, hurt the economy. First, in an overreaction to high inflation, the Reserve Bank of India curbed the growth of the money supply through 13 consecutive increases in the interest rate. The resulting increase in the cost of funds had an adverse impact on private investment. In parallel, high fiscal deficits had the obvious effect of crowding out some private investment.

Secondly, and more importantly, almost from the beginning of the second term of the UPA a paralysis gripped the administrative and policy-making processes of the government. The paralysis began with a hyperactive environment minister blocking clearances to hundreds of projects around the country. Later, revelations of a large number of corruption scandals, followed by the imprisonment of two ministers, one Member of Parliament and several civil servants, led to a chill in the entire decision-making machinery. Civil servants would no longer take action on the basis of verbal orders by their ministers, while the latter came to fear issuing even legitimate orders in writing lest they were accused of doing so in return for a bribe.

This paralysis in decision-making in the administrative machinery has been accompanied by paralysis in policy making. The Prime Minister and his Congress party have been utterly unsuccessful in negotiating policy changes with their coalition partners. One or the other coalition member has gone on to block every important policy initiative of the government. The result has been legislative paralysis as well.

These two factors have been largely behind the recent growth slowdown. While the Reserve Bank of India is beginning to reverse its tight monetary policy, its ability to continue doing so is constrained by fiscal deficits. Accommodation of large fiscal deficits by the Bank inevitably risks fuelling inflation. At the same time, the paralysis in administrative and policy-making processes has not gone away either. Without corrective action by the government on both fronts, a perfectly plausible growth story runs the risk of being stopped dead in its tracks.

Medium-Term Growth Prospects

Setting aside these two considerations, the prospects for growth in India over the next fifteen years are excellent. To fully appreciate this fact and its implications for India's position in the global economy, consider first the growth that India has achieved during the last nine years in US dollar terms. The simple average of annual growth rates in current dollars during the nine years beginning in 2003–04 and ending in 2011–12 has been 15.8%. Even allowing for 3% per year inflation in the USA, this figure implies a growth rate of 12.8% in real dollars.

Making next the conservative assumption that the GDP in real dollars will continue to grow 10% per year in constant dollars, it will expand from a GDP of 1.8 trillion dollars in 2011–12 to 7.5 trillion in 2025–26 in 2011–12 dollars. India would then become the third largest economy in the world after the USA and China. Moreover, even applying the current population growth rate of 1.8% per annum, which is bound to decline, this GDP will imply a per capita GDP of $4,800 at 2011–12 prices. That would spell the end of poverty as currently defined with near certainty.

Demographically, the number of workers aged 20 to 49 years is predicted to decline by 37 million in developed countries and 63 million in China between 2010 and 2025. In India, this number is predicted to increase by a gigantic 131 million. With an increased international mobility of workers, these numbers are likely to translate into young Indian workers becoming far more ubiquitous around the globe than today. Rising incomes within India, which would make it possible for parents to send their children abroad for education, will only facilitate this process of emigration.

The critical question to which we must return is why the prospects of 10% growth in real dollars are good for the next 15 years. At least four factors allow us to make a compelling case. First, investment rates in India have hovered around 35% during the last several years. This investment is largely financed by domestic savings, which means that the savings rate has also been 30% or more during these years. Going by the historical experience of countries such as South Korea, Taiwan, Singapore and China, it is quite unlikely that these savings and investment rates will collapse in the near future. Given that India is predicted to become progressively younger, labour shortages will not act as a brake on growth either.

Second, the reforms introduced during the 1990s and early 2000s have remained intact. This means that India remains a highly open economy in at least industrial goods and services, although it is still highly protected in agriculture. Domestic entry is also relatively free. Therefore, entrepreneurs must compete intensely with one another. Large inefficiencies remain in check.

Third, complementing this competition effect is the gap between productivity in India and that in the 'best-practice' countries. This large gap offers India significant scope for technological catch-up. Therefore, in addition to growth through increased factor supply (capital and labour), India has the possibility of adding to its growth rate through productivity gains. Because entrepreneurs are subject to intense competitive forces, it is likely that such productivity gains through technological advance will be realised.

Finally, rapid growth also requires entrepreneurs willing to take risks. Luckily here as well India has had a longstanding tradition of entrepreneurship. The fact that even during the age of licensing, with both hands virtually tied, Indian entrepreneurs could produce 3–4% growth almost steadily is evidence of their skills and talent. Surely, in the current reformed environment and with further reforms likely in the forthcoming years, the chances of their performance improving yet more are very good.

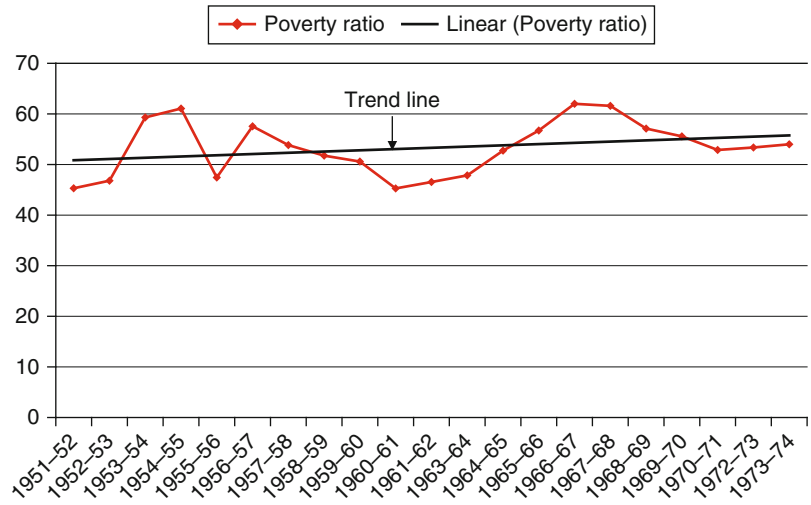
Poverty and Inequality

An issue of great importance is the impact the reforms and growth have had on poverty. Evidence is now compelling that growth has not only been accompanied by a decline in poverty, but that the acceleration of this growth has been accompanied by an accelerated decline in poverty.

In 1950–51, India started at an extremely low per capita income and a large percentage of the population was in poverty at the beginning. But the country also grew slowly during the first 25 years. That in turn meant that even in the mid-1970s, per capita incomes remained quite low and no progress could be made in poverty alleviation. With such low per capita income, even the scope for poverty alleviation through redistribution was extremely limited. It was only when growth accelerated and per capita income began rising more rapidly that an impact on poverty was discernible. Not only did growth begin to 'pull up' people into gainful employment, it also produced larger tax revenues that could be used to finance enhanced redistribution programs, such as the National Rural Employment Guarantee Scheme.

Before presenting the evolution of poverty, it should be noted that there has been some controversy in India about the level at which official Indian poverty lines are set. The original official rural and urban poverty lines, known as the Lakdawala poverty lines, had been set at the recommendations of a 1993 expert group headed by the then leading poverty expert Professor D. T. Lakdawala. Although the Planning Commission recently revised the rural poverty line upwards at the recommendation of the Tendulkar Committee report, thereby aligning it to the urban poverty line in real terms, many have argued that the poverty line still remains low. My own view is that in a country with widespread poverty, an important role of the poverty line is to allow tracking of the fortunes of those living in destitution. Therefore, setting this line near the subsistence level has some merit.

Whatever one's view with respect to the level at which poverty line is set, if we are interested in comparable estimates for the entire sixty-year period under consideration we are confined to



Indian Economy: Yesterday, Today and Tomorrow, Fig. 2 Poverty ratio, 1951–52 to 1973–74 (Source: author's construction using data from Datt (1998, Table 1))

the Lakdawala poverty lines. Even at the Tendulkar lines, estimates go only as far back as 1993–94. In principle, it is possible to extend the estimates at the Tendulkar lines back in time or to calculate them at alternative lines, but they are not readily available.

Accordingly, the estimates presented here are based on the Lakdawala lines. Figure 2 shows the evolution of the poverty ratio – the proportion of the population below the poverty line – from 1951–52 to 1973–74. As is readily seen from the trend line, there was no long-term reduction in poverty during this period. Indeed, the trend line shows a slight upward movement over time. Neither was growth robust enough to pull people out of poverty nor did the meagre tax revenues generated by low levels of income provide enough resources for significant redistribution. But this changed as growth picked up and income began to rise.

Table 1 reports the poverty ratio in rural and urban India and the two regions taken together approximately every five years beginning in 1973–74. (There is one exception since the estimates jump to 2004–05 after 1993–94. Although a thick expenditure survey was conducted during this year, due to a change in the sample design estimates based on it are not strictly comparable to those in the other years. Therefore the estimates associated with this year have been suppressed.) These estimates are based on the so-called thick surveys that typically collect expenditure data on over a hundred thousand households nationwide. As is readily seen, the acceleration in growth beginning in 2003–04 also translates to accelerated poverty reduction. For example, reduction in total poverty was 0.77 percentage points per year from 1993–94 to 2004–05 but 1.44 percentage points per year from 2004–05 to 2009–10. Mukim and Panagariya (2012) provide a comprehensive analysis of the evolution of poverty in India. They show that poverty has fallen steadily since 1983 for all major social and religious groups and states. There is simply no truth in the common assertions that growth has impoverished

Indian Economy: Yesterday, Today and Tomorrow, Table 1 Poverty ratio, 1973–74 to 2009–10 (Source: Planning Commission for estimates until 2004–05 and Mukim and Panagariya (2012) for 2009–10)

Year	Rural (%)	Urban (%)	Total (%)
1973–74	56.4	49	54.9
1977–78	53.1	45.2	51.3
1983	45.6	40.8	44.5
1987–88	39.1	38.2	38.9
1993–94	37.3	32.4	36
2004–05	28.3	25.7	27.5
2009–10	20.2	20.7	20.3

the socially disadvantaged or that it has failed to benefit specific religious minorities.

Recent research also shows that contrary to common assertions that growth has increased inequality in India, no unique relationship is observed between these two variables. Krishna and Sethupathy (2012) measured inequality using the Theil index. This index allows them to distinguish between within group and between group inequalities. Using the expenditure data from surveys conducted in 1987–88, 1993–94, 1999–2000 and 2004–05, they show that the overall inequality shows only modest variation over the period. It rises slightly between 1987–88 and 1993–94 and again between 1993–94 and 1999–2000, but falls by 2004–05 to roughly the 1987–88 level.

Hnatkovska et al. (2012a) also show that the gaps in wages and education levels between scheduled castes and tribes on the one hand, and non-scheduled-caste groups on the other, have steadily declined between 1983 and 2004–05 (scheduled castes and scheduled tribes refer to historically socially disadvantaged groups in India). The gaps exhibit a decline when measured using mean and median wages and education levels over time as well as when evaluated in terms of intergenerational mobility rates. Indeed, scheduled caste and scheduled tribe children have changed their status relative to their parents in terms of wages and education even faster than non-scheduled caste children between 1983 and 2004–05 (Hnatkovska et al. 2012b).

Regional inequality, rural–urban inequality and inequality between the richest and the poorest (however defined) have certainly risen. But a moment's reflection will show that these forms of inequality are nearly impossible to escape in fast-growing economies and have been a part of all growth miracles, such as South Korea and Taiwan in the 1960s and 1970s and China more recently. Growth involves wealth generation, and those creating wealth are bound to end up with at least a small part of it for themselves, while the remainder is distributed over the rest of the population. And when the wealth generated runs into tens of billions of dollars, even a small fraction of it is a lot of wealth for a single individual. This fact alone suffices to raise the inequality between the richest and the poorest. Likewise, fast growth concentrates in a small number of agglomerations that are located in urban areas; even if they begin in rural locations, the growth turns them into urban areas over time. This pattern necessarily leads to regional and rural–urban inequality.

The Challenge Facing India

A key difference between India and other fast-growing economies, such as South Korea and Taiwan in the 1960s and 1970s and China more recently is that poverty reduction per percentage-point growth in India has been significantly smaller. Whereas two decades of rapid growth in these other countries was sufficient to wipe out abject poverty, this has not been the case in India. By all measures, at least a fifth of the Indian population still lives in what is sometimes called extreme poverty.

This slow progress in combatting poverty has in turn been due to a development pattern that is so far unique to India. In almost all cases of rapid growth in labour-abundant developing countries, manufacturing in general and labour-intensive manufacturing in particular have led the process. In turn, this process has allowed the countries to shift the workforce rapidly out of agriculture and into well-paid jobs in manufacturing activities while also fuelling urbanisation. In addition to providing gainful employment to those migrating from the countryside, this process has also helped raise output per worker in agriculture by reducing the land-to-workers ratio.

Unfortunately, capital-intensive and skilled-labour-intensive manufacturing and services sectors have led the growth process in India. The successful sectors in India are telecommunications, information technology, automobiles, motorbikes, petroleum refining, finance and pharmaceuticals. Labour-intensive sectors such as apparel, footwear and light consumer goods manufacture have not flourished. For example, apparel exports from India are less than those from Bangladesh and one-tenth of those from China. This pattern has meant that while the

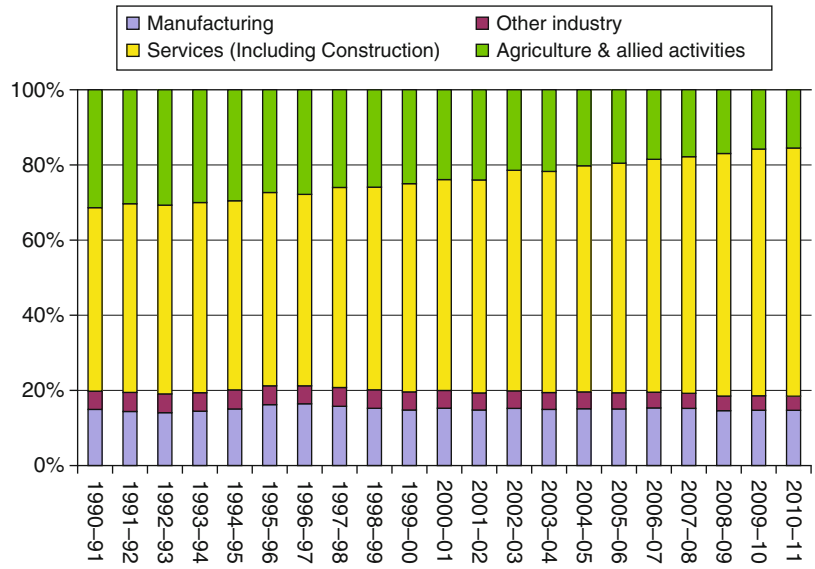
share of agriculture in the GDP has significantly declined, just as it did in South Korea and Taiwan in the 1960s and 1970s and China more recently, the employment share of agriculture has fallen more gradually (see Table 2). Indeed, until recently, the absolute number of workers in agriculture has continued to grow. The net effect of this pattern has been slow growth in gainful employment in industry and services, slow growth in output per worker in agriculture and slow pace of urbanisation. All of these factors have had a dampening effect on the pace of poverty reduction.

For a labour-abundant country like India, with more than 500 million workers, the greatest potential comparative advantage lies in labour-intensive manufacturing. With specialisation in these products, it could exploit the vast world markets. The same opportunities do not exist in the capital- and skilled-labour-intensive products. As a result, specialisation in the latter, being at least partially limited by the size of the domestic market, has meant that manufacturing as a whole has grown far slower than in other successful labour-abundant economies. This fact is clearly illustrated by Fig. 3, which shows the evolution of the shares of the major sectors of the economy during the post-reform era. While agriculture has rapidly lost share in the GDP, the shares of manufacturing and other industry sectors have remained essentially unchanged. Services have in turn taken up the slack, expanding their share of GDP.

From a good jobs perspective, this pattern would not be all bad if services had generated a

Indian Economy: Yesterday, Today and Tomorrow, Table 2 Pattern of development in the post-reform era (Source: author's calculations using the data from the *Handbook of Statistics on Indian Economy, 2012* by the Reserve Bank of India at http://www.rbi.org.in/, reports on employment–unemployment survey by the National Sample Survey Organization, various years, and the Census of India, various years)

Item	1993–94	2004–05	2009–10
GDP share of agriculture and allied activities	30	20.2	15.8
Share of agriculture and allied activities in rural workforce	78.4	72.7	68
Urbanisation (nearest census: 1991, 2001 and 2011)	25.7	27.8	31.2



Indian Economy: Yesterday, Today and Tomorrow, Fig. 3 Composition of GDP, 1990–91 to 2008–09

large number of formal sector jobs. But this has simply not been the case. The work by Dehejia and Panagariya (2016) shows that almost three-fifths of services sector workers are employed in own-account enterprises that employ no hired workers on a regular basis. The small proportion of workers that has moved out of agriculture has largely ended up in low-paid informal sector jobs. The critical questions are why has the pattern of development in India been so different and what can be done to stimulate faster growth in well-paid jobs?

Walking on Two Legs: What India Must Do

Because half of the workforce in India still remains in agriculture and lives on a meagre income, it is tempting to conclude that improving incomes in that sector can bring the fastest relief to the poor. Yet this is somewhat misleading, since growth in agriculture has rarely exceeded 4% per year on a sustained basis in India. Therefore, while there is merit in doing what can be done to improve agricultural incomes, there is no alternative to creating well-paid jobs in industry and services, paving the way for a rapid movement of workers out of agriculture into these sectors. Indeed, such movement will contribute the most to increased incomes in agriculture by rapidly bringing down the worker-to-land ratio.

Even though past experiences have seen manufacturing largely leading the growth process, given that India has already achieved some success in the services sector it makes more sense to now walk on two legs: manufacturing and services. Future reforms must focus both on stimulating labour-intensive manufacturing and on strengthening India's lead in services.

The key reason for the failure of labour-intensive manufacturing to flourish in India is the stringency of labour laws. As discussed in detail in Bhagwati and Panagariya (2012), labour laws become progressively more stringent as a firm's size increases above just six employees. At 100 workers, a manufacturing firm effectively loses the right to lay off workers under any circumstances, including bankruptcy. The law requires the firm to seek permission from the local state labour department to sack or make employees redundant, and the labour department almost never grants permission.

The result of these inhibiting labour laws has been that, in contrast to China, where large and medium firms dominate the employment scene, such firms are a rarity in India. In India, it is small firms that dominate the employment scene. In an important paper, Hasan and Jandoc (2012) compared the firm size distributions of India and China in the apparel industry. They found that these distributions are diametrically opposed to one another. In India, firms with 10 or fewer workers accounted for 87.4% of apparel employment in 2005. In China, 87.7% of apparel workers were employed in firms with 50 or more workers. Large firms in India typically dominate in highly capital-intensive sectors such as auto manufacture and auto parts, where labour costs are often a small part of the total costs.

Hasan and Jandoc also show that when large firms do exist in the labour-intensive sectors, they locate themselves with greater preponderance in states with less stringent labour laws. Similar cross-state differences do not arise in capital-intensive manufacturing sectors, nor do other factors, such as the availability of infrastructure in the states, produce similar cross-state differences. These factors point to an acute need for labour law reforms that would pave the way for the emergence of medium and large firms in labour-intensive sectors on a substantial scale. The small firms that currently dominate the scene simply do not have the incentive to exploit the vast world markets and are therefore unable to produce large numbers of well-paid jobs.

Reforms are, of course, required in several other areas as well. Land markets remain highly distorted, for instance. One particular area related to land in which reform is necessary and relatively straightforward is land acquisition. The current law governing land acquisition dates back to the 19th century and needs to be replaced by a more modern law that allows entrepreneurs to buy land freely from the current owners, including farm land, at competitive prices. There is also an acute

need for proper ownership titles to land and other property.

India also needs to build infrastructure in a major way. The past decade has seen considerable slowdown in the building of roads and this process must be reinvigorated. Likewise, with one-third of Indian households still without electricity, it is essential to reform the electricity sector. Electricity subsidies, which have left the distribution companies effectively bankrupt and discouraged electricity generation, need to be ended. Electricity tariffs need to be rationalised so that the industry is not charged punishing electricity prices to cross-subsidise other consumers.

India also needs to return forcefully to the opening of the external sector. Trade liberalisation has come to a virtual standstill under the current United Progressive Alliance, which originally came to power in May 2004. The outgoing government had dropped the top industrial tariff (with some exceptions) to 10% and it remains at that level to date. India will benefit from further liberalisation in all sectors: industry, agriculture and services. Liberalisation in agriculture has scarcely begun, so the scope for reform in this area is enormous. Likewise, in services, the multi-brand retail trade needs to be opened up to foreign investors. Large retailers from around the world can play a major role in modernising this sector. They can help build the supply chains both from retail to manufacturers and from manufacturers to the export markets.

To strengthen the services leg of the economy, higher education also needs urgent attention. The gross enrollment ratio in higher education at below 14% is a solid ten percentage points behind China. Shortages of qualified skilled workers may eventually slow the expansion of the information technology industry. Already, IT has been experiencing the fastest rise in wages over the last several years. In view of the need for an increased enrollment ratio, as well as to accommodate its burgeoning young population, India needs many hundreds of new universities. Given the fiscal constraints, the ability of the public sector to undertake the necessary expansion is limited. Therefore the conditions under which new private universities could be set up need to be liberalised as well. The current system, which requires legislation by Parliament or a state legislative assembly, is extremely cumbersome. What is needed, instead, is a set of administrative procedures that allow new universities to be opened up quickly and efficiently. India also needs to make the policy environment friendlier to virtual universities that can bring higher education to vast numbers of individuals at low cost.

A final important area in which India needs reforms is that of redistribution policies. The government has so far resisted even experimenting with direct cash transfers as the redistribution instrument. Instead, it has insisted on creating large supply chains in food distribution and the provision of education and health. Unfortunately, these supply chains have been hampered by corruption and huge inefficiencies that the government has been unable to keep in check. As a result, potential recipients of the service have steadily exited public supply, even when provided at highly subsidised rates. Cash transfers to the poor and allowing them to choose between public and private providers can considerably alleviate this problem. It will also empower the poor rather than providers. Under the current system, the poor are at the mercy of public sector providers. But once they hold the cash, they will be in a position to go to the provider of their choice, forcing the public provider either to improve efficiency or lose its business.

Concluding Remarks

Recent policy paralysis and the subsequent decline in the growth rate below 6% during the first two quarters of 2012 has driven home the lesson that government complacency is extremely costly. The 8–9% growth that the reforms of the Rao and Vajpayee administrations made possible over the last decade cannot be taken for granted. Continued reforms are required not only to sustain and accelerate the growth that has already been achieved, but also to prevent backsliding and an economic slowdown. The long-term reform agenda must address the continuing distortions in the factor markets. The creation of well-paid

jobs requires a policy environment that is friendly to large firms. In turn, this requires major reforms in labour laws that encourage rather than deter entrepreneurs from opting for labour-intensive technologies and labour-intensive sectors. Without such reform employment will be concentrated in tiny firms operating in the informal sector.

India needs to walk on two legs – manufacturing and services – and to that end needs to maintain momentum in services. Fulfilling this objective requires major reforms in higher education that help improve both the quality and quantity of skilled workers. It must invest in infrastructure, address land market distortions and liberalise trade. Evidence shows that economic growth in India has led to substantial reduction in poverty. Therefore, future growth will not only help eliminate the poverty that remains but also turn India a major global player. If the growth rate achieved during 2003–04 to 2010–11 is sustained, which is entirely feasible in view of the high investment rate and the competitiveness of the economy, India will become the third largest economy in the world by 2025. With its rising population of the young, it will also become a large supplier of the global workforce. The prospects for India to regain some of its lost glory have, thus, never been brighter.

Indicative Planning

Klaus Nielsen

Abstract

Indicative planning aims to coordinate private and public investment and output plans through forecasts or targets. Compliance is voluntary. The underlying logic is that the plan can supply economically valuable information which, as a public good, the market mechanism cannot disseminate efficiently. It may be perceived as a substitute for non-existing forward markets. However, indicative planning takes into account only endogenous market uncertainty, not exogenous uncertainty (technology, foreign trade and so on). Indicative planning has been most consistently and continuously implemented in France and Japan

but has been used in many other countries, although decreasingly so since the 1970s.

Indicative planning is a means of improving the performance of an economy through the elaboration of a set of consistent numerical forecasts or targets for the economic future. The aim is to coordinate private and public sector investment and output plans through the provision of economically valuable information. As distinct from directive central planning, as practised in the Soviet Union from the late 1920s, it is planning without compulsion. Compliance is purely voluntary. It is based on the idea that, if the plan is appropriately constructed, it will indicate an optimal path for the economy, which would then be spontaneously followed by the economic actors, without the need for compulsion. Decision-making is formally fully decentralized, but some versions of indicative planning include consultation with major private actors and the concertation of private investment plans. Furthermore, compliance is encouraged and facilitated by persuasion and cognitive framing and is sometimes supported by incentives. In addition, state-controlled investment funds may be guided into favoured projects in accordance with the plan. Furthermore, public sector commitment to implement planned public investment and output targets may constitute an element of certainty that facilitates the intended voluntary compliance.

The best-known examples of indicative planning are the plans elaborated by the French Commissariat Général du Plan and the Japanese Planning Agency since the Second World War. After the Second World War several European countries, such as the Netherlands, developed some sort of indicative planning, often linked to the building of multi-sector econometric models of the economy. Indicative planning was widely practised in developing countries during the post-war period until the 1980s (Belassa 1990). After the collapse of Communism, indicative planning was briefly adopted in Poland, and is still being used in some of the former republics of the Soviet Union. In 1965 an indicative National Plan was implemented in the United Kingdom, but was abandoned after a year as an effect of a balance of payment crisis. Today (in 2007), the European Union is involved in soft coordination activities that have some resemblance to indicative planning.

The presence of imperfect information is a market failure, and indicative planning can be seen as an attempt to bridge the information gap. The underlying logic is that the plan can supply economically valuable information which, as a public good, the market mechanism does not disseminate efficiently. Indicative planning makes it possible to overcome the problems that arise from the economic actors' ignorance of the intentions of the other actors. The collective market research involved in indicative planning should, in principle, make it possible to anticipate potential overcapacity and shortage and to avoid states of disequilibrium with unfulfilled expectations. If every economic actor informs the planners about their prospective demand and supply intentions for the forthcoming plan period, this information could be aggregated into an indicative plan and appropriate adaptations could be made by the economic actors.

The indicative plan may be perceived as a substitute for non-existing forward markets, or as a calculated general equilibrium representing an optimal allocation of resources that it would be in everybody's interest to implement on condition that the plan was correctly worked out. J.L. Meade (1971) demonstrates that the optimality features of the welfare-maximizing general equilibrium model can be obtained even if a full set of forward markets does not exist, provided that the economic agents make honest non-binding declarations about intended actions for any future date.

Based on this information, equilibrium prices and quantities could be calculated and the

forecasts of the indicative plan would necessarily be realized, since they correspond to optimal behaviour by market agents.

However, the assumption that agents declare their true intentions contradicts the assumption of rational behaviour if individual agents are large enough to influence prices that provide them with an incentive not to reveal their true preferences.

Furthermore, indicative planning is capable of taking into account only endogenous market uncertainty, and works only in a closed economy. Environmental, or exogenous, uncertainty (including changes in technology and foreign trade) is ignored. In theory, the indicative plan may operate with as many future paths as there are possible scenarios for the exogenous environment. However, this procedure for transformation of uncertainty to risk is hardly of any practical relevance, and it does not recognize the existence of genuine uncertainty that makes it impossible to elaborate appropriate scenarios, even in theory.

Economic internationalization and technological change have the effect that the overwhelming source of uncertainty has become exogenous, which has made the forecasting exercises of indicative planning increasingly difficult and ultimately useless. As a result, indicative planning has been widely abandoned or its ambitions have been significantly curtailed. France is the major example of a continuous commitment to indicative planning. Until 2006, planning documents covering successive 5-year planning periods were elaborated by the Commissariat Général du Plan. However, from the early 1970s and onwards, the plans became less ambitious and less influential. Targets and concertation were abandoned. The plans became internal governmental strategic documents that were, from 1993, no longer presented to Parliament. From 2006, indicative planning was formally abandoned, and the Commissariat Général du Plan was succeeded by a new Centre d'Analyse Stratégique.

It is fair to ask whether indicative planning, following its almost universal decline, is now devoid of contemporary relevance, if it ever had some, and has become a phenomenon of merely historical interest. Is indicative planning irrelevant, even in its less comprehensive and more pragmatic version that stresses the virtues of its contribution to develop shared expectations, or 'a common view of the future?' If the economic agents are seen as capable of developing rational expectations there is surely no role for indicative planning. In this view, attempts to influence expectations are ineffective and wasteful. From the point of view of Austrian economics, collective forecasting is even worse; it is not only ineffective but harmful. Indicative planning can be misleading, which may lead to too many eggs being put into one wrong basket. The plurality of information in a world of decentralized decision-making with no public attempts to influence expectations is seen as preferable by far.

However, from a more pragmatic point of view, it is exactly the role of indicative planning in forming common expectations concerning macroeconomic development trends that may contribute, not to the achievement of the nirvana of an optimal growth path, but rather to an improved state of disequilibrium (Holmes 1987). If optimal equilibrium is seen to be of little practical relevance as a result of widespread genuine uncertainty and the bounded rationality of economic agents, pragmatic means to improve the situation are important, although these may not in any way be seen as leading to a utopian state of optimal allocation of resources. At least three factors make indicative planning in the form of macroeconomic forecasts highly valuable in this context: (*a*) the public good character of the collected information, (*b*) the economies of scale of information processing, and (*c*) the fact that the government is no doubt a particularly well-informed actor in relation to macroeconomic developments.

Indicators

V. Zarnowitz

Types and Structure

Economic indicators, as a general category, are descriptive and anticipatory data used as tools for the analysis of business conditions and forecasting. There are potentially as many subsets of indicators in this sense as there are different targets at which they can be directed. For example, some indicators may relate to employment, others to inflation.

This brings to mind the uses of such time series as lagged explanatory variables in econometric models and regression equations. But there is a different, established meaning to what is often called the 'indicator approach'. This is a system of data and procedures designed to monitor, signal and confirm cyclical changes, especially turning points, in the economy at large. The series that serve this purpose are selected for being comprehensive and systematically related to business cycles and are known as *cyclical indicators*.

Business cycles are recurrent sequences of alternating phases of expansion and contraction that involve a great number of diverse economic processes. These movements are both sufficiently diffused and sufficiently synchronized to show up as distinct fluctuations in comprehensive series that measure production, employment, income and trade-aspects of aggregate economic activity. The end of each expansion is marked by a cluster of peaks in such series, the end of each contraction by a cluster of troughs. Analysts at the National Bureau of Economic Research (NBER) base the dating of business cycle peaks and troughs on the identification and analysis of such clusters, that is, the consensus of the corresponding turning points in the principal *coincident indicators*. This is done because (1) the co-movement of the indicators is itself an essential characteristic of the business cycle; (2) no single adequate measure of aggregate economic activity is available in a consistent form for a long historical period; and (3) economic statistics generally are subject to error, so that the evidence from a number of independently compiled indicators tends to be more reliable than the evidence from any individual series. The NBER reference chronologies of business cycle peaks and troughs (Burns and Mitchell 1946, ch. 4; Moore 1961, chs 5 and 6; Zarnowitz and Moore 1977, 1981) are widely used in academic as well as current business research.

The specific cycles observed across a wide spectrum of variables differ greatly and in part systematically. Thus many economic time series called the *leading indicators* tend to reach their turning points *before* the corresponding business cycle turns. There are also many series that tend to reach their turning points *after* the peaks and troughs in the business cycle, and they are the *lagging indicators*. The leading series represent largely flow and price variables that are highly sensitive to the overall cyclical influences but also to shorter random disturbances; hence they show large cyclical rises and declines but also high volatility. Coincident series have generally smaller cyclical movements and are at the same time much smoother. Lagging indicators include some massive stock variables which have modest cyclical functions yet are extremely smooth.

Most indicators display, in addition to the cyclical fluctuations that dominate the developments over spans of several years, trends that prevail across decades and reflect largely economic growth and, for nominal variables, inflation. Seasonal variations are likewise widespread but these stable or evolving patterns of intra-year change show much diversity, hence are often weakened by

aggregation, unlike the longer movements which are in general positively cross-correlated. It is a common practice to assume that the seasonal movements are exogeneous and separable, and cyclical indicators are used predominantly in 'seasonally adjusted' form. The reason is to show the trends and cycles in monthly or quarterly data more clearly, but control against significant errors from faulty seasonal adjustments is also necessary, and often neglected.

The indicators, then, are viewed as composites of trends, cyclical and 'irregular' movements. The latter are generally small and of stable random appearance, apart from occasional outliers due to some particular disturbances such as major strikes or unseasonable weather. The 'classical' decomposition approach does not rule out some interactions among the component movements. What is alien to the indicator analysis, however, is the more recent notion that the trends and cycles themselves are purely stochastic phenomena, essentially random walks or results of the cumulation of random changes.

In a growing economy business expansions must be on the average larger than contractions in terms of output, employment, etc., and they are also likely to be longer. The individual cycles and their phases, however, vary greatly in duration and amplitude. These differences are systematically related to the scope or diffusion of the cyclical movements among different units of observation (e.g. activities, regions, industries). Vigorous expansions are generally more widespread than weak expansions; severe contractions are more widespread then mild contractions. But the timing sequences and amplitude differences among the indicators are observed during long and short, strong and weak cycles.

Diffusion indexes are time series showing the percentage of items in a given population that are rising over a specified unit period. Information about the direction of the change can often be obtained much more readily than information about the size of the change, hence surveys designed to produce timely diffusion measures on actual or expected sales, prices, profits, etc., are popular in many countries. Moreover, diffusion indices are correlated with rates of change in the corresponding aggregates and tend to lead the levels of these aggregates.

Significance in Business Cycle Theories

The indicators in current use play important roles in many areas viewed as critical in business cycle theories. This is illustrated by the summary in Table 1, based on a long series of studies (for references, see Zarnowitz 1972, 1985; Moore 1983, pp. 347–351).

Indicators, Table 1

Theories or models	Some of the main factors	Evidence from time series
Accelerator-multiplier models; hypotheses on autonomous investment, innovations, and gestation lags	Interaction between investment, final demand and savings	Large cyclical movements in business investment commitments (orders, contracts) lead total output and employment; smaller movements in investment realizations (shipments, outlays) coincide or lag
Inventory investment models	Stock adjustments in response to sales changes and their effects on production	Inventory investment tends to lead; its declines during mild recessions are large relative to those in final sales
Old monetary over-investment and current monetarist theories	Changes in the supply of money, bank credit, interest rates, and the burden of private debt	Money and credit flows (rates of change) are highly sensitive, early leaders; velocity, market rates of interest, credit outstanding coincide or lag
Hypotheses of cost-price imbalances, volatility of prospective rates of return, and expectational errors	Changes in costs and prices, in the diffusion, margins, and totals of profits, and in business expectations	Profit variables and stock price indexes are sensitive early leaders. Unit labor costs lag

The literature on business cycles, though rich in ingenious hypotheses of varying plausibility and compatibility, produced no unified theory (Haberler 1964; Zarnowitz 1985). There is evidence in support of a number of different models that focus on period-specific or sector-specific aspects of the economy's motion. Monocausal theories may help explain some episodes but are invalidated by long experience. The regularities noted above are complementary in the interdependent economic system but some of them may be more important under certain temporarily prevailing conditions, others under different conditions. Thus, for business cycles analysis and forecasting, groups of leading, coincident and lagging indicators representing a whole set of these relationships are expected to outperform any individual indicators or subsets representing fewer regularities. This insight provides a general rationale for the line of research summarized below.

Selecting and Explaining the Principal Indicators

Cyclical indicators have been selected and analysed in a series of studies by the NBER and most recently by the Bureau of Economic Analysis (BEA) in the US Department of Commerce (Mitchell and Burns 1938; Moore 1950, 1961; Moore and Shiskin 1967; Zarnowitz and Boschan 1975a, b). The results include a cross-classification of over 100 series by several broad 'economic-process' groups (e.g. production and income, fixed capital investment, money and credit) and typical timing at business cycle peaks and troughs. The data are regularly presented in a monthly report of BEA, *Business Conditions Digest* (BCD). A detailed weighting scheme was developed to score each of these series by seven major criteria: economic significance, statistical adquacy, consistency of cyclical timing, conformity to business expansions and contractions, smoothness, prompt availability or currency, and reliability of preliminary as compared with revised data. As far as possible, the assessments were based on statistical measures to ensure their consistency and replicability.

The information thus collected served as a basis for the construction of *composite indexes* of leading, coincident and lagging indicators. These indexes incorporate the best-scoring series from the different economic-process categories and combine those with similar cyclical timing, using their overall performance scores as weights. The series are all monthly; all but a few, as noted below, represent real rather than nominal variables.

The coincident index comprises non-farm employment, industrial production, real personal income less transfer payments, and real manufacturing and trade sales. Repeated tests showed this index to have a better record of conformity, timing and currency than alternative indexes including real GNP and the unemployment rate.

There are good reasons to expect the sequences of the leading, coincident and lagging indexes to persist, as indeed they do. Several of the component leaders represent early stages of production and investment processes – commitments that precede the later stages of outlays, construction put in place and deliveries. This subset includes new business formation, contracts and orders for plant and equipment, new orders for consumer goods and materials, and permits for new housing.

The timing relations depend not only on technology but also on the state of the economy. Thus delivery periods get progressively longer just before and during recoveries and especially in booms when orders back up and strain the capacity to produce; and they get progressively shorter when an expansion slows down and a contraction develops. This explains the leads of vendor performance, percent of companies receiving slower deliveries and also, in part, the fact that the leads of the indicators tend to be considerably longer, but also more variable, at peaks than at troughs.

The change in manufacturing and trade inventories on hand and on order tends to turn before sales to which the desired level of the stocks is adjusted (a type of accelerator relationship). This series, a volatile mixture of intended and unintended investment, requires some smoothing. Total inventories move sluggishly; the ratio of inventories to sales is a component of the lagging index.

Sensitive prices of industrial materials are related to new orders, vendor performance and

inventory investment. The leading composite now includes the rate of change in an index of these prices but this is a very volatile series, even in somewhat smoothed form. In times of low inflation, the index itself (i.e. the level of such prices) would probably make a better indicator.

Another nominal indicator, the rate of change in business and consumer credit outstanding, leads because the new loans principally serve to finance investment in processes that are themselves leading (in inventories, housing and consumer durables; also in plant and equipment, where the loans are largely taken out early in the process). Here too, there are timing sequences that reflect stock-flow relationships: new increments lead, totals lag. The stock of commercial and industrial loans outstanding (deflated) is a component of the lagging index, and so is the ratio of consumer installment credit outstanding to personal income.

Compared with the overall credit flows, rates of growth in monetary aggregates show in general lower cyclical conformities and amplitudes and more random variations. They have historically led at business cycles turns by highly variable but mostly long intervals. The aggregates themselves are dominated by strong upward trends and show persistent declines only in cycles with severe contractions. However, a measure of 'real balances', the broadly defined money supply M2 deflated by a consumer price index, anticipated most of the recent business turns and is included in the current leading index. In late stages of expansion (contraction) money increased less (more) than prices.

The Standard & Poor's price index of 500 common stocks is included in the leading composite without adjustment for inflation. The market apparently tracks or anticipates well the movement of corporate earnings which is itself characterized by early timing. Money wages often rise less than prices in recoveries and more than prices late in expansion, while output per hour of labour fluctuates procyclically around a rising trend, generally with leads. Labour costs per unit of output, therefore, also move procyclically relative to their upward trends but with lags (they are a component of the lagging index). As a result of these tendencies connected with cyclical changes in sales and the rates of utilization of labour and capital, profit margins and totals swing widely in each cycle with sizeable leads.

Stock prices also tend to react inversely to changes in market interest rates. It is when an expansion (contraction) is well advanced and sufficiently strong that bank rates and bond yields tend to rise (decline) substantially, that is, interest rates generally lag. The average prime rate charged by banks is included in the lagging index.

Finally, there are the labour market indicators. Changes in hours are less binding than changes in the number employed, so the average workweek in manufacturing leads because it is altered early in response to uncertain signs of shifts in the demand for output. Initial claims for unemployment insurance lead the unemployment rate by short intervals. The average duration of unemployment lags the unemployment rate and is a component of the lagging index. These series, of course, show strong countercyclical movements, so they are used in inverted form.

Functions

When used collectively, the indicators provide over the course of business cycles a revolving flow of signals. Shallow and spotty declines in the leading series provide only weak and uncertain warnings; a run of several large declines increases a risk of a general and serious slow-down or recession. The latter may suggest some stabilizing policy actions which, if effective, could falsify the warning. The coincident indicators confirm or invalidate the expectations based on the behaviour of the leaders and any related policy decisions.

The lagging indicators provide further checks on the previously derived inferences, in particular on any early designation of the timing of a business cycle turn. Moreover, they also act as predictors. The turning points in the lagging index systematically precede the opposite turns in the leading index. Unit labour costs, interest rates, outstanding debt, and inventories measure or reflect the costs of doing business. For this reason, these series, when inverted, show very long leads.

For example, declines in inventories and interest rates during a recession pave the way for an upturn in new orders and then output of materials and finished goods (Zarnowitz and Boschan 1975b; Moore 1983, ch. 23).

Critique and Evidence

Enough has been said above on the reasons for the observed behaviour of indicators and their links to business cycle theories to weaken if not disprove the charge of 'measurement without theory'. If the reasons are simple so much the better. Macroeconomic forecasting, which the indicator system is designed to aid, must be essentially consistent with the ascertained regularities of business fluctuations, however difficult it may be to reconcile these 'stylized facts' with the preconceptions of general equilibrium theory.

The real problems with the indicators are mainly practical. Large amounts of random noise, large revisions of originally published figures, and short lead times (which occur mostly at troughs of short recessions) detract from the usefulness of some leading series. Those irregular variations and data errors in its components that are independent tend to cancel out in the leading index, which is therefore relatively smooth. This reduces but does not eliminate the problem of extra turns or false warnings. The index signalled each of the eight recessions but also each of the four major slow-downs (phases of below-average but still positive growth) in 1948–85. In sum, the leading indicators predict best the 'growth cycles', that is, fluctuations in trend-adjusted aggregates of output, employment, etc. This was found to be true as well for Japan, Canada and the major countries of Western Europe (Moore 1983, chs 5 and 6). A sequential signalling system designed to safeguard against false signals and discriminate in a timely fashion between recessions and slow-downs has been devised and tested with promising results (Zarnowitz and Moore 1982).

Forecasting with leading indicators has a long history of applications, elaborations, and revisions occasioned by new data and research findings, and changes in the workings of the economy (Burns 1950; Moore 1983, ch. 24). Repeated tests were made of both the turning-point predictions and forecasts of series such as real GNP and industrial production (Hymans 1973; Neftci 1979; Auerbach 1982). Tests have also been made by duplicating the US indicator test using data for other countries (Klein and Moore 1985). The most demanding, correctly performed tests produced generally positive results (see Auerbach 1982; Moore 1983, chs 24 and 25).

Indifference, Law Of

F. Y. Edgeworth

A designation applied by Jevons to the following fundamental proposition: 'In the same open market, at any one moment, there cannot be two prices for the same kind of article.'

This proposition, which is at the foundation of a large part of economic science, itself rests on certain ulterior grounds: namely, certain conditions of a perfect market. One is that monopolies should not exist, or at least should not exert that power in virtue of which a proprietor of a theatre, in Germany for instance, can make a different charge for the admission of soldiers and civilians, of men and women. The indivisibility of the articles dealt in appears to be another circumstance which may counteract the law of indifference in some kinds of market, where price is not regulated by cost of production.

Indirect Inference

Anthony A. Smith, Jr.

Abstract

Indirect inference is a simulation-based method for estimating the parameters of economic models. Its hallmark is the use of an auxiliary model to capture aspects of the data upon which to base the estimation. The parameters of the auxiliary model can be estimated using either the observed data or data simulated from the economic model. Indirect inference chooses the parameters of the economic model so that these two estimates of the parameters of the auxiliary model are as close as possible. The auxiliary model need not be correctly specified; when it is, indirect inference is equivalent to maximum likelihood.

Keywords

Auxiliary models; Bayesian inference; Criterion functions; Discrete-choice models; Dynamic stochastic general equilibrium (DSGE) models; Estimation; Lagrange multipliers; Likelihood; Likelihood ratios; Linear probability models; Maximum likelihood; Models; Probability density functions;

Reduced-form models; Seminonparametric (SNP) models; Simulated moments estimation; Simultaneous equations; Vector autoregressions; Wald test

Indirect inference is a simulation-based method for estimating, or making inferences about, the parameters of economic models. It is most useful in estimating models for which the likelihood function (or any other criterion function that might form the basis of estimation) is analytically intractable or too difficult to evaluate. Such models abound in modern economic analysis and include nonlinear dynamic models, models with latent (or unobserved) variables, and models with missing or incomplete data.

Like other simulation-based methods, indirect inference requires only that it be possible to simulate data from the economic model for different values of its parameters. Unlike other simulation-based methods, indirect inference uses an approximate, or auxiliary, model to form a criterion function. The auxiliary model does not need to be an accurate description of the data generating process. Instead, the auxiliary model serves as a window through which to view both the actual, observed data and the simulated data generated by the economic model: it selects aspects of the data upon which to focus the analysis.

The goal of indirect inference is to choose the parameters of the economic model so that the observed data and the simulated data look the same from the vantage point of the chosen window (or auxiliary model). In practice, the auxiliary model is itself characterized by a set of parameters. These parameters can themselves be estimated using either the observed data or the simulated data. Indirect inference chooses the parameters of the underlying economic model so that these two sets of estimates of the parameters of the auxiliary model are as close as possible.

A Formal Definition

To put these ideas in concrete form, suppose that the economic model takes the form:

$$y_t = G(y_{t-1}, x_t, u_t; \beta), t = 1, 2, \ldots, T, \qquad (1)$$

where $\{x_t\}_{t=1}^{T}$ is a sequence of observed exogenous variables, $\{y_t\}_{t=1}^{T}$ is a sequence of observed endogenous variables, and $\{u_t\}_{t=1}^{T}$ is a sequence of unobserved random errors. Assume that the initial value y_0 is known and that the random errors are independent and identically distributed (i.i.d.) with a known probability distribution F. Equation (1) determines, in effect, a probability density function for y_t conditional on y_{t-1} and x_t. Indirect inference does not require analytical tractability of this density, relying instead on numerical simulation of the economic model. This is not the most general model that indirect inference can accommodate – indirect inference can be used to estimate virtually any model from which it is possible to simulate data – but it is a useful starting point for understanding the principles underlying indirect inference. The econometrician seeks to use the observed data to estimate the k-dimensional parameter vector β.

The auxiliary model, in turn, is defined by a conditional probability density function, $f(y_t \mid y_{t-1}, x_t, 0)$, which depends on a p-dimensional parameter vector θ. In a typical application of indirect inference, this density has a convenient analytical expression. The number of parameters in the auxiliary model must be at least as large as the number of parameters in the economic model (that is, $p \geq k$).

The auxiliary model is, in general, incorrectly specified: that is, the density f need not describe accurately the conditional distribution of y_t determined by Eq. (1). Nonetheless, the parameters of the auxiliary model can be estimated using the observed data by maximizing the log of the likelihood function defined by f:

$$\hat{\theta} = \arg\max_{\theta} \sum_{t=1}^{T} \log f(y_t \mid y_{t-1}, x_t, \theta).$$

The estimated parameter vector $\hat{\theta}$ serves as a set of 'statistics' that capture, or summarize, certain features of the observed data; indirect inference chooses the parameters of the economic model to reproduce this set of statistics as closely as possible.

The parameters of the auxiliary model can also be estimated using simulated data generated by the economic model. First, using a random number generator, draw a sequence of random errors $\{\tilde{u}_t^m\}_{t=1}^T$ from the distribution F. Typically, indirect inference uses M such sequences, so the superscript m indicates the number of the simulation. These sequences are drawn only once and then held fixed throughout the estimation procedure. Second, pick a parameter vector β and then iterate on Eq. (1), using the observed exogenous variables and the simulated random errors, to generate a simulated sequence of endogenous variables: $\{\tilde{y}_t^m(\beta)\}_{t=1}^T$, where the dependence of this simulated sequence on β is made explicit. Third and finally, maximize the average of the log of the likelihood across the M simulations to obtain:

$$\hat{\theta}(\beta) = \arg\max_{\theta} \sum_{m=1}^{M} \sum_{t=1}^{T} \log f\left(\tilde{y}_t^m(\beta) \middle| \tilde{y}_{t-1}^m(\beta), x_t, \theta\right).$$

The central idea of indirect inference is to choose β so that $\hat{\theta}(\beta)$ and $\hat{\theta}$ are as close as possible. When the economic model is exactly identified (that is, when $p = k$), it is, in general, possible to choose β so that the economic model reproduces exactly the estimated parameters of the auxiliary model. Typically, though, the economic model is over-identified (that is, $p > k$): in this case, it is necessary to choose a metric for measuring the distance between $\hat{\theta}$ and $\hat{\theta}(\beta)$; indirect inference then picks β to minimize this distance.

As the observed sample size T grows large (with M held fixed), the estimated parameter vector in the simulated data, $\hat{\theta}(\beta)$, converges to a so-called 'pseudo-true value' that depends on β; call it $h(\beta)$. The function h is sometimes called the binding function: it maps the parameters of the economic model into the parameters of the auxiliary model. Similarly, the estimated parameter vector in the observed data, $\hat{\theta}$, converges to a pseudo-true value θ_0. In the limit as T grows large, then, indirect inference chooses β to satisfy the equation $\theta_0 = h(\beta)$. Under the assumption that the observed data is generated by the economic model for a particular value, β_0, of its parameter vector, the value of β that satisfies this equation is precisely β_0. This heuristic argument explains why indirect inference generates consistent estimates of the parameters of the economic model.

Three Examples

Example 1: A Simple System of Simultaneous Equations

The first example is drawn from the classical literature on simultaneous equations to which indirect inference is, in many ways, a close cousin. Consider a simple macroeconomic model, adapted from Johnston (1984), with two simultaneous equations: $C_t = \beta Y_t + u_t$ and $Y_t = C_t + X_t$. In this model, consumption expenditure in period t, C_t, and output (or income) in period t, Y_t, are endogenous, whereas nonconsumption expenditure in period t, X_t, is exogenous. Assume that the random error u_t is i.i.d. and normally distributed with mean zero and a known variance; the only unknown parameter, then, is β.

There are many ways to estimate β without using indirect inference, but this example is useful for illustrating how indirect inference works. To wit, suppose that the auxiliary model specifies that C_t is normally distributed with conditional mean θX_t and a fixed variance. In this simple example, the binding function can be computed without using simulation: a little algebra reveals that $\theta = \beta/(1 - \beta) \equiv h(\beta)$. To estimate β, first use ordinary least squares (which is equivalent to maximum likelihood in this example) to obtain a consistent estimate, $\hat{\theta}$, of θ. Then evaluate the inverse of h at $\hat{\theta}$ to obtain a consistent estimate of β : $\hat{\beta} = \hat{\theta}/\left(1 + \hat{\theta}\right)$. This is precisely the indirect inference estimator of β. This estimator uses an indirect approach: it first estimates an auxiliary (or, in the language of simultaneous equations, a reduced-form) model whose parameters are

complicated functions of the parameters of the underlying economic model and then works backwards to recover estimates of these parameters.

Example 2: A General Equilibrium Model of the Macroeconomy

In this example, the economic model is a dynamic, stochastic, general equilibrium (DSGE) model of the macroeconomy (for a prototype, see Hansen 1985). Given choices for the parameters describing the economic environment, this class of models determines the evolution of aggregate macroeconomic time series such as output, consumption, and the capital stock. The law of motion for these variables implied by the economic model is, in general, nonlinear. In addition, some of the key variables in this law of motion (for example, the capital stock) are poorly measured or even unobserved. For these reasons, in these models it is often difficult to obtain a closedform expression for the likelihood function.

To surmount these obstacles, indirect inference can be used to obtain estimates of the parameters of the economic model. A natural choice for the auxiliary model is a vector autoregression (VAR) for the variables of interest. As an example, let y_t be a vector containing the values of output and consumption in period t (expressed as deviations from steady-state values) and let the VAR for y_t have one lag: $y_{t+1} = Ay_t + \varepsilon_{t+1}$, where the ε_ts are normally distributed, i.i.d. random variables with mean 0 and covariance matrix Σ.

In this example, the binding function maps the parameters of the economic model into the parameters A and Σ of the VAR. To obtain a simulated approximation to the binding function, pick a set of parameters for the economic model, compute the law of motion implied by this set of parameters, simulate data using this law of motion, and then use OLS to fit a VAR to the simulated data. Indirect inference chooses the parameters of the economic model so that the VAR parameters implied by the model are as close as possible to the VAR parameters estimated using observed macroeconomic time series. Smith (1993) illustrates the use of indirect inference to estimate DSGE models.

Example 3: A Discrete-Choice Model

In this example, the economic model describes the behaviour of a decision-maker who must choose one of several discrete alternatives. These models typically specify a random utility for each alternative; the decision-maker is assumed to pick the alternative with the highest utility. The random utilities are latent: the econometrician does not observe them, but does observe the decision-maker's choice. Except in special cases, evaluating the likelihood of the observed discrete choices requires the evaluation of high-dimensional integrals which do not have closed-form expressions.

To use indirect inference to estimate discrete-choice models, one possible choice for the auxiliary model is a linear probability model. In this case, the binding function maps the parameters describing the probability distribution of the latent random utilities into the parameters of the linear probability model. Indirect inference chooses the parameters of the economic model so that the estimated parameters of the linear probability model using the observed data are as close as possible to those obtained using the simulated data. Implementing indirect inference in discrete-choice models poses a potentially difficult computational problem because it requires the optimization of a non-smooth objective function. Keane and Smith (2003), who illustrate the use of indirect inference to estimate discrete-choice models, also suggest a way to smooth the objective surface.

Three Metrics

To implement indirect inference when the economic model is over-identified, it is necessary to choose a metric for measuring the distance between the auxiliary model parameters estimated using the observed data and the simulated data, respectively. There are three possibilities corresponding to the three classical hypothesis tests: Wald, likelihood ratio (LR), and Lagrange multiplier (LM).

In the Wald approach, the indirect inference estimator of the parameters of the economic model minimizes a quadratic form in the

difference between the two vectors of estimated parameters:

$$\hat{\beta}^{Wald} = \arg\min_{\beta} \left(\hat{\theta} - \hat{\theta}(\beta)\right)' W \left(\hat{\theta} - \hat{\theta}(\beta)\right),$$

where W is a positive definite 'weighting' matrix.

The LR approach to indirect inference forms a metric using the (approximate) likelihood function defined by the auxiliary model. In particular,

$$\hat{\beta}^{LR} = \arg\min_{\beta} \left(\sum_{t=1}^{T} \log f\left(y_t | y_{t-1}, x_t, \hat{\theta}\right) - \sum_{t=1}^{T} \log f\left(y_t | y_{t-1}, x_t, \hat{\theta}(\beta)\right). \right).$$

By the definition of $\hat{\theta}$, the objective function on the right-hand side is non-negative, and its value approaches zero as $\hat{\theta}(\beta)$ approaches $\hat{\theta}$. The LR approach to indirect inference chooses β so as to make this value as close to zero as possible. Because the first term on the right-hand side does not depend on β, the LR approach can also be viewed as maximizing the approximate likelihood subject to the restrictions, summarized (for large T) by the binding function h, that the economic model imposes on the parameters of the auxiliary model.

Finally, the LM approach to indirect inference forms a metric using the derivative (or score) of the log of the likelihood function defined by the auxiliary model. In particular,

$$\hat{\beta}^{LM} = \arg\min_{\beta} S(\beta)' V S(\beta),$$

where

$$S(\beta) = \sum_{m-1}^{M} \sum_{t=1}^{T} \frac{\partial}{\partial \theta} \log f\left(\tilde{y}_t^m(\beta), x_t, \hat{\theta}\right)$$

and V is a positive definite matrix. By definition, $\hat{\theta}$ sets the score in the observed data to zero. The goal of the LM approach, then, is to choose β so that the (average) score in the simulated data, evaluated at $\hat{\theta}$, is as close to zero as possible.

For any number, M, of simulated data-sets, all three approaches deliver consistent and asymptotically normal estimates of β as T grows large. The use of simulation inflates asymptotic standard errors by the factor $(1 + M^{-1})^{1/2}$; for $M \geq 10$, this factor is negligible. When the economic model is exactly identified, all three approaches to indirect inference yield numerically identical estimates; in this case, they all choose β to solve $\hat{\theta}(\beta) = \hat{\theta}$.

When the economic model is over-identified, the minimized values of the three metrics are, in general, greater than zero. These minimized values can be used to test the hypothesis that the economic model is correctly specified: sufficiently large minimized values constitute evidence against the economic model.

If the weighting matrices W and V are chosen appropriately, then the Wald and LM approaches are asymptotically equivalent in the sense that they have the same asymptotic covariance matrix; by contrast, the LR approach, in general, has a larger asymptotic covariance matrix. If, however, the auxiliary model is correctly specified, then all three approaches are asymptotically equivalent not only to each other but also to maximum likelihood (for large M). Because maximum likelihood is asymptotically efficient (that is, its asymptotic covariance matrix is as small as possible), the LM approach is sometimes called the 'efficient method of moments' when the auxiliary model is close to being correctly specified; in such a case, this name could also be applied to the Wald approach.

When estimating the parameters of the auxiliary model is difficult or timeconsuming, the LM approach has an important computational advantage over the other two approaches. In particular, it does not require that the auxiliary model be estimated repeatedly for different values of the parameters of the economic model. To estimate continuous-time models of asset prices, for example, Gallant and Tauchen (2005) advocate using a semi-nonparametric (SNP) model as the auxiliary model. As the number of its parameters increases, an SNP model provides an arbitrarily accurate approximation to the data generating process, thereby permitting indirect inference to approach the asymptotic efficiency of maximum likelihood. For this class of auxiliary models, which are nonlinear and often have a large number of parameters, the LM approach is a computationally attractive way to implement indirect inference.

Concluding Remarks

Indirect inference is a simulation-based method for estimating the parameters of economic models. Like other simulation-based methods, such as simulated moments estimation (see, for example, Duffie and Singleton 1993), it requires little analytical tractability, relying instead on numerical simulation of the economic model. Unlike other methods, the 'moments' that guide the estimation of the parameters of the economic model are themselves the parameters of an auxiliary model. If the auxiliary model comes close to providing a correct statistical description of the economic model, then indirect inference comes close to matching the asymptotic efficiency of maximum likelihood. In many applications, however, the auxiliary model is chosen, not to provide a good statistical description of the economic model, but instead to select important features of the data upon which to focus the analysis.

There is a large literature on indirect inference, much of which is beyond the scope of this article. Gouriéroux and Monfort (1996) provide a useful survey of indirect inference. Indirect inference was first introduced by Smith (1990, 1993) and later extended in important ways by Gouriéroux et al. (1993) and Gallant and Tauchen (1996). Although indirect inference is a classical estimation method, Gallant and McCulloch (2004) show how ideas from indirect inference can be used to conduct Bayesian inference in models with intractable likelihood functions. There have been many interesting applications of indirect inference to the estimation of economic models, mainly in finance, macroeconomics, and labour economics. Because of its flexibility, indirect inference can be a useful way to estimate models in all areas of economics.

Indirect Taxes

John Kay

It is conventional to describe direct taxes as taxes where the person legally liable to pay the tax is also the person whose income or welfare is reduced as a result of its imposition: while indirect taxes are those where liability can be shifted to someone else. This distinction is essentially an arbitrary one. All taxes can be shifted to some degree: only in exceptional circumstances can any agent shift a tax completely. In common usage, indirect taxes are those which are paid by retailers, wholesalers or manufacturers, but

believed to be shifted toward final consumers. In this entry indirect taxation is regarded as synonymous with commodity taxation.

There are three main categories of indirect tax. Excise duties fall on particular commodities, especially those goods which are traditionally subject to particularly heavy taxation, such as tobacco products and alcoholic drinks. Such taxes are often specific – charged per unit of the commodity concerned – but may be ad valorem – assessed as a percentage of the retail price. In many countries these specific tax rates have failed to keep pace with inflation, and this has tended to reduce the incidence of these taxes in relation to total revenue and to the price of the commodities concerned.

More broadly based indirect taxes are usually set at ad valorem rates. These may be single stage taxes, collected at wholesale or retail level. Alternatively, multi-stage taxes may be imposed at each part of the production process. Turnover or cascade taxes are of this kind, but the most common multi-stage tax is a value added tax. This has been obligatory for member states of the EEC since directives based on the Neumark Report of 1963, and is now used in around forty countries. This tax is payable at all stages of production, but recoverable by all business purchasers, who are however obliged to charge tax on their own output. The consequence is that net tax is payable only on sales to final consumers.

The value added tax is consistent with one important result from the theory of commodity taxation. This is that commodity taxes should be levied only on purchases of goods by final consumers, and not on intermediate transactions between producers (Diamond and Mirrlees 1971). The reason for this is that the distributional or other objectives of commodity taxation can in all cases be achieved equally well by the taxation of final commodities; the taxation of intermediate goods achieves no advantage in this but additionally distorts the choices of inputs made by producers. It therefore imposes the avoidable distortion of production inefficiency on top of the inevitable deadweight loss in consumption which is common to any system of commodity taxation.

Commodity taxes impose deadweight losses on consumers. These arise from the distortions of consumer choice which create costs over and above the tax revenue derived by governments. Traditionally these have been expressed in terms of consumer surplus triangles but are now more effectively expressed using the dual formulation of demand theory implied by the expenditure function (Diamond and McFadden 1974). This gives deadweight loss as

$$\mathrm{L} = \mathrm{E}(p^{+}t, u) - \mathrm{E}(p, u) - tx$$

where p is a vector of producer prices, t is the tax vector, x the purchased commodity vector and u the reference utility level for evaluation of the expenditure function.

The optimal structure of commodity taxation may be derived from the minimization of L, and this leads to two schools of thought on the appropriate structure of commodity taxes. By choosing a vector t to minimize L we derive the Ramsey (1927) rules for optimal commodity tax rates in the implicit form

$$\sum_j t_j \left(\frac{\partial x_i}{\partial t_j}\right)_u = \lambda x_i$$

for some λ increasing in tax revenue. This can be interpreted as requiring that the compensated demand for all goods should be reduced in the same proportion. If there is no net complementarity or substitutability, this condition reduces to

$$\frac{t_i}{p_i} = \lambda \frac{x_i}{p_i}\left(\frac{\partial x_i}{\partial t_i}\right)_u$$

which yields an inverse elasticity rule: tax should bear most heavily on commodities in inelastic demand.

A weakness of this analysis is that L is still more effectively minimized – indeed reduced to zero – by the imposition of a lump sum tax. While lump sum taxes varying across individuals and independent of their economic behaviour are generally reckoned to be impracticable, a uniform lump sum is feasible. The primary reasons for

rejecting a poll tax – concern for distributional effects among households with different tastes and endowments – are abstracted from in the Ramsey formulation. A more direct way of reaching the same conclusion is to observe that life is the most inelastically demanded commodity of all. It follows that any set of Ramsey taxes will always be dominated by a poll tax.

If, however, a distributional objective is introduced then any set of commodity taxes will generally be inferior to a tax related to the total income of the consumer (or his total consumption, since there is no difference at the present level of abstraction). Thus there is a role for commodity taxes only if they are related to other household characteristics which cannot be observed and taxed directly, such as household skill levels. The argument illustrates a general feature of recent optimal tax theory, which shows that efficient tax structures are often very sensitive to the assumptions made about the other policy instruments available.

These results direct attention towards a different tradition (see, for example Hotelling 1938), which favours uniformity of rates of commodity taxes, on the grounds that this leaves relative commodity prices equal to relative marginal costs. This would be appropriate if all commodities were taxable, but there is at least one important good – leisure – which cannot be subjected to taxation. This takes the problem of optimal commodity taxes into the realm of the second best and suggests relatively high rates of taxation on those goods which are complementary with leisure and lower rates on those which are substitutes for it.

There are other reasons for departures from uniformity. Merit goods (Musgrave 1959) are commodities, such as education, whose consumption is thought to have some value, either social or for the individual concerned, beyond his own personal assessment. This may be a reason for specially low rates of tax on particular commodities or, more commonly, for specially high excise taxes. Corrective taxes are also a means by which market outcomes can be induced to reflect the externalities – good or bad – which are associated with particular kinds of production or consumption.

With these exceptions, the theoretical arguments for extensive departures from a general principle of uniformity in commodity taxation do not seem strong. In the main, most objectives which governments seek through elaborately differentiated rate structures can be more effectively achieved in other ways. Since this uniformity has considerable administrative advantages, both analytical and practical considerations point in a similar direction. The widespread move throughout the world to broadly based value-added taxes as a primary instrument of indirect taxation reflects the application of these principles.

Indirect Utility Function

Peter Newman

JEL Classifications
D1

After many independent discoveries that were widely separated in time and space, the indirect utility function has in the last 35 years gradually

become a standard part of demand theory. Its first discovery was made as early as 1886 by Antonelli in Italy, who also derived what has come to be known as Roy's Identity (see Chipman's introduction to the translation of Antonelli (1886) in Chipman et al. 1971). Later contributions came from Konyus (1924, 1926) and Byushgens in Russia, from Hotelling (1932) and Court (1941, pp. 284–97) in the United States, from Roy (1942, 1947) and Ville (1946) in France, and from Wold (1943–4) and Malmquist (1953) in Sweden; a good brief history may be found in Diewert (1982, pp. 547–50).

But it was not until the early 1950s and the contributions of Houthakker (1951–2, 1960) that the indirect utility function became an integral part of the theory of consumer's behaviour. Indeed, the very names in standard use appear to be due to him, 'indirect utility function' in (1951–2, p. 157) and 'Roy's Identity' in (1960, p. 250).

Definition and Simple Properties

Suppose that the consumer has completely preordered preferences defined over the commodity space R^{n+} of non-negative bundles $x = (x_1, x_2, \ldots, x_n)$, that those preferences are representable by a real-valued utility function u, that he (or she) faces competitively determined positive money prices $(p_1, p_2, \ldots, p_n) = p$ for the n goods, and has exogenously determined monetary wealth $\omega > 0$. It is standard in demand theory to assume that the consumer chooses a bundle x^* by solving the optimization problem:

$$\text{Max } (p, \omega) \text{ Find } x \in R^{n+} \text{ to max } u(x) \text{ subject to } \langle p, x \rangle \leq \omega \quad (1)$$

where the notation $\langle \cdot, \cdot \rangle$ means the inner product of the two vectors concerned.

Assume that Max (p, ω) has a unique solution x^*, for which it suffices that preferences be monotonically increasing and strictly convex. Then the number

$$\tau^* = u(x^*) \quad (2)$$

is the *value* of Max(p, ω). This joint determination of solution and value once p and ω are known implies the existence of two functions of the price-wealth pair (p, ω), called respectively the *ordinary* (or Marshallian) *demand function* f: $R^{n++} \times R^{++} \to R^{n++}$, defined by

$$x^* = f(p, \omega) \quad (3)$$

and the *indirect utility function* v: $R^{n++} \times R^{++} \to R$, defined by

$$\tau^* = v(p, \omega) \quad (4)$$

Define the attainable (or budget) set $A(p, \omega)$ by

$$A(p, \omega) = \{x \in R^{n+} : \langle p, w \rangle \leq \omega\}$$

From (1) it follows that for any $\lambda > 0$, $A(\lambda p, \lambda\omega) = A(p, \omega)$, so that both f and v are positively homogeneous of degree zero in (p, ω). Next, if $(p^1 - p^2) \in R^{n+}$ and $p^1 \neq p^2$ then $A(p^1, \omega) \subset A(p^2, \omega)$, from which $v(p^1, \omega) \leq v(p^2, \omega)$; for similar reasons, $v(p, \cdot)$ is nondecreasing. It can be shown further that if u is continuous then so is v (see e.g. Varian 1984, pp. 121, 326–7).

A useful result is that $v(\cdot, \omega)$ is quasi-convex. To prove this let $p^t = tp^1 + (1 - t)p^2$, where $t \in [0, 1]$. Then for any $x \in A(p^t, \omega)$,

$$t\langle p^1, x \rangle + (1 - t)\langle p^2, x \rangle < \omega. \quad (5)$$

If $t = 0$, $x \in A(p^2, \omega)$, while if $t = 1$, $x \in A(p^1, \omega)$. Otherwise, suppose that x is in neither $A(p^1, \omega)$ nor $A(p^2, \omega)$. Then $t\langle p^1, x \rangle > t\omega$ and $(1 - t)\langle p^2, x \rangle > (1 - t)\omega$, which on addition yield a contradiction to (5). So x is in either $A(p^1, \omega)$ or $A(p^2, \omega)$. Hence $v(p^t, \omega)$, which is the sup of $u(\cdot)$ on $A(p^1, \omega)$, can be no larger than $\max[v(p^1, \omega), v(p^2, \omega)]$, which are themselves the sups of u$(\cdot)$ on $A(p^1, \omega)$ and $A(p^2, \omega)$, respectively. But the condition $v(p^t, \omega) \leq \max[v(p^1, \omega), v(p^2, \omega)]$ is the original definition of the quasi-convexity of the function $v(\cdot, \omega)$ (see Fenchel 1953, p. 117).

Relations Between the Ordinary Demand Functions and the Indirect Utility Function

For simplicity, the following assumptions are made: (a) x^* is a strictly positive vector. (b) Each function involved is as differentiable as required. (c) At any $x \in R^{n+}$ there is at least one commodity in which u is strictly increasing (this implies local non-satiation of preferences).

Suppose that at x^* the constraint (1) is 'slack', i.e. $\omega - \langle p, x^* \rangle = \delta > 0$. Let k be any good with property (c) at x^*, and define a new bundle x^1 by putting $x_i^i = x_i^*$ for $i \neq k$, and $x_k^1 = x_k^* + (\delta/p_k)$. Then by construction $\langle p, x^1 \rangle = \omega$, while from (c) $u(x^1) > u(x^*)$, contradicting the hypothesis that x^* solves max(p, ω). So

$$\langle p, x^* \rangle = \omega \tag{6}$$

Next, define $L: R^{n+} \times R^{n++} \rightarrow R$ by

$$L(x^1, p^1) = v(p^1, \langle p^1, x^1 \rangle) - u(x^1) \tag{7}$$

where x^1 and p^1 are arbitrary. From (2) and (4), for any x^1 the value $v(p^1, \langle p^1\ x^1 \rangle)$is the *maximized* level of utility when prices are p^1 and wealth $\langle p^1, x^1 \rangle > 0$. Hence, $L(\cdot, p^1)$ is positive semi-definite, i.e. $x^1 \in R^{n+}$ implies $L(x^1, p^1) \geq 0$ for any p^1. Putting $p^1 = p$, the actual prices, if x^* solves Max(p, ω) it follows from (2), (4) and (6) that

$$L(x^*, p) = v(p, \langle p, x^* \rangle) - u(x^*) = 0 \tag{8}$$

Hence x^* attains the infimum of L$(\cdot, p)$. So from (6), (8) and the Chain Rule,

$$\forall i = 1, 2 \ldots, n \quad v\omega(p, \omega) p_i = u_i(x^*) \tag{9}$$

From (c), $u_i(x^*) > 0$ for at least one i. Since $p_i > 0$ this implies the simple but important result

$$v\omega(p, \omega) > 0 \tag{10}$$

i.e. the marginal utility of wealth is positive.

From (2), (3) and (4) the equation

$$v(p, \omega) = (f(p, \omega))$$

is an identity in (p, ω). So differentiating each of the individual demand functions f_i with respect to (wrt) each p_j and ω yields,

$$\begin{gathered} \forall\ j = 1, 2, \ldots, n \quad v_j(p, \omega) = \sum u_i(x^*) f_{ij}(p, \omega) \\ v\omega(p, \omega) = \sum u_i(x^*) f_i \omega(p, \omega) \end{gathered} \tag{11}$$

From (6) and (3),

$$\langle p, f(p, \omega) \rangle = \omega$$

This is another identity in (p, ω), and differentiating it wrt each p_j and ω results in

$$\begin{gathered} \forall j = 1, 2, \ldots, n \ f_i(p, \omega) + \Sigma p_i f_{ij}(p, \omega) = 0 \\ \Sigma p_i f_{i\omega}(p, \omega) = 1 \end{gathered} \tag{12}$$

$$\sum p_i f_i \omega(p, \omega) = 1$$

From (11) and (9),

$$\begin{aligned} \forall j = 1, 2, \ldots, n \quad & v_j(p, \omega) \\ & = v\omega(p, \omega) \sum p_i f_{ij}(p, \omega) \end{aligned}$$

and from this and (12),

$$\begin{aligned} \forall j = 1, 2, \ldots, n \qquad & v_j(p, \omega) \\ & = -f_j(p, \omega) v\omega(p, \omega) \end{aligned} \tag{13}$$

Equation (13) is the main result connecting v with f. From (3), (a), (10) and (13) there follow

$$\forall j = 1, 2, \ldots, n \quad v_j(p, \omega) < 0 \tag{14}$$

and Roy's Identity (1942, p. 24; 1947, p. 217),

$$\begin{aligned} \forall j = 1, 2, \ldots, n \quad & x_j^* \\ & = -v_j(p, \omega) | v\omega(p, \omega) \end{aligned} \tag{15}$$

As deservedly famous as is (15), its equivalent version (13) reveals the structures involved more clearly, since it focuses sharply on the relations

between the functions v and f rather than the particular quantities x_j^*. In each of Roy's contributions the identity is first given in the form $v_j(p,\omega)|x_j^* = -v\omega(p,\omega)$, and is used primarily to prove (14); later, in Roy (1947, p. 220), the identity takes the more usual form (15).

Since (13) is an identity, differentiating it wrt any p_i yields $\forall i, j = 1, 2, \ldots, n$

$$-v_{ji}(p,\omega) = f_{ji}(p,\omega)v\omega(p,\omega) + f_j(p,\omega)v\omega_i(p,\omega)$$

Applying Young's Theorem to these equations, by symmetry,

$$\begin{aligned}\forall i,j = 1,2,\ldots,n\ & f_{ij}(p,\omega)v\omega(p,\omega) \\ & + f_i(p,\omega)v_{\omega j}(p,\omega) \\ & = f_{ij}(p,\omega)v_{\omega i}(p,\omega)\end{aligned} \tag{16}$$

Now make the quite restrictive assumption that for each p_i, $v_{\omega i}(p,\omega) = 0$; this requires in effect that each good have unitary elasticity of demand (see Samuelson, 1942, pp. 80–81). Then from (10) and (16).

$$\forall i,j = 1,2,\ldots,n\quad f_{ij}(p,\omega) = f_{ij}(p,\omega)$$

which are Slutsky-like equations that apply not to compensated but to ordinary demand functions.

Relations with the Cost Function and the Compensated Demand Functions

Suppose now that a *target* level of utility is specified and the following new optimization problem posed:

$$\begin{aligned}&\text{Min}(p,\ \tau) : \text{Find} \\ &x \in R^{n+}\ \text{to min}\ \langle p,x\rangle\ \text{subject to}\ u(x)\ \geq\ \tau\end{aligned} \tag{17}$$

Assume that a unique solution x^{**} to this problem exists, yielding a value $\langle p, x^{**}\rangle$. This implies the existence of two functions of the price-target pair (p, τ), called the *compensated* (or Hicksian) demand function h: $R^{n++} \times R \rightarrow R^{n+}$, defined by

$$x^{**} = h(p,\tau) \tag{18}$$

and the *cost (or expenditure)* function γ: $R^{n++} \times R \rightarrow R^{+}$, given by

$$\langle p^1, x^{**}\rangle = \gamma(p,\tau) \tag{19}$$

Retain assumptions (a)–(c), replacing x^* by x^{**}. Define M: $R^{n+} \times R^{n++} \rightarrow R$ by putting

$$M(x^1,p^1) = \gamma(p^1, u(x^1)) - \langle p^1, x^1\rangle \tag{20}$$

where x^1 and p^1 are arbitrary, as before. It follows that $M(\cdot, p^1)$ is negative semi-definite. Putting $p^1 = p$, the actual prices, it follows that if x^{**} solves Max (p, ω) then

$$M(x^{**},p) = \gamma(p,u(x^{**})) - \langle p,x^{**}\rangle = 0 \tag{21}$$

so that x^{**} maximizes $M(\cdot, p)$. Then a development *exactly* like that of the last section leads to a simple but basic result on the interrelations betwen h and γ, namely:

$$\forall j = 1,2,\ldots,n\quad \gamma_j(p,\tau) = h_j(p,\tau) \tag{22}$$

where h_j is the compensated demand function for the jth good. From (22) and (a),

$$\forall j = 1,2,\ldots,n\quad \gamma_j(p,\tau) > 0 \tag{23}$$

From (18), (22) can be rewritten in the more customary version that has come to be called *Shephard's Lemma* (Shephard 1953), although it dates back at least to Hotelling (1932).

$$\forall j = 1,2,\ldots,n\quad x_j^{**} = \gamma_j(p,\tau) \tag{24}$$

Thus (22) (or the Lemma) plays a role in the analysis of this problem which is symmetrical to that played by (13) (or Roy's Identity) in the analysis of Max(p, ω).

However, there are two important structural asymmetries between the problems max(p, ω)

and min(p, τ). First, suppose that for some reason (such as incompleteness of preferences) the utility function u does not exist, so that v does not exist either. Clearly, since Max(p, ω) requires a scalar measure of utility it cannot be defined in this new situation. However, by replacing the target level τ of utility by a target bundle x^τ, one can still define a perfectly sensible minimum problem Min(p, x^τ).

The second asymmetry is that while $v(\cdot, \omega)$ is only quasiconvex, $\gamma(\cdot, \tau)$is actually concave, and this without any assumptions on preferences. Since (full) concavity imposes sharper restrictions on any function than does quasi-convexity, the analysis of Min (p, τ) (or of Min (p, x^τ)) yields easier proofs of basic results than does that of Max (p, ω). For example, from (22) $h_{jj}(p, \tau) = \gamma_{jj}(p, \tau)$, and since $\gamma(\cdot, \tau)$ is concave $\gamma_{jj}(p, \tau) \leq 0$, proving that the substitution effect is non-positive.

Duality

It is not productive to oppose the virtues of minimum problems to those of maximum problems. Indeed, the most efficient path of the derivation of such propositions as the 'Fundamental Equation or Value Theory' (Hicks 1939, p. 309) is by a judicious mixture of the two, i.e. by first solving max(p, ω) to obtain $\tau^* = v(p, \omega)$ and $x^* = f(p, \omega)$, and then showing that x^* also solves min(p, τ^*). One interesting result that one can reach by this route relates all four functions v, f, γ and h in one equation:

$$\forall\ i, j = 1, 2, \ldots, n \qquad \gamma_i(p, \tau^*) f_j \omega(p, \omega) = -\ v_i(p, \omega) h_{j\tau}(p, \tau^*) \tag{25}$$

Since from Shephard's Lemma the left-hand side of (25) is the Hicksian income effect of a change in p_i on the demand for good j, so is the right-hand side (RHS). Notice that although each of the components of the RHS is affected by choice of the utility index u, their product is not.

Revert now to the assumptions of section "Definition and Simple Properties". The problems Max(p, ω) and Min (p, τ^*) are often referred to in the literature as dual to each other. For reasons given in detail in the entry on cost minimization and utility maximization, this usage seems inappropriate. However, as pointed out by Konyus and Byushgens (1926, p. 159) and Houthakker (1951–2, pp. 157–8), there *is* an interesting duality between the functions u and v. To show this, first rewrite the given prices and income (p, ω) as (p^*, ω^*), where $\omega^* > 0$ will be kept constant throughout. Next, define new income-normalized prices $q \in R^{n++}$ for any p by

$$q = (\omega^*) - 1p \tag{26}$$

Then use the homogeneity of f and v in (p, ω) to put them in the normalized forms F: $R^{n++} \to R^{n+}$ and w: $R^{n++} \to R$, defined by

$$F(q^*) \equiv f(p^*, \omega^*)$$

and

$$w(q^*) \equiv v(p^*, \omega^*) \tag{27}$$

Let

$$A(q^*) = \{x \in R^{n+} : \langle q^*, x\rangle \leq 1\} = A(p, \omega).$$

Then Max(p^*, ω^*) can also be written in a new form:

$$\text{Max}(q^*) : \text{Find}\ \ x \in A(q^*)\ \ \text{to}\ \ \max\ \ u(x).$$

The data of Max(q^*) are q^* and u. In the same way, the chosen bundle x^* and w are the data for a problem dual to Max(q^*). Let $B(x^*) = \{q \in R^{n+}; \langle x^*, q\rangle \leq 1\}$.Then the dual problem, situated in the space of normalized prices q, is

$$\text{Min}(x^*) : \text{Find}\ \ q \in B(x^*)\ \ \text{to}\ \ \min\ \ w(q).$$

A unique solution q^{**} to Min(x^*) (for which the strict quasi-convexity of w would suffice) implies the existence of two functions $\varphi : R^{n++} \to R^{n++}$ and $U : \varphi : R^{n++} \to R$, defined analogously to (3) and to (2)-cum-(4) by

$$q^{**} = \varphi(x^*) \tag{28}$$

$$U(x^*) = w(q^{**}). \tag{29}$$

By the construction of Min(x^*), $x^* \in A(q)$ for any q. So $w(q)$ must be at least as large as the utility level at x^*. But since x^* is bought at q^*, that utility level is $w(q^*)$.

Thus

$$\forall q \in B(x^*)\ w(q) \geq w(q^*) \tag{30}$$

Since min(x^*) is assumed to have a unique solution, (30) says that it must be q^*. If follows from this, (26) and (28) that φ is actually the inverse demand function F^{-1}. Moreover, $U(x^*) = w(q^*)$. So from this, (27), (4) and (2),

$$U(x^*) = u(x^*) \tag{31}$$

However, it cannot be concluded from (31) that $U \equiv u$ unless every bundle x in the domain of u is bought at some price-income pair (p, ω) and so can be an optimizing bundle such as x^*. This property requires that u be strictly quasiconcave. Granted that, (31) shows that the direct utility function u is recoverable from the indirect utility function w, just as w is obtainable from u.

Individual Learning in Games

Teck H. Ho

Abstract

This article reviews individual models of learning in games. We show that the experience-weighted attraction (EWA) learning nests different forms of reinforcement and belief learning, and that belief learning is mathematically equivalent to generalized reinforcement, where

even unchosen strategies are reinforced. Many studies consisting of thousands of observations suggest that the EWA model predicts behaviour out-of-sample better than its special cases. We also describe a generalization of EWA learning to investigate anticipation by some players that others are learning. This generalized framework links equilibrium and learning models, and improves predictive performance when players are experienced and sophisticated.

Introduction

Economic experiments on strategic games typically generate data that, in early rounds, violate standard equilibrium predictions. However, subjects normally change their behaviour over time in response to experience. The study of learning in games is about how this behavioural change works empirically. This empirical investigation also has a theoretical payoff: if subjects' behaviour converges to an equilibrium, the underlying learning model becomes a theory of equilibration. In games with multiple equilibria, this same model can also serve as a theory of equilibrium selection, a long-standing challenge for theorists.

There are two general approaches to studying learning: population models and individual models.

Population models make predictions about how the aggregate behaviour in a population will change as a result of aggregate experience. For example, in replicator dynamics, a population's propensity to play a certain strategy will depend on its 'fitness' (payoff) relative to the mixture of strategies played previously (Friedman 1991; Weibull 1995). Models like this submerge differences in individual learning paths.

Individual learning models allow each person to choose differently, depending on the experiences each person has. For example, in Cournot dynamics, subjects form a belief that other players will always repeat their most recent choice and best-respond accordingly. Since players are matched with different opponents, their best responses vary across the population. Aggregate behaviour in the population can be obtained by summing individual paths of learning.

This article reviews three major approaches to individual learning in games: experience-weighted attraction (EWA) learning, reinforcement learning, and belief learning (including Cournot and fictitious play). These models of learning strive to explain, for every choice in an experiment, how that choice arose from players' previous behaviour and experience. These models assume strategies have numerical evaluations, which are called 'attractions'. Learning rules are defined by how attractions are updated in response to experience. Attractions are then mapped into predicted choice probabilities for strategies using some well-known statistical rule (such as logit).

The three major approaches to learning assume players that are adaptive (that is, they respond only to their own previous experience and ignore others' payoff information) and that their behaviour is not sensitive to the way in which players are matched. Empirical evidence suggests otherwise. There are subjects who can anticipate how others learn and choose actions to influence others' path of learning in order to benefit themselves. So we describe a generalization of these adaptive learning models to allow for this kind of sophisticated behaviour. This generalized model assumes that there is a mixture of adaptive learners and sophisticated players. An adaptive learner adjusts his behaviour according to one of

the above learning rules. A sophisticated player does not learn and rationally best-responds to his forecast of others' learning behaviour. This model therefore allows 'one-stop shopping' for investigating the various statistical comparisons of learning and equilibrium models.

EWA Learning

Denote player i's jth strategy by s_i^j and the other player(s)' strategy by s_{-i}^k. The strategy actually chosen in period t is $s_i(t)$. Player i's payoff for choosing s_i^j in period t is $\pi_i\left(s_i^j, s_{-1}^k(t)\right)$. Each strategy has a numerical evaluation at time t, called an attraction $A_i^j(t)$. The model also has an experience weight, $N(t)$. The variables $N(t)$ and $A_i^j(t)$ begin with prior values and are updated each period. The rule for updating attraction sets $A_i^j(t)$ to be the sum of a depreciated, experience-weighted previous attraction $A_i^j(t-1)$ plus the (weighted) payoff from period t, normalized by the updated experience weight:

$$A_i^j(t) = \frac{\varphi \cdot N(t-1) \cdot A_i^j(t-1) + \left[\delta + (1-\delta) \cdot I\left(s_i^j, s_i(t)\right)\right] \cdot \pi_i\left(s_i^j, s_{-i}(t)\right)}{N(t)} \tag{2.1}$$

where indicator variable $I(x, y)$ is 1 if $x = y$ and 0 otherwise. The experience weight is updated by:

$$N(t) = \rho \cdot N(t-1) + 1. \tag{2.2}$$

Let $\kappa = \frac{\varphi - \rho}{\varphi}$. Then $\rho = \varphi \cdot (1 - \kappa)$ and $N(t)$ approaches the steady-state value of $\frac{1}{1-\varphi \cdot (1-\kappa)}$. If $N(0)$ begins below this value, it steadily rises, capturing an increase in the weight placed on previous attractions and a (relative) decrease in the impact of recent observations, so that learning slows down.

Attractions are mapped into choice probabilities using a logit rule (other functional forms fit about equally well; Camerer and Ho 1999):

$$P_i^j(t+1) = \frac{e^{\lambda \cdot A_i^j(t)}}{\sum_k e^{\lambda \cdot A_i^k(t)}}, \tag{2.3}$$

where λ is the payoff sensitivity parameter. The key parameters are δ, φ and κ (which are generally assumed to be in the [0,1] interval).

The most important parameter, δ, is the weight on forgone payoffs relative to realized payoffs. It can be interpreted as a kind of 'imagination' of forgone payoffs, or responsiveness to forgone payoffs (when δ is larger players move more strongly toward *ex post* best responses). We call it 'consideration' of forgone payoffs. The weight on forgone payoff δ is also an intuitive way to formalize the 'learning direction' theory of Selten and Stoecker (1986). Their theory consists of an appealing property of learning: subjects move in the direction of *ex post* best-response. Broad applicability of the theory has been hindered by defining 'direction' only in terms of numerical properties of ordered strategies (for example, choosing 'higher prices' if the *ex post* best response is a higher price than the chosen price). The parameter δ defines the 'direction' of learning set-theoretically by shifting probability towards the set of strategies with higher payoffs than the chosen ones.

The parameter φ is naturally interpreted as depreciation of past attractions, $A_i^j(t-1)$. In a game-theoretic context, φ will be affected by the degree to which players realize other players are adapting, so that old observations on what others did become less and less useful. So we can interpret φ as an index of (perceived) 'change' in the environment.

The parameter κ determines the growth rate of attractions, which in turn affects how sharply players converge. When $\kappa = 0$, the attractions are weighted averages of lagged attractions and payoff reinforcements (with weights $\varphi \cdot N(t-1)/(\varphi \cdot N(t-1) + 1)$ and $1/(\varphi \cdot N(t-1) + 1)$. When $\kappa = 1$ and $N(t) = 1$, the attractions are

cumulations of previous reinforcements rather than averages (that is, $A_i^j(t) = \varphi \cdot A_i^j(t-1) + \left[\delta + (1-\delta) \cdot I\left(s_i^j, s_i(t)\right)\right] \cdot \pi_i\left(s_i^j, s_{-i}(t)\right)\Big)$. In the logit model, the *differences* in strategy attractions determine their choice probabilities. When κ is high the attractions can grow furthest apart over time, making choice probabilities closer to zero and one. We therefore interpret κ as an index of 'commitment'.

Reinforcement Learning

In cumulative reinforcement learning (Harley 1981; Roth and Erev 1995), strategies have levels of attraction which are incremented by only received payoffs. The initial reinforcement level of strategy j of player i, s_i^j, is $R_i^j(0)$. Reinforcements are updated as follows:

$$R_i^j(t) = \begin{cases} \varphi \cdot R_i^j(t-1) + \pi_i\left(s_i^j, s_{-i}(t)\right) & \text{if } s_i^j = s_i(t), \\ \varphi \cdot R_i^j(t-1) & \text{if } s_i^j \neq s_i(t). \end{cases} \tag{3.1}$$

Using the indicator function, the two equations can be reduced to one:

$$R_i^j(t) = \varphi \cdot R_i^j(t-1) + I\left(s_i^j, s_i(t)\right) \cdot \pi_i\left(s_i^j, s_{-i}(t)\right). \tag{3.2}$$

This updating formula is a special case of the EWA rule, when $\delta = 0$, $N(0) = 1$, and $\kappa = 1$.

In average reinforcement learning, updated attractions are *averages* of previous attractions and received payoffs (for example, Mookerjhee and Sopher 1994; 1997; Erev and Roth 1998). For example

$$R_i^j(t) = \varphi \cdot R_i^j(t-1) + (1-\varphi) \cdot I\left(s_i^j, s_i(t)\right) \cdot \pi_i\left(s_i^j, s_{-i}(t)\right). \tag{3.3}$$

A little algebra shows that this updating formula is also a special case of the EWA rule, when $\delta = 0$, $N(0) = \frac{1}{1-\varphi}$, and $\kappa = 0$. Since the two reinforcement models are special cases of EWA learning, their predictive adequacy can be tested empirically by setting the appropriate EWA parameters to their restricted values and seeing how much fit is compromised (adjusting, of course, for degrees of freedom).

Belief Learning

In belief-based models, adaptive players base their responses on beliefs formed by observing their opponents' past plays. While there are many ways of forming beliefs, we consider a fairly general 'weighted fictitious play' model, which includes fictitious play (Brown 1951; Fudenberg and Levine 1998) and Cournot best-response (Cournot 1960) as special cases. It corresponds to Bayesian learning if players have a Dirichlet prior belief.

In weighted fictitious play, players begin with prior beliefs about what the other players will do, which are expressed as ratios of strategy choice counts to the total experience. Denote total experience by $N(t) = \sum_k N_{-i}^k(t)$. Express the belief that others will play strategy k as $B_{-i}^k(t) = \frac{N_{-i}^k(t)}{N(t)}$, with $N_{-i}^k(t) \geq 0$ and $N(t) > 0$.

Beliefs are updated by depreciating the previous counts by φ, and adding one for the strategy combination actually chosen by the other players. That is,

$$B_{-i}^k(t) = \frac{\varphi \cdot N_{-i}^k(t-1) + I\left(s_{-i}^k, s_{-i}(t)\right)}{\sum_h \left[\varphi \cdot N_{-i}^h(t-1) + I\left(s_{-i}^h, s_{-i}(t)\right)\right]}. \tag{4.1}$$

This form of belief updating weights the belief from one period ago φ times as much as the most recent observation, so φ can be interpreted as how quickly previous experience is discarded. When $\varphi = 0$ players weight only the most recent observation (Cournot dynamics); when $\varphi = 1$ all previous observations count equally (fictitious play).

Given these beliefs, we can compute expected payoffs in each period t,

$$E_i^j(t) = \sum_k B_{-i}^k(t)\pi\left(s_i^j, s_{-i}^k\right). \quad (4.2)$$

The crucial step is to express period t expected payoffs as a function of period $t - 1$ expected payoffs. This yields:

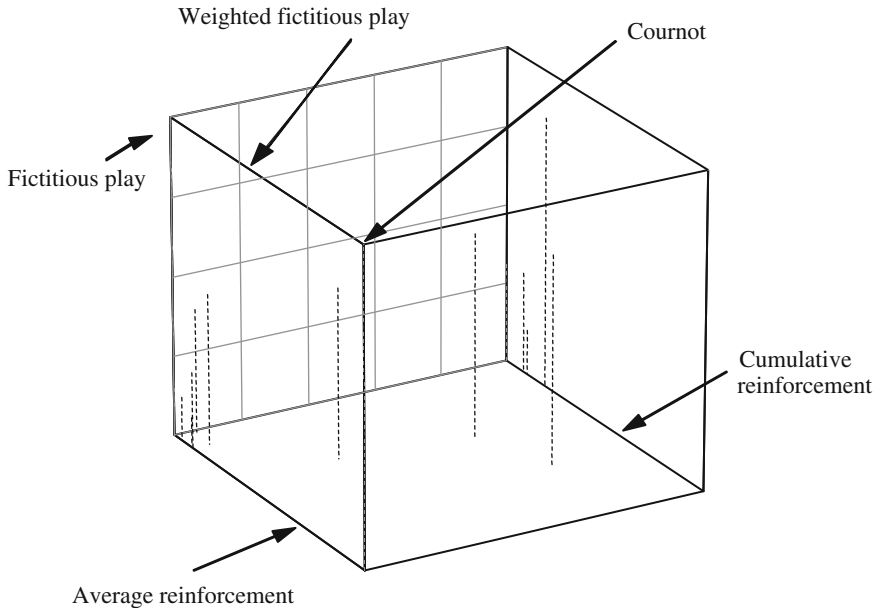
$$E_i^j(t) = \frac{\varphi \cdot N(t-1) \cdot E_i^j(t-1) + \pi\left(s_i^j, s_{-i}(t)\right)}{\varphi \cdot N(t-1) + 1}. \quad (4.3)$$

By expressing expected payoffs as a function of lagged expected payoffs, we make the belief terms disappear. This is because the beliefs are only used to compute expected payoffs, and when beliefs are formed according to weighted fictitious play, the expected payoffs which result can also be generated by generalized reinforcement according to previous payoffs. More precisely, if the initial attractions in the EWA model are expected payoffs given some initial beliefs (that is, $A_i^j(0) = E_i^j(0)$, $\kappa = 0$ (or $\varphi = \rho$), and foregone payoffs are weighted as strongly as received payoffs ($\delta = 1$), then EWA attractions are *exactly* the same as expected payoffs. Put differently, belief learning is 'mathematically equivalent' or 'observationally equivalent' to EWA learning with $\delta = 1$, $\kappa = 0$ and $A_i^j(0) = E_i^j(0)$.

This demonstrates a close kinship between reinforcement and belief approaches. Belief learning is nothing more than generalized attraction learning in which strategies are reinforced equally strongly by actual payoffs and foregone payoffs and attractions are weighted averages of past attractions and reinforcements. Hopkins (2002) compares the convergence properties of reinforcement and fictitious play and finds that they are quite similar in nature and that they will in many cases have the same asymptotic behaviour.

A Graphical Representation

Since reinforcement and belief learning are special cases of EWA learning, it is possible to represent all three learning models in a three-dimensional EWA cube (see Fig. 1). The vertex $\delta = 1$ and $\kappa = 0$ corresponds, to weighted fictitious play models. The corners $\varphi = 0$ and $\varphi = 1$



Individual Learning in Games, Fig. 1 EWA's model parametric space

correspond to Cournot best-response dynamics and fictitious play, respectively. Reinforcement models in which only chosen strategies are reinforced according to their payoffs correspond to vertices in which $\varphi = 0$, and $\kappa = 1$ (cumulative reinforcement) or $\kappa = 0$ (averaged reinforcement). Interior configurations of parameter values incorporate both the intuition behind reinforcement learning, that realized payoffs weigh most heavily ($\delta < 1$), and the intuition implicit in belief learning, that foregone payoffs matter too ($\delta > 0$).

The cube shows that contrary to popular belief for many decades, reinforcement and belief learning are simply two extreme configurations on opposite edges of a three-dimensional cube, rather than fundamentally unrelated models. Figure 1 also shows estimates of the three parameters in 20 different studies (Camerer et al. 2002). Each point is a triple of estimates. These parameter estimates were typically obtained by the maximum likelihood method. Initial attractions could be either estimated using data or set to plausible values using the cognitive hierarchy model of one-shot games; see Camerer et al. (2004) for details. Most points are sprinkled throughout the cube, rather than at the extreme vertices mentioned in the previous paragraph, although some (generally from games with mixed-strategy equilibria) are near the averaged reinforcement corner $\delta = 0$ and $\kappa = \varphi = 1$. Ho et al. (2007) provide an explanation for how δ and φ vary across games by endogenizing them as functions of game experience. Parameter estimates are generally significantly inside the interior of the cube rather than near the vertices. Thus, we may conclude that subjects' behaviour is often neither belief nor reinforcement learning.

Linking Learning and Equilibrium Models

The adaptive learning models presented above do not permit players to anticipate learning by others. Omitting anticipation logically implies that players do not use information about the payoffs of other players, and that whether players are matched together repeatedly or are randomly re-matched should not matter. Both of the latter implications are unintuitive, and experiments with experienced subjects have provided evidence to show otherwise.

In Camerer et al. (2002) and Chong et al. (2006), we proposed a simple way to include 'sophisticated' anticipation by some players that others are learning, using two additional parameters. We assume a fraction α of players are sophisticated. Sophisticated players think that a fraction $(1 - \alpha')$ of players are adaptive and the remaining fraction α' of players are sophisticated like themselves. They use the EWA model (which nests reinforcement and belief learning as special cases) to forecast what the adaptive players will do, and choose strategies with high expected payoffs given their forecast.

All the adaptive models discussed above (EWA, reinforcement, belief learning) are special cases of this generalized model with $\alpha = 0$. The assumption that sophisticated players think some others are sophisticated creates a small whirlpool of recursive thinking which implies that quantal response equilibrium (QRE; McKelvey and Palfrey 1995) and Nash equilibrium are special cases of this generalized model. Our specification also shows that equilibrium concepts combine two features which are empirically and psychologically separable: 'social calibration' (accurate guesses about the fraction of players who are sophisticated, $\alpha = \alpha'$); and full sophistication ($\alpha = 1$). Psychologists have identified systematic departures from social calibration called 'false uniqueness' or overconfidence ($\alpha > \alpha'$) and 'false consensus' or curse of knowledge ($\alpha > \alpha'$).

Formally, adaptive learners follow the EWA updating equations given above (that is, (2.1) and (2.2)). Sophisticated players have attractions $B_i^j(t)$ and choice probabilities $Q_i^j(t+1)$ specified as follows:

$$B_i^j(t) = \sum_k \left[(1-\alpha') \cdot P_{-i}^k(t+1) + \alpha' Q_{-i}^k(t+1)\right] \cdot \pi_i\left(s_i^j, s_{-i}^k\right), \tag{6.1}$$

$$Q_i^j(t+1) = \frac{e^{\lambda \cdot B_i^j(t)}}{\sum_k e^{\lambda \cdot B_i^k(t)}}. \tag{6.2}$$

The generalized model has been applied to experimental data from ten-period p-beauty contest games (specific details of data collection are given in Ho et al. 1998). In these games, seven subjects choose numbers in [0,100] simultaneously. The subject whose number is closest to p times the average (where $p = .7$ or .9) wins a fixed prize. Subjects playing for the first time are called 'inexperienced'; those playing another ten-period game (with a different p) are called 'experienced'.

The estimation results show that for inexperienced subjects, adding sophistication to adaptive EWA improves log likelihood (LL) substantially both in-and out-of-sample. The estimated fraction of sophisticated players is $\hat{\alpha} = .24$ and their estimated perception $\hat{\alpha}' = 0$. Experienced subjects show a much larger improved fit from sophistication, and a larger estimated proportion, $\hat{\alpha} = .75$. Their perceptions are again too low, $\hat{\alpha}' = .41$, showing a degree of overconfidence. The increase in sophistication due to experience reflects a kind of 'learning about learning', which is similar to rule learning (that is, subjects switch their learning rule over time (Stahl 2000; Ho et al. 2007). Overall, these results suggest that subjects are not socially calibrated, that not all subjects are sophisticated, and that the proportion of sophistication grows with experience.

Conclusions and Future Research

We describe three major approaches of adaptive learning models. We show that EWA learning is a generalization of reinforcement and belief learning and that the latter two nested models are intimately related. Specifically, they differ mainly in the way they treat forgone payoffs; reinforcement learning ignores them and belief learning treats them the same as actual payoffs. Estimation results from dozens of studies show that the emergence of behaviour is neither reinforcement nor belief learning in most games. The EWA cube provides a simple way for detecting how these simpler models fail and why.

We also describe a generalization of these adaptive models to study anticipation by some players that others are learning. This generalized model nests equilibrium and the adaptive learning models as special cases and is a powerful framework for analysing both equilibrium and learning simultaneously. We show that it can improve the predictive performance of the adaptive learning models when players are experienced and able to anticipate how others learn.

There are three promising areas of future research, all of which aim to make the above learning models more amenable to field applications.

1. *Transfer of learning across similar games.* In practice, it is unreasonable to expect people play the identical game again and again. Since people are more likely to face with similar but non-identical strategic situations, it is important to determine whether they are able to transfer learning from one situation to another. Cooper and Kagel (2004) provide evidence that subjects who have learned to play strategically in one signalling game can transfer most of this knowledge to related games. This transfer of learning occurs because the proportion of sophisticated players grows with experience (just like what we observed in p-beauty contest games discussed above). This positive evidence is encouraging but more work is necessary to determine whether this finding indeed generalizes to other games.
2. *Learning in extensive-form games.* Most of the learning literature focuses on strategic or normal-form games (for an exception see Anderson and Camerer 2000). This is done in part to simplify the learning context to situations where each action unambiguously corresponds to a final outcome. In extensive-form games or many field settings, where a final outcome is typically a result of a series of actions taken sequentially over time, there is a natural question how an action step taken at a particular time contributes to the final outcome. This 'credit assignment' problem is important because different agents might be responsible for different action steps, and some steps might be more crucial than others at determining the final outcome. A good

learning model should assign credit appropriately to each action step.

3. *Learning in noisy experiments.* There is a general belief that, given a sufficiently high stake and that people play repeatedly with a clear feedback, their behaviour will converge to equilibrium in the long run. However many real-world environments provide noisy feedback. So it is important to study how noise in feedback affects rates of learning and the likelihood of convergence to equilibrium.

Individual Retirement Accounts

Jonathan Skinner

Abstract

Individual Retirement Accounts in the United States are tax-preferred saving vehicles designed to encourage saving for retirement. Many countries have adopted similar saving mechanisms such as Individual Saving Accounts in Britain, Special Saving Incentive Accounts in Ireland, and Tax-Preferred Deposit Accounts in Belgium. Enrolment rates are substantially higher among high income taxpayers, while the saving effects are

often found to be quite modest. However, given the often low revenue cost of these tax preferred accounts, they may be reasonably cost-effective in terms of new saving per lost unit of revenue.

The Individual Retirement Account (IRA) in the United States was first introduced in 1974, but languished in relative obscurity until the Economic Recovery Tax Act of 1981 expanded eligibility to all US taxpayers. Contributions jumped from $4.8 billion in 1981 to $28.3 billion in 1982, before peaking at $37.8 billion in 1986 (Holden et al. 2005). The traditional IRA provided a tax break when contributions were made to qualified accounts, but taxed the entire withdrawal (principle plus interest) upon withdrawal. Restrictions included a ten per cent penalty for withdrawing money before age $59\frac{1}{2}$, and the requirement that the taxpayer implement a systematic withdrawal plan by age $70\frac{1}{2}$. In 2007, the limit for tax-deductible contributions was $4,000, or $5,000 for taxpayers over age 50.

The IRA came under fire during the mid-1980s because of revenue costs and concerns that it was being used as a tax shelter for high-income taxpayers. The Tax Reform Act of 1986 tax instituted income limits and, as a result, contributions dropped off rapidly, from 37.8 billion in 1986 to 14.1 billion in 1987 (Holden et al. 2005). That contributions even fell by 30 per cent among those still eligible to contribute suggests that confusion about eligibility (Hrung 2001), or a decline in advertising, may have affected taxpayer participation adversely. While the introduction of the eponymous Roth IRA, under which the taxpayer contributed after-tax dollars which were allowed to accumulate (and be withdrawn) tax-free, was popular among contributors, IRAs remain a relatively unimportant source of new saving, accounting for less than 0.2 per cent of GDP.

Nonetheless, the stock of IRA assets had grown to $3 trillion by 2007, when it comprised 20 per cent of US retirement saving (Holden et al. 2005). The reason IRAs comprise such a large fraction of wealth is that workers changing jobs or retiring are allowed to 'roll over' defined contribution (401(k)) balances into IRAs without any tax penalty. Thus IRA growth has been fuelled by these rollovers, which in 2000–1 comprised more than $200 billion annually, or about ten times the contributions by savers (Holden et al. 2005).

A number of IRA-like saving vehicles have been introduced in other countries, often with more generous eligibility and contribution rules. For example, the current (2007) contribution limit for Registered Retirement Saving Plans (RRSPs) in Canada is C$19,000. As well, taxpayers may carry forward past unused contributions, so the effective limit is generally much larger. In the United Kingdom, Individual Saving Accounts (ISAs) were introduced in 1999, replacing Personal Equity Plans (PEPs) and Tax-Exempt Special Saving Accounts (TESSAs) (Attanasio, Banks and Wakefield 2004). The contribution limit for the ISA in 2007 was £7,000 and resembled a Roth IRA in that contributions were made after taxes were paid but withdrawals and accumulated build-up were tax-free. Many other developed countries offer similar tax incentives, such as tax-preferred saving accounts for children and grandchildren in Denmark, Special Saving Incentive Accounts in Ireland, and Tax-Preferred Deposit Accounts in Belgium (see Maffini 2007). Other tax-preferred saving schemes, most notably employer-based defined-contribution pension plans such as 401(k)s in the United States, are discussed elsewhere (see pensions).

Economic Incentives

As noted above, there are two basic flavours of IRAs, traditional IRAs with an 'up-front' deduction and Roth-style IRAs, whereby taxpayers

invest tax-free dollars and withdraw the accumulated amount tax-free. The economic effects of IRAs are simplest to see in the case of a standard bond that pays a constant rate of return r^* for n years until retirement when the entire IRA is withdrawn. The marginal tax rate on an extra dollar of interest income is τ_m, at which point the tax rate shifts to τ_o while retired. If the investor invests one dollar in the conventional bond, her after-tax return at retirement will be $(1 + r^*(1-\tau_m))^n$, while an investment in a classic IRA will yield

$$\frac{(1-\tau_o)(1+r^*)^n}{1-\tau_m}$$

and a Roth IRA will return $(1 + r^*)^n$. It is straightforward to demonstrate that both the classic and the Roth IRA strictly dominate the conventional bond investment, and that the classic IRA dominates the Roth IRA under the assumption that $\tau_o < \tau_m$. This may not always be a sound assumption, particularly if retirees are too worried about higher future tax rates to pay for financially strained social insurance programmes. Gokhale et al. (2001) have observed that in some cases taxable income while retired may be subject to a higher marginal tax rate because of peculiarities in the US tax code, diminishing the advantage of traditional IRAs relative to Roth IRAs.

The decision becomes more complex when considering whether to hold equity investments inside an IRA. When a substantial fraction of the asset appreciation occurs through capital gains, one must trade off the tax advantages of the conventional IRA with the necessity to withdraw the (appreciated) assets from the IRA account starting in age $70\frac{1}{2}$ (Note that the Roth IRA does not require a withdrawal plan). As well, keeping the stock outside of an IRA retains its availability for precautionary purposes, and makes it eligible for preferential treatment of capital gains and dividends, and the possibility of stepping up the tax basis at death.

There are two key reasons why countries may decide to create IRA-style accounts. The first is to stimulate national saving, while the second is to improve the financial security of retirees, particularly those without access to employer-based pensions. The two are not necessarily overlapping. A programme that successfully stimulates saving among millionaires and billionaires may have a large impact on aggregate national saving, but do little or nothing to enhance the financial security of these households already well-prepared for the risks of retirement. Similarly, a programme that encourages low-or lower-middle-class savers by supplementing financial resources by (say) $10,000 would have a small impact on national saving but could exert a much larger proportional impact on available financial resources. That IRA inflows (excluding rollovers) in the United States comprise less than 0.2 per cent of GDP suggests a small upper limit for its impact on aggregate saving. (The size of these plans in other countries, relative to GDP, also appears modest; see Maffini 2007.)

Whether as a mechanism to increase aggregate saving or to encourage retirement security for specific households, the impact of IRAs on net saving is theoretically ambiguous. If IRA wealth and non-IRA taxable wealth were perfect substitutes, clever taxpayers could simply shuffle money from their taxable wealth accounts into IRAs, and enjoy the future or current tax rebate. If the tax incentive is further financed through deficit spending, and taxpayers spent part of the tax break, net national saving could *decline* following the introduction of an IRA programme. How individual accounts affect individual and national saving is therefore an empirical question.

Empirical Evidence

There has been considerable debate regarding the impact of IRAs on net saving. The first set of studies was by Venti and Wise (1986, 1990) who estimated that IRA and non-IRA savings were imperfect substitutes, thus suggesting that IRAs led to roughly 60 cents of new saving per dollar of IRA contributions, with most of the remaining 40 cents representing the tax subsidy. Similarly,

Engelhardt (1996) found large saving effects by comparing saving rates in Canada before and after the cessation of the tax-subsidized Registered Home Ownership Savings Plan.

Gale and Scholz (1994) specified a more general model allowing for differences in tastes for saving between IRA and non-IRA contributions, and using the nonlinearity of the budget constraint – due to the IRA limits – to help identify the true saving effects of IRAs. They arrived at a quite different conclusion, namely, that IRAs in fact reduced net saving because contributors 'shuffled' savings from taxable accounts. Ultimately, their estimates were found to be very sensitive to the inclusion or exclusion of a few observations (Poterba et al. 1996), underscoring the difficultly of testing for causality using observational data. Even in a dynamic setting (as in Feenberg and Skinner 1989) one cannot rule out the possibility that former spendthrifts who suddenly start pouring money into IRAs would have done so even without IRAs available for their use.

Attanasio et al. (2004) used the natural experiment of the 1999 shift in the United Kingdom from PEPs and TESSAs to the less restrictive (and hence more popular) ISAs to test the resulting impact on saving. The resulting (albeit very noisy) patterns of changes in saving rates were not supportive of a positive impact on national saving. Another study used the difference between contribution rates of taxpayers making their first year's contribution to an IRA and those of later contributors (Attanasio and De Leire 2002; see also Joines and Manegold 1995). They found that new contributors exhibit shuffling behaviour from existing assets into IRAs. Less clear is whether later contributors (the majority of IRA inflows) were increasing net national saving (Hubbard and Skinner 1996; Attanasio et al. 2004).

The strongest evidence of how IRAs affect saving comes from a randomized trial conducted in the St. Louis metropolitan area by H&R Block, a large tax preparation firm (Duflo et al. 2006). In this study, tax filers at H&R Block were provided with different incentives to open an 'express' IRA funded with either tax refunds or other sources. Duflo et al. found enrolment rates of 3 per cent for the control group, 10 per cent for the treatment group with a 20 per cent match and 17 per cent for those with the 50 per cent match. Conditional on enrolment, contributions (excluding the match) amounted to $860, $1,280, and $1,310, respectively. The researchers were not able to measure offsetting effects for non-IRA wealth, but large and significant effects in the treatment group were observed even in households with low median income or without saving accounts, thus minimizing the potential for 'shuffling' from other assets within these groups.

However, these results cannot be generalized to the saving effects of conventional IRAs in the United States or in other countries. As the authors noted, the treatment effect depended strongly on the specific tax professional; some tax professionals just couldn't 'sell' the IRAs no matter how attractive the match. Furthermore, the IRA was offered at an auspicious time when the refund had not yet been issued. The IRA match may have been a necessary, but apparently it was not a sufficient, condition to persuade all contributors (even those in high income brackets) to sign up.

Conclusions

It is unfortunate that we still know so little about the saving effects of IRAs and similar saving incentives. While we don't know the incremental effect of IRAs, we might expect the strongest saving effects to arise among lower-income households where the opportunity to shuffle assets is most constrained (for example, Engen and Gale 2000; Benjamin 2005 in the case of 401(ks)). And the evidence we do observe the sharp drops in contributions among those still eligible following the 1986 cutbacks, and the importance of individual tax professional effects, for example – suggests that behavioural or marketing factors are critically important in 'selling' IRAs to the households where the tax advantages are perhaps no so apparent and the distributional effects of the subsidy are not so inequitable (see Bernheim 1997).

What about the saving effects of IRAs among higher-income households? Because IRA accounts typically require the enrolee to write a check, one may never expect it to exhibit the same saving effects of a 401(k) plan that automatically withdraws money before the paycheck is cashed. But, as Hubbard and Skinner (1996) argue, the saving effects need not be large in order to justify the government provision of saving accounts. Recall that the net revenue loss to the government for the traditional IRA is the up-front deduction, less the present value of the discounted future tax payments. This difference may be quite modest when strong stock market gains build up equity inside traditional IRAs, leading to higher future revenue collections as the IRAs are gradually drawn down (Dusseault and Skinner 2000; also see Gravelle 2000).

In sum, IRAs provide tax-preferred wealth accumulation to those without employer pensions or who seek to accumulate something extra for retirement. Saving effects are likely to be largest when IRAs are designed to appeal to low-or middle-income households where opportunities for shuffling are minimized. Finally, governments may find policy changes irresistible as they realize how much future tax revenue lies within traditional IRA assets, or how much potential tax liability lies within rapidly growing Roth or ISA assets.

Individualism

C. B. Macpherson

Individualism is social theory or ideology which assigns a higher moral value to the individual than to the community or society, and which consequently advocates leaving individuals free to act as they think most conducive to their self-interest. The term was also, as noted below, sometimes used in the 19th century as a name for an actual economic system. When so used, the term denoted the competitive market system which lets the direction of the economy be the unintended outcome of the decisions made by myriad individuals about the uses to which they will put their own labour and resources.

The first edition (1896) of Palgrave's *Dictionary of Political Economy* defined individualism in the latter, narrower sense. The article entitled Individualism began by reporting that John Stuart Mill had applied the term to 'that system of industrial organisation in which all initiative is due to private individuals, and all organisation to their voluntary agreement'. The article then remarked: 'The natural antithesis to individualism is COLLECTIVISM or we may say SOCIALISM, a system under which industry is directly organized by the state, which owns all means of production and manages all processes by appointed officers.' The author defined the fundamentals of the system of individualism quite precisely:

The essential features of individualism are, (1) private property in capital, to which are added almost of necessity the rights of bequest and inheritance, thus permitting unlimited transfer and accumulation. (2) competition, a rivalry between individuals in the acquisition of wealth, a struggle for existence in which the fittest survive.

There could hardly be a better definition of capitalism, at least of the neo-classical economists' model of capitalism. John Stuart Mill's *Socialism* is cited as authority for such a use of 'individualism', properly enough: his *Chapters on Socialism* (1879) does describe 'the principle of individualism' as 'competition, each one for himself and against all the rest. It is grounded on the opposition of interests, not the harmony of interests, and under it everyone is required to find his place by struggle, by pushing others back or being pushed back by them'; and later in the same work individualism is equated with 'quarrelling about material interests'. One might also cite Mill's earlier (1851) 'Newman's Political Economy', where 'the existing individualism', described as 'arming one human being against another, making the good of each depend upon evil to others', is said to be so morally inferior to socialism that socialism is 'easily triumphant' over it.

It may be thought that the Palgrave definition of individualism is unduly narrow: a modern scholar (Lukes 1973) has distinguished no less than eleven meanings the term may have, ranging from respect for human dignity, autonomy, privacy, and self-development, to epistemological and methodological individualism. Most of these meanings are indeed not considered in Palgrave's *Dictionary*, but since it is a dictionary *of political economy*, only meanings with an economic connotation can be expected to be treated. However, although that charge of undue narrowness may be dismissed, it may still appear that, considered historically, his usage is too narrow to be accurate for the whole modern Western tradition down to his own time.

The idea that the individual is morally more important than society goes back of course, in modern times, to the Renaissance. The same view, in religious terms, emerged at the Reformation, which made each individual, rather than the Church, the guardian of his own salvation; and this view got wider currency in 17th-century Puritanism. Neither the Renaissance nor the Reformation and the subsequent Puritanism reduced individuals to atoms of matter in motion, each seeking power and wealth at the expense of every other one. That step was taken by Hobbes in the mid-17th century: in his view, society was simply a congeries of colliding atoms in

unceasing motion. That puts Hobbes's individualism close to, but leaves it broader than, Palgrave's concept.

In the 18th century Adam Smith gave full market individualism a more pleasant face, arguing that the most beneficent possible social result would be attained by leaving individuals free to make self-interested bargains in a competitive market: that was the doctrine of *laissez-faire*. And the market economy was solidly enough established in England by Smith's time that it could be accepted as a part of the natural order by that venerator of the traditional hierarchy of ranks, Smith's contemporary, Edmund Burke, though in Burke's hands the market economy became a much less pleasant affair. His *Thoughts and Details on Scarcity* (1795) was an unqualified endorsement of *laissez-faire*: it issued a shrill warning against 'breaking the laws of commerce, which are the laws of nature, and consequently the laws of God'. Governments must not interfere with 'the great wheel of circulation' even though it dooms 'so many wretches' to 'innumerable servile, degrading, unseemly, unmanly, and often most unwholesome and pestiferous occupations'.

In the 19th century, Bentham relentlessly restated and elaborated Hobbes's atomic individualism, and Benthamism became the dominant ideology. Its doctrine of human nature was summed up in its crudest form in James Mill's article *Government* (1820): 'The desire . . . of that power which is necessary to render the persons and properties of human beings subservient to our pleasures in a grand governing law of human nature.'

So we may say that historically, at least down to 1820 or so, the Palgrave definition is not at all too narrow. But it is too narrow for the latter part of the century, for it leaves out a quite different idea of individualism, one which John Stuart Mill promoted implicitly in his *Principles of Political Economy* (1848) and explicitly in his *On Liberty* (1859), with its opening laudatory quotation from Wilhelm von Humboldt: 'The grand, leading principle, towards which every argument unfolded in these pages directly converges, is the absolute and essential importance of human development in its richest diversity.'

Let us call this *developmental individualism*. It is the antithesis of *possessive individualism*, which assumes that the human being is essentially a striver for, and a receptacle for the acquisition of, material goods. The whole doctrine of *On Liberty* puts Mill squarely in the camp of developmental individualism. And the famous chapter 'Of the Stationary State' (*Principles*, Bk. IV, ch. 6) is eloquent testimony to the depth of his revulsion from the existing acquisitive individualism of the competitive market economy. So, although the developmental ideal of individualism is not found as positively in Mill's *Political Economy* as it is in his *On Liberty*, we may treat the former text also as being on the developmental side. If we do so, however, we must add that Mill was himself so confused a political economist that he did not see that the acquisitive behaviour he denounced was entailed in the capitalist structure he accepted: he did not see that it was that structure which effectively denied a developmental life to the bulk of the wage earners.

A greater political economist than Mill, namely Marx, saw through this confusion and took the logical way out. Marx may be classified as the ultra-collectivist but it is important to see that for him the collective control of the economy was simply a necessary means to an end which was ultra-individualistic, that is, to a flowering of individuality which would be possible when capitalism with its alienation of labour had been surpassed. Marx condemned capitalism morally because it denied any such flowering.

> In bourgeois society . . . the past dominates the present; in Communist society, the present dominates the past. In bourgeois society capital is independent and has individuality, while the living person is dependent and has no individuality. And the abolition of this state of things is called by the bourgeois, abolition of individuality and freedom! And rightly so. The abolition of bourgeois individuality, bourgeois independence, and bourgeois freedom is undoubtedly aimed at (Communist Manifesto, 1848, sect. 2).

And the final outcome of the communist revolution was to be 'an association, in which the free

development of each is the condition for the free development of all' (ibid.).

Similarly:

> In a higher phase of communist society ... after labour has become not only a means of life but life's prime want; after the productive forces have also increased with the all-round development of the individual, and all the springs of co-operative wealth flow more abundantly – only then can the narrow horizon of bourgeois right be crossed in its entirety and society inscribe on its banner: From each according to his ability, to each according to his needs! (Critique of the Gotha Programme, 1875, I, 3).

The *Manifesto's* vision of a fully developed individual as the highest human attainment, echoed in the *Critique of the Gotha Programme*, puts Marx as firmly as Mill in the developmental camp. And just as Mill is there not only by virtue of his *On Liberty* but also by virtue of his *Political Economy*, so Marx is there not only by virtue of the *Manifesto* but also of the *Critique*. And we may add that Marx is there just as firmly in Volume I of *Capital* (1867), where he refers scornfully to the capitalist mode of production as that 'in which the labourer exists to satisfy the needs of self-expansion of existing values instead of, on the contrary, material wealth existing to satisfy the needs of *development on the part of the labourer*' (emphasis added).

There is no warrant in any of this for trying, as some commentators used to do, to drive a wedge between the young 'humanist' Marx and the 'mature' political economist. And, of course, Marx had a strongly developmental vision in his earliest work, the *Economic-Philosophic Manuscripts of 1844*. Thus from his earliest to his latest economic writings there is this development vision. Development individualism is at the very heart of his political economy.

We find, then, that by the time of Mill and Marx developmental individualism is well established: in the liberal tradition it takes place alongside the continuing possessive individualism; in Marx's theory it was inherent from the beginning.

What of the late 20th century? The liberal tradition still contains the two strands of individualism. On the one hand, two of the most esteemed liberal individualists of our time – Isaiah Berlin and John Rawls – are clearly developmental individualists. And on the other hand, the two most noted economic individualists – Friedrich Hayek and Milton Friedman – are equally clearly possessive individualists. Friedman, who would dismantle the welfare state and leave the distribution of economic benefits to an unrestrained competitive market, may be cited as the very model of a possessive individualist. Hayek, whose economic philosophy was set out succinctly in his 1945 lecture *Individualism, True and False*, tries to give market individualism a more agreeable image. He does this by claiming as 'true' individualists the great names in one line of the British tradition, a line from Locke through Mandeville, Hume, Tucker, Ferguson, Smith and Burke, down to Lord Acton, and by categorizing as false individualists the 19th-century Benthamists and Philosophical Radicals, and, on the continent, those infected by Cartesian rationalism, notably the French Encyclopaedists, Rousseau and the Physiocrats. True individualism, he says,

> affirms the value of the family and all the common efforts of the small community and group,... believes in local autonomy and voluntary associations ..., and ... its case rests largely on the contention that much for which the coercive action of the state is usually invoked can be done better by voluntary collaboration.

In sharp contrast, false individualism 'wants to dissolve all these smaller groups into atoms which have no cohesion other than the coercive rules imposed by the state ...'. But Hayek's attempt to humanize market individualism cannot hide the fact that his 'true' individualism, being tied to the free market economy, compels everyone to compete atomistically. Both his kinds of individualism must be graded possessive. Market freedom, the individual freedom to choose between different uses of one's abilities and resources, is, he recognizes, 'incompatible with a full satisfaction of our individual views of distributive justice'. And the individual's freedom is limited by 'the hard discipline of the market'. Hayek's 'true' individualism, for all its smoothness, in the end comes down to

the atomistic 'rugged individualism' of Calvin Coolidge and Herbet Hoover: it is rugged individualism with a smooth false front.

It is clear, then, that the liberal tradition in the late 20th century, including within itself both the developmental individualism of Berlin and Rawls and the possessive individualism of Hayek and Friedman, does contain two antithetical positions and cannot be reduced to either one.

We have said that the old Palgrave definition of individualism was an accurate enough description of the prevailing ideology in the earlier part of the 19th century but was too narrow for the latter part of the century, when the view we have called developmental individualism emerged alongside of the earlier purely possessive individualism. We may go on to ask, what brought about this change? What brought developmental individualism into the picture?

Clues are to be found in John Stuart Mill's own writings. In the first place is his perception that the unrestrained market economy had produced a kind of society which would no longer be tolerated by the working class it had produced. In his 1845 article 'The Claims of Labour' he took the rise of the Chartist movement, with its threat of physical force, to be evidence that the British working classes would no longer put up with things as they were, and he believed that 'the more fortunate classes' must see the writing on the wall: 'While some, by the physical and moral circumstances which they saw around them, were made to feel that the condition of the labouring classes *ought* to be attended to, others were made to see that it *would* be attended to, whether they wished to be blind to it or not.'

In the second place, perhaps partly because of this apprehension of class violence, Mill became a more sensitive and humane liberal than his father or Bentham, denouncing as utterly unjust the existing relation of effort and reward, by which the produce of labour was apportioned 'almost in an inverse ratio to the labour' (*Principles of Political Economy*, Bk. II, ch. 1, sect. 3), and deploring the fiercely competitive character of the market-dominated society of his day, 'the trampling, crushing, elbowing, and treading on each other's heels, which form the existing type of social life' (*Principles*, Bk. IV, ch. 6, sect. 2). In reacting as early as 1848 against this kind of society, Mill was a harbinger of the more humane social conscience which became noticeable in early 20th-century liberal thinking and which in mid-20th century brought the welfare state.

We conclude that the old Palgrave definition of individualism, already too narrow when it was promulgated, became increasingly inadequate in the subsequent decades. It was made inadequate by the rise and growth of developmental individualism, which in turn was the result of two distinct but related phenomena – the apprehension by middle-class thinkers of a danger of working-class violence, and the somewhat delayed reaction of those same minds to the shocking brutality of the industrial *laissez-faire* society. The two factors together ensured that developmental individualism would coexist with possessive individualism in the heyday of free capitalist enterprise.

How much longer they will coexist is not readily predictable. The danger of class violence now within advanced capitalist welfare states is less than Mill thought it to be in the society of his time, but what may well be called class violence as between undeveloped (or misdeveloped) and developed states is not far to seek in our time. And the working and living conditions of wageearners in developed countries are less savage now than they were in Mill's day, but the increasing speed and tension of much of the work presses heavily on them. All we can say is that the probability of our advanced societies continuing to afford any substantial measure of developmental individualism varies inversely with the degree of industrial speed-up and the amount of class violence, national and international.

Individualism Versus Holism

Harold Kincaid

Abstract

Issues about individualism and holism in economics surface because economics is committed to understanding both institutions and large-scale economic processes, in terms of constrained maximizing of individuals. Three key questions are at issue. Can a theory of individual economic behaviour capture everything we want to explain about the economy in principle? To what extent do our accounts of individual economic behaviour trump or constrain other economic explanations that are not directly about individuals? Are non-individual economic entities real, and what is their relation to individual behaviour? These questions are answered in light of developments in economics and in philosophy of science.

The idea that economic outcomes result from and thus are to be explained by the maximizing choices of individual human beings has been essential to economics at least since Adam Smith. Yet this maxim of methodological individualism has consistently existed alongside and in tension with the important role that institutions play in economic outcomes and the desire of economists to explain large-scale phenomena such as the rate of inflation and unemployment. Debates over individualism and holism have generally been vaguely formulated and argued at an abstract level with a questionable relationship to the actual practice of economics. The purpose of this article is to clarify the theses and arguments at work and replace rhetoric with identifiable empirical issues with real ties to economic practice. Some recent developments in economics – for example, the new economics of information asymmetry and institutions, and the obstacles to the refinement programme in classical rational choice game theory and to rational expectations programmes in macroeconomics – argue against

the most extreme forms of individualism while leaving a plausible place for various more modest individualist constraints.

There are at least three questions at the centre of economic debates over holism and individualism:

1. Can a theory of individual economic behaviour capture everything we want to explain about the economy in principle?
2. To what extent do our accounts of individual economic behaviour trump or constrain other economic explanations that are not directly about individuals?
3. Are non-individual economic entities real, and what is their relation to individual behaviour?

The first question can be thought of as a question about theory reduction. Can a well-formulated theory of individual behaviour replace all economic explanations that are not directly about individuals, at least those we think are relatively well confirmed? The second question is usually put as a thesis about mechanism: every economic explanation has to be given individualist mechanisms. The final question is about ontology: what entities populate the economic realm and how are they related?

Individualists tend to answer the first two questions affirmatively and either deny that social entities exist at all or assert that individuals are in some sense prior to them. Extreme holists take the opposite stance, answering negatively to the first two questions and arguing that social entities are real and in some sense prior to individuals.

These three questions are no doubt related, and it is often asserted that an answer to one of these questions tells us the answer to the others. Yet, for the most part, discussions in the literature do not clearly identify which theses are at issue nor exactly what their relationship is to each other.

To what extent is economics committed to a version of individualism? Schumpeter (1954), in his classic history of economic analysis, apparently coined the term 'methodological individualism' and argued that it, along with a fundamental focus on prices and general equilibrium analysis, was the common core of economics since Smith. There is little evidence that Schumpeter was right about the classical economists. They were interested in the distribution of the total economic product to social classes and the factors influencing its growth. Their accounts frequently involved taking institutional structure as given rather than explained; Smith explicitly acknowledged that invisible hand processes work against a background of social institutions, customs, and the like (Gordon 1991).

However, the neoclassical revolution certainly ushered in an explicit commitment to individualism. Many past and recent elements of modern economics are directly motivated by the individualist theses mentioned above, among them:

(a) the general equilibrium programme of explaining all economic phenomena on the basis of individual preferences and initial endowments;
(b) the rational choice game-theory programme of explaining norms, institutions, the behaviour of the firm, and so on, completely in terms of the behaviour of maximizing individuals; and
(c) the rational-expectations programme which seeks to model macroeconomic phenomena in terms of the expectations states of individual maximizing agents with given preferences, technology, and so on.

These doctrines make the three kinds of claims listed above: (*a*) the ontological claim that all economic phenomena consist of the actions of individuals, (*b*) the reductive claim that a theory based on such primitives can explain and thus reduce all economic phenomena to individual behaviour, and (*c*) the claim that individual-based mechanisms are a requirement of good explanation. Thus the individualism–holism controversy in economics crucially involves, at a minimum, evaluating the extent to which these programmes succeed in realizing their individualism, putting aside other worries such as the assumption of equilibrium outcomes and so on.

To start with the ontological issues first, there is no good evidence that I know of that any major economist from the classicals on affirmed the

extreme holist ontological thesis that society acts or exists entirely independently of the behaviour of individuals. Moreover, the question whether aggregate economic entities are real seems to me to be the least interesting and controversial issue in the individualism–holism debate in economics. No one denies that firms, for example, are collections of individuals. If each of the individuals in the firm exists, then the sum of them exists as well. The real issue I would argue is how far we can go in *explaining* the aggregate in terms of the individuals composing it – that is a question of reduction.

Hoover (2001) has argued for the reality of macroeconomic aggregates on the grounds that something is real if it stands in causal relations and that macroeconomic aggregates do stand in such relations. However, the advocate of rational expectations is not denying that the GDP or the rate of inflation exists but instead is asserting that their causal efficacy can be explained in terms of the actions of individuals and that, given rational expectations, we cannot expect there to be stable causal relations among aggregates invariant to policy changes. Again the issues seem to be more about explanation, not whether aggregates are real.

The second ontological claim – that the characteristics of economic aggregates are dependent upon the facts about individuals – has more content. Borrowing from philosophical discussions of physicalism (Hellman and Thompson 1975), reductionism in general and in the philosophy of mind in particular (Fodor 1974), we can take this claim to be asserting that all non-individual facts supervene on or are determined by the facts about individuals. The basic idea is that one set of facts A supervenes on or is determined by another set B just in case once the B facts are set, so are the A facts. In other words, there is no difference in the A facts without a corresponding difference in the B facts. As we will see below, this asserts only a one-way conditional from the Bs to the As and not the stronger biconditional of A if and only if B that is typical of reduction. (So the individualist thesis would be that the economic facts about individuals fix the facts about other aggregate or collective economic entities.)

Talk of 'facts' is vague. We can be more precise by asking if the truths or assertions of a particular theory fix those of another – in this case, whether a particular economic theory referring only to individuals determines or fixes the truths of an economic theory that includes terms referring to collective economic phenomena. Put this way, the debate over this individualist thesis is really many different debates, depending on what particular models are at issue, and individualism might be plausible in some cases and not others. So, for example, we can ask whether downward-sloping demand curves of consumer choice theory ensure that aggregate market demand curves are likewise downward-sloping. The evidence seems to be that they are only under very restrictive conditions that are unlikely to hold (Deaton and Muellbauer 1980). More generally, the Sonnenschein–Mantel–Debreu theorem shows that individual excess demand functions do not ensure a unique equilibrium. Similar difficulties face some attempts to derive macroeconomic implications from choice theoretic models of individual behaviour (Martel 1996). Yet it seems clear that there must be *some* model of individual behaviour that determines such aggregate relations.

Individualism acquires it clearest statement as a claim about theory reduction. There is an extensive literature on the requirements for theory reduction in general as exemplified by the reduction of the gas laws to statistical mechanics. The gas laws refer essentially to temperature while no such notion is a fundamental category in statistical mechanics. However, temperature has an analogue in the mean kinetic energy of the molecules in a gas – we can define the former in terms of the latter. A definition requires at a minimum some kind of biconditional relationship between the terms involved. When we can produce such a definition, then to reduce we should be able to reproduce the explanation given by one theory in the vocabulary of another, for example, by showing that the gas laws follow from laws of statistical mechanics once temperature is equated with mean kinetic energy.

There are at least three possible ways that one theory might turn out to be irreducible (Kincaid 1996, 1997).

I

Multiple realizations: if we wanted to reduce ordinary claims about chairs, for example, to particle physics, then we would need to find a one-to-one correspondence between chair categories and quantum mechanical descriptions, because there are indefinitely many ways to bring chairs about in physical terms and no natural way to capture them in terms of physics. Chairs are in that sense multiply realized and thus there is no link that allows physical explanations to replace common sense ones. The root idea here is thus that categories at one level of description may pick out kinds that look disparate in another vocabulary. It is important to note that the multiple realizations problem undermines the common conclusion that aggregate economic phenomena *must* be reducible because they are made from individual behaviour. Reduction is a claim about what specific theories can in principle explain. From the fact that As are composed of Bs it does not follow that a specific theory applying to the Bs has the explanatory resources to eliminate explanations in the categories that describe the As – we make various claims about chairs that cannot be cashed out in quantum mechanics even though chairs are made entirely of atoms.

One–many relations: reductive definitions can fail in the other direction in that in the reducing theory the descriptions used are not sufficient to fix the descriptions in the theory to be reduced. This is failure of the one-to-one mapping as well, but in the other direction.

Presuppositions: the reducing theory may find itself implicitly in need of categories from the theory to be reduced in its own accounts. To take an example from reductionism debates outside economics, attempts to explain antibodies in purely biochemical structural terms arguably fail, because in the end none of the physical descriptions suffices unless an immune response also occurs (Kincaid 1997). But appealing to immune response seems not be giving a physical explanation but a biological one.

It is an empirical issue whether in fact these sorts of obstacles are real for reduction in economics. When and where they are real need not be uniform across every economic sub-domain and economic model – reduction might be feasible for some and not for others. However, there is some good evidence to think that reduction is often unfeasible for the following kinds of reasons:

1. Much explanation in economics that might seem individualist in spirit is really nothing of the sort. One case in point is the widespread use of representative agents who are not flesh and blood individuals and who cannot be legitimized as reasonable aggregations of individual behaviour. Another is the widespread practice of taking household and firms as basic entities. These are social, aggregative entities that, when treated as black boxes, belie a commitment to individualism.
2. There are various reasons to think that multiple realizations of economic categories in terms of individual behaviour are likely. (a) Many claims in economics are at least implicitly motivated by selectionist arguments, for example, that firms must be profit maximizers if they are not to be weeded out by competitive selection. However, such selective mechanisms do not 'care' about how profitability comes about, only that it does. This means that there may be multiple ways of organizing individual behaviour that meet the criterion. This possibility is reinforced by results in the theory of the firm, where there are many plausible models of how profit- maximizing behaviour might be brought about by the organization of individual incentives. (b) Much applied economics consists of estimating aggregate supply and demand curves in specific markets. This work proceeds quite well without estimating individual utility functions. This suggests that these aggregate phenomena are indifferent to the exact details of individual behaviour. Becker's (1976) argument that downward-sloping demand curves would be expected from random choices given budget constraints provides a theoretical account of why this is likely to be the case. (c) Solid results from physics and elsewhere suggest that complex causality in aggregate phenomena often show structural relations or 'universalities' (Batterman 2001) that are indifferent to a wide range of underlying detail and that in fact are described by categories that are

'scale relative' in that they have no counterpart in smaller scales of resolution (Ladyman and Ross 2007). Hoover (2001) makes an argument like this about macroeconomic variables: the rate of inflation or the GDP has no obvious meaning at very fine scales of measurement. Similarly, equilibrium analysis in terms of strong attractors and the like in evolutionary game theory also presents a parallel situation. The properties of an equilibrium can be understood while there is a wide range of actual dynamic paths to that equilibrium, the details of which are inessential to the equilibrium explanation.

3. Economic explanations involving individuals often rest on – they take as given and unexplained – information about institutions, structures, norms, and so on that are not cashed out in individualist terms. In short, they presuppose rather than eliminate social processes. As we noted above, Schumpeter's claim that economics since its inception has been methodological individualist in orientation is implausible in any strong form, because Smith, for example, is quite clear that institutions and customs matter in fundamental ways. Not surprisingly much work in economics after the neoclassical revolution has carried the banner of methodological individualism in its rhetoric but its practice is much closer to Smith.

One clear illustration of this comes from recent developments in rational choice game theory explanations in economics. The failure of the refinement programme to plausibly eliminate all multiple equilibria means that the focal points that are often used to explain which equilibrium is selected will bring in unexplained norms. Bayesian agents in games reach equilibrium when they have sufficiently similar priors, assuming rather than explaining the social processes that produce consensus (Janssen 1993). Most fundamentally, game theory explanations have to take as given the possible payoffs, the utility functions of individuals, the information available to them, and the initial distribution of resources. This assumes rather than explains much institutional structure. Property rights have to be defined and so on. Much of the new institutional economics is about how these institutional differences can have strong influences on outcomes. The conclusion to draw is that explanations in terms of individuals have to be supplemented with accounts of collective social and economic phenomena, making reduction – full explanation in individual terms – unlikely.

Another example where the individualist rhetoric can outrun the actual practice comes from explanations of the distribution of income in standard neoclassical models. The goal is to explain what individuals get in terms of the traits of individuals, for example, investment in human capital and so on. Institutional structure is in the background here as well. The preferences of workers and initial distributions of wealth are taken as given. It is generally assumed that there is a direct link between productivity and earnings, which the considerable work on the theory of the firm shows holds only under specific institutional contexts that are often not satisfied. Most fundamental, those models generally take the distribution of jobs or positions as given. In effect, what is being explained concerns what determines on which rung on the ladder individuals stand. Left unexplained is the number of rungs and the distances between them (see Sattinger 1993).

Of course, nothing precludes the individualist from seeking further explanations of all these unexplained collective phenomena in purely individual terms. But the breath of these problems and the lack of individualist explanations at this point suggest that the current evidence for the reductionist version of individualism in economics is slim.

I turn finally to the version of individualism claiming that individualist *mechanisms* are necessary. Here I think is the most important individualist insight, though it is important to distinguish various versions of this claim, for some are considerably more plausible than others. The notion of a mechanism is nebulous. The root idea, going back to Maxwell and before in physics, seems to be that of a continuous causal process – one that is not gappy as it were. Taken that way, a mechanism might be either horizontal or vertical. To find the causes between A and B is to find a horizontal

mechanism and explaining how the parts of A contribute to its causal influence on B is identifying the vertical sense of mechanism. A related important distinction concerns how a mechanism is described and in what detail. An 'antibody' and a 'compound of such and such a structure' may commit us to different things.

With these distinctions in hand, here are some general things that can be said about mechanisms in science in general. We can sometimes know that A causes B without knowing either the horizontal or the vertical mechanism. To cite a common sense example, I can know that the flying baseball caused the broken window without knowing the quantum descriptions of the baseball's constitution or the exact details of how the ball surface interacted with the glass. Furthermore, the notion of knowing the 'full' mechanism is not well defined, since we can generally give more fine-grained descriptions of the constituting parts of or of the time periods between causes; no account of a causal process is a complete explanation in the sense that there are no unanswered questioned that might be answered. Finally, the place of specific mechanisms in our accounts of the world seems to depend on three things: how solid our knowledge is at the level of description we are using to pick out the mechanism, how solid our knowledge is about that process for which we are seeking mechanisms, and to what extent the two make presuppositions about the other. An account of large-scale brain structures, for example, that required neuronal processes at speeds beyond the known synaptic firing times would be suspect. An explanation that was well confirmed at the scale of brain structures through experiment and physical tracing and that relied on no very specific view of neuronal details should not be strongly constrained by molecular mechanism, particularly if our understanding of the molecular details was much less solid than our understanding at the level of brain structure.

From this general perspective, some claims that individualist mechanisms are essential in economics are plausible and some are not. Among the implausible is that no economic explanation ever succeeds until there is an account in terms of individual maximizing behaviour and general equilibrium. There is just too much good work in economics that provides apparently well-confirmed explanations without meeting this requirement. As noted above, much applied economics is about aggregate supply and demand that has no general equilibrium foundations. Other compelling explanations in industrial organization describe firm behaviour in competitive environments of various kinds with no pretence of providing a foundation in individual (as opposed to firm) maximizing behaviour. Good econometric work in macroeconomics can use structure breaks between macroeconomic variables to show causation without any account of underlying individual behaviour (see Hoover 2001).

Of course, these accounts could certainly be made stronger by providing some account of how they relate to individual behaviour. Given everything we know from experimental and behavioural economics, however, the theory would not be a simple picture of individuals maximizing utility functions. In any case, the fact that nonindividualist explanations can be made stronger does not thereby mean they are bad explanations – if does not follow from the fact that I cannot answer all questions about a domain that I can answer none.

Alternatively, mechanisms in terms of individual behaviour can be plausible requirements indeed in the right circumstances. Critics of Keynesian orthodoxy had reason to be critical in that Keynesian models required individuals to be systematically fooled. Critics of rational expectations models, however, could with equal justification turn the tables and reject those models because of their lack of individualist mechanisms in that they require individuals to make the best econometric forecast given the available data. This thus illustrates the theme of this article, which is that, once we move beyond the individualist rhetoric typical of the economics profession, individualism and holism have many different claims that vary enormously in plausibility – the devil is in the details.

Indivisibilities

William J. Baumol

Abstract

A commodity is indivisible if it has a minimum size below which it is unavailable, at least without significant qualitative change. Indivisible inputs yield economies of scale and scope. But even where indivisibilities impose large fixed costs, if they are not sunk, potential competition can impose behaviour upon incumbents that is consistent with economic efficiency. Perhaps the most significant way in which indivisibilities can impede efficiency in pricing is the existence of indivisible input–output vectors that are efficient but which are not profit maximizing at any positive scalar prices. Integer programming is naturally suited to optimality analysis involving indivisibilities.

A commodity is indivisible if it has a minimum size below which it is unavailable, at least without significant qualitative change. Most commodities are indivisible but this is often unimportant. Half a chair has little use, but this makes little difference for analysis of market demand because so many are sold that there is little inaccuracy in treating an increase in sales of chairs from 10 million to 10,000,001 as a change in a continuous variable. In other cases, minimum size is so large relative to usage that it requires special analytic approaches and has substantial behavioural consequences: a Boeing 747 passenger aircraft is a large outlay for any airline; to carry *any* freight from New York to Chicago a railroad must lay at least two rails, each about 1,000 miles long.

Fixed Cost and Sunk Cost

The *fixed cost* of a firm is defined as the minimum outlay it must incur to carry out any activity. If we write (assuming input prices fixed) the long-run

cost function as $C(y) = k + f(y)$, where $k =$ constant, $f(0) = 0$, and $y =$ the vector of output quantities, then k is the fixed cost. As in the railroad example, the need for indivisible equipment is the normal source of fixed costs.

Fixed costs are important in economics as a source of economies of scale, of impediments to the workings of the price mechanism, of breakdown in the convexity conditions usually relied upon in optimization calculations and in the uniqueness of solutions.

Fixed costs are often confused with *sunk costs*, which are also related to indivisibilities. A sunk cost may or may not be larger than the minimum outlay a firm needs to operate but, once incurred, it cannot be withdrawn for some substantial period without significant loss. An automobile producer may build a plant much larger than the minimum needed to turn out one car, and once the capital is sunk it may only be possible to retrieve it gradually as vehicles are sold. Thus, sunk costs (like the car plant) need not be fixed and fixed costs (like an aircraft) need not be sunk.

Economies of Scale and Scope

Indivisible inputs by their nature yield economies of scale and scope. An indivisibility requires a producer of even a small output volume to acquire relatively large capacity, part of which must be unused. The firm can then increase its outputs without increasing costs proportionately (economies of scale). Formally, strict economies of scale are defined to be present at output vector y if $C(ay)/a > C(y)$, where $0 < a < 1$, that is, if average cost is declining along the ray ay. With fixed costs this becomes $[k + f(ay)]/a > k + f(y)$, $k > 0$. Then, assuming that $f(y)$ is bounded from both above and below, say, $0 \leq f(y) \leq M < \infty$, the scale economies criterion must clearly be satisfied as a approaches zero. Thus, the presence of fixed costs always introduces scale economies (so defined), at least in any neighbourhood of the origin.

If the indivisible item is not too specialized, the firm can add commodities to its product line without the combined costs equalling the sum of those of several more specialized enterprises which together produce the same output vector as our firm. The latter attribute is referred to as *economies of scope*. Formally, using the three product case $y = (y_1, y_2, y_3)$ for simplicity, strict economies of scope are defined by $C(y) < C(y_1, 0, 0) + C(0, y_2, 0) + C(0, 0, y_3)$.

Together, economies of scale and scope are what underlie the phenomenon of natural monopoly. An industry is said to be a *natural monopoly* at output y if one single firm can produce y more cheaply than can be done by any combination of two or more firms. Formally, if y^i is the output vector of firm i, then the industry is a natural monopoly at y if $C(y) < \Sigma\ C(y^i)$ for each and every set of y^i such that $\Sigma\ y^i = y$.

Scale economies lead to natural monopoly because in their absence it may be possible to save resources by dividing the industry's output among several firms, each providing similar proportions of the industry's output vector. Specifically, the absence of (weak) scale economies at y means that, for some values of a, $C(ay)/a < C(y)$, $0 < a < 1$. Suppose there exists such a value of a at which $b = 1/a$ is an integer. Then the industry can reduce cost by dividing output among b firms each producing $y^i = ay$, at total cost

$$\sum C(y^i) = bC(ay) = C(ay)/a < C(y),$$

thus violating the criterion of natural monopoly. Economies of scope are relevant because in their absence it may be possible to save resources by dividing up theindustry's products among specialized enterprises. Specifically, for example in the two-product case, absence of weak economies of scope means $C(y_1, 0) + C(0, y_2) < C(y) = C(y_1, y_2)$, also violating the natural monopoly requirement.

It can also be shown that scale economies together with an attribute closely related to economies of scope are sufficient (but not necessary)

for an industry to be a natural monopoly (see Baumol et al. 1982, pp. 178, 187–8).

Indivisibilities, Sunk Costs and Barriers to Entry

The literature offers various definitions of 'barriers to entry', some mutually inconsistent. If one defines them as impediments to the invisible hand mechanism, then sunk costs are entry barriers while fixed costs are not.

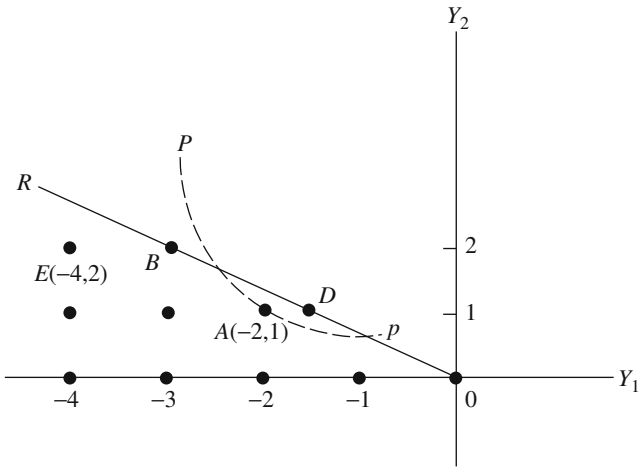
The need to sink capital into an enterprise constitutes a risk which obviously can deter a potential entrant and thus can protect incumbents from potential competition. So, in an industry with relatively large sunk costs, monopoly profits and inefficiencies become possible.

On the other hand, even where indivisibilities impose large fixed costs, if they are not sunk, potential competition can impose behaviour upon incumbents that is consistent with economic efficiency. Where the fixed capital is highly mobile and there is an active market on which it can readily be sold (as with, for example, ocean cargo vessels) then the fixed capital constitutes no special risk and is no impediment to entry. Even if the indivisibilities make the industry a natural monopoly it will be unable to earn excess profits, operate inefficiently or behave like a protected monopolist in other ways, because this will attract entry that – with no sunk costs – incurs little risk and punishes the misbehaving monopolist.

Indivisibilities as Impediment to Efficient Pricing

Perhaps the most significant of the ways in which indivisibilities can impede efficiency in pricing is the existence of indivisible input–output vectors that are efficient but which are not profit maximizing at any positive scalar prices. This is best shown diagrammatically. In Fig. 1 (Frank 1969, pp. 5, 42–3), $y_1 \leq 0$ and $y_2 \geq 0$ are the input and ouput quantities respectively. With both of them indivisible, the dots, or *lattice points*, represent the only feasible input–output combinations. Point $A = (-2, 1)$ is efficient since no feasible lattice point lies to its northeast. However, A lies inside the convex hull of the (non-convex) feasible region whose northeast boundary is ray OR. Hence, any line given by $p_1y_1 + p_2y_2 =$ profit, through point A must lie below at least one lattice point on OR (here, either B or 0). Thus, at any non-negative prices efficient point A must be less profitable than 0 or B – no simple prices can lead profit maximizing firms to produce A. Only a set of

Indivisibilities, Fig. 1



'nonlinear prices' (for example, two-part tariffs), which lead to a curved isoprofit locus such as *PP*, can induce production of *A*.

The diagram demonstrates how indivisibilities lead to non-convexity. For example, a line segment connecting points *A* and *B* in Fig. 1 clearly is not composed entirely of lattice points, that is, it is not entirely contained in the feasible set of lattice points, and so that set is not convex.

The graph also shows in another way how indivisibilities introduce scale economies. *C*onsider *D*, a non-lattice point on *OR* to the right of *A*. Let c be the smallest integer for which c(distance AD) ≥ 1 (in the graph $c = 2$). Then cA will be a feasible lattice point (point *E*), but there will be a point (*B*) between *E* and $E - c(AD)$ which is a feasible lattice point, with the same output and a smaller input quantity than those at *E*. Since *E* is an integer multiple of efficient point *A*, one can multiply output by $c > 1$ while multiplying input by a smaller amount, that is, there must be scale economies.

Indivisibilities impede the price system in yet another way. By creating scale economies they make marginal cost pricing unprofitable. Specifically, let y be an output vector at which there are scale economies so that $C(ay) = a^b C(y)$ in the neighbourhood of y, with $b < 1$. Then, the function is locally (approximately) homogeneous of degree b and by Euler's theorem $\Sigma\, y_i \partial\, C/\partial y_i = bC < C$. Hence, if prices are set equal to marginal costs the supplier must lose money. In that case, financial feasibility requires the substitution of Ramsey prices (see Ramsey pricing) for marginal cost prices to achieve a second-best optimal resource allocation. This is true not only for the individual firm – the entire economy may have no parametric price option that is superior to Ramsey prices. For all outputs must be sold to suppliers of inputs and the receipts from output sales are paid out as wages, profits, and so on, to the input suppliers. This imposes (in the absence of lump sum payments with parametric prices of inputs and outputs) the economy's circular flow requirement $\Sigma\, p_i y_i = 0$, again taking input quantities to be negative. Now, a set of Pareto will, in optimal prices p_i^* general, not satisfy this constraint. The second-best prices, p_i, which are constrained to satisfy this requirement, are by definition the Ramsey prices and the differences $t = p_i - p_i^*$ between Ramsey prices and optimal prices may be interpreted as the optimal vector of taxes needed for compliance with the economy's circular flow constraint.

That is the form in which Frank Ramsey's original treatment is expressed. As we have just seen from the Euler's theorem argument, where costs are differentiable with respect to outputs, the first-best prices of the outputs, which are their marginalcosts, will not satisfy the circular flow constraint when there are scale economies. This shows that in general, where indivisibilities create scale economies, optimality in pricing cannot avoid the complications of Ramsey theory.

There is a third way in which indivisibilities complicate the optimization process. As is well known, where the feasible set is not convex, as must be true when there are indivisibilities, a multiplicity of local maxima is likely to be present and an iterative solution process that always follows a direction in which profit (or the value of the social objective function) is increasing may well lead towards a local optimum rather than one which is global.

Integer Programming and the Analysis of Indivisibilities

Integer programming is the mathematical technique that is naturally suited to optimality analysis involving indivisibilities. An integer programme is a mathematical programme in which only integer values are admissible for some or all of the variables. The constraint requiring $x =$ number of locomotives to be an integer is what keeps the solution from including the absurd recommendation that 1.783 locomotives be produced.

Integer programming also permits the solution of more subtle indivisibility problems, such as those involving scale economies or either/or choices, which have resisted other analytical techniques. As an example, consider a firm required to produce y units of output using either a machine of type 1 or a machine of type 2, where x is the

vector of other inputs, and x_1 and x_2 are the respective numbers of the two types of machines purchased, $\Pi(y, x, x_1, x_2)$ is the profit function and $y \leq f(x, x_1, x_2)$ is the production constraint. Then the firm must

$$\text{maximize } \Pi\,(y, x, x_1, x_2)$$

subject to the constraints

$$\begin{aligned} y &\leq f(x,\ x_1,\ x_2) \\ y, x, x_1, x_2 &\geq 0 \\ x_1 + x_2 &\leq 1 \\ x_1, x_2 &\text{ integer.} \end{aligned}$$

The last two constraints guarantee that x_1 will take either the value zero or unity and that (at least) one of them will be zero, as an either/or decision requires.

Economies of scale and scope raise related issues. Such cases tend to yield corner rather than interior solutions. If there are n firms, each with different attributes, which are candidate producers of industry output vector y, it is likely to be most economical for just one of them to produce all of y. But which one of the n firms should do the job? That is obviously an extended either/or issue whose formal statement is perfectly analogous to that just described.

Indivisibilities give rise to other complex combinatorial problems. The choice among m machines may, for example be constrained by the fact that a machine of type A will work only if a machine of type B is also purchased. This is dealt with via the constraints $x_a \leq x_b$, x_a, x_b integer. In such problems the indivisibility feature is fundamental and cannot be avoided by non-integer approximation. In sum, indivisibilities raise basic issues for theory and for methods of analysis which bear little resemblance to those pertinent to cases of divisibility.

Induction

Paul W. Humphreys

Induction, in its most general form, is the making of inferences from the observed to the unobserved. Thus, inferences from the past to the future, from a sample to the population, from data to an hypothesis, and from observed effects to unobserved causes are all aspects of induction, as are arguments from analogy. A successful account of induction is required for a satisfactory theory of causality, scientific laws, and predictive applications of economic theory. But induction is a dangerous thing, and especially so for those who lean towards empiricism, the view that only experience can serve as the grounds for genuine knowledge. Because induction, by its very nature, goes beyond the observed, its use is inevitably difficult to justify for the empiricist. In addition, inductive inferences differ from deductive inferences in three crucial respects. First, the conclusion of an inductive inference does not follow with certainty from the premises, but only with some degree of probability. Second, whereas valid deductive inferences retain their validity when

extra information is added to the premises, inductive inferences may be seriously weakened. Third, whereas there is widespread agreement upon the correct characterization of deductive validity, there is widespread disagreement about what constitutes a correct inductive argument, and indeed whether induction is a legitimate part of science at all.

Approaches to these issues generally fall into two categories. The older, more philosophical approaches attempt to provide an extremely general justification for the use of inductive methods and to isolate the universal characteristics which make for a correct inductive inference. The second kind of approach focuses on what are called 'local inductions' – analyses of very specific kinds of inferences, applicable in precisely detailed circumstances. With the enormously increased power of statistical methods which is characteristic of this century, the second approach has become more and more the province of theoretical and applied statistics. It would be inappropriate to discuss specifically statistical issues here and the reader is referred to the excellent Barnett (1982). However, it should be recognized that although these detailed mathematical techniques have increased our understanding of induction immensely, they do not by themselves answer all questions about the soundness of inductive procedures. In collecting data, for example, judgements must be made about which situations are similar to one another, and hence a combination of analogical principles and judgements of causal relevance will be needed. The principles of experimental design, not only for field data but also in the growing subject of experimental economics, generally require such judgements. Bayesian statistical methods need principles on which to attribute prior probabilities, and there is an extensive philosophical literature on the acceptability of such principles. Finally, it should be emphasized that most statistical techniques were developed within a climate of extreme empiricism or positivism, and that the application and integration of statistical models to economic systems requires a delicate inductive sensibility that cannot be reduced to algorithmic procedures.

Philosophical Approaches

The use of induction as the basis of a general scientific method was first systematically advocated by Francis Bacon. His suggested methods will seem queer to the modern reader, but the importance of his break with the deductive traditions of Greek and medieval thought should not be undervalued. He himself realized this in entitling his principal work *Novum Organum* to mirror Aristotle's *Organum* of logic, and his methods partially anticipate the eliminative methods later championed by J.S. Mill and Popper. Important as Bacon's work was, all modern work on induction lives under the shadow of the later 'problem of induction'.

The problem of induction' is to state conditions under which an inductive inference can be rationally justified. Ever since its statement in his *Treatise of Human Nature* (1739), it has been associated with the name of the Scots philosopher David Hume. It can be broadly stated in this way: when one infers from the observed O to the unobserved U, O and U are always logically distinct, at least in the sense that one can conceive of O holding, yet U not. So there is no logical necessity for U to follow from O. What then could form the grounds for asserting U, given O? For an empiricist (such as Hume) there was nothing that one could observe which would fit the bill – possible stopgaps such as natural necessity or causal powers were simply metaphysical fictions. There was, in short, merely a succession of events, and nothing we can observe guarantees that the unobserved will continue the pattern of the observed. Furthermore, any attempt to justify induction by a deductive argument would be inappropriate, for induction is essentially ampliative, in that the conclusion goes beyond what is contained in the premises, whereas deductive inferences are always conservative. Conversely, an inductive justification of induction, on the grounds that it has worked well so far, would appear to be circular.

The philosophical responses to this problem can be of two kinds. One response is to acknowledge that inductive inferences are unjustifiable, and that consequently they should play no role

in a rational enterprise such as science. Thus many authors have placed great emphasis on eliminative methods, whereby various potential explanations of the inductive evidence are eliminated as impossible or highly improbable, using primarily deductive methods. The best-known modern advocate of this view is Karl Popper, whose *Logic of Scientific Discovery* (1959) is, in part, a sustained defence of a purely deductive scientific methodology. Mill's famous methods of experimental inquiry (1843, Book III) are eliminative, as is part of Keynes's (1921) theory of induction, and a large portion of Bacon's approach. It is also possible to view in this way the objectivist statistical methodology of hypothesis testing, where the emphasis is on the rejection of statistical hypotheses. There is serious doubt with all of these approaches, however, as to whether they can function properly without tacitly employing inductive methods at some stage.

The second, and more common response is to provide some reasons why inductive inferences are indeed rationally justifiable. The 'missing premise' approach, for example, suggests that we view inductive arguments as incomplete deductive arguments, or enthymemes. By adding some extra assumption, usually a variant of a uniformity of nature principle, one can convert inductive arguments into deductive. Holders of this view have often felt compelled to adopt such a uniformity of nature principle as an a priori truth, one without which science would be impossible. The problems with this approach are many, primarily: what exact form should the uniformity of nature principle take, and how is it to be justified? 'The future resembles the past' is too vague, and almost certainly false, for dissimilarities are at least as common as similarities. 'Every event falls under a law of nature' may be true, but which law for which event? Mill tried to solve the problem by claiming that all inductions were inferences from particulars to particulars, although also asserting that a general uniformity of nature principle could be established inductively using the success of many more specific inductive generalizations.

The pragmatic approach to induction, credited to Hans Reichenbach (1949, pp. 469–82), argues that while induction cannot be guaranteed to work, if any method succeeds then induction will do just as well. Hence one may as well employ what Reichenbach called the 'straight rule', – infer that the relative frequency of observed positive instances of an effect will continue in the future. There is, however, an infinite number of alternative rules that are consistent with Reichenbach's procedure, and hence the vagueness problem is still with him.

Much philosophical work was done in the middle part of this century to construct systems of inductive logic using a logical probability function i.e. a numerical function which attributes a degree of inductive confirmation to an hypothesis, given certain evidence statements. This work, the most developed of which was carried out by Rudolf Carnap (1950), is generally regarded as having failed to achieve its aims. It did, however, produce a number of useful insights into the nature of inductive inferences, among which was the principle of total evidence, which asserts that in applications of inductive logic, no relevant evidence should be omitted.

Contributions of Economists

Among those who have made important contributions to both economics and the study of induction, we may count primarily J.S. Mill (1843), W.S. Jevons (1874), J.M. Keynes (1921), and R.F. Harrod (1956). Economists who have also written explicitly on induction include A.A. Cournot, F.Y. Edgeworth, F.P. Ramsey, John Hicks, Herbert Simon, and F.A. Hayek. (It is worth mentioning that Hume himself made a seminal contribution to economics with his theory of gold-flow equilibrium and defence of free trade.) Mill's views have been described earlier. Jevons's principal work is *The Principles of Science* (1874), within which the use of the hypotheticodeductive method is heavily stressed, as well as the allocation of subjective probabilities to those hypotheses by means of inverse probability methods. Jevons's inductive views are now for the most part regarded as combining exceptional insight with generally fallacious reasoning.

Keynes's only philosophical book, *A Treatise on Probability* (1921), is, like most of his work, of great originality. Here one can find one of the first systematic expositions of logical probability. Keynes is also perhaps the first to have insisted that logical probabilities are relative to evidence and cannot be separated from such. Hence there is no rule of detachment for probabilistic inductive logic, in the sense that evidence premises cannot be detached from the inductively supported conclusion, as is possible in deductive logic. This work on inductive logic was an important precursor of Rudolf Carnap's contributions in this area. Keynes also introduced the Principle of Limited Independent Variety, which essentially asserts that all inductive inferences concern objects with a finite number of independent properties, or, that there cannot be an infinite plurality of causes for an effect. This principle was necessary in order to attribute finite prior probabilities to the hypotheses under consideration. Harrod's (1956) theory cannot be swiftly stated: suffice it to say that he argues for the intrinsic acceptability of certain inductive arguments based on probability without supplementation by additional assumptions. His work has not attracted wide support.

Prospects

Is there a solution to Hume's problem? A characteristic of both kinds of approach discussed above has been their tendency towards an increased level of abstraction, symbolized by increasingly powerful mathematical and logical techniques. Useful as these techniques are, inductive inferences can rarely be made confidently without careful attention to causal relationships. Hume's problem itself arose directly from his argument that there is nothing more to causal connections than the regular succession of temporally ordered contiguous events. Mill gave careful attention to the causal foundations of inductions, but many empiricists are uneasy with causal talk, and the 20th century has largely eschewed causes in favour of mathematics. Because induction, causality and probability are so intimately connected, one may be able to rectify this neglect by making use of a specifically causal concept of probability (e.g. Humphreys 1985). That is, rather than construing probabilities as logical relations, subjective degrees of belief, or relative frequencies, one may take them to be propensities, i.e. probabilistic dispositions whose concrete structural basis is the economic system under investigation. Indeed, much of the work by Marschak, Hurwicz and by Simon (1977) on identifiability of structural parameters within causally isolated systems lends itself to this kind of approach. Those theories are ultimately reliant upon an understanding of causation which comes from experimental interventions, and since we are undoubtedly acquainted with primitive causal relations in that way, using such relations to justify others will not result in circularity. By localizing such inferences, there need be no vagueness about the inductive claims made. This approach does suffer from the extreme difficulty of identifying causal relationships within complex economic systems, and this difficulty is, of course, why one often must replace the experimental controls of simpler physical sciences by statistical surrogates for economic purposes. Complete certainty about inductive inferences is impossible, but the clear and discoverable differences between stable and unstable systems, equilibrium and disequilibrium, and isolated and non-isolated systems lie at the heart of the difference between secure and insecure inductive inferences from the past to the future, and a judicious mixture of statistical techniques with causal models seems to offer a promising alternative to the acausal inductive heritage of Hume.

A comprehensive bibliography up to 1921 may be found in Keynes (1921). More recent work is cited in Swinburne (1974). The best survey is still Kneale (1949) and an elementary source is Skyrms (1986).

Industrial Organization

Richard Schmalensee

Based on the activities of those who consider themselves in the field, industrial organization (or industrial economics) today may be broadly defined as the field of economics concerned with markets that cannot easily be analysed using the standard textbook competitive model. In such markets the positive and normative implications of models of imperfect competition are generally of interest, as are the design and effects of government antitrust and regulatory policies aimed at improving market performance. Because there are many models of imperfect competition, and because general policies must be applied to particular cases, much of the research in industrial organization has been and continues to be empirical.

Historically, industrial organization emerged as a distinct field after the rise of the modern manufacturing enterprise around the turn of the century (compare Chandler 1977 and Hay and Morris 1979, ch. 1). Early writers largely equated 'industrial' with 'manufacturing' and focused on markets for manufactured products. Students of industrial organization today do not limit themselves exclusively to the manufacturing sector, but, in part because of the availability of data, departures from that sector are selective.

Thus securities markets, which seem to approximate perfect competition well, are not studied in industrial organization, but competition among financial institutions and regulation of their behaviour have been investigated. Studies of transportation and traditional public utilities are common, in part because of the important role played by government policy in these sectors.

Industrial organization has also retained a strong focus on the firm as an object of study. In microeconomic theory, the firm is a given cost or production function assumed to be operated to maximize profits; in industrial organization the structure and behaviour of firms are objects of study. In contrast, relatively little attention is devoted to household behaviour.

The national markets for manufactured goods that were created early in this century have two important and apparently novel characteristics, stressed in Chamberlin's (1933) seminal and controversial analysis. First, products in many manufacturing markets are *differentiated*; that is, buyers do not view them as perfect substitutes. In such markets, non-price competition, involving product design, advertising, and other selling expenses, is often important. The sources and consequences of product differentiation and non-price competition have been intensively studied.

Second, some industrial markets came to be dominated by a relatively small number of firms. A good deal of work in industrial organization has attempted to explain differences in the

'organization' of markets, focusing on *seller concentration*, the extent to which sales are concentrated in the hands of a small number of firms. The consequences of seller concentration have also been intensively studied, and the analysis of oligopoly behaviour has accordingly played a central role in industrial organization.

The main objective of the field has been to develop tools to analyse market processes and their consequences for economic performance. Since Bain (1959), it has been customary to work with the concepts of structure, conduct, and performance. Market *structure* refers to a set of variables that are relatively stable over time, observable (at least in principle), and that are important determinants of buyer or seller behaviour. All scholars in the field agree implicitly or explicitly that there exists such a set of variables; otherwise market behaviour is in principle unpredictable.

Intrinsic market structure variables (termed *basic conditions* by Scherer 1980, ch. 1) are essentially completely determined by the nature of the product and the available technology: all modern steel industries are capital-intensive, for instance. Other elements of market structure are *derived* in that they may reflect government policy, corporate strategies, or accidents of history: the concentration that was created by the US Steel merger in the USA in 1901 is an obvious example (see Chandler 1977, ch. 11 and Stigler 1968, ch. 9). Intrinsic structural variables also affect derived variables to some extent: even if the US Steel merger was not inevitable, it is difficult to imagine an atomistic steel industry. The strength of these effects is perhaps inevitably controversial, since the stronger they are, the less scope there is for governments to enhance efficiency by changing market structures.

In any complete market model, market structure determines the *conduct* of buyers and sellers. Compare, for instance, structure and conduct (rules for output choice) in pure monopoly and in perfect competition. An important objective of industrial organization is to describe and predict the conduct of actual industries in terms of a continuum joining these two polar cases: as one moves toward the competitive end, the intensity of *rivalry* increases and profits fall accordingly. But a single dimension cannot describe conduct fully; market behaviour typically involves choosing which products to produce, the corresponding vector of prices or outputs, distribution and advertising strategies, and levels and directions of research and development activity.

Market *performance* is assessed by comparing the results of market behaviour in efficiency terms to first-best ideals or feasible alternatives. One might compare prices with marginal costs, for instance, or the array of products produced with some ideal array. Performance is determined by all aspects of conduct, along with the intrinsic elements of market structure.

To this relatively static framework, one must add dynamic effects of buyer and seller behaviour on market structure. Intrinsic structural variables can be changed by innovation, for instance, and seller concentration can be changed by mergers. Established sellers may be able to take actions to inhibit the entry of new rivals.

Much early work in industrial organization eschewed formal theory, in part because there did not exist an adequate general theory of behaviour in oligopolistic markets. Many scholars concentrated on induction from case studies of particular markets. At the same time, others sought to reinterpret and extend the standard competitive and monopoly models to enhance their explanatory power. Beginning in the 1950s, cross-section statistical work on samples of manufacturing industries became common. In the 1960s, particularly in the USA, industrial organization economists began to look beyond antitrust policy and to examine systematically the effects of government regulatory programmes.

Recently, formal models of imperfect competition have been studied intensively, and the tools of noncooperative, extensive form game theory have assumed central importance in this work (see Schmalensee 1982; Waterson 1984; Roberts 1985). Laboratory experiments are being performed more frequently, as are case studies relying heavily on formal models and econometric analysis of firm behaviour. Implications of imperfect competition for international trade and for national welfare in a world economy are receiving increased attention.

In the remainder of this essay I discuss briefly some of the questions that have been studied intensively by industrial organization economists. For more detailed treatments of many of these issues, see Bain ([1959], 1968), Hay and Morris (1979), Scherer (1980), Schmalensee and Willig (1988), Stigler (1968), and Waterson (1984). Space constraints preclude an explicit discussion of antitrust or regulatory policy.

Are firms managed so as to maximize profit (or, more generally, the wealth of their owners), as microeconomic theory assumes? This question is most important in imperfectly competitive markets, since non-maximizing firms cannot survive in the long run under perfect competition. Two alternatives to profit-maximization have been advanced. Neither has yet proved to be more generally useful, though both yield valuable insights in some situations.

First, some scholars have argued that firms' problems are so complex and their information so imperfect that maximization is effectively impossible. They stress the importance of routines, rules of thumb, experimentation, and learning in actual business behaviour.

Second, others note that the many shareholders who nominally own large corporations cannot effectively review managers' decision-making. These scholars model managers as pursuing a variety of their own objectives (such as firm size or growth) subject to constraints (often relating to profitability) imposed by owners. Recent work using agency theory to model the manager–owner relation shows considerable promise here.

In an ideal world, shareholders would always use the *market for corporate control* to replace managers who did not effectively pursue the owners' interests. And shareholders in fact often force mergers and sometimes elect boards of directors opposed by incumbent managers. But ours is not an ideal world, and the importance of frictions and imperfections in the market for corporate control is widely debated.

What determines the boundaries between firms and markets? A number of authors have focused on the implications of cost minimization for firm structure. Oliver Williamson (1975) has stressed the difficulty of writing long-term contracts that allow for all possible contingencies. If efficient production requires making investments that cannot be easily shifted to alternative uses, this difficulty may make it more efficient to integrate related activities within a single firm, rather than to attempt to coordinate them by contract and risk the effects of contractual breakdown.

Stigler (1968, ch. 12) stressed the importance of *economies of scale*. He argued that, as markets grew, specialized firms would arise to perform functions in which economies of scale were important. More recently, Baumol et al. (1982) have argued that multiproduct firms may arise to take advantage of *economies of scope*, which lower cost when the production of multiple products is carefully coordinated. Scope economies arise when assets can be readily shared among processes producing several outputs.

Another even more diverse body of theoretical literature argues that imperfections in competition may produce other incentives for firms to expand their activities. Relatively few empirical tests of any of these models have been performed, however.

What is a market? In microeconomic theory, a market is the locus of trades in a single, perfectly homogeneous product. This definition would make almost all real firms monopolists. In practice, markets must be defined by aggregating products that are relatively close substitutes in demand or supply. For most purposes, particularly in the context of antitrust policy, it is useful to define a market as the smallest aggregate that could profitably be monopolized. It is rarely easy to implement this definition in a fully satisfactory way, however, and government datacollection agencies rarely try. This poses real problems for empirical work.

What are the key elements of market structure? In the seminal work on this point, Bain (1959) argued that there were four such elements, all of which he seemed to treat as derived: the extent of seller concentration, the extent of buyer concentration, the importance of product differentiation, and the conditions of entry. Seller concentration was held to facilitate noncompetitive behaviour; buyer concentration was held to make such behaviour harder to sustain. Bain argued that product differentiation insulated sellers from each others' actions and changed the focus of rivalry from

price to non-price competition. He also argued that the easier it was for new competitors to enter an industry, the more difficult it would be for established firms to maintain prices above costs and earn supra-normal profits. (Baumol et al. (1982) have coined the term *contestable* to describe markets in which entry is so easy that potential competition alone suffices to eliminate excess profits.)

Bain (1956) went on to identify four sources of *barriers to entry*, four reasons why established firms might be able to earn excess profits without facing the threat of entry. (See Stigler 1968, ch. 6 for an important alternative definition of this term.) First, substantial economies of scale might make potential entrants reluctant to enter at efficient scale for fear of depressing prices below costs. Second, established firms might have cost advantages over potential entrants, perhaps because of proprietary production processes. Third, established firms might have demand-side or product differentiation advantages over potential entrants, perhaps because of patented products or buyers' reluctance to switch brands. Finally, Bain felt it was possible that imperfections in capital markets would inhibit entry when large initial investments were required. This last possibility remains controversial.

While this framework remains influential, it is increasingly under attack. Bain and many of his followers assigned what now seems to be excessive importance to seller concentration. Bain's framework neglects firm structure, but firms that operate in many markets may behave differently from single-market enterprises, since actions taken in one market may affect costs or strategic opportunities in others. Caves and Porter (1977) have argued that the notion of entry barriers must be generalized to include *mobility barriers*, which impede entry into *strategic groups* of sellers with similar capabilities and strategic objectives. They and others contend that the structure of strategic groups within industries can materially affect conduct.

Bain's framework now seems to many scholars to omit a number of critical structural variables. Recent work attaches particular importance to cost conditions and information. Baumol et al. (1982) have stressed the impact of *sunk costs*, costs required to enter a market that cannot be recovered if the market is later abandoned. The more important sunk costs are, the greater the risk of entry, and the more important scale economies are as a barrier to entry, all else being equal.

Stigler (1968, ch. 5) pointed out that sellers are more likely to be able to sustain non-competitive behaviour the better their information on each others' actions. Recent game-theoretic work has expanded on this insight and stressed the importance of information about rivals' capabilities and objectives as well. Buyers' information about prices and qualities may also play a central role in determining marketing and distribution arrangements and the form and intensity of rivalrous behaviour. If buyers must spend time to learn the prices of competing sellers, for instance, each seller has some monopoly power even if there are many firms marketing identical products.

Bain ([1959] 1968, p. 9) argued that one ought to restrict attention to a small number of structural characteristics because 'meaningful intermarket comparisons and meaningful generalizations about the influence of structure on behaviour are effectively forestalled if the content of "structure" is made so comprehensive that no two markets could be viewed as structurally alike'. But many scholars now feel that simple generalizations of the type that Bain sought may not have much predictive power.

How are the derived elements of market structure determined? Most work has focused on the determinants of seller concentration, with special attention given to the hypothesis that concentration is determined by economies of scale. This hypothesis is supported by the observation that the same industries tend to be concentrated in all developed economies, despite different histories and government policies.

Scale economies in manufacturing at the plant and firm levels have been measured by statistical methods, by interview studies (the 'engineering' approach), and by comparing the sizes of units that prosper and decline (the 'supervisorship' approach'. These studies have been criticized because of the inherent difficulty of measuring non-production scale economies (those in

marketing and distribution, for instance) that occur at the firm level. In general this work suggests that concentration in most US manufacturing industries is higher than required for the exploitation of economies of scale in production. This is consistent with the observation that among large industrialized economies, absolute levels of concentration in particular industries are not sensitive to differences in the size of the national market.

A number of other potential sources of concentration have been identified. Spence (1981) has shown that *economies of learning*, which cause unit cost to decline with cumulative production, can mandate high concentration even when scale economies are absent. Demsetz (1973) has argued that persistent efficiency differences, along with the tendency for efficient firms to expand at the expense of their rivals, are an important source of concentration. Many others have studied the impacts of random variations in firm growth rates and of mergers on concentration. Mergers are an important source of concentration in some countries but not in others; the empirical importance of the other factors remains controversial.

What determines the intensity of rivalry in oligopolies? We still have no fully satisfactory, general model of oligopoly, but theoretical work has yielded a number of valuable insights.

The basic problem faced by any set of sellers is that posed by the classic prisoners' dilemma game. In a static setting, all sellers do well if prices are kept high. If all other sellers set high prices, however, any single firm can usually increase its profits by charging a lower price (or producing more than its assigned quota). If all behave selfishly in this fashion, all will charge low prices and receive low profits. That is, *non-cooperative*, selfish behaviour in this setting tends to produce competitive, low-profit outcomes.

Interest thus attaches to the possibility of *cooperative* or *collusive* behaviour that can produce monopolistic performance, with high prices and high profits. In principle, collusive behaviour can be overt, with firms explicitly agreeing on strategies, or tacit, with firms reaching an unspoken understanding about acceptable policies. It is more difficult to reach agreement tacitly than overtly; agreement is also more difficult the more firms there are and the greater the differences among them. Collusion can either be total, covering all decisions, or partial, covering only some variables under firms' control. It may be easier to collude on price than on advertising, for instance.

Collusive agreements are inherently unstable, since individual sellers can usually increase their profits, as in the prisoners' dilemma game, by departing unilaterally from the agreement. Stability requires the ability to detect cheating and to make a *credible threat* (one that it would actually be rational to carry out) to impose a sufficiently severe penalty to render cheating unprofitable. The game-theoretic notion of *perfect* (Nash) *equilibrium,* in which players noncooperatively pursue their own interests but noncredible threats are ruled out, has been used heavily in recent work on oligopoly theory and entry deterrence (discussed below).

Stigler (1968, ch. 5) argued that cheating can be more reliably detected in concentrated markets. A number of authors have recently built on his work and devised multi-period gametheoretic models in which firms announce credible threats that make cheating irrational, even when cheating can only be imperfectly detected. In these models threats are sometimes carried out (price wars occur) even though nobody ever cheats.

A number of econometric time-series studies of individual oligopolistic markets have been undertaken in recent years. These often employ the non-game-theoretic formalism of *conjectural variations*. In a market in which products are undifferentiated and firms set outputs, a firm's conjectural variation is its expectation of the derivative of all other firms' output with respect to its own. Estimates of the conjectural variations consistent with observed market outcomes provide a summary description of the intensity or rivalry. If all conjectural variations equal minus one, behaviour is perfectly competitive; larger values imply departures from the competitive ideal. Data limitations make it hard to apply this approach to many industries.

Can the conduct of established sellers discourage the entry of new rivals? In the classical limit-

pricing model of Bain (1956), an established monopoly in an industry with significant scale economies could discourage entry by raising output above the monopoly level and threatening not to reduce production if entry occurred. The incumbent would optimally select its output so that entry at efficient scale would raise total output so much as to depress price (just) below cost.

Unfortunately, the threat in this model is not credible (i.e., the no-entry equilibrium is not perfect). If entry did occur, the incumbent could generally increase its own profits by reducing its output, and a potential entrant has no reason to believe that the incumbent would forego such an opportunity. Recent work (see, especially, Roberts 1987) imposes the requirement of credibility. There are three strands to this literature.

First, when information is imperfect, incumbent firms may attempt to use pre-entry price to deceive potential entrants. If potential entrants don't know the incumbent's costs, for instance, the incumbent may lower its pre-entry price below the monopoly level in order to persuade potential rivals that its costs are too low to permit viable entry. This resembles classic limitpricing, but it turns out on average not to deter sophisticated entrants, who understand the incumbent's incentive to attempt deception.

Second, an incumbent may be able to make credible threats by making *commitments* in advance of entry. That is, it may be able to take actions before entry that alter its post-entry incentives in a way that makes a hostile response to entry more attractive. Spence (1977), who began this line of work, considered investment in production capacity as a vehicle for commitment.

Third, if entrants are uncertain about an incumbent's objectives, it may be rational for the incumbent to take predatory actions designed to eliminate entrants when they appear. Such a policy may give it a *reputation* for aggressive (or irrational) behaviour, which may serve to deter even sophisticated potential entrants.

Do statistical analyses of data from multiple industries shed light on the validity of the hypotheses discussed above? Many cross-section studies have been performed by students of industrial organization, but the interpretation of many of their statistical findings is controversial, and the intertemporal stability of some key relationships has recently been questioned.

All cross-section studies employ accounting data, and most focus on determinants of profitability. But accounting data do not provide exact measures of real, economic profitability, in part because of differences in riskiness, the way in which long-lived investments are depreciated, and the possible ability of labour unions to capture rents generated by collusive behaviour. It has proven difficult to obtain good measures of other theoretical constructs as well, particularly product differentiation and barriers to entry. The growing importance of firms operating in several markets poses yet another measurement problem.

Many cross-section studies find a weak but statistically significant positive relation between seller concentration and industry profitability. Until recently this was generally interpreted as supporting the Bainian hypothesis that concentration facilitates collusion. But Demsetz (1973) has offered an alternative explanation: in a world without collusion, substantial efficiency differences among rival sellers are likely to produce both concentration, as noted above, and high industry-level profits, because efficient firms earn rents. Where efficiency differences are unimportant, one would expect both concentration and profits to be low. This hypothesis is consistent with the strong positive correlation between market share and profitability in some industries, but not many industries follow this pattern. It has proven difficult to discriminate between these two hypotheses empirically.

Similarly, numerous studies have found a strong positive correlation between advertising/sales ratios and profitability. This has often been taken to support Bain's (1956, 1959) hypotheses about the effects of product differentiation and product differentiation advantages of established firms. But advertising is logically only one input affecting those structural variables, and it is an endogeneous variable, determined by profit-seeking sellers. Unfortunately, it has been difficult to specify good simultaneous equations models in this area. Finally, the effects of advertising on demand probably persist over time, so that

advertising should be treated as an investment, not a current expense. If advertising's effects are assumed generally to decay slowly enough, the correlation between advertising intensity and (corrected) profitability measures disappears, but the appropriate decay rate assumption remains controversial.

Because of these and other problems of measurement and interpretation, inter-industry empirical work seem to have lost the central place it formerly held in industrial organization. Still, such work remains an important source of the general stylized facts needed to guide the construction of useful theoretical tools.

What sorts of price structures are imposed by firms with market power? What are the welfare implications of price discrimination? If a seller has some control over its price (i.e., it is not a perfect competitor), can identify (even imperfectly) customers with different demand characteristics, and can prevent (or at least inhibit) trade among its customers, it will generally pay it to practise price discrimination. That is, it will adopt a price policy in which different customers pay different marginal or average prices depending on their demand characteristics. The ability to earn excess profits is not required; price discrimination can persist in a free-entry equilibrium of the Chamberlin (1933) type.

In practice, sellers employ many devices for identifying customers of different types. Bulk discounts, in which the average price paid falls with volume, provide one method. (This is a special case of *non-linear pricing*, in which the buyer's bill is a nonlinear function of the quantity he purchases.) Delivered pricing, in which a buyer's price depends on his location, provides another. Discrimination may also be effected by bundling or tying arrangements, which require buyers to purchase related products from a single seller. And there are a host of market-specific devices: US airlines, for instance, charge a much lower fare for trips that involve spending a Saturday away from home, thus generally charging lower prices to tourists than to business travellers.

The large theoretical literature on the consequences of such practices contains few sharp results. Prohibiting price discrimination in most cases produces both gainers and losers; the net welfare effect is usually ambiguous.

How are product quality and variety determined in imperfect markets? Are the outcomes likely to be optimal in any sense? If 'quality' is simply inserted as an additional variable in a standard monopoly model, one can show that 'quality' may be either too high or too low in equilibrium, depending on the details of the demand function. If there are many sellers and buyers rely on firms' reputations for quality in making decisions, firms producing high quality (and thus high cost) products must be able to charge prices above marginal cost in equilibrium. If not, they would have an incentive to lower quality and exploit their reputations until buyers caught on.

Models in which variety is determined usually assume economies of scale in the form of brand-specific fixed costs; otherwise it would generally be socially efficient and privately optimal to produce all possible brands. This assumption rules out purely competitive equilibria and forces second-best welfare comparisons. It also provides a rationale for intra-industry international trade: such trade expands the market and makes greater variety economically feasible.

In some models of variety determination, the demand side of the market is a single representative consumer who desires variety. In others, consumers have different ideal brands, and each desires, all else equal, to consume the brand that is 'closest' to his ideal in the space of all possible brands. In a third class of models, consumers agree on the ranking of all possible brands but differ in their willingness to pay for quality. Market equilibria in all these models generally involve a non-optimal set of brands, but the nature of deviations from optimality depends on the details of the model. Chamberlin's (1933) view that monopolistic competition implies excessive variety is not generally valid.

Are market-determined levels of advertising excessive? Do they increase barriers to entry? Neither of these traditional questions has yet been answered, and neither may in fact have a general answer.

In order to assess the optimality of any level of advertising, one must make some assumption

about how advertising affects consumer behaviour. One extreme assumption is that advertising simply provides consumers with information; the other is that it simply changes their tastes. Under the first assumption, market-determined advertising levels are optimal only under very special conditions; under the second assumption the optimal level of advertising depends on what tastes are used as a yardstick. In fact, neither extreme assumption is likely to be generally correct.

The theoretical effect of advertising on conditions of entry depends, again, on the way advertising affects consumers, and this is likely to differ among markets. In some markets restrictions on advertising are observed to increase prices; in others, heavily advertised brands sell at substantially higher prices than apparently physically identical brands that are not advertised. Advertising may be less important in markets in which retailers are an important source of information. Product differentiation advantages of established brands may depend more on satisfied buyers' rational reluctance to experiment with new brands than on the effects of advertising.

Are large firms in concentrated markets the major sources of technical progress, as Schumpeter (1942) *argued*? It is difficult to measure any firm's contribution to technical progress; counts of patents or significant innovations are frequently used but obviously imperfect indicators. Most studies have found that, in most industries, large firms are not disproportionate sources of innovations, especially not significant innovations, but there are exceptions. It is more difficult to assess the impact of market structure on technical progress, since one must control for differences in the opportunities for innovation across markets. The available evidence provides at most weak support for Schumpeter's view of the effects of concentration.

On the theoretical side, a number of authors have recently modelled research and development rivalry in game-theoretic terms. In many of these models, firms spend money (perhaps over time) to increase their chances of winning a single prize, usually interpreted as a patent. Under some conditions, it may be rational for an incumbent monopolist to outspend potential entrants in order to prevent their entry. In general, theoretical work indicates that market-determined levels of research and development spending may be excessive or inadequate. This work also makes clear that concentration and other structural variables are in the long run determined by the intrinsic opportunities for innovation. Concentration and innovative activity are thus both endogeneous variables.

How important are departures from competitive performance? Early studies of this question, which associated differences in profit rates with departures from the competitive ideal, concluded that monopoly power imposed relatively small costs on society. It is now clear that a proper general equilibrium analysis of this issue may imply much larger or even smaller effects, depending on the values of unknown parameters.

Some authors have argued that differences in observed profit rates understate the actual effects of monopoly power because monopoly profits are to some extent dissipated in actions taken to achieve or protect monopoly positions, captured by labour unions, or simply foregone by lazy or inept managers not subject to market discipline. On the other hand, if Schumpeter (1942) was right, short-run measures of the cost of monopoly omit important long-run benefits. Like so much else in this field, the actual importance of departures from pure competition in modern economies remains controversial.

Industrial Relations

Thomas A. Kochan

Abstract

Industrial relations is an interdisciplinary field of study that encompasses all aspects of work and employment relations. Originating in institutional economics and Fabian socialism, it has evolved to address employment problems and issues ranging from wage determination and collective bargaining to human resource management and labour market dynamics and policies. Globalization has increased the importance of international and comparative analysis of employment practices and outcomes. Shifts in employment from manufacturing to services has rendered the term 'industrial relations' obsolete and led scholars to use the term 'work and employment relations' to describe their work and this field of study.

Industrial relations is an interdisciplinary field devoted to the study of all aspects of work and employment relations. It emerged historically out of the works of the Fabian Socialists Sydney and Beatrice Webb (1894, 1897) in Great Britain and institutional economists such as John R. Commons (1909, 1934) in the United States. Both sets of scholars and their students were searching for ways to understand *and* influence

employment relations in ways that distinguished their normative, theoretical and methodological approaches from Marx (1849) on the one hand and classical or neoclassical economics (Marshall 1920) on the other.

Over the years the field has evolved and broadened considerably to incorporate concepts and methods from other social sciences such as psychology, sociology, and political science and from disciplines outside the social sciences such as history and law. In recent years the term 'industrial relations' has become somewhat dated, given the growth of the service sector and the decline of traditional manufacturing industries, leading a number of research units working in this scholarly tradition to redefine the field as the study of 'work and employment relations'. But the underlying normative, theoretical and methodological features of the field carry on the distinctive features of industrial relations.

Origins and Initial Intellectual Debates

Karl Marx provided the intellectual rationale and stimulus to the field of industrial relations. His most enduring contribution was to assert that labour was more than just a commodity or factor of production subject to deterministic laws of supply and demand. Instead, the free will and power that reside in human beings make labour more than an inanimate object. This basic insight serves as an enduring normative premise in industrial relations and motivates much of the work in the field to this day. That is, while affected by market forces similar to other factors, labour deserves and requires special treatment in theory and public policy because workers can take individual or collective actions to influence market outcomes, and work and employment relationships affect important human values and have important social as well as economic consequences. For these reasons, industrial relations research, public policies and practices need to be as concerned about equity as efficiency at work (Barbash 1984; Meltz 1989). Moreover, freedom of association at work is recognized as a fundamental human right in democratic societies and, therefore, the ability of workers to have a voice in determining their employment conditions serves as an equally important industrial relations outcome (Budd 2004).

While Marx provided the starting point for the field of industrial relations, much of the scholarship in the field has taken issue with other aspects of Marxian analysis. This is especially true of the Marxian view of the source of labour conflict in employment relations. Marx saw conflict at work as inevitable and all-encompassing, arising out of class differences rooted in the capitalist system of production. Conflict could be eliminated only by the revolutionary overthrow of that system. This became a major point of differentiation between Marxist and labour process schools of industrial relations on the one hand (Hyman 1975) and on the other hand the more mainstream pluralist model which has grown to dominate European and Anglo-Saxon research traditions (Clegg 1970; Fox 1971; Kochan 1980).

Sidney and Beatrice Webb (the Webbs) were among the first to challenge Marx with their model of Fabian socialism. They shared with Marx a concern for the plight of the growing working class. Beatrice Webb was a student of the factory conditions prevailing in 19th century as Britain ushered in the first Industrial Revolution. Her empirical observations of factory conditions convinced her that the average worker suffered from an inherent imbalance of power in dealing with his or her employer. Trade unions were therefore needed to provide increased social support and bargaining power. Over time, however, unions were expected to evolve into institutions that promoted orderly government regulation that worked to the common benefit of all workers and for the overall community. Thus through evolution, not the revolution predicted by Marx, societies would evolve to better balance the needs of workers, employers and the communities in which they were embedded.

At about the same time as the Webbs were doing their work in Britain a quiet revolt was taking place in the field of economics in the United States. Leading economists were frustrated with the highly deductive and mathematical features of late 19th-century economic research.

As a result, in 1886 Robert Ely at the University of Wisconsin led other colleagues to form a new American Economic Association in an effort to bring a more inductive, empirical, and institutional brand of economics to bear on the critical problems of the day. Labour economics, more than any other sub-field within the economics profession, took up the institutional approach. Led by Ely's protégé at Wisconsin, John R. Commons, a new field was born. It focused on the study of labour and working conditions using empirically based, inductive methodological methods and focused as much on the collective institutions and organizations of workers and employers governing work and employment relations as on the actions of individuals in response to market forces.

Like Marx, these institutionalists believed that labour was more than a commodity. But unlike Marx, Commons and those that followed in building the field of industrial relations saw the conflicts of interests between employers and employees as part of natural, legitimate and ongoing differences in economic interests, not as a function of the capitalist system. Employers have the responsibility of promoting efficient use of scarce resources, including labour. Employees have the right and need to pursue their self-interests, individually or collectively, to improve their security, wages, working conditions, and other features of their work lives they value. These conflicting interests are not, however, absolute. Employers and employees also have some common interests that tie them together in ongoing interdependent relationships. Both want to generate value from their relationships so that there is more value to share. Safety and security may be other shared values. Commitment to the mission of the organization and service to their clients, customers, patients and so forth may be other shared values and objectives. Thus employment relations involve an inevitable mix of separate, perhaps conflicting, and common or shared goals. The task of industrial relations theory, research, teaching and policy therefore focuses on both finding an equitable resolution of differences or conflicts and ways to support value, creating solutions where interests overlap or are held in common (Walton and McKersie 1965).

The early institutionalists were strong proponents of empirical research and active involvement in policymaking and institution building. They studied labour market dynamics and labour management relations through field work more than through deductive model building. Their collective body of research and personal involvement generated most of the ideas and policy proposals embedded in the labour legislation of the New Deal. Unemployment insurance, workers' compensation, child and women's labour protections, minimum wages and social security all were ideas developed and studied at state and local levels of the economy between 1900 and 1930. Commons is now widely recognized as the intellectual father both of the New Deal labour legislation and the study of industrial relations in America (Kaufman 1993).

Debates with Alternative Disciplines

Kuhn (1970) argues that a new paradigm for the study of a phenomenon must be judged ultimately by whether it is better able than its alternatives to solve problems. So it is appropriate to examine industrial relations against this criterion at critical stages in its development.

Scientific Management Scientific management and industrial engineering dominated the study and practice of management and the design of work systems in the United States in the first two decades of the 20th century. The objective was to use engineering principles to find the optimal, most efficient methods for carrying out tasks, organizing them into a clear hierarchy and controlling labour through appropriate economic incentives and supervision to conform to the specified work process. In following these scientific engineering principles one would eliminate any potential conflicts of interests at work (Taylor 1895). This view of work and employment relations saw no rationale for worker voice, representation, or policies that would balance power between workers and managers. Its primary

theoretical prediction was that efficient organization and supervision of work, when supported by the right individual incentive compensation system, would generate maximum efficiency. Because efficient work would be rewarded, it would in turn generate worker satisfaction. This virtuous cycle would keep conflict from emerging in employment relationships. Thus, scientific management theory and efforts to implement it in practice stood in sharp contrast to industrial relations theories and normative assumptions.

Industrial Psychology At the same time industrial psychology was emerging as a field of study that paralleled and complemented the engineering approach. The study of personnel management largely grew out of industrial psychology. In contrast with the institutional economists, individuals, not collective groups or organizations, were the central unit of analysis and the firm was viewed more as a closed system, on the assumption that management controlled workplace decisions. Institutionalists reflected their economics' training by treating work and organizational practices as influenced by both organizational and external market and technological forces.

Human Relations In the 1920s the field of human relations was born out of the Hawthorne experiments (social-psychological experiments conducted at the Hawthorne Works' plant of Western Electric) in group behaviour and gave rise to another competing paradigm for the study of work and employment relations. The human relations school focused on work groups as the key unit of analysis and the social dynamics that shaped worker attitudes and behaviour. Human relations theorists reversed the theoretical argument of scientific management by proposing that worker satisfaction drove efficiency at work rather than the other way around (Roethlisberger and Dickson 1939). This school of thought provided intellectual foundation for the emergence of welfare capitalism in the 1920s. Large firms sought to provide a set of benefits and positive working conditions in order to achieve efficiency and in the process of doing so eliminate the incentives of workers to join trade unions (Jacoby 1991).

These were the alternative paradigms competing for influence with industrial relations over the first 30 years of the 20th century. The Great Depression of the 1930s raised industrial relations ideas, policies and research to a more prominent and perhaps dominant place in the intellectual and policy debates about work and employment relations. With the rise in industrial conflict and massive unemployment came the recognition of the need to establish a floor on labour standards and a means for workers to bargain as relative equals with their employers to improve on these minimum conditions. Thus, it was the dramatic deterioration in economic conditions, the threats unregulated conflict posed to democracy and social stability, and the shift in the political environment that allowed the ideas and research evidence of the institutional economists to emerge as the intellectual basis for much of the New Deal legislation passed in the 1930s.

The New Deal Era, the Second World War and the War Labor Board

From 1932 to 1945 industrial relations scholars and practitioners had an unprecedented impact on national policy and private practices of employment relations in the United States. The War Labor Board (WLB) (1941–5) that was charged with controlling wages and mediating collective bargaining negotiations played a key role in legitimating and starting the long-term diffusion of many modern personnel and labour relations practices and benefits including grievance arbitration, cost of living wage increases, paid time off for holidays and sick leave, paid health insurance and private pensions.

The first two decades of the post-war era were dominated by institutional economists and scholars from sociology, political science, law, labour history, and psychology who united around a common desire to better understand and regulate labour management relations. In 1946 strike levels in the USA reached their historic peak. Concern over the escalating labour-management conflict led a number of state legislatures to create new multidisciplinary schools or centres of

industrial relations in leading universities such as Cornell, Wisconsin, Illinois, Michigan State, Rutgers and the University of California at both Berkeley and UCLA. In 1947 a new scholarly professional association, the Industrial Relations Research Association, was created. This association continues today under the name of the Labor and Employment Relations Association.

Two sets of questions featured prominently in industrial relations research in decades following the Second World War: (*a*) how does collective bargaining work and (*b*) what are the effects of unions and collective bargaining on management, the workforce and the economy? A debate arose over whether political (that is, pressures from union members and the need for union leaders to match settlements achieved in closely aligned industries or occupations) (Ross 1948) or economic forces (Dunlop 1944) were the primary drivers of wage determination. While never fully resolved, the evidence suggested that both play roles – political forces are influential within a range but are limited by market conditions. A reformulation of the debate by one institutional economist suggested that bargaining power includes a mixture of political, economic and 'pure power' forces and that these should be incorporated into a more complete theory of wage determination under collective bargaining (Levinson 1968).

The growing presence and pressure of unions and collective bargaining from the 1930s through the 1950s exerted what one set of researchers called a shock effect on management. Personnel practices had become more professionalized and applied in more uniform fashion and management had to search for ways to improve productivity to recoup the higher wage costs resulting from collective bargaining (Slichter et al. 1960). Much of industrial relations research over this time period examined the dynamics of labour management relations and the causes of strikes and/or industrial peace (Golden and Parker 1955). Most of this work was carried out using qualitative case studies or historical studies of specific unions or of industrial relations in particular industries.

Dunlop (1958) criticized post-war industrial relations research for being characterized by too many facts chasing too little theory. He sought to correct this problem by proposing a general systems theory of industrial relations. He argued that the central task for industrial relations theory was to explain variations in the rules governing employment relations. These rules were set in interactions among three key actors – labour, management and government – and conditioned by external market, technological and societal forces. The system was bound together by what Dunlop argued was a shared ideology valuing democracy, respect for market forces and worker rights. Although Dunlop's framework never reached the level of being accepted as a general theory of industrial relations, it became the starting point for much of what constituted industrial relations research in the decades following publication of this important work.

Public Sector Unions and Collective Bargaining

Government employees were not covered under the National Labor Relations Act (NRLA) of 1935 and, with a few exceptions such as postal employees, remained largely non-union until the 1960s. In 1958 Wisconsin enacted the first of what would grow to be a surge of state legislation protecting state and local employees' right to unionize and engage in bargaining. By 1976 38 states had enacted similar statutes, employing various forms of mediation, fact-finding, and arbitration to resolve contract disputes in lieu of the right to strike. Only a handful of states provided public employees the right to strike and even in these cases police and firefighters were not given the right to strike. Federal employees were granted similar rights to negotiate over non-wage and benefit issues, first through an Executive Order enacted in 1962 and then through legislation enacted in 1978.

As a result, unionism among public employees grew from its minimal level prior to 1960 to reach its present level (in 2007) of approximately 37 per cent of all government employees. These developments produced a significant body of new research on public sector collective bargaining

throughout the 1960s and 1970s. Most of this work focused on the performance of mediation, fact-finding and arbitration as deterrents to strikes. The consensus findings of these studies is that arbitration has been successful in deterring strikes of public employees (Olson 1988). Other studies have focused on the effects of public sector unions and collective bargaining on wages and government budgets. The general findings of these studies are that unions can increase wages. Prior to 1980, estimates suggested the union effect was around five per cent. After 1980 it rose to 20 per cent for local government employees and ten per cent for federal employees (Gunderson 2007).

Internal Labour Markets

The study of labour market behaviour represents another longstanding strand of research in industrial relations, dating back to Commons's (1909) classic historical study of changes in labour and product markets of shoemakers. Throughout the 1940s and 1950s studies of the dynamics of external labour markets followed the institutional tradition by examining the development of industry and regional wage structures (Lester 1952; Rees and Shultz 1970).

Interest turned to the study of internal labour markets in the 1970s and thereafter by both economists (Doeringer and Piore 1972; Osterman 1984) and sociologists (Baron and Bielby 1980; Pfeiffer and Baron 1988). Internal labour markets refer to firm-level rules governing hiring and termination, arrangement of jobs into job ladders, compensation structures that link jobs, and access to and mobility of personnel within and across job ladders. The primary questions of interest in these studies is what substantive rules govern the organization of jobs and job ladders and what factors give rise to the development, continuity and decline of internal labour market rules and practices. There is more consensus over the factors giving rise to internal labour markets than to the degree to which are the causes of their decline. Internal labour markets arise as a function of pressure from unions, governments and tight labour markets (Jacoby 1985). Over time these rules gain sufficient acceptance to become norms that sustain them even in the face of changing conditions in the external labour market (Osterman 1984). A major topic of debate in emerged in the 1990s over whether, and if so why, internal labour markets are declining in importance as firms appear to be more willing to lay off workers, adjust compensation to external market signals and hire more workers from outside the firm rather than train and promote current employees (Cappelli 1999; Jacoby 1999). There is no conclusive outcome to this debate. Micro firm-level studies tend to find more significant changes in firm-level rules and employment practices and outcomes while macro labour market studies tend to observe modest reductions in employee tenure (for men but not for women). The relative consensus is that norms governing layoff decisions and internal wage structures have led leading firms to be less reluctant to lay off hourly and managerial employees and more willing to allow their internal wage structures to become more disparate or unequal.

Resurgence of the Basic Disciplines

In the 1960s and 1970s the disciplines and methodologies from which industrial relations researchers drew became more quantitative as econometric and psychometric tools advanced, micro data-sets on labour market behaviour became more readily available, and computer power became more readily accessible. The vast majority of newly trained labour economists moved away from institutional analysis in favour of drawing propositions from neoclassical economics that could be tested with econometric methods. Studies of individual labour market behaviour grew and studies of collective behaviour, where data were less available, declined. Research on discrimination, mobility, labour supply, returns to education, and human capital flourished while the study of unions and collective bargaining declined.

The exception to the shift away from unions and collective bargaining was the use of econometrics to estimate the impact of unions on

relative wages of individuals (Lewis 1963). The consensus estimates of these studies were that private sector unions raised wages of their members relative to comparable non-members between 10 and 15 per cent. These estimates rose to 15 to 22 per cent in the 1970s (Kochan and Helfman 1981). Unions also were shown to have positive effects on other outcomes such as health and pension coverage, wage inequality, productivity, worker retention and satisfaction with wages (Bennett and Kaufman 2007). Unions have negative effects on firm profits and satisfaction with non-wage outcomes (such as satisfaction with job content) (Kochan and Helfman 1981; Freeman and Medoff 1984).

The development of human capital theory (Becker 1975) further encouraged the movement of labour economics back into the mainstream of the economics discipline and away from its institutional orientation. Becker's work stimulated others (Lazear 1998) to apply economic analysis to personnel decisions and practice. The study of alternative forms of incentive compensation and their effects on motivation and performance lies at the heart of personnel economics. A paradox appears to exist: the empirical evidence documents the economic value of incentive compensation to the firm, while use of individual incentives has not grown and in some countries appears to be in decline. Explaining this paradox requires consideration of the social context and other institutional forces that seek to reduce competition among workers and enhance social cohesion at work. Personnel economics' models of incentive compensation, therefore, need to be supplemented with sociological theories of group norms and other institutional factors that shape wage determination in contemporary organizations.

The same movement back to their mother disciplines could be observed by the 1970s in the work of psychologists and sociologists studying work and employment issues. Models of motivation, job satisfaction, work performance, turnover, and other aspects of individual attitudes and behaviours, based most often on survey, laboratory, or other data-sets assembled by these researchers, became the dominant topics and methodologies. This has given rise to the more applied field of human resource management research. Human resource management combines analysis of firm-level personnel functions (selection, compensation, performance appraisal, and so forth) with analysis of the links between human resource strategies and individual or organizational performance (Dyer 1984; Schuler and Jackson 1987). Most of this work adopted the normative premises of the human relations and scientific management schools rather than those of industrial relations. Thus they focused on how to manage employees through the use of modern personnel and human resource practices and strategies to overcome any sources of conflict in the employment relationship and to foster firm performance.

1980s: A Time of Transformation

The 1980s proved to be a watershed decade for both the study and practice of industrial relations. A central debate arose over whether reductions in real and nominal wage and other changes observed in collective bargaining were simply temporary adjustments to the deep recession of 1981–3 or signalled a more permanent structural shift in the wage determination process and in industrial relations more generally. Few today doubt that the wage determination and industrial relations practices shifted in fundamental ways in the 1980s by reducing the power of the strike threat, and weakening unions in general. Strike rates (measured in percentage of contract negotiations that involve a strike or percentage of annual work hours lost to strikes) have declined precipitously to the point they are no longer reported by government agencies.

The confluence of the deep recession, increased international competition and a shift to a conservative government in the United States under President Ronald Reagan unleashed a set of changes that created a set of anomalies for much of postwar industrial relations theory and empirical research. Management became more openly hostile and aggressive in avoiding new union organizing, moving operations from union to non-union workplaces. Management replaced

unions as the driving force in shaping the process and outcomes of collective bargaining. Nominal wage reductions were negotiated in many employment contracts. New approaches to work organization and employee participation challenged traditional job structures and labour management relations. These developments led to an expanded model of industrial relations that emphasized how the choices made by management in particular (but labour and government as well) in structuring relations at the workplace, in collective bargaining or personnel policies and in high-level business/ competitive strategies shape employment relationships and outcomes (Kochan et al. 1986).

Analysis of how these choices played out and affected outcomes featured significantly in industrial relations research throughout the 1980s and 1990s. Researchers began to assess the effects of different combinations of employment practices on firm performance, reflecting the systems' perspective of industrial relations and the emerging emphasis on complementary practices in personnel economics (Milgrom and Roberts 1992). By the end of the 20th century the evidence suggested that flexible work systems and employee involvement in production and workplace decisions served as positive complements to investments in technology and training, produced significant improvements in productivity and service quality (Ichniowski et al. 1996; Appelbaum et al. 2000). The theory and evidence suggested a high-wage, high-productivity equilibrium was possible in sectors as diverse as manufacturing, airlines, health care and financial services. Yet these 'high performance' work systems did not diffuse naturally across the economy, in part because of the costs of transitioning from more traditional practices, and in part because they competed with a low-wage, low-cost equilibrium. These two competing models of human resource practice and industrial relations compete with each other across most industries and occupations in the USA and other countries. A central theoretical and policy question in the field today focuses on whether a highwage, high-productivity equilibrium can be sustained in the face of low-wage, low- cost competition in domestic *and* international labour and product markets, and, if so, how to best encourage adoption of these strategies.

Policy Debates

Concerns over public policy rose in parallel to these theoretical and empirical developments. The central proposition driving policy debates was that the changes in the workforce, nature of work, and the economy had outpaced adaptations in public policies, institutions, and practices in employment relations and that this gap was imposing costs on workers and the economy (Osterman et al. 2001). Efforts to build consensus on changes needed in labour and employment policies consistently failed from the late 1970s to the 1990s (Kochan 1995). The result is that the field of industrial relations has come full circle to where it began in the early years of the 20th century when Commons and his students documented the mismatch between policies and institutions and workplace relations as the economy transitioned from its agrarian base to a manufacturing base. Today the mismatch is playing out on a global rather than a domestic scale, and therefore the theoretical, institution building, and public policy challenges are broader and perhaps more complex than ever before. As yet, however, there is little public or political support for comprehensive reforms of labour and employment policies. Consistent with the history of policy changes in the United States, it will likely take a significant crisis, combined with a major shift in political power, to achieve a change in policy.

Rebirth of Sociological Studies of Work and Labour Markets

While sociologists have studied various aspects of work, employment and careers throughout the 20th century (Hughes 1958; Barley and Kunda 2001), since the 1980s there has been a significant growth in interest in these topics among sociologists, who now label their work as the study of economic sociology.

Economic sociologists implicitly (and sometimes explicitly) seek to counter purely economic models of labour-market behaviour by demonstrating that individual and organizational decisions reflect the social and institutional structures in which they are embedded. Much of this work examines how networks of workers and/or organizations influence labour market behaviour. An early study in this tradition (Granovetter 1974) documented how networks affect access to job opportunities. Later studies have shown networks to be important in influencing migration (Portes and Sensenbrenner 1993; Saxenian et al. 2002), promotions and upward mobility (Burt 1992), and cooperative relationships among firms in industrial regions (Putnam 1973; Piore and Sabel 1984; Locke 1995). These studies extend the institutional tradition of industrial relations by drawing more heavily on classical sociological theories of Weber (1962), Durkheim (1893) and Selznick (1984).

From Industrial Relations to Work and Employment Relations

By the beginning of the 21st century many scholars began to recognize that the term 'industrial relations' had become increasingly problematic as a label of the study of people at work. The majority of the workforce is employed in services, not manufacturing. Thus many researchers and university programmes have gradually changed the labels used to describe their field of enquiry and/or teaching from industrial relations to work and employment relations, human resource management, work and organizational relations, and a variety of other terms. At the same time, more scholars from traditional disciplines of sociology, political science, economics and social psychology have taken up the study of work and employment issues, which has led to an expansion of the field and to a new round of competition among these different disciplines for influence in shaping the future study and practice of employment relations.

The research questions that are most central to this field today reflect two interrelated realities: (*a*) globalization of economic activity, and (*b*) the importance of knowledge and innovation in structuring work and shaping economic outcomes. Globalization and changes in technology have increased the mobility of capital, work, and workers thereby weakening the influence of national laws, institutions, and norms in shaping employment relationships and outcomes. Once again, today as in the Commons era of the early 20th century, wages and labour costs are under intense competition, only this time more labour markets are international in scope.

The increased ease of locating work and expansion of trade across national borders affects a wide range of work and employment issues and outcomes. Globalization has been associated with, among other things, changes in the distribution of wages and profits, growth in income inequality, and greater and more widely distributed job insecurity. Within firms, globalization of production and supply chains diffuses responsibility for employment decisions and policies, blurring the traditional distinction between employers and employees. All these effects are being subjected to intense analysis, debate, measurement of the direction and magnitude of their effects, and debate over how to adapt policies and institutions to cope with them. These international and organizational developments also make it more difficult to regulate employment relations with national laws and firm-centred rules and policies.

These developments have also generated a debate over the appropriate goals of the modern corporation and its role in society and as an employer. Since the early 1980s the view that firms exist primarily or even solely to maximize shareholder value has dominated academic and public discourse. This view is now being challenged. Blair and Stout (1999) offer a critique of the view that firms exist solely or primarily to maximize shareholder wealth and instead propose a team production theory of the firm. In their view the appropriate underlying view is that the firm should maximize the total value of wealth produced for all the constituents that supply resources and add value to the organization. Human capital plays a central role in this theory since workers

contribute and put at risk their human capital by joining and staying with a given firm. The longer workers stay with a given firm, the higher the costs of losing their job. Thus, like those who invest and put at risk their financial capital, workers are residual risk bearers should the firm fail.

The outcome of this debate could have important consequences for the design of institutions of worker voice in employment relationships. Since 1935 American labour law has taken as a guiding premise that employees should be allowed to bargain over wages, hours, and working conditions and that management should remain free to make strategic business decisions on its own. If by investing their human capital employees become a residual risk bearer similar to financial investors, then there is no logical basis for excluding workers from a voice in strategic decisions and corporate governance. Thus the study of industrial relations has expanded to engage issues of corporate strategy and governance and theories of the firm.

The field has also expanded in response to changes in the relationships between work and family–personal life. Work and family life were tightly linked in the preindustrial agrarian economy because they were co-located (families lived and worked on the farm) and men, women, and children all contributed to the production process. With the growth of the industrial economy came a clearer division of labour and physical separation in work and family life. The male breadwinner emerged as the prototypical worker, with the assumption that he had a wife at home attending to family responsibilities. With the growth in the labour-force participation of women from the 1960s onward and the slowdown in the growth of real wages, working hours have both been spread more evenly between men and women, and particularly between mothers and fathers. This once again increases the interdependence of work and family life and calls for changes in workplace and human resource practices to provide flexibility in hours and career options for women and men. Thus work and family issues have become an important topic of research and policy analysis within the field of work and employment relations (Bailyn 2006; Kossak 2006; Drago 2007).

International Studies

The study of work and employment relations across the world parallels most of the trends observed in the USA. Throughout much of the 20th century, studies of labour movements and labour conflict dominated both country-specific research and international comparisons of industrial relations systems. In the 1960s a debate arose over whether technological changes and increasing economic interdependencies would lead to a convergence in employment systems and practices or whether differences observed across countries would endure because of the influence of national culture and other institutional forces (Kerr et al. 1960). This debate continues today, although researchers have shifted to more micro level (industry, occupational and regional) comparisons to sort out forces leading to convergence and divergence in employment relationships (Katz and Darbashire 2000; Bamber et al. 2004). Moreover, researchers active in the field of international industrial relations (Kaufman 2004) are actively analysing and debating most of the issues and developments discussed in this article in countries across the globe.

Historical Parallel

In the USA and Britain, the field of work and employment issues of industrial relations have come full circle to their origins. As in the first two decades of the 20th century, contemporary researchers are driven by a broad proposition that the nature of the economy, workforce, the nature of work and its relationship to other institutions such as family life have all changed dramatically while public policies and institutions remain tailored to a fading industrial-based economy. The gap between policies and institutions and the contemporary realities of work and family life lie at the heart of the tensions and pressures building up in workplaces in America and,

increasingly, across the world. The central task of work and employment researchers today, as for their industrial relations forefathers, is to conduct research and policy analysis that prepares for the day that the political forces align to make it possible to begin the updating and modernization process.

Industrial Revolution

Gregory Clark

Abstract

The term 'Industrial Revolution' has come to mean two very different things: first, the transformation the British economy experienced between 1760 and 1850, to become the first modern industrialized, fast-growing economy; second, the general switch between the pre-industrial world of slow technological advance, high fertility and little human capital to the modern world of rapid efficiency gains, low fertility and large investments in human capital. Modern economists' theories of this second worldwide transition have proved difficult to reconcile with the details of Britain's transition.

The Industrial Revolution is an ambiguous term, freighted with multiple meanings, interpreted differently by different writers. First, it describes the extraordinary transformation the British economy experienced between 1760 and 1850. In these years Britain moved from being a largely self-sufficient, self-sustaining, and still principally agrarian society, to being an economy where a substantial fraction of food, raw materials and energy was imported, or mined from the earth as coal, and where the great majority of the population was engaged in industry and commerce. But second, and more importantly, it has come to mean the general move in the world economy in about 1800 from the pre-industrial economy, which experienced extremely low rates of efficiency growth, to the modern economy, where efficiency growth is rapid and persistent. That shift from low rates of efficiency advance to rapid rates had nothing inherently to do with industry or industrialization. Efficiency advance in agriculture has been as rapid as in the rest of the economy since 1800. So for the more general use of the term 'Industrial Revolution' the 'industrial' component is a misnomer, but a misnomer that we have to live with.

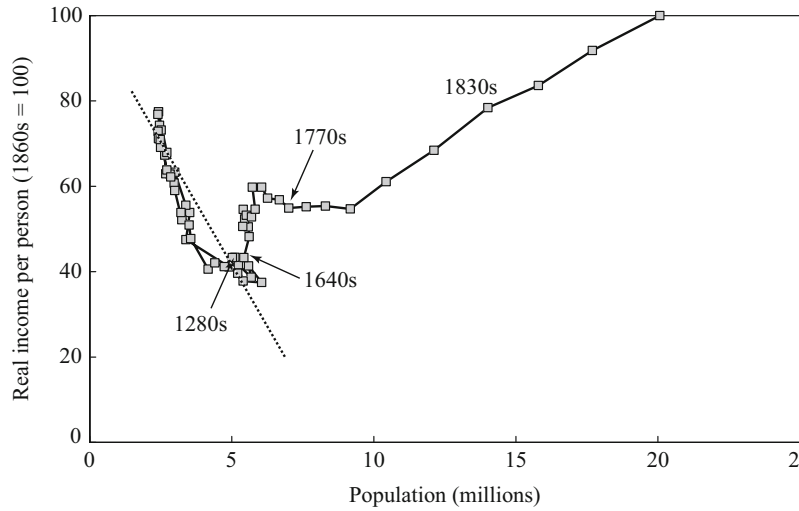
The Industrial Revolution of the Historians

The 'Industrial Revolution' more traditionally describes a specific period in British history, most commonly taken as 1760 to 1850. In 1760 Britain was a prosperous but still heavily agrarian economy, with half the labour force employed in agriculture. Foreign trade was insubstantial. Britain was largely self-sufficient in staple foods. The main imports were Mediterranean or tropical products such as sugar and spices, wines, raisins, coffee and tea. The main export was woollen cloth produced by domestic weavers or handloom workshops. London was already a huge city with over 750,000 inhabitants, but the other towns in England circa 1760 were mostly small. The next biggest city was Bristol with only 50,000 people. Travel and communication were slow and costly. The road system was poorly maintained, and there were few canals.

By 1850 the share of the population employed in agriculture in Britain had dropped to less than a quarter. Staple foods and raw materials such as timber had become major imports. Exports were dominated by factory-produced textiles, but included a whole range of manufactured goods and even substantial amounts of coal. The urban population had grown enormously. Manchester, for example, had grown from about 20,000 in 1770 to over 300,000 by 1851. London had nearly 2.4 million by 1851, more than 13 per cent of English people, and was the largest city in the world. The road system had greatly improved, and alongside the roads there were now about 2000 miles of canals and improved river navigations, as well as more than 5000 miles of the new railways.

Rapid population growth accompanied the change in occupational structure, location and trade patterns. The English population grew from seven million in the 1770s to 19 million by the 1850s. Periods of population growth earlier in English history, as in the 13th and the 16th centuries, were associated with declining living standards. The Industrial Revolution represented a sharp break with this past. For the first time living standards improved even as the population swelled. Figure 1 shows the real wage of building workers vis-à-vis the English population from 1250 to 1850. The unusual character of experience in the Industrial Revolution era is clear.

Between 1760 and 1850 England experienced what was cumulatively profound economic change, though the actual rate of change for



Industrial Revolution, Fig. 1 Real building workers' day wages vis-à-vis population by decade, 1280–1849. *Note*: The line summarizing the trade-off between population and real wages for the pre-industrial era is fitted using the data from 1280–9 to 1590–9 (*Source*: Clark 2005b, Fig. 5)

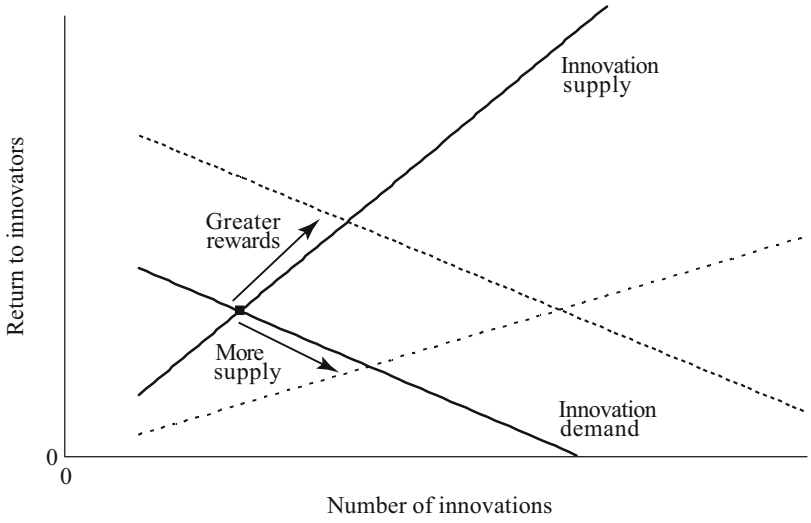
most measures of the economy such as gross output per person or the fraction of the population employed in agriculture was by modern standards very slow. Indeed, the changes were so slow that many economists writing in this period – such as Adam Smith, Thomas Malthus and David Ricardo – had little comprehension of the fundamental break from the past that was occurring.

The recent consensus has been that the immediate cause of the Industrial Revolution was the dramatic increase in efficiency in a minority of the economy: yarn and cloth production, iron and steel making, and rail transport. Most of the economy, including surprisingly the coal industry, saw little technological advance (Clark and Jacks 2007). Textiles alone explain perhaps 60 per cent of all measured technological advance from 1760 to 1850. The concentration of technological advance in textiles, aligned with the move of production there into factories, explains why the general move around 1800 towards economies with faster technological advance came to be labelled the 'Industrial Revolution'.

In textiles we see a whole series of innovations, especially from the 1760s onwards, which transformed the industry. These innovations had no direct connection with the scientific advances of the previous 150 years and were indeed mainly made by artisans and craftsmen with no formal scientific training. Nor were the new production processes in these industries particularly capital-using. Water and steam powered textile mills were modest in their capital requirements compared with later innovations like the railways, but also compared with existing industries like agriculture. The demands of these mills were mainly for unskilled labour. Tending the new spinning and weaving machines did not require literacy, and involved skills fully mastered within a year of employment. Thus the Industrial Revolution in the first instance did not involve great investments in either physical or human capital.

The question of why England first experienced the Industrial Revolution, and why only in the 1760s, has occupied the energies of an enormous number of historians and economists. There has been an intense debate on the features of the British economy in 1760 that precipitated the break from the past. Generations of economic historians have thrown themselves at the problem, like waves of infantry in the First World War going over the top of the trenches. Their explanations, however, have generally fared no better than the average First World War soldier when tested against the history of England in these years.

Putative explanations of the Industrial Revolution can be separated into those based on the supply of or the demand for innovations, as portrayed in Fig. 2. Some emphasize greater returns to innovation as inducing more innovation, others a greater supply of innovators.



Industrial Revolution, Fig. 2 Demand and supply interpretations of the Industrial Revolution

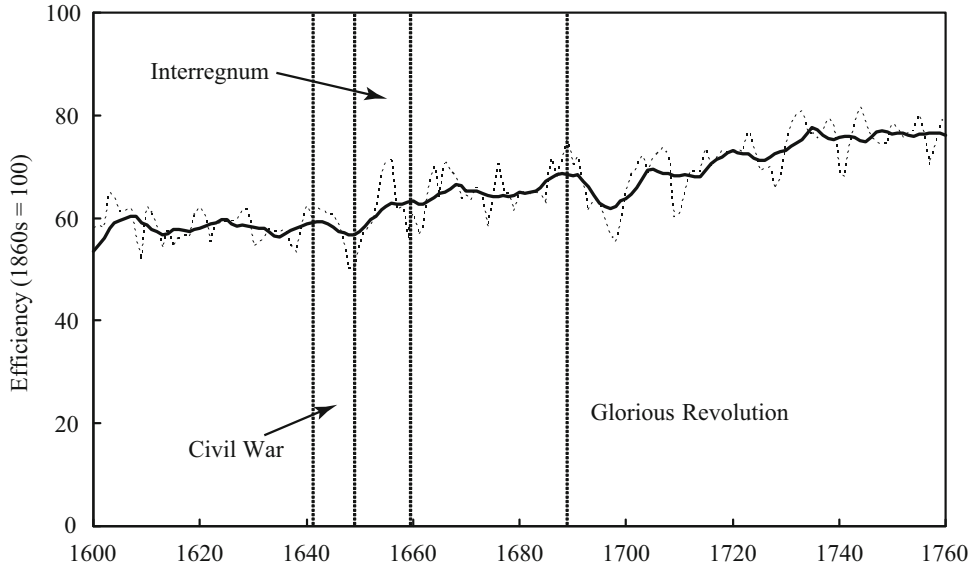
Much attention has been given, for example, to the institutional changes that preceded the English Industrial Revolution, and raised the benefits to innovation. Douglass North and Barry Weingast proclaimed the Glorious Revolution of 1688–9, which established the institutional framework of the modern British state with a figurehead monarch and control by an elected parliament, as the key precondition for economic growth (North and Weingast 1989). The development of a government restrained from seizing the profits of investors increased the expected returns to investment in general in the economy.

There are numerous problems with this identification. The gap between the institutional changes and the onset of the Industrial Revolution is a generous 80 years or so. In those 80 years there were was no speed up in the rate of efficiency advance in the economy, as Fig. 3 shows. The efficiency of the economy, known also as the total factor productivity (TFP), is the amount of output delivered per unit of input of capital, labour and land. From 1689 to 1760 the English economy had efficiency growth rates no faster than those of the 'bad' days of the old regime in 1600–89, when England experienced considerable political turmoil.

Also, contemporary economic actors seem to have attached no importance to the political changes of 1688–9. Gross rates of return on capital in the private economy, for example, did not decline, as would be expected if the new regime had ushered in more secure property rights (Clark 1996). Finally, societies such as that of England had most of the institutional prerequisites of modern growth – stable politics, free markets, factor mobility, and low taxation – hundreds of years before any growth appeared (Clark 2007, ch. 8).

Kenneth Pomeranz has argued that the Industrial Revolution was triggered in England in the 1760s, and not in other sophisticated societies such as China, because of the accidents of coal and colonies (Pomeranz 2000). The chance location of coal fields in England, and the ability of North America to supply massive imports of raw materials liberated England from the energy and raw material constraints that had limited growth before in the self-sustaining organic pre-industrial economy. But the concentration of growth in cotton textiles, an industry that was present also in Japan and China by 1800, where water power could supply all the energy required, suggests that the elements Pomeranz concentrates on were actually peripheral to the Industrial Revolution (Clark and Jacks 2007).

Other economists, such as Joel Mokyr, have argued alternately that the root cause of the Industrial Revolution was an increased supply of innovation, promoted by the Enlightenment, the intellectual movement which swept Europe in



Industrial Revolution, Fig. 3 Efficiency level of the English economy, 1600–1860. *Notes*: The figure shows the estimated efficiency of the English economy by year (*dotted line*) and as an 11-year moving average (*solid line*) (*Source*: Clark 2007, Fig. 12.6)

the 18th century (Mokyr 2005). Mokyr shows that while the Enlightenment was an important intellectual movement in many European countries such as France it was a particularly prominent part of intellectual life in England. And if we look at many other measures – literacy, numeracy, publications – England was becoming a more intellectually sophisticated society in the years leading up to the Industrial Revolution at all levels of the society. But Mokyr offers no account of why this intellectual movement should have taken hold in England in particular, and only in the 18th century.

The Industrial Revolution of the Economists

From a broader perspective, the Industrial Revolution that brought us from the static pre-industrial economy to the modern dynamic economy is characterized by a three key features.

Most important is the appearance of persistent total factor productivity growth. Such growth occurs when output rises faster than the measured inputs. Thus if y is output per worker hour, k capital services per worker hour, and z land services per worker hour, and A the level of efficiency (TFP) of the economy, A grows at the rate

$$g_A = g_y - a \cdot g_k - c \cdot g_z$$

where g denotes a growth rate, and a and c are the shares of capital and land in total factor costs. Since 1850 in the most successful economies TFP has grown at one per cent or more per year. Before 1800, over extended periods, even for successful economies TFP grew at rates of 0.01–0.1 per cent per year.

We can estimate TFP growth before 1800 using population. On average before 1800 output per worker-hour, y, did not rise (see the ▶ Malthusian Economy). In this case we can simplify the equation above. In such a static economy, labour hours L will be proportionate to population N. Since the land area is fixed

$$g_z = -gL = -gN.$$

Similarly income per capita was constant over the long run. On the assumption that the rate of return on capital did not change, capital per person would have been constant, so that,

$$g_k = 0.$$

Substituting both these relations into the basic equation above implies that for the pre-industrial world the growth rate of efficiency over the long run was just

$$g_A = c \cdot g_N.$$

Thus long-run technological advance at a world scale before 1800 is proportionate to long-run population growth, as Kremer (1993) pointed out. Since plagues or disorder can result in wages departing from the long-run equilibrium, this calculation serves only for the long run. Table 1 shows the details. For the world as a whole there is no long period before 1700 when the rate of technological advance even exceeds 0.1 per cent per year.

The second general feature of the broader Industrial Revolution has been declining fertility, measured as births per woman. English women, for example, average five births each all the way from the 1540s to the 1890s. Figure 4 shows the

Industrial Revolution, Table 1 Growth rate of world population and TFP before 1800

Year	Population (millions)	Population growth rate (%)	Technology growth rate(%)
130,000 BC	0.1	–	–
10,000 BC	7	0.004	0.001
1 AD	300	0.038	0.009
1000 AD	310	0.003	0.001
1250 AD	400	0.102	0.025
1500 AD	490	0.081	0.020
1750 AD	770	0.181	0.045

Industrial Revolution, Fig. 4 English fertility history, 1540–2000. *Notes*: *GRR* gross reproduction rate. *NRR* net reproduction rate. The data for the years after 1837 is for the whole population. Before 1837 it is from a sample of parishes (*Sources*: Clark 2005a, Fig. 2)

gross reproduction rate (GRR), the number of daughters born per woman living to the age of 50, by decade in England from the 1540s to 1990s. The 'demographic transition' to modern fertility rates in Europe and North America, except for France, began only in the 1880s. By 2000 English women gave birth on average to fewer than two children.

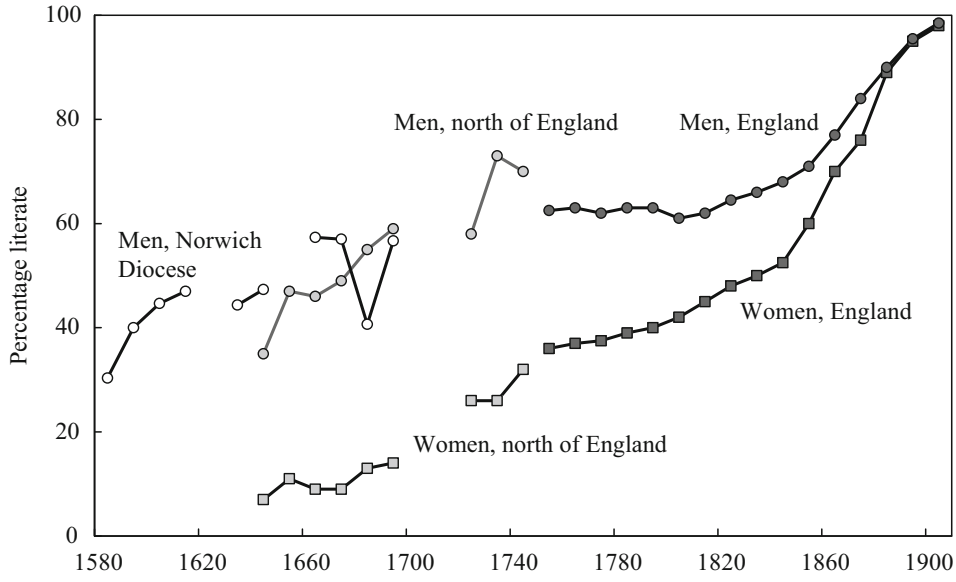
Since pre-industrial child mortality rates were high, however, the net reproduction rate (NRR), the number of daughters the average woman gave birth to over her lifetime, fell much less in the modern world than in the pre-industrial era. Figure 4 shows also the NRR for England. England in 1540–1800 had an unusually high NRR for pre-industrial society, where this number would normally be just slightly above 1. Note that the GRR and NRR both rose in England in the course of the classic Industrial Revolution.

The decline in gross fertility after the 1880s was crucial in allowing enhanced efficiency in the economy to translate into higher incomes. Had this not happened, so that population growth would have been much more rapid, then the share of payments to land as a factor, c, would not have declined so rapidly and might even have increased. Then in the first equation above the increase of population per acre would have been faster, and its weight greater, leading to a greater drag on income growth.

The third key feature of the transition to the modern world has been an increase in human capital per person, investments in education and training. In most pre- industrial societies the mass of the population was illiterate and innumerate. Along with the Industrial Revolution came a transition to a society where the implied value of human capital is nearly as great as for physical capital.

English education levels increased over the Industrial Revolution years. Figure 5 shows a measure of basic literacy, the fraction of men and women signing their names on witness statements or marriage registers. However, if one compares Fig. 5 with Fig. 4 there appears to be no connection between changes in literacy rates and changes in fertility: the fertility transition in England occurred after the attainment of mass literacy.

The coincidence of these three great changes in societies – technological advance, declining birth rates and increased education – has led economists in recent years to attempt theories of the broader Industrial Revolution that unify these



Industrial Revolution, Fig. 5 Literacy in England, 1580–1920 (*Source*: Clark 2005a, Fig. 3)

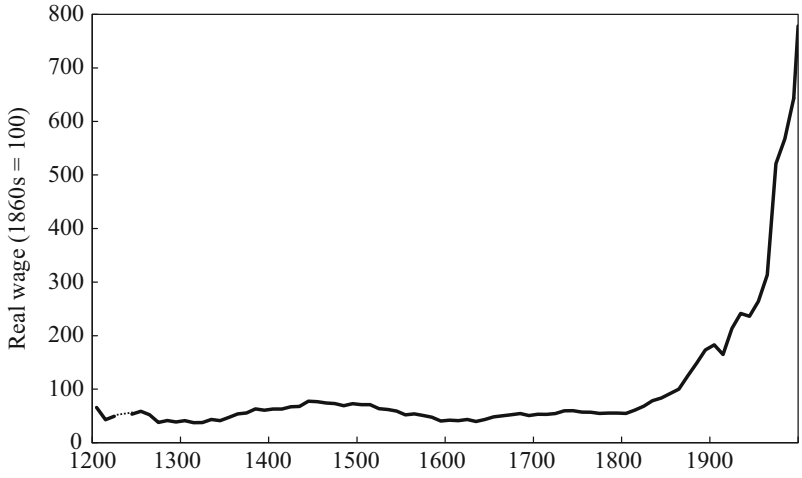
elements (Becker et al. 1990; Galor 2005; Galor and Moav 2002; Galor and Weil 2000; Lucas 2002). These theories, however, face formidable obstacles in reconciling themselves to the facts of the Industrial Revolution in England.

One method of unification would posit the technological advances as primary, and have the income gains from these spur both lower fertility and more investment in human capital. In the years of the demographic transition in both the USA and in Europe between 1880 and 1920, higher-income families were the first to reduce fertility (Clark 2007, Table 14.5; Jones and Tertilt 2006, pp. 23–7). Indeed, Larry Jones and Michele Tertilt conclude that, for female birth cohorts in the USA between 1828 and 1958, income explains most of the decline in gross fertility. Figure 6, for example, shows the hourly real wage of building workers in England from 1200 to 2000. After the 1860s real wages begin to rise rapidly, and after the 1860s fertility declined substantially. In the modern world there is a strong negative fertility–income relationship across countries.

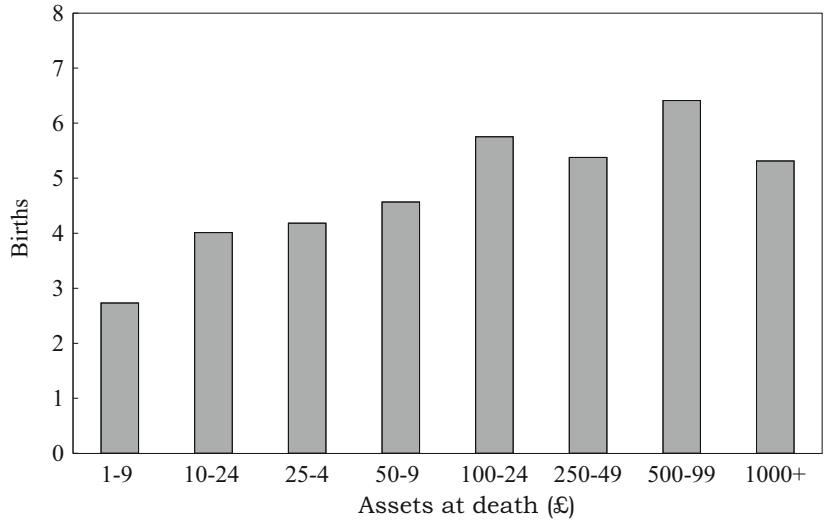
The problem with explaining the fertility transition through income is that all plausible models of population regulation before 1800 depend on a *positive* association between fertility and income. Empirical information on pre-industrial fertility and income is rare. But in pre-industrial England we get an insight into the connection through evidence from the wills of male testators (Clark and Hamilton 2006). Connecting information on assets at death to parish records reveals the average numbers of births per testator for each bequest class. Figure 7 shows that a man leaving less than £25 at death would typically father fewer than four children, while one with assets of more than £1000, six children. Thus in pre-industrial England there was a positive association between income and both gross and net fertility over a wide range of incomes. This stands in sharp contrast to the association in the modern world.

This positive association between fertility and income became negative in the period of demographic transition. But in current high-income, low-fertility societies there seems to be only the most modest negative association between income and fertility. A recent study of female fertility found on average little association between household income and fertility, measured as the numbers of children present in the households of married women aged 30–42, for 1980 and 2000, for the six Organisation for Economic Cooperation and Development (OECD) countries (Dickmann 2003, Table 2). The income–fertility relationship within societies has changed dramatically over time.

All this makes constructing a link between fertility and income challenging. Why does fertility increase with income in the pre-industrial world? Authors who have addressed this have concentrated on explaining the association for incomes close to subsistence level. Galor and



Industrial Revolution, Fig. 6 Real day wages of English building workers, 1200–2000 (*Source*: Clark 2005b, Fig. 1)



Industrial Revolution, Fig. 7 Births by assets of testator, 1585–1636 (*Source*: Clark 2007, Fig. 4.3)

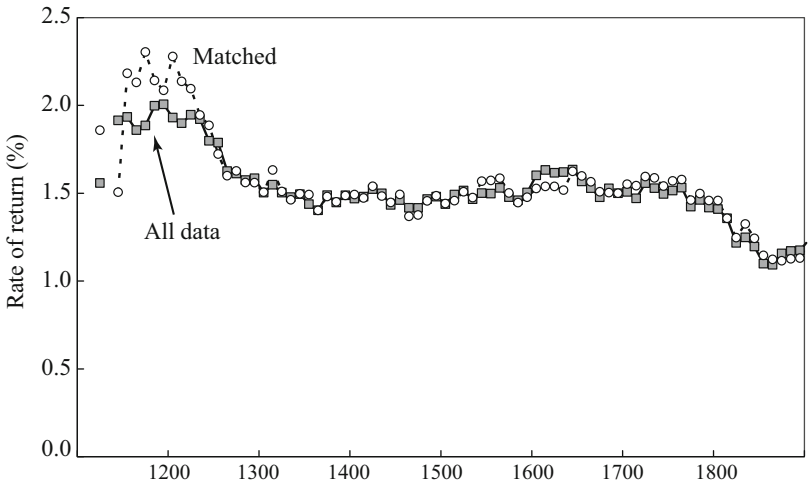
Weil (2000) and Galor and Moav (2002) assume a minimum consumption level that parents must achieve before producing children. Lucas (2002) assumes children require a minimum consumption transfer. We see in Fig. 7, however, that the richest families in pre-industrial England, people who would have high incomes even by the standards of 1900 showed high gross fertility rates.

The third problem with using income to explain declining family size is that, as Fig. 6 shows, we cannot explain rising human capital in the years prior to Industrial Revolution through income gains. Human capital gains preceded the income gains of the Industrial Revolution. Finally, as noted above, we still lack any institutional or other explanation for the transition towards higher rates of efficiency advance after 1800.

Another mechanism that might explain both the rise in human capital and the decline in fertility and the Industrial Revolution would be an increase in the premium paid for human capital in the Industrial Revolution era. In most settled pre-industrial economies the bulk of labour demand was for agricultural work, where levels of human capital were low. In such an economy, it is argued, parents would favour quantity over 'quality' in children.

However, for this explanation is to be compatible with individual incentives, the return from investments in human capital before the Industrial Revolution has to be low. In England, and in a variety of other pre-industrial economies, rewards to human capital were higher than in the modern economy. We have, for example, the skill premium in the building industry: the ratio of the wages of craftsmen to building labourers. Figure 8 shows the wages of craftsmen relative to labourers in England by decade from 1200. The period 1600–1900, when literacy rates increased markedly, featured a near constant skill premium. When fertility rates fell after 1800 it was in a labour market where the premium for skills was also declining markedly. Thus gross fertility is highest where the premium for skills in the labour market is greatest. A demand interpretation of fertility decline, on its own, will not work either in England or as a general explanation of the fertility transition.

Since the expansion of human capital first occurred when the return to human capital was constant, the gains of human capital in the Industrial Revolution era had to involve significant supply shifts. Galor and Moav (2002) posit that the supply shift was created by Darwinian competition in the pre-industrial economy between families with different tastes for child 'quality'. In the Malthusian world each family can have a NRR only slightly above 1. But 'high-quality'



Industrial Revolution, Fig. 8 The skill premium for building workers, 1200–2000 (*Source*: Clark 2005b, Fig. 2)

families do better. High- quality types produce offspring who, because of their greater human capital and hence higher incomes, have more children. Thus, when incomes are close to subsistence, but only then, they out-produce the 'low-quality' types. There should be an inverse U-shape of fertility with income. Figure 7, however, is inconsistent with this proposed mechanism. Even the richest in pre-industrial England show the highest gross and net fertility rates.

Clark (2007), however, argues that more general Darwinian selection mechanisms in the pre-industrial era could explain the move to more human capital, and the greater supply of innovations in the Industrial Revolution. Just as people were shaping economies, the economy of the pre-industrial era was shaping people, at the least culturally, perhaps also genetically. The Neolithic revolution created agrarian societies that were just as capital intensive as the modern world. At least in England, the emergence of such an institutionally stable, capital-intensive economic system created a society that rewarded middle-class values with reproductive success, generation after generation. This selection process was accompanied by changes in characteristics of the pre-industrial economy that owe much to the population displaying more middle-class preferences. Interest rates fell, murder rates declined, work hours increased, the taste for violence declined, and numeracy and literacy spread even to the lower reaches of society. These selection mechanisms thus provide an economic underpinning to the intellectual developments such as the Enlightenment of the 18th century that Mokyr identifies as a key background to the Industrial Revolution in England.

But such an explanation for the onset of the Industrial Revolution, which emphasizes the greater fertility of the rich in the pre-industrial era, leaves declining fertility after 1880 as a conundrum. If the economic system prior to the Industrial Revolution selected those with a tendency to use higher incomes to achieve greater net fertility, why did all this change in the 1880s? There are several possible explanations.

One is that the desired number of children per married couple is actually independent of income, and was always for just two or three surviving children. But to ensure a completed family size of even two children in the high-mortality environment of the Malthusian era required six or more births. For example, in pre- industrial England where 60 per cent of children died before adulthood, to ensure a 90 per cent chance of getting a surviving son would require giving birth to seven children. Nearly 40 per cent of the poorest married men leaving wills in 17th century England had no surviving son. Even among the richest married men nearly one-fifth left no son. The average rich man left four children because some families had large numbers of surviving children. Hence the absence of any sign of fertility control by richer families in pre-industrial England may

stem largely from the uncertainties of child survival in the Malthusian era. This may have led to an unwillingness on the part of all families to limit births. As the fraction of children surviving increased in the late 19th century, even risk-averse families could afford to begin limiting births.

In the late 19th century child mortality in England had fallen substantially from the levels of the 18th century, and the rate of that decline was strongly correlated with income. For families living in homes with ten or more rooms only 13 per cent of children failed to reach the age of 15, while for those in one room still 47 per cent of children failed to reach that age (Clark 2007, p. 00). Thus the lower gross fertility of high-income groups at the end of the 19th century translates into a more muted decline in net fertility. And these groups faced a substantially reduced variance in family size outcomes compared with low-income groups.

Another possible element in the decline of fertility since the Industrial Revolution is the increased social status of women. Men may well have had greater desire for children in pre-industrial society than women. Women, not men, bore the very real health risks of pregnancy, and did most of the work involved in bringing up the children. But typically men had a much more powerful position within the family. Thus women may always have desired smaller numbers of surviving children than men, but have been able to effect those desires only in the late 19th century.

Women's relative status and voice was clearly increasing in the late 19th century in England, when literacy rates for women had advanced to near equality with those of men. Women had gained access to universities by 1869, enhanced property rights within marriage by 1882, votes in local elections in 1894, and finally a vote in national elections in 1918. The gain in the relative status and voice of women proceeded most rapidly among higher-income groups.

These assumptions could explain why net fertility falls after the late 19th century – even though in cross section in the 16th century – and in 2000 there is either a positive connection between income and net fertility or no connection. They could also explain why the demographic transition appeared first in the higher socio- economic status groups, so that net fertility is negatively related to income in the transition period.

Industrialization

Amiya Kumar Bagchi

Industrialization is a process. The following are essential characteristics of an unambiguous industrialization process. First, the proportion of the national (or territorial) income derived from manufacturing activities and from secondary industry in general goes up, except perhaps for cyclical interruptions. Secondly, the proportion of the working population engaged in manufacturing and secondary industry in general also shows a rising trend. While these two ratios are increasing, the income per head of the population also goes up except again for temporary interruptions (Datta 1952; Kuznets 1966, 1971; Sutcliffe 1971). There are cases in which the per capita income goes up, income derived from secondary industry per head of the population also goes up, but there may be little growth either in the proportion of income derived from the secondary sector or in the ratio of the working force engaged in that sector. Such cases, except when they are observed for a highly developed country, not only make the unambiguous labelling of the process of development as industrialization difficult; they also pose questions regarding the sustainability of the process that has been observed.

Other characteristics are also often associated with industrialization or a more general process of what Kuznets has called 'modern economic growth' (Kuznets 1966, ch. 1). These include a narrowing and ultimate closing of the gap between productivity per head in the secondary sector and in the primary sector (that is, agriculture, forestry and fishing), continual changes in the methods of production, the fashioning of new products, rise in the proportion of population living in towns, changes in the relative ratios of expenditures on capital formation and consumption and so on.

Most of these associated characteristics were derived from the experience of Great Britain, or more narrowly, England and Wales, which was the first country to industrialize. That experience has remained unique in many ways. But since England was the original centre for diffusion of the economic and technical changes associated with the industrialization process, it is important to understand what happened in that country.

At least since the days of Karl Marx, England has been known as the first country in which feudalism broke down, and capitalism brought the economy under its sway (Dobb 1946). This meant that all means of production came to be owned by a small group of property-owners called capitalists, and the rest of the working people became free wage-workers who earned their livelihood by selling their labour power to the capitalists (Dobb 1946). It has been claimed that while serfdom broke down all over western Europe, England was the only country where a group of landlords managed to concentrate most of the land in their hands and prevent the consolidation of a free peasantry which could be used by an absolutist state to defeat the rise of capitalist agriculture (Moore 1967, ch. 1; Brenner 1976). It has been further claimed that economic individualism which has been taken as the hallmark of the motivation of an entrepreneur in capitalist society, goes back in England to the 12th–13th centuries,

so that capitalism went through a long process of birth in the first industrializing nation (Macfarlane 1978, chs 5–7). By the time of the first industrial revolution, England was a society in which the abiding interest of the rulers was to make money from agriculture, trade and industry, and in which the rulers were prepared rationally to order the affairs of the state so as to enable the entrepreneurs to conquer foreign countries and markets, by the force of arms if need be and had the financial and military might to carry out those plans. England had also become the leader in trade and finance among the countries of western Europe, after the decline of Amsterdam (Braudel 1984).

The English industrial revolution is traditionally associated with the rise of machine-based industry powered by steam (Marx 1887, chs XIV and XV; Mantoux 1928). Certainly the classic age of British dominance of world industry, which is roughly the period from the end of the Napoleonic wars up to 1870, was characterized by the conquest of production methods by machines with moving parts of iron and steel, powered by steam, and operated by scores or even hundreds of operatives concentrated in single factories. However, what is becoming apparent is that for practically the whole of the eighteenth century, traditional techniques and materials (such as wood), and traditional sources of power such as muscles of men, women and children, animals, and water and wind, were responsible for the growth and spread of factory industry (Musson 1972; Von Tunzelmann 1978; Crafts 1985).

The experience of England lends credence to the postulation of a stage of 'industrialization before industrialization' or 'proto-industrialization' (Mendels 1972). This has been defined as 'the development of rural regions in which a large part of the population lived entirely or to a considerable extent from industrial mass production for inter-regional and international markets' (Kriedte et al. 1981, p. 6). The growth of industry in England was spearheaded by an explosion in the development of cotton spinning; and the cotton mills which utilized the new spinning machines sought out suitable sources of water power and labour – mostly in the rural areas or small towns. Steam engines were an element in the industrial revolution, but they did not come into their own as the major prime movers in manufacturing industry until perhaps the second quarter of the nineteenth century.

In England, cotton textiles were a relatively new industry; and they grew at first by redressing the balance of labour power needed in traditional spinning methods, so that no major displacement of labour took place within the system of proto-industrialization, in the 18th century. But machine spinning stimulated handloom production, and handloom weavers were pauperized even in England when powerlooms displaced handlooms (Bythell 1969). In other countries, where traditional handicrafts were displaced by the new machine-made fabrics, and because of political or internal social factors they were not replaced, or not replaced quickly enough, by any considerable growth of machine industry, pauperization and de-industrialization were widespread and in some cases they became endemic phenomena (Bagchi 1976; Kriedte 1981). So Ricardo's worries about the possible employment-displacing effects of machinery were justified after all (Ricardo 1821, ch. 31; see also Hicks 1969). But in Britain, continued growth of external trade and the coming of the railway age helped in overcompensating the labour-displacing effects. Not all countries had the same advantages.

The proto-industrialized order was succeeded in England by the system of machine manufacture perhaps because the former faced its severest crisis there: social relations there had already been transformed in a fully capitalist mould by the time smallscale manufacture reached its fullest development. Developments in science, technology and statecraft almost certainly helped resolve the crisis in favour of a higher stage of industrial development.

The fact that England had a decisive lead in the use of machine manufacture and steam power, and had formal or informal colonies where she could ignore barriers erected by the USA or Continental European countries made her the supreme industrial nation of the world for almost three quarters of a century (cf. Robinson 1954).

Once the revolution in textiles and steam power had been pioneered in England it could,

however, be diffused to other countries, provided the latter possessed suitable political and social conditions. It is on the basis of the timing, speed and social mechanism of diffusion of the industrial revolution that we can distinguish three clusters of countries which have gone through an unambiguous process of industrialization. The first is the cluster of countries on both sides of the North Atlantic seaboard and overseas colonies with populations of predominantly European origin; the second consists of Japan and the four islands of industrialization in the Far East, viz., South Korea, Taiwan, Hong Kong and Singapore, and the third is the cluster of socialist countries led by the Soviet Union. The rest of the world are still struggling, with only varying degrees of success, to get a sustained process of industrialization going (Bagchi 1982).

The English industrial revolution was, to start with, very much a matter of textiles; it was only in the 19th century that it affected other industries, especially iron and steel and mechanical engineering in general, on a large scale. The uniqueness of England, with all the advantages of a first start (Robinson 1954) allowed her to expand her markets overseas in an almost unrestrained manner until the USA and other western European countries expanded their home production, not only of textiles, but also of other manufactures, often behind walls of protection against the English manufactures. The west European industrialization was helped very much by the nearness of England: from Britain flowed information about the new inventions, machines, men and capital, although there was for a time an attempt to restrict the exports of new machinery from England (Landes 1965). Capital flows from England and to a lesser extent from France, were particularly important in supporting the movement of European populations to the USA, Canada, Australia, South Africa, New Zealand and Argentina (Kuznets 1971; Bagchi 1972; Edelstein 1982).

Yet despite more active support by politically independent governments, the spread of industrialization to western Europe took a surprisingly long time to get going (Lewis 1978, chs 7 and 8; Crafts 1985, ch. 3). One set of reasons had to do with political, social and structural factors. The French needed a major revolution before the bourgeoisie could take possession of the state apparatus. Even then, the entrenchment of peasant agriculture in the countryside probably delayed the full conversion of the primary sector to capitalist relations. In other countries, even the 1848 revolution did not complete the process of capitalist take-over. Associated with these lags went the fact that by English standards, too high a proportion of population continued to depend on agriculture and a large gap between agricultural and industrial productivity continued to persist down to the eve of World War I. Such political and social lags, of course, even more impeded the process of industrialization in the countries of central, southern and eastern Europe down to the period between the two world wars. We will have to pay separate attention to the case where the logjam in the process of industrialization was only broken with the Bolshevik Revolution, with most other countries of eastern Europe following after World War II (Berend and Ranki 1982).

As the process of industrialization spread, the supply of importable technologies and the financial requirements for implementing such technologies both increased. According to one estimate, gross domestic investment as a proportion of GDP in Great Britain increased from around 4 per cent in 1700 to 5.7 per cent in 1760, 7.9 per cent in 1801 and 11.7 per cent in 1831 (Crafts 1983), and remained between 10 and 12 per cent between 1831 and 1860 (Feinstein 1978, p. 91). By contrast in countries such as Germany, Sweden or Denmark the rate of investment in their phase of industrialization (after 1860) often reached 15 per cent and more of GDP. In the USA the social preconditions for industrialization were much more favourable than in most European countries, and the export of capital from Europe considerably aided her industrialization process until she in turn became a creditor nation around the turn of the 19th century.

The latecomers among the western European countries, and Japan on the other side of the world, used state intervention on a much wider scale and much more purposively than Britain did. This intervention did not take the same form in all countries: in a country such as Germany,

financing of industry was far more widely supported by the state and by new instruments of finance created for the purpose than, say, in Italy. It is doubtful whether a general pattern of successful state intervention to overcome economic backwardness can be discerned from the historical experience as has sometimes been claimed (Gerschenkron 1962). What can be asserted is that state intervention in industry was much more likely to succeed in countries where capitalist relations had advanced far than where intervention from the top was used as a substitute for social change which might upset the balance of class forces among the rulers (cf. Berend and Ranki 1982).

The example of Russia is especially instructive in showing the limits of state action in a society where capitalist relations had taken root only to an imperfect degree. In Russia serfdom had been consciously introduced in the 17th century, and the system bore particularly heavily on regions producing grain which was a major export of eastern European lands. The so-called village communes (*obschina*) produced both agricultural products and handicrafts. Beginning around the 1830s modern machinery was employed in the processing of beet sugar and in the spinning of cotton yarn. Even after the abolition of serfdom in 1861, handicrafts remained predominant (Crisp 1978), but later on, the system of domestic production and production by handicrafts became more and more integrated into the system of capitalist production (Lenin 1898). It was only in the 1880s that large-scale industry employing modern machines experienced an accelerated growth in Russia (Lyaschenko 1949; Crisp 1978).

The development of modern industry and capitalism in general in Russia gave rise to a vigorous debate which still has contemporary relevance in many countries of the third world. Some of the Russian Populists (*Narodniks*) contended that the development of capitalist industry was impossible in a backward country such as Russia. They argued that modern machine-based industry destroys handicrafts and small peasant agriculture, the incomes of people dependent on them consequently shrink, and thus modern industry faces a severe – indeed insurmountable – realization problem. Countering this argument, Lenin pointed out that capitalism created its own markets by converting goods produced within a household or barter economy into tradable commodities and by continually generating new methods of production. The latter in their turn create demands for new equipment and materials (Lenin 1897, 1899). Lenin did not deny that capitalism needed foreign markets. But at that stage he attributed the need not to the impossibility of realizing the surplus value but to intercapitalist competition and the continuous drive of capital towards expansion. In the process of discussing the analytical issues involved Lenin enunciated a law of development of capital, namely, that 'constant capital grows faster than variable capital, that is to say, an ever larger share of newly-formed capital is turned into that department of the social economy which produces means of production' (Lenin 1897, pp. 155–6).

While markets expanded in Russia with state support for development of railways and warrelated industries, the process of industrialization before the Revolution of 1917 remained ridden with numerous contradictions. Before the Stolypin reforms (which were initiated after the abortive revolution of 1905) the spread of individual ownership in agriculture was held up by numerous restrictions on peasant mobility and on the transferability of land. Even after the Stolypin reforms (or reaction) landlords' social and economic power continued to limit the development of capitalism in agriculture (see, e.g., Lenin 1912). A substantial proportion of growth in the industrial capital stock was financed by foreign banks and foreign entrepreneurs (McKay 1970). Large-scale industry was regionally and sectorally concentrated (Portal 1965) and the proportion of the working force engaged in industry (including construction) was only 9 per cent in 1913; it was only after the Bolshevik Revolution and the implementation of the two Five Year Plans that there was a decisive change in the occupational structure. The proportion of the working force engaged in industry and construction climbed to 23 per cent in 1940 and 39 per cent in 1979; correspondingly the proportion engaged

in the agriculture and forestry declined from 75 per cent in 1913 to 54 per cent in 1940 and 21 per cent in 1979 (Sarkisyants 1977, p. 180; see also Kuznets 1966, p. 107).

In Japan, the course and the pattern of industrialization differed considerably from the sequence witnessed in western Europe and the USA, and also from that followed in socialist countries. Under Tokugawa rule, Japan was characterized by what has been called 'centralized feudalism' (Ohkawa 1978, p. 140) with the *shogun* exercising supreme power through the *daimyos* and a rigid hierarchy going down to the village level. But the increasing use of money for the payment of taxes, countrywide transactions in money required to support the *daimyos'* and their retainers' expenditures in their travels to the capital and back, and the increasing indebtedness of many *daimyos* to merchants enhanced the power of the latter. The merchants' ambitions, the peasants' discontent and the frustrations of many of the feudal lords in the face of the increasing threat posed by the military and technological advance of the Western powers ultimately led to the end of the shogunate and the restoration of the Meiji emperor. The fierce nationalism bred among the nobility under the isolation enforced on the country earlier by the shogunate led them to define their objectives in the image of the activities of the Western imperialist powers (Beasley 1963; Norman 1943; Smith 1961).

While abolishing many of the privileges of the warrior class the new Japanese rulers held on to the rigid rules of hierarchal control descending from the emperor through the nobility and the higher ranks of merchants to the village headmen, and down to the peasants working in the fields. The rigid subjugation of family members, especially of women, to the patriarch and the use of communal ties to enforce authoritarian rule continued unabated, and was adapted to the requirements of modern industry (Morishima 1982). A high level of land taxes imposed on the peasantry financed much of the economic growth in Japan which accelerated from the 1880s. Young women, more or less bonded to the factories by their fathers or other family heads provided cheap labour. The first steps in the industrialization process were taken under the guidance of the state which built or financed shipyards, telegraph lines, railways and armament works (Lockwood 1968). The actual pace-setter in the industrialization process, in Japan as in Britain, was textiles, and for a long time, handicraft methods continued to be used alongside of machine methods in producing Japan's industrial goods. Silk, indemnities from foreign conquest, and exports of cotton yarn and cotton goods allowed Japan to do without much foreign investment in her drive towards industrialization. As in Britain, so in Japan, external markets and imperial conquest played an important role in the rise of modern industry (Lockwood 1968).

Japan's industrial growth was already impressive in its diversity and sophistication during the interwar years. But it is since World War II that her growth has surpassed earlier historical standards (Ohkawa 1978; Armstrong et al. 1984). The reserve army of labour in agriculture was finally exhausted there under the dual impact of land reforms imposed by the American occupation authorities and rates of industrial growth that often exceeded 15 per cent per year. Accompanying the Japanese growth was domination of trade and industry by a handful of giant conglomerates, the *zaibatsu*, giant firms and general trading corporations or *soga soshas*, acting in close collaboration with the Ministry of International Trade and Industry, and the subjugation of the labour movement to company objectives. It is these characteristics combined with a systematic exclusion of foreign capital from practically all fields that led observers to use the phrase 'Japan Inc.' to characterize the Japanese system of management. Japan eventually surpassed all capitalist countries except the USA in the value of her industrial production and in her technological advance.

While the countries on the two sides of the north Atlantic seaboard were industrializing and Japan was slowly emerging as a challenger to the industrial and political supremacy of the Western powers in the Far East, the majority of the people living in Asia, Africa and Latin America hardly experienced any positive process of industrialization. The movement of neither capital nor labour

favoured such a process in China, India, Egypt, Peru, Brazil or Mexico, even in the exceptional days of massive British investments overseas that enriched the USA, Australia or Canada with men or materials (Edelstein 1982; Davis and Huttenback 1985). Only a small fraction of foreign investment made by Britain and France went to the non-white, dependent colonies, or formally independent, but effectively dependent countries peopled by non-white populations. These investments went generally into plantations, mines, railways rather than manufacturing industries. While the British dominions such as Canada or Australia pursued their economic policies largely independently of metropolitan control and protected their nascent industries, India, Egypt or even China and Turkey were forced to pursue *laissez faire* policies under the pressure of the metropolitan powers. The small flows of foreign investment into the colonies were swamped in the case of India, West Indies or even Brazil by the outflow of capital to the metropolitan countries (and thence to their colonies of settlement) as political tribute, and profit on external trade, foreign exchange transactions or plantation and railway enterprises (Bagchi 1982, chs. 3 and 4).

Policies of free trade or state intervention in favour of metropolitan trade and industry generally led to a decline in handicrafts and domestic industry on a large scale in such countries as India, China and Turkey. This erosion of proto-industrial output and employment was only very inadequately compensated by the rise of modern industry. Colonial rule also led in many cases to the strengthening of ties of bondage of various kinds in the rural areas. When migration occurred on a large scale from these countries, it was often organized by the merchants from the metropolitan countries, and the migrants often entered into a semiservile condition in the plantations of Assam (India), Trinidad, Guiana, or mines of South Africa. The effective control of modern plantation and mining enterprises and many areas of trade, especially wholesale internal and external trade by merchants from metropolitan countries, policies of free trade and processes of de-industrialization retarded the development of an indigenous mercantile community in most of the dependent colonies and often delayed the onset of any process of industrialization until the 1950s.

In many Latin American countries industrialization was quickened in the 1930s as a result of import restriction policies forced on the governments by the deep depression, especially in primary commodity exports, and attendant balance of payments crises. Following on from this experience, many of them adopted industrialization as a strategy of development and the basic objective of planning. The Prebisch–Singer thesis of a secular decline in terms of trade of primary products provided the rationale for such a strategy in Latin America (Prebisch 1950; Singer 1950; Spraos 1982). Elsewhere, the success of the Soviet experiment provided an inspiration for planning.

However, after some initial successes, in most countries of the third world, the process of industrialization was caught up in multiple contradictions. In few countries were there land reforms conferring the right of ownership and control on the cultivating peasantry. This failure rendered the supply of food grains and other farm products inelastic and enabled the entrenched landlords and traders to speculate in these commodities. As a result, any stepping up of investment through governmental efforts soon met inflation barriers and balance of payments crises. The latter were aggravated by a tendency to import newer and newer consumer goods for the upper and the middle classes, by an inability to bargain from a position of strength with the suppliers of technology, and by the oversell practised by many of the aid-givers wanting to tie the loans or grants to purchases of goods from the donor country. In many Latin American countries, threats of social revolution were met by imposition of authoritarian regimes, generally with US connivance or assistance. The case of Chile where a popular government under the presidentship of Salvador Allende was replaced by a brutal military dictatorship is perhaps the most glaring example of this tendency, but Argentina, Brazil and Uruguay all fitted the same pattern. The primary commodities boom in the early 1970s, rise in oil prices in 1973–4 and 1978–9 along with the attraction provided to transnational corporations by explicit policies of wage repression and labour

regimentation boosted the rate of industrial growth in countries as widely dispersed as Brazil and Iran. However, in most of these countries, including some oilexporters such as Mexico and Nigeria, astronomically large external debts and debt servicing charges put a stop to most development efforts by the early 1980s.

A few economies in east Asia, more specifically the two enclaves of Hong Kong and Singapore, and the two medium-sized economies of South Korea and Taiwan went through a process of successful industrialization. In South Korea and Taiwan, radical land reforms, partly brought about through the defeat of the Japanese in 1945 who had been major land-holders in these two provinces, and partly imposed by the US authorities fearing a Communist revolution in emulation of the People's Republic of China, enormously speeded up the movement of trading capital into industry, increased the elasticity of supply of farm products and widened the market for basic consumer and producer goods. Chinese overseas capital had for a long time dominated trade and money-lending in many countries of east and south-east Asia. Communist take-over of mainland China drove out a sizeable section of big mercantile capital. The newly migrating and old Chinese overseas capital then turned to industrial investment in many of these countries. Increased US military activities in the region, attempted economic blockade of Communist China by the Western capitalist countries and the large expenditures attending US military aggression in Vietnam provided multiple opportunities to the traders and industrialists in the region for capital accumulation and expansion. Many Japanese, American and western European transnational corporations found Singapore, Hong Kong, Taiwan and South Korea useful as export platforms since these four economies provided the attraction of low wages, a disciplined (and regimented) labour force and privileged access to US, EEC and Japanese markets.

However, despite the fact that many Asian economies have continued to experience positive growth in a period of global recession, it cannot be said yet that the east Asian experience is catching or easily diffusible. Most of Africa is experiencing negative growth, and large clusters of population are caught there in the clutches of famine. Most Latin American economies are yet to get out of the debt trap. The only other countries which are still experiencing a positive process of industrialization to a greater or lesser extent are the socialist countries which have embraced some variant of Marxism as their guiding ideology. The share of industry in GNP rose steeply in most of these countries and often exceeded 40 per cent. The high rate of economic growth in these countries was financed by the confiscation of rent incomes from land, by the channelling of all surpluses into investment and by allowing only a moderate rise in real wages until an acceptable level of GNP was reached (cf. Ellman 1975; Lippit 1974). One feature that has distinguished socialist industrialization is that usually the share of services in GNP and employment has been lower than in most non-socialist economies. In a country such as China, the abnormally low share of services has been seen as a defect associated with the phase of extensive growth.

Most of the socialist countries are also now grappling with problems of lower productivity growth. Effective decentralization of planning processes, increased responsiveness to changes in relative scarcity and signalling of such changes through changes in relative prices and provision of adequate incentives to managers and workers have been generally seen as the answer to these problems. Increased imports of technology from the OECD countries and their effective absorption are also seen as part of the answer, but the successful pursuit of such strategies is intertwined with the issue of economic reforms on the one hand and geopolitical manoeuvring between the two blocks on the other.

One problem that will continue to bedevil industrialization strategies in most large third world countries for a long time is the very high ratio of the working population engaged in agriculture to the total working force. Even in a country such as China, which has experienced a trend rate of industrial growth of more than 10 per cent over the years since the Communist revolution in 1949, and where the share of industry in national income went up to 42.2 per cent in 1982,

agriculture and forestry continued to employ 71.6 per cent of the labour force in the same year (China 1983, pp. 24, 121). It is only some medium-sized economies with a high rate of industrial growth such as South Korea and Taiwan that have experienced any major shift in the population balance towards industrial employment.

The experience of the structural changes within the east Asian group of capitalist economies shows that under favourable circumstances, it is possible for the less industrialized economies to grow at high rates if there is a sustained shedding off of the lower-productivity sectors by the more advanced regions and the grafting of the shedded output on to the structures of the less developed economies (Yamazawa et al. 1983). The process is very similar to that observed in western Europe in the early part of the 19th century, except that the role of migration of population to countries outside the region (such as the USA in the case of western Europe) in easing population pressure has been minimal. But the roles of direct investment by Japanese and other OECD firms and of privileged access to extra-regional markets have been more significant than in the case of western Europe. (It could, of course, be argued that western European countries had a privileged access to markets in their dependent colonies.)

The general developments in the advanced capitalist bloc of countries (within which Japan occupies a unique position because of her maintenance of moderate to high rates of growth and near full employment and her large trade surpluses with most other countries), however, preclude the replication of the east Asian pattern in the rest of the third world. Most of them are afflicted by high rates of unemployment – exceeding levels witnessed since the end of the 1930s. Some countries such as the UK experienced an absolute decline in manufacturing (Singh 1977). These developments aggravated protectionism in these countries, thus creating barriers against the expansion of exports from the third world countries, while the OECD group of countries continued to constitute the biggest market for manufactured goods in the world. Developments in microelectronic technology posed major threats to the further expansion of labour-intensive textile products and clothing exports from the third world to the OECD countries (UNCTAD 1981). More generally, the spread of microelectronic technologies embracing whole branches of manufacture are threatening to remove many assembly operations which the OECD-based transnational corporations had earlier found it profitable to subcontract to the favoured export enclaves including the east Asian group of newly industrializing countries (Kaplinsky 1984).

Within the OECD group, the USA has become the biggest magnet for capital flows from all over the world. The high interest rate and large budget deficits maintained by the US government have forced most other OECD governments to pursue deflationary policies within their borders. There is little sign as yet that such trends will be reversed. The Japanese, who have run up large trade surpluses (exceeding US $40 billion) with the USA have proceeded to invest most of their export surplus in the US. Thus the diffusion that is borne on the backs of foreign investment within the order of capitalism has been severely hampered by these developments.

The only alternative that is left for most third world countries is to rely on building industries on the basis of domestic resources and domestic markets. But the guidelines laid down by the International Monetary Fund seeking to impose severely deflationary policies on most countries applying for its assistance in meeting their debt problems, the power exerted by OECD-based transnational corporations in effectively restricting the flow of technology, and the internal social structures in most of these countries blocking the spread of literacy and accrual of purchasing power to common people are likely to hamper the feeble efforts at industrialization on a self-reliant basis. The other path of industrialization, building on growing exports and expanding international investment flows, would appear also to be beset with dangerous pitfalls for most of the poor countries of the world. Thus the spread of industrialization in the near term to the poorer countries is likely to be very slow compared with the speed witnessed between, say, 1950 and 1978. At the other end of

the spectrum, in countries such as the USA and UK, services and finance have gained tremendously at the expense of manufacturing industry, and it is through the use of financial instruments as much as advanced technology in manufacturing (including armaments production) and services that the USA dominates the economies of most of the capitalist countries. But as Japan continues to forge ahead even in frontier technologies such as the mass production of semiconductor chips for use in the most advanced microelectronic processes (cf. Gregory 1985), a change in the balance within the capitalist order is very likely. In the meanwhile continued growth in the socialist world will also affect the global balance in manufacturing and economic power.

Inequalities

Peter Newman

Mathematical inequalities are pervasive in economic theory, just as economic inequalities are pervasive in social life. The insistence that quantities (always) and prices (usually) be nonnegative, the constraint that expenditure not exceed wealth, the necessity in proving existence of competitive equilibrium that each agent's resources have positive value, are so familiar that we

scarcely think of them as requirements of inequality, though that is what they are.

Many of the basic results of economic theory (such as the non-positivity of the substitution effect) take the form of inequalities. These in turn often arise from the definiteness or semi-definitenes of certain matrices, such definiteness being again expressed by inequalities. Yet further along the chain of reasoning, those matrices usually derive such properties from their origin in the convexity or concavity of various functions. For real-valued functions, convexity is defined by *Jensen's Inequality* (1906): The function $f: X \subset R^n \to R$ is *convex* if

$$\forall x^1, x^2 \in X, \quad \forall \alpha \in [0,1] \; f\left(\alpha x^1 + (1-\alpha)x^2\right) \times \leq \alpha f\left(x^1\right) + (1-\alpha) f\left(x^2\right) \quad (1)$$

(A function g is concave if $-g$ is convex).

There are close connections between convex functions and inequalities in general. Indeed, 'The classical inequalities are . . . obtained by verifying that a certain function is convex and by calculating its transforms.' (Young 1969, p. 112). To illustrate this general proposition by an important special case, consider the *gauge* $J(\cdot|C)$ of any set $C \subset R^n$, together with its *polar transform* $J^0(\cdot|C)$, which is the gauge of the polar set C^0 of C (see GAUGE FUNCTIONS). When C is convex and closed and contains the origin, $J^0(\cdot|C)$ becomes the *support function* $S(\cdot|C)$ of C. A fundamental inequality of convexity for gauges and their polar transforms is *Mahler's Inequality* (1939), which applied to the present situation reads:

$$\forall x \in R^n, \quad \forall y \in R^n \quad \sum x_i y_i \leq J(x|C) S(y|C) \quad (2)$$

Consider now R^n with its standard Euclidean norm $\| x\|_2 = \left(\sum x_i^2\right)^{1/2}$, and suppose that C is the closed unit sphere $Sc = \{x \in R^n : \| x\|_2 \leq 1\}$ of R^n. In this special case it happens that

$$J(\cdot|S_z) = \|\cdot\|_z = S(\cdot|S_c) \quad (3)$$

(see e.g. Rockafellar 1970, p. 130). So from (2) and (3),

$$\forall x \in R^n, \quad \forall y \in R^n \quad \sum x_i y_i = \left(\sum x_i^2\right)^{1/2} \quad \left(\sum y_i^2\right)^{1/2} \quad (4)$$

Since (4) is the famous *Cauchy–Buniakowski–Schwarz Inequality*, this illustrates Young's general proposition above. Young (1969, pp. 112–113) gives further examples (with proofs) of the connections between convexity and the classical inequalities, such as that relating the arithmetic and geometric means, and *Holder's Inequality* (1889):

$$\forall x \in R^n, \quad \forall y \in R^n \quad \sum x_i y_i \leq \left(\sum |x_i|^p\right)^{1/p} \quad \left(\sum |y_i|^q\right)^{1/q} \quad (5)$$

(where $p > 0$, $q > 0$, and $p^{-1} + q^{-1} = 1$), of which (4) is the special case $p = 2 = q$.

It is not surprising then that the classic work on inequalities, the delightful and indispensable book by Hardy et al. (1934), contains one of the earliest systematic treatments of convex functions in English. A later survey is Beckenbach and Bellman (1961).

Inequality

Erik Olin Wright

To speak of a social inequality is to describe some valued attribute which can be distributed across the relevant units of a society in different quantities, where 'inequality' therefore implies that different units possess different amounts of this attribute. The units can be individuals, families, social groups, communities, nations; the attributes include such things as income, wealth, status, knowledge, power. The study of inequality then consists of explaining the determinants and consequences of the distribution of these attributes across the appropriate units.

This essay on Inequality has four principal objectives. First, I will propose a general typology of *forms of inequality*. This typology will help to map out the conceptual terrain of the discussion. Second, I will examine debates on the conceptual status of one particular type of inequality within this typology, inequality in material welfare. In particular, I will examine the debate over whether or not material inequalities in contemporary societies should be viewed as rooted in *exploitation*. Third, I will examine the implications of these contending views of material inequality for strategies for empirical research on income inequality. Finally, I will discuss the relationship between contending accounts of income inequality and the analysis of social classes.

A Typology of Inequalities

Social inequalities can be distinguished along two dimensions: first, whether the unequally distributed attribute in question is a *monadic* attribute or a *relational* attribute; and second, whether the process of acquisition of a particular magnitude of this attribute by the individual can be considered a monadic or relational *process*.

Monadic and Relational Attributes

A monadic attribute is any property of a given unit (individual, family, community, etc.) whose magnitude can be defined without any reference to other units. Material consumption is a good example: one can assess how much an individual unit consumes in either real terms or monetary terms without knowing how much any other unit consumes. This does not mean that the attribute in question has no social content to it. Monetary income, for example, is certainly a social category: having an annual income of a $30,000 only represents a source of inequality given that other people are willing to exchange commodities for that income, and this implies that the income has an irreducibly social content to it. Nevertheless, income is a monadic attribute in the present sense in so far as one can measure its magnitude without knowing the income of other units. Of course, we would not know whether this magnitude was high or low – that requires comparisons with other units. But the magnitude of any given unit is measurable independently of any other unit.

Relational attributes, in contrast, cannot be defined independently of other units. 'Power' is a good example. As Jon Elster (1985, p. 94) writes, 'In one simple conceptualization of power, my amount of power is defined by the number of people *over whom* I have control, so the relational character of power appears explicitly.' To be powerless is to be controlled by others; to be powerful is to control others. It is impossible to measure the power of any unit without reference to the power of others.

Monadic and Relational Processes

Certain unequally distributed attributes are acquired through what can be called a monadic process. To describe the distribution process (as opposed to the attribute itself) as monadic is to say that the immediate mechanisms which cause the magnitude in question are attached to

the individual units and generate their effects autonomously from other units.

A simple example of a monadic process that generates inequalities is the distribution of body weight in a population. The distribution of weight in a population of adults is certainly unequal – some people weigh three times the average weight of the population, some people weigh half as much as the average. An individual's weight is a monadic attribute – it can be measured independently of the weight of any other individual. And the weight acquisition process is also essentially monadic: it is the result of mechanisms (genes, eating habits, etc.) directly attached to the individual. This is not to say, of course, that these mechanisms are not themselves shaped by social (relational) causes: social causes may influence genetic endowments (through marriage patterns – e.g. norms governing skinny people marrying fat people) and social causes may shape eating habits. Such social explanations of body weight distributions, however, would still generally be part of a monadic process in the following sense: social causes may help to explain why individuals have the weight-regulating mechanisms they have (genes, habits), but the actual weight of any given individual results from these individual weight-regulating mechanisms acting in isolation from the weight-regulating mechanisms of other individuals. The empirical distribution of weights in the population is therefore simply the sum of these monadic processes of the individuals within the distribution.

Now, we can imagine a social process through which weight was determined in which this description would be radically unsatisfactory. Imagine a society in which there was insufficient food for every member of the society to be adequately nourished, and further, that social power among individuals determined how much food each individual consumed. Under these conditions there is a *causal* relation between how much food a fat (powerful) person eats and how little is consumed by a skinny (powerless) person. In such a situation, the immediate explanation of any given individual's consumption of food depends upon the social *relations* that link that individual to others, not simply on monadic mechanisms. Such an inequality generating process, therefore, would be described as relational rather than a monadic process. More generally, to describe the process by which inequalities are generated as relational, therefore, is to say that the mechanisms which determine the magnitude of the unequally distributed attribute for each individual unit causally depends upon the mechanisms generating the magnitude for other individuals.

Taking these two dimensions of inequality together, we can generate the following typology of ideal-typical forms of inequality. This typology (Table 1) is deliberately a simplification: the causal processes underlying the distribution of most inequalities will involve both monadic and relational mechanisms. Nevertheless, the simplification will help to clarify the conceptual map of inequalities which we have been discussing.

'Power' is perhaps the paradigmatic example of a relationally determined relational inequality. Not only is power measurable only relationally, but power is acquired and distributed through a relational process of competition and conflict between contending individuals, groups, nations, etc. (For discussions of power as form of inequality see Lenski 1966; Lukes 1974.)

Power is not, however, the only example. Social status is also generally an example of a relationally determined relational attribute. Status is intrinsically a relational attribute in that 'high' status only has meaning relative to lower statuses; there is no absolute metric of status. The process of acquisition of such high status is also generally a relational process of exclusion of rival contenders for status through competitive and coercive means. (Under special circumstances status-acquisition may be a largely monadic process. In

Inequality, Table 1 Typology of forms of inequality

		Form of the unequal attribute	
		Relational	Monadic
Form of the Process of Distribution of Attributes	Relational	Power, status Talent	Income Health, Weight
	Monadic		

artistic production, for example, one could imagine a situation in which each individual simply does the best he or she can and achieves a certain level of performance. There is nothing in one person's achievement of a given level of performance that precludes anyone else achieving a similar level. The status that results from that achievement, however, is still relational: if many people achieve the highest possible level of performance, then this level accords them less status than if few do, but the acquisition process would not itself be a relational one. In general, however, since the process by which the level of performance itself is achieved is a competitive one in which people are excluded from facilities for learning and enhancing performance, status acquisition is itself a relational process.)

The distribution of health is largely a monadic process for the distribution of a monadic attribute. In general, as in the weight acquisition case, the mechanisms which determine an individual's health – genetic dispositions, personal habits, etc. – do not causally affect the health of anyone else. There are, however, two important kinds of exceptions to this monadic causal process, both of which imply a relational process for the distribution of health as a monadic inequality. First, infectious diseases are clearly an example of a process through which the mechanisms affecting health in one person causally affect the health of another. More significantly for social theory, where the distribution of health in a population is shaped by the distribution of medical services, and medical services are relatively fixed in quantity and unequally distributed, then the causal mechanism producing health in one person may well affect the health of another in a relational manner.

Talent is an example of a relational attribute that is unequally distributed through a monadic process. A 'talent' can be viewed as a particular kind of genetic endowment – one that enhances the individual's ability to acquire various skills. To be musically talented means to be able to learn to play and compose music easily, not actually to play and compose music well (a potential prodigy who has never seen a piano cannot play it well). Talents are caused through a monadic process since the causal mechanism which determines one person's latent capacities to acquire skills does not affect anyone else's. (Obviously, parents' talent-generating mechanisms – genes – can affect their children's through inheritance. This is identical to the effect of parents' genes in the weight example. The point is that the effectiveness of one person's genes is independent of anyone else's.) The attribute so produced, however, is clearly relational: a talent is only a talent by virtue of being a deviation from the norm. If everyone had the same capacity to write music as Mozart, he would not have been considered talented.

Income inequality, at least according to certain theories of income determination (see below), could be viewed as an example of a relational process for distributing a monadic attribute. Income is a monadic attribute in so far as one individual's income is definable independently of the income of anyone else. But the process of acquisition of income is plausibly a relational one: the mechanisms by which one person acquires an income causally affects the income of others.

Inequalities in Material Welfare: Achievement Versus Exploitation

More than any other single kind of inequality, inequality of material welfare has been the object of study by social scientists. Broadly speaking, there are two distinct conceptualizations which have dominated the analysis of this kind of inequality in market societies. These I will call the achievement and exploitation perspectives.

Achievement Models

The achievement model of income determination fundamentally views income acquisition as a process of individuals acquiring income as a return for their own efforts, past and present. The paradigm case would be two farmers on adjacent plots of land: one works hard and conscientiously, the other is lazy and irresponsible. Assuming no externalities, at the end of a production cycle one has twice the income of the other. This is clearly a monadic process producing a distribution of a monadic outcome.

The story then continues: the conscientious farmer saves and reinvests part of the income earned during the first cycle and thus expands production; the lazy farmer does not have anything left over to invest and thus continues production at the same level. The result is that over time the inequalities between the two farmers increases, but still through a strictly monadic process.

Eventually, because of a continually expanding scale of production, the conscientious farmer is unable to farm his/her entire assets through his/her own work. Meanwhile the lazy farmer has wasted his/her resources and is unable to support him/herself adequately on his/her land. The lazy farmer therefore goes to work as a wage-earner for the conscientious farmer. Now, clearly, a relational mechanism enters the analysis, since the farm labourer acquires income in a wage paid by the farmer-employer. However, in the theory of wage-determination adopted in these kinds of models in which the labourer is paid exactly the marginal product of labour, this wage is exactly equivalent to the income the labourer would have received simply by producing the same commodities on his/her own account for the market. The relational mechanism, therefore, simply mirrors the initial monadic process.

In such achievement models of income acquisition genuinely relational processes may exist, but generally speaking these have the conceptual status of deviations from the pure model reflecting various kinds of disequilibria. In the sociological versions of achievement models – typically referred to as 'status attainment' models of stratification – these deviations are treated as effects of various kinds of ascriptive factors (race, sex, ethnicity) which act as obstacles to 'equal opportunity'. (The best example of status attainment models of inequality is Sewell and Hauser 1975.) Similarly, in the economic versions of such models – generally referred to as 'human capital' models – the deviations either reflect transitory market disequilibria or the effects of various kinds of extra-economic discrimination. (The classic account of human capital theory is given by Becker 1975. For his analysis of discrimination see Becker 1971.) In both the sociological and economic versions, these relational mechanisms of income determination that produce deviations from the pure achievement models mean that certain kinds of people are prevented from getting full income pay-offs from their individual efforts. The inner logic of the process, in short, is monadic with contingent relational disturbances.

Exploitation Models

Exploitation models of income inequality regard the income distribution process as fundamentally relational. The basic argument is as follows: In order to obtain income, people enter into a variety of different kinds of social relations. These will vary historically and can be broadly classified as based in different 'modes of production'. Through a variety of different mechanisms, these relations enable one group of people to appropriate the fruits of labour of another group (Cohen 1979). This appropriation is called exploitation. Exploitation implies that the income of the exploiting group at least in part depends on the efforts of the exploited group rather than simply their own effort. It is in this sense that income inequality generated within exploitative modes of production is intrinsically relational.

There are a variety of different concepts of exploitation contending in current debates. The most promising, in my judgement, is based on the work of Roemer (1983). (For a debate over Roemer's formulation, see *Politics & Society*, 11(2), 1982.) In Roemer's account, different forms of exploitation are rooted in different forms of property relations, based on the ownership of different kinds of productive assets. Roemer emphasizes two types of property in his analysis: property in the means of production (or alienable assets) and property in skills (or inalienable assets). Unequal distribution of the first of these constitutes the basis for capitalist exploitation; unequal distribution of the second constitutes the basis, in his analysis, for socialist exploitation.

While Roemer criticizes the labour theory of value as a technical basis for analysing capitalist exploitation, nevertheless his basic defence of the logic of capitalist exploitation is quite in tune with traditional Marxist intuitions: capitalists

appropriate part of the surplus produced by workers by virtue of having exclusive ownership of the means of production. Socialist or skill exploitation is a less familiar notion. Such exploitation is reflected in income returns to skills which is out of proportion to the costs of acquiring the skills. Typically this disproportion – or 'rent' component of the wage – will be reproduced through the institutionalization of credentials. Credentials, therefore, constitute the legal form of property that typically underwrites exploitation based in skills.

Two additional assets can be added to Roemer's analysis. Unequal distribution of *labour power* assets can be seen as the basis for feudal exploitation, and unequal distribution of *organization* assets can be viewed as the basis for state bureaucratic exploitation (i.e. the distinctive form of exploitation in 'actually existing socialism'). The argument for feudalism is basically as follows: in feudal society, individual serfs own less than one unit of labour power (i.e. they do not fully own their own labour power) while the lord owns part of the labour power of each of his serfs. The property right in the serf's labour power is the basis for the lord forcing the serf to work on the manorial land in the case of corv*é*e labour, or paying feudal rents in cases where corv*é*e labour has been converted into other forms of payment. The flight of peasants to the cities, in these terms, is a form of theft from the lord: the theft of the lord's labour power assets. The argument for state bureaucratic societies is based on the claim that control over the organizational resources of production – basically control over the planning and coordination of the division of labour – is the material basis for appropriation of the surplus by state bureaucrats. (For a detailed discussion of these additional types of assets and their relationship to exploitation, see Wright 1985.) In all of these cases, the ownership and/or control of particular types of productive assets enables one class to appropriate part of the social surplus produced by other classes.

In exploitation models of income distribution, monadic processes can have some effects. Some income differences, for example, may simply reflect different preferences of individuals for work and leisure (or other trade-offs). Some of the income difference across skills may simply reflect different costs of acquiring the skills and therefore have nothing to do with exploitation. Such monadic process of income determination, however, are secondary to the more fundamental relational mechanisms.

Implications for Empirical Research Strategies

As one would suspect, rather different empirical research strategies follow from monadic versus relational conceptions of the process of generating income inequality. In a strictly monadic approach, a full account of the individual (non-relational) determinants of individual income is sufficient to explain the overall distribution of income. This suggests that the central empirical task is first, to assemble an inventory of all of the individual attributes that influence the income of individuals, and second, to evaluate their relative contributions to explaining variance across individuals in income attainment. In the case of the example of the two farmers discussed above this would mean examining the relative influence of family background, personalities, education and other individual attributes in accounting for their different performances. The sum of such explanations of autonomously determined individual outcomes would constitute the basic explanation of the aggregate income distribution.

It follows from this that the heart of statistical studies of income inequality within an achievement perspective would be multivariate micro-analyses of variations in income across individuals. The study of overall income distributions as such would have a strictly secondary role.

In exploitation models of income distribution, the central empirical problem is to investigate the relationship between the variability in the form and degree of exploitation and income inequality. This implies a variety of specific research tasks, including such things as studying the relationship between the overall distribution of exploitation-generating assets in a society and its overall distribution of income, the different processes of

income determination within different relationally defined class positions (see Wright 1979), and the effects of various forms of collective struggle which potentially can counteract (or intensify) the effects of exploitation-mechanisms on income inequalities.

This does not imply, of course, that achievement models of income inequality have no interest in macro-studies of income distribution, nor that exploitation models have no interest in micro-studies of individual income determination. But it does mean that the core empirical agendas of each model of income inequality will generally be quite different.

Material Inequality and Class Analysis

Sociologists are interested in inequalities of material welfare not simply for their own sake, but because such inequality is thought to be consequential for various other social phenomena. Above all, material inequality is one of the central factors underlying the formation of social classes and class conflict.

The two models of income inequality we have been discussing have radically different implications for class analysis. In achievement models of income distribution, there is nothing intrinsically antagonistic about the interests implicated in the income determination process. In the example we discussed, the material interests of the lazy farmer are in no sense intrinsically opposed to those of the industrious farmer. The strictly economic logic of the system, therefore, generates autonomous interests of different economic actors, not conflictual ones.

Contingently, of course, there may be conflicts of interest in the income determination process. This is particularly the case where discrimination of various sorts creates noncompetitive privileges based on ascriptive characteristics such as sex and race. These conflicts, however, are not fundamental to the logic of market economies and they do not constitute the basis for conflicts between economic classes as such.

Conflicts between classes in capitalist societies, therefore, basically reflect either cognitive distortions on the part of economic actors (e.g. misperceptions of the causes of inequality) or irrational motivations (e.g. envy). Conflicts do not grow out of any objective antagonism of interests rooted in the very relations through which income inequalities are generated.

Exploitation models of income inequality, in contrast, see class conflict as structured by the inherently antagonistic logic of the relational process of income determination. Workers and capitalists have fundamentally opposed interests in so far as the income of capitalists depends upon the exploitation of workers. Conflict, therefore, is not a contingent fact of particular market situations, nor does it reflect ideological mystifications of economic actors; conflict is organic to the structure of the inequality-generating mechanisms themselves.

These different stances towards the relationship between interests and inequality in the two approaches means that for each perspective different social facts are treated as theoretically problematic, requiring special explanations: conflict for achievement theories, consensus for exploitation theories. Both models, however, tend to explain their respective problematic facts through the same kinds of factors, namely combinations of ideology and deviations from the pure logic of the competitive market. Exploitation theories typically explain cooperation between antagonistic class actors on the basis 'false consciousness' and various types of 'class compromises' between capitalists and workers, typically institutionalized through the state, which modify the operation of the market (see Przeworski 1985). Achievement theories, on the other hand, use discriminatory preferences and market imperfections to explain conflict.

Inequality (Global)

Steve Dowrick

Abstract

The seemingly inexorable rise in global inequality from the early 19th century may have reached a plateau at the end of the 20th century, although there are disputes about the methodology underlying that conclusion. Increasing global inequality in the 20th century was driven largely by increasing income gaps between nations. Inequality within countries fell sharply at the beginning of the 20th century, rising slightly towards the end. The strong economic growth of the Chinese economy is tending to reduce global inequality as China moves up towards the middle of the income ladder.

The seemingly inexorable rise in global inequality in the 19th and 20th centuries may have reached a plateau in the 1980s.

The causes and consequences of changing global inequality are a hotly contested area of economic research and debate. The intensity of the debate is in part due to the moral outrage felt by many at revelations such as those from the International Comparison Program (2007), henceforth ICP. The ICP 1996 data on average real expenditures per person reveal expenditure exceeding 1,000 dollars on the luxuries of alcoholic beverages, recreation and restaurant meals in each of the world's 20 richest countries, an amount that exceeds the total national income in each of the world's 12 poorest countries and exceeds total expenditure on food in each of the world's 70 poorest countries.

Income distribution estimates reveal that in the year 2000 more than one in ten of the world's population eked out a living around or below the World Bank's intermediate poverty line of two dollars per person per day, whilst the richest five per cent enjoyed incomes at or above 100 dollars per person per day. According to the World Bank (2006a), out of every 100 child born today, less

than one child in the USA is expected to die before the age of five, but for children born in Mali, 24 children will not survive.

The extent of current global inequality far exceeds the inequalities of previous eras, apparently giving the lie to theories that the forces of global integration reduce inequality through factor-price equalizing trade, boosting demand for low-wage labour in the poorest countries, and through capital mobility, whereby global investment flows to the poorest and least capital-intensive countries, boosting labour productivity and real wages – although these observations must be tempered by the evidence that some aggregate measures of global inequality peaked towards the end of the 20th century and by the evidence of the highly successful catch-up growth of many East Asian economies in the second half of that century.

There are many problems in conceptualizing and measuring inequality: are we concerned with measured incomes, with consumption or with well-being? Is inequality measured across nations, across households or across individuals? What is the appropriate index of inequality to use? For the most part I will focus on inequalities in measured income based on national accounting conventions or on survey data. Rather than debate the merits of different indices of inequality, I report a range of commonly used measures – noting that many studies find that different indices tend to move in the same direction over time even if their levels differ. Towards the end of this article I consider some of the methodological problems.

Inequality Over the Centuries

Looking back to the year 1500, Angus Maddison (2003) has dared to publish estimates of average income levels – or, more precisely, real GDP per capita measured at 1990 international prices, which I refer to as 'income' for short. His estimates suggest that over the first three centuries global income rose very slowly – from 566 dollars per person in 1500 to 667 dollars in 1820. Over this period, national income levels did not differ by very much, most of the nations being less than 50 per cent above or below the world average. As world income growth began to accelerate through the 19th and 20th centuries, led first by the United Kingdom and then by the United States, income gaps began to widen. By the end of the 20th century the world's richest major nation, the United States, was more than 100 times richer than the world's poorest nation.

These broad trends in growth and inequality are illustrated in Fig. 1, which displays average income levels across eight populous countries and regions at approximately 50-year intervals from 1500 to 2000. Averaging incomes across regions does of course understate the true extent of inter-country inequality, particularly in the case of Africa where the 2000 average of nearly 1,500 dollars disguises a maximum income of over 10,000 dollars in Mauritius and a minimum of just 218 dollars in Zaire.

It is also the case that averaging incomes within countries disguises the true extent of inequality across individuals or households (or inequality by gender or ethnic groups). The paucity of historical data on income distribution within countries makes disaggregation below the national level an extremely difficult task for eras before the late 20th century. This task has, however, been attempted by François Bourguignon and Christian Morrisson (2002), who estimate global inequality across a group of 33 countries/country-groups reaching back to 1820 using historical income distribution data and extrapolating across countries judged to be similar. Their results are displayed as the four solid lines in Fig. 2.

It is apparent that global income inequality rose strongly in the 19th century on all four of their measures: the Gini index, the Theil index, the mean logarithmic deviation (MLD) and the standard deviation of logarithmic income. Bourguignon and Morrisson's estimates indicate a slowing down in the rate of increase in inequality in the 20th century, although each measure displays slightly different trends. The Gini flattens out after 1970, both of the logarithmic measures peak in 1980, whilst the Theil measure is flat between 1910 and 1970 but rises up to 1992.

Both the Theil and the MLD can be decomposed exactly into the contributions of

inequality within countries and inequality between countries. The within-country contributions to global inequality are shown as the dashed lines in Fig. 2. It is apparent that within-country inequality was high and stable in the 19th century but fell substantially in the first half of the 20th century. On both measures, the contribution of within-country inequality to total inequality fell from nearly 90 per cent in 1820 to 40 per cent over the second half of the 20th century.

Global Income Inequality in the Late 20th Century

Data availability is far less of a problem for the second half of the 20th century than for previous eras (though problems of data definition and reliability persist) due to the publication of time series data on real GDP across most of the world's economies by Maddison (2003), by Robert Summers and Alan Heston (1991) and by Heston, Summers and Bettina Aten (2002) – the latter two studies producing successive versions of the Penn World Table. All these authors extrapolate over time and across countries from the benchmark price surveys, which are carried out periodically by the International Comparison Program.

Klaus Deininger and Lyn Squire (1996) have compiled sporadic time series on income distribution within countries – typically by decile or quintile groups. The gaps in their annual and country coverage have been filled by James K. Galbraith and Hyunsub Kum (2003), who extrapolate using data on wage inequality. Branko Milanovic (2002, 2005) has independently compiled a large number of national surveys of the distribution of income or expenditure at household level. I draw on a number of studies that have analysed global inequality using these sources of data.

A majority of these studies concludes that global income inequality peaked in the 1970s or 1980s and has subsequently declined slightly. The majority position has been challenged by Milanovic (2002, 2005) who uses household income surveys and World Bank estimates of current purchasing power of currencies to show that global inequality rose in the 1990s, in contradiction to Xavier Sala-i-Martin (2006) who demonstrates falling global inequality over the same period. Sala-i-Martin's methodology differs from that of Milanovic in that he uses the Deininger and Squire data on within-country inequality and converts currencies using the constant price estimates of purchasing power parity from the Penn World Table. The majority position is also contested by Steve Dowrick and Mohammed Akmal (2005), who show that the Penn World Table's method of measuring real GDP at constant prices is subject to time-varying substitution bias, which understates the true level of inequality across countries. The evidence on this debate from Bourguignon and Morrisson (2002) is equivocal since two of their measures of global inequality, the standard deviation and the mean deviation of logarithmic income, fall between 1980 and 2000 whilst their other two measures, the Gini and Theil indices, are flat or rising after 1980.

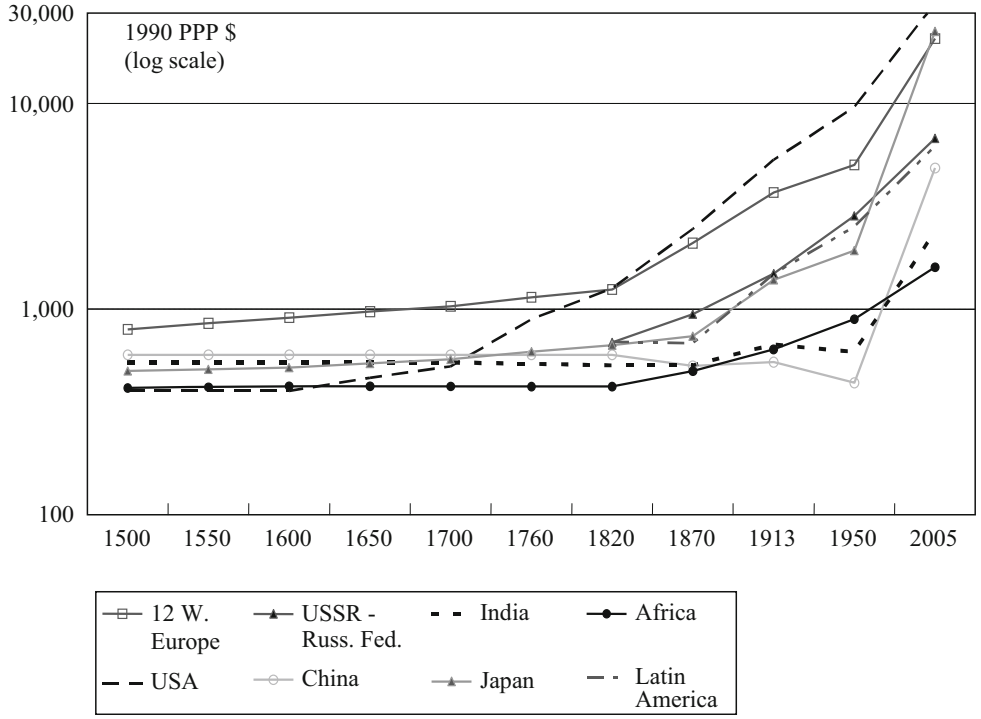
This debate on recent trends is important in that it identifies key methodological problems and it emphasizes the fact that any attempt to measure global inequality is subject to a considerable margin of error. The debate is heated because the majority view can be interpreted as support for the equalizing tendencies of global capitalism, giving some comfort to those embarrassed by the evidence of relentless growth in inequality.

Nevertheless, the 'big pictures' of both Maddison (2003) and Bourguignon and Morrisson (2002) – see Figs. 1 and 2 – prevail. After 150 years of unparalleled growth and rising inequality, global inequality appears to have stabilized towards the end of the 20th century.

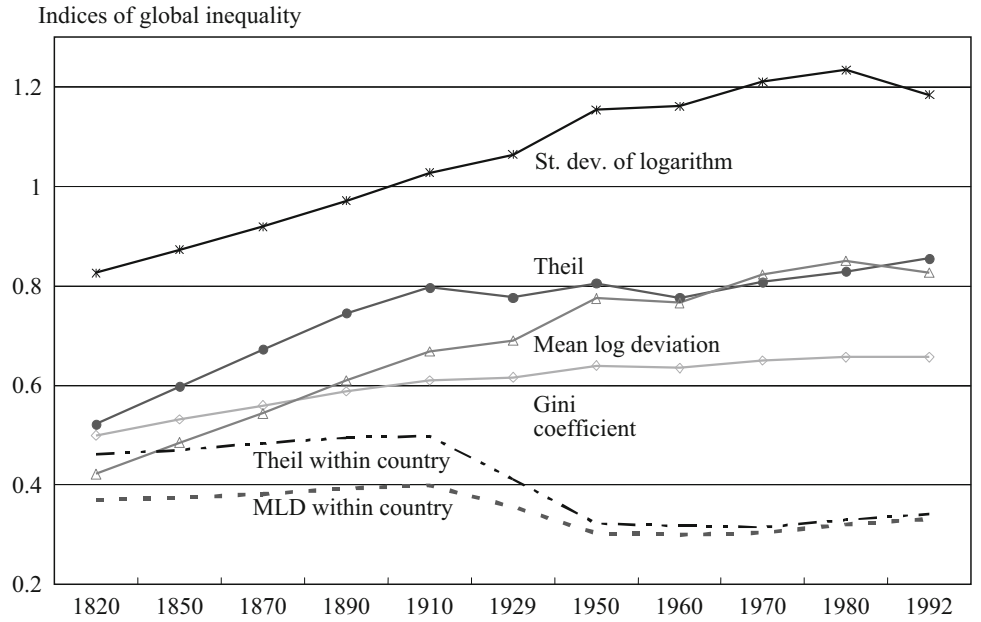
Decomposing Global Income Inequality

Within the context of this big picture, I will examine the principal components that contribute to the overall extent of global inequality: inequality across countries; weighting countries by population; and inequalities within countries.

Examining inequality in national average incomes (or GDP per capita) has been part of the focus of research into economic growth and



Inequality (Global), Fig. 1 Long-run development: real GDP per capita, 1500–2005 (*Note*: Data for 1550, 1650 and 1760 have been interpolated. *Source*: Maddison (2003) extended to 2005 using World Bank (2006b))

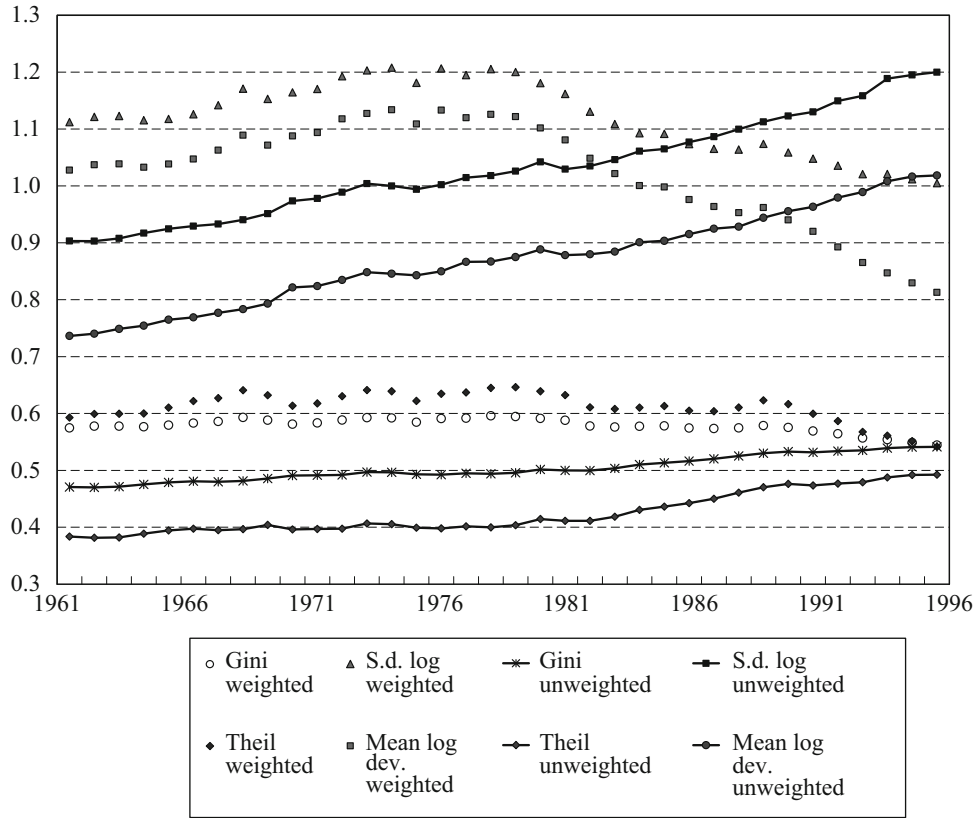


Inequality (Global), Fig. 2 Inequality within and between 33 countries, 1820–1992 (*Source*: Bourguignon and Morrison (2002))

convergence. The consensus in that literature has been aptly summarized in the title of a paper by Lant Pritchett (1997), 'Divergence, big time'. Some of the growth research has concentrated on evidence of conditional convergence, whereby there is a tendency for poorer countries to grow faster than richer countries provided that some growth determinants are held constant. Conditional convergence is not, however, a sufficient condition for inequality to fall over time, since random shocks will tend to increase dispersion of income levels, and many of the common conditioning factors, such as investment rates or levels of human capital, are distributed in such a way as to limit the growth rates of the poorer countries. So there is no logical contradiction between evidence of conditional convergence and evidence of increasing inequality between countries.

Trends in inter-country inequality are illustrated in Fig. 3, where I plot four measures of inequality across 112 countries which together account for nearly 90 per cent of the global population. The time series are represented by the four solid lines. All four measures trend upwards between 1961 and 1996.

The proximate causes of this rise in inequality between countries in the period include the relatively rapid growth of the already rich United States (averaging 2.2 per cent per year in growth of real GDP per capita), the even faster growth of the relatively rich economies of western Europe (averaging 2.7 per cent per year) which have benefited from technological catch-up with the USA, and the tragedy of African economies which, on average, recorded less than one per cent growth per year. Fifteen African economies experienced falling income levels. With the rich



Inequality (Global), Fig. 3 Inequality across 112 countries, 1961–1996: population weighted and unweighted (*Source*: Penn World Table 6.1 (Heston et al. 2002))

nations becoming relatively richer and the poorest nations becoming relatively poorer, it is no surprise that all four measures of inter-country inequality record increases.

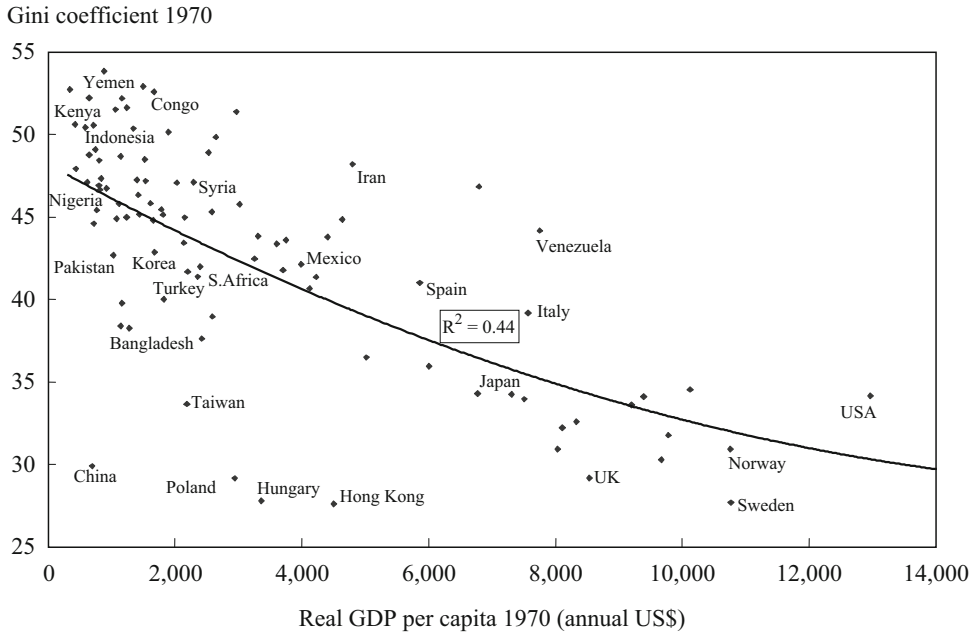
These comparisons, in the tradition of the literature on economic growth, give equal weight to each country. When examining inequality, however, we are often interested in inequality across households or individuals, so it makes sense to weight each country's average income by the population of that country. As many researchers have pointed out, this procedure changes the picture drastically – as illustrated by the dashed lines in Fig. 3, which are non-monotonic.

All four of the population-weighted measures of inequality between countries reach a peak in the late 1970s. This peak corresponds to the time when the growth rate of the Chinese economy took off. Through the 1960s and 1970s the Chinese economy grew at a moderate rate, moving average income from 21 per cent of the world average in 1960 to 26 per cent by 1978, still below African income levels. Over the next two decades, the growth rate accelerated, moving Chinese average income in 1996 up to 69 per cent of the world average. This movement of one-fifth of the world's population away from the bottom and towards the middle of the country income distribution is the principal cause of the substantial fall in population-weighted inequality across countries. Another contributory factor was the rise in the growth rate of the Indian economy, which moved from income at 21 per cent of the world average in 1980 to 32 per cent by 2000. (Relative income levels are derived from Maddison 2003.)

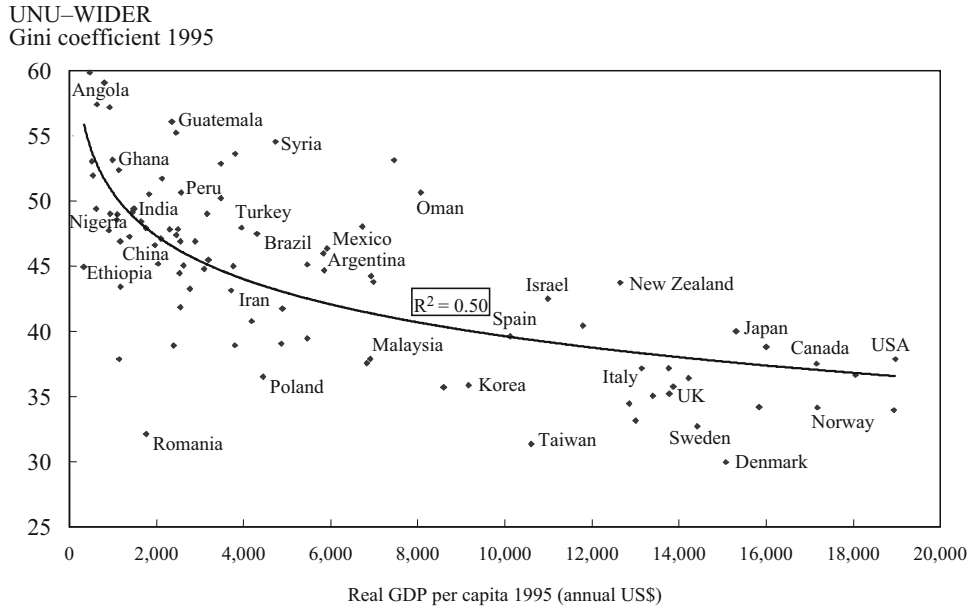
The final dimension to global inequality is inequality within countries. There has been widespread concern within the rich industrialized economies that the rapid expansion in the 1980s and 1990s of trade with low-wage economies such as China would cause increasing inequality as less skilled workers faced wage cuts or unemployment in the face of competitive imports. At the same time, real wages were rising for workers in developing economies who found jobs in the expanding export sectors. Indeed, it has been the case that many of the richest economies have experienced rising income inequality, with Gini coefficients averaging a rise of 3.5 points between 1970 and 1995 in the richer half of the sample of countries. Income inequality also increased in many of the poorer countries, averaging a rise of 2.2 points. (Data on inequality within countries are from Galbraith and Kum 2003, supplemented by estimates for China in 1970 and 1995 from the UNU-WIIDER data-set, sourced to Dowling and Soo 1983, and to Khan and Riskin 1998, respectively.)

Kuznets (1955) has famously observed that, over the course of economic development in the 19th century and the first half of the 20th century, income inequality first rose as labour moved from agriculture into industrial sectors with higher wages and then declined as industrial employment stabilized and wages were equalized. The ensuing implication of a hump-shaped cross-sectional relationship between inequality and income levels is not, however, supported by the crosssectional evidence from 1970 and 1995, which is illustrated in Figs. 4 and 5. Each figure plots the Gini coefficient on the vertical axis against the income level. The best-fit quadratic regression line has been added to each figure. For each year, it is evident that there is a fairly strong tendency for income inequality to fall as average income levels rise. This graphical analysis confirms the results of the econometric study conducted by Schultz (1998).

Comparison of Figs. 4 and 5 confirms the tendency for inequality to have risen within countries over the 25-year period. It is of particular interest to note the sharp rise in estimated inequality for China, from a Gini around 30 in 1970 – commensurate with the low levels of inequality observed in the Communist countries of eastern Europe – to a Gini of 45 in 1995 – commensurate with the more generally observed levels of inequality amongst other countries at the same level of development. This sharp rise in inequality is in keeping with accounts of rising inequality between the provinces in China, reflecting uneven development between rural regions and the rapidly industrializing coastal cities. Over the same period, the Indian Gini



Inequality (Global), Fig. 4 Intra-country inequality, 1970 (*Source*: Galbraith and Kum (2003) and UNU–WIDER (2005))



Inequality (Global), Fig. 5 Intra-country inequality, 1995 (*Source*: Galbraith and Kum (2003) and UNU–WIDER (2005))

coefficient of inequality was fairly stable at 46.9 in 1970 and 47.2 in 1995.

It might be expected that the general rise in inequality within countries after 1970, particularly within China, would offset any tendency for population-weighted inequality between countries to decline in the 1980s and 1990s. There is some evidence of this offsetting in the Bourguignon and Morrisson (2002, Table 2) data on global inequality, which is illustrated in Fig. 2. Two of their measures, the Theil index and the MLD, allow an exact decomposition into within-country and between-country inequality. The within component of the Theil index rises from 0.315 in 1970 to 0.342 in 1992, whilst the within component of the MLD rises from 0.304 to 0.332. Their Theil measure of global inequality does indeed continue to rise after 1980, although the MLD falls slightly.

Similar results on within-country inequality are reported by Sala-i-Martin (2006), who finds that the within component of the Theil index rises from 0.255 to 0.284 between 1970 and 2000, and the within component of the MLD rises from 0.246 to 0.319. However, his methodology differs from Bourguignon and Morrisson (2002) in that he studies a much larger number of countries and uses nonparametric estimates of within-country distribution. His overall conclusion is that global inequality fell towards the end of the 20th century despite the rise in inequality within countries.

It is noteworthy that 20th century movements in within-country inequality tend to be dominated by movements in population-weighted inequality across countries. This is not surprising since the most glaring inequalities are found in comparisons across countries. Typical values for the quintile ratio (the income of the richest fifth relative to the income of the poorest fifth) are around seven or eight when we look within countries, but across countries the quintile ratio is over 20. This is very different from the situation at the beginning of the 19th century when the dominating influence on global inequality was the extent of inequality within countries.

Methods of Comparing Income Levels Across Countries

Most studies that examine population-weighted inequality between countries conclude that inequality peaked in the 1970s and declined in the 1980s and 1990s. These studies depend on estimates of GDP per capita evaluated at purchasing power parities (PPP) using data from either Maddison (2003) or the Penn World Table. Maddison's data is used by Bourguignon and Morrisson (2002) and by Sutcliffe (2004). The Penn World Table data are used by Schultz (1998), Firebaugh (1999), Melchior et al. (2000) and Sala-i-Martin (2006), among others.

Several of these studies have contrasted their results with those obtained by Korzeniewicz and Moran (1997) and the United Nations Development Report (UNDP 2006), who use market rates of exchange rather than PPP exchange rates to compare incomes across countries. The use of market exchange rates leads to the conclusion that income inequality across countries was rising rather than falling over the final decades of the 20th century. There is widespread agreement that exchange rate comparisons are not appropriate if income inequality measures are being calculated in an attempt to evaluate inequality in human welfare. They suffer from two major defects. Market exchange rates are volatile, implying unrealistically sharp short-term movements in real incomes. They also systematically exaggerate real income differentials due to the Balassa–Samuelson effect whereby market exchange rates take no account of the relative cheapness of non-traded goods and services in low-wage low-income countries. Market rates of exchange systematically undervalue incomes in poor countries.

There are, however, some purposes for which the exchange rate measures of inequality may be more appropriate than PPPs. If we are concerned with the ability of poor countries to catch up with the technologies of the rich, and if this depends on their ability to purchase high-tech equipment from the major exporters of capital equipment, then it is

the exchange rate which is the appropriate measure of their capacity to develop. The same may well be true when we consider the bargaining power of the poorer nations at international forums such as the World Trade Organization.

To the extent that we are interested in income comparison as an approximation to welfare comparison, it is clearly preferable to compare incomes across countries at purchasing power parity. There is, however, a complication: which measure of purchasing power parity should we use? The PPPs used by both Maddison and the Penn World Table rely on the Geary–Khamis method, which calculates a weighted average of relative prices across all of the countries surveyed by the International Comparison Project in a benchmark year and values the GDP bundles of all countries in all years at that fixed set of prices. The weighting procedure uses country expenditure shares in world GDP, generating 'world prices' which are close to the price relativities prevailing in the rich countries of the Organisation for Economic Co-operation and Development (OECD) but very different from the relative prices prevailing in the world's poorer economies. The Geary–Khamis procedure induces substitution bias, valuing the abundant and cheap local services in low-wage economies at the much higher relative price of the rich economies. The effect is the opposite of the bias in the exchange rate comparisons. The Geary–Khamis PPPs systematically overvalue incomes in poorer countries, resulting in measures of global income inequality which are biased downwards. Dowrick and Akmal (2005) demonstrate that the use of Geary–Khamis PPPs can also distort the trend, since the magnitude of the bias changes over time, and show that an unbiased measure of global inequality does not fall between 1980 and 1993.

Further problems with the standard methods of comparing incomes across countries are pointed out by Milanovic (2005). He argues that it is illogical or at least inconsistent to use household survey data to estimate income distribution within countries, but to use national accounting measures rather than the survey measures when computing differences in average income levels across countries. Using average survey income, converted at PPP, he finds that global inequality rose between 1988 and 1993 before falling slightly by 1998. Milanovic notes that average survey income is always less than national accounts measures of average income, or GDP per capita, because it omits public expenditures. Lacking data on the distribution of public expenditures, he argues that survey income is the preferable measure.

Concluding Remarks

Global income inequality rose to historically unprecedented proportions, morally repugnant to many, through most of the 19th and 20th centuries – at the same time as average income levels rose to previously unimaginable heights. Since the 1970s, the level of inequality appears to have halted or, by some measures, has begun to fall slightly.

Prospects for the future evolution of global inequality depend crucially on two questions. First, will China continue to follow the trail of development blazed by Japan and Korea several decades earlier? If one-fifth of the world's population does indeed follow this path, then we can expect measures of global inequality to fall as Chinese income level approach the world average; but inequality will then increase as Chinese income levels catch up with those of the global rich. Second, can the desperately poor nations of Africa find a way, with or without the assistance of the rest of the world, to follow the successful development path on which China and India embarked in the 1980s and the 1990s? If African development fails to take off and if population growth continues to exceed that of the other continents, then global inequality may well resume its rising trend in the course of the 21st century.

Inequality (International Evidence)

Andrea Brandolini and Timothy M. Smeeding

I

Abstract

The methodological assumptions underlying international comparisons of levels and trends in inequality are discussed, starting with the choice of the evaluative space. Empirical evidence shows that at the end of the 1990s, the United States had the highest level of disposable income inequality among high-income economies, while northern and central European countries had the lowest levels. Only in Russia and Mexico, two middle-income economies, was disposable income more unequally distributed. No common trend in inequality is observed since the 1970s across rich nations. Public redistribution through taxes and benefits influence both levels and changes in inequality.

The comparison of inequality across countries and over time has a long tradition in economics. In 1897 Pareto used data from tax returns for a heterogeneous group of nations, spanning a period of almost four centuries, to conclude that income inequality was remarkably constant over time and space. An intense debate followed, such that the editors of *Econometrica* devoted the second 'Annual Survey of Statistical Data' to Pareto's law (Bresciani-Turroni 1939), which served to bring to an end the idea of a 'natural' constancy of the distribution of income.

The study of international differences in income distribution gathered new momentum after the Second World War. In the 1950s, United Nations agencies pioneered the assembly of international datasets on income inequality (for example, United Nations 1951) and Kuznets (1955) stated his celebrated hypothesis of an inverted-U relationship between inequality and growth. Since those early days, international agencies and individual scholars have increasingly been engaged in collecting information on income distribution and comparing levels and trends of inequality across nations (Gottschalk and Smeeding 1997; Atkinson and Brandolini 2001). Cross-country comparisons of income inequality have become common in analysis that informs policymaking: measures of income distribution are featured among the indicators of social cohesion agreed by the European Union to monitor the performance of member countries (Atkinson et al. 2002), and one of the first charts of the 2006 *World Development Report* ranks nations by the Gini index of income (or expenditure) to show that 'Africa and Latin America have the world's highest levels of inequality' (World Bank 2005, Fig. 2.9, p. 39; the underlying data are reported in Table 1).

Focal Variable

As Sen suggests, the relative advantages and disadvantages that people have, compared with each other, can be judged in terms of many different variables, e.g. their respective incomes, wealths, utilities, resources, liberties, rights, quality of life, and so on. The plurality of variables on which we can possibly focus (the *focal variables*) to evaluate interpersonal inequality makes it necessary to face, at a very elementary level, a hard decision regarding the perspective to be adopted. (Sen 1992, p. 20)

Pareto saw the distribution of income as a reflection of the natural distribution of abilities among persons, while Kuznets regarded its evolution as one of the characteristics of the process of economic growth; but they both agreed that the focal variable should be income. However, other dimensions of economic inequality are relevant in international comparisons. Earnings dispersion and differences in employment rates capture inequality in the labour market. Wealth may be seen as an indicator of the capacity to face adverse events or of the power to control the resources of the society. The standard of living is much influenced by non-monetary aspects, such as a person's health status or human capital – as stressed by the 'capability approach' advocated by Sen (1992).

In this article, the focal variable is taken to be income, the most common indicator of (current) economic resources in rich countries. Expenditure is an alternative variable often used, especially in less developed countries. The World Bank (2005, Table A2, pp. 280–1) reports income-based Gini indices for 22 of the 27 high-income economies for which the statistics are available vis-à-vis 20 of the 60 middle-income economies and only one of the 39 low-income economies. Mixing income-based and consumption-based statistics confounds international comparisons, as income tends to be more unequally distributed than expenditure – and to an extent that varies considerably from country to country (for example, World Bank 2005, Box 2.5, p. 38).

Wealth (net worth) is much more concentrated than income. Moreover, international comparisons of net worth are very problematic (Wolff 1996; Davies and Shorrocks 2000) as the assembling of cross-nationally comparable databases on household net worth is still in its infancy (Sierminska et al. 2006).

Notes: Economies are classified by the World Bank according to 2004 per capita gross national income in the following income groups: low-income economies (LIC), $825 or less; lower-middle- income economies (LMC), $826–$3255; upper-middle income economies (UMC), $3256–$10,065; and high-income economies (HIC), $10,066 or more. (*Source*: World Bank (2005, Table A2, pp. 280–1))

Methodology

International comparisons of income inequality crucially depend on the underlying measurement assumptions. This has been known at least since Kravis (1962) and Kuznets (1963) and has received growing attention from the mid-1970s (for example, Atkinson 1974; Sawyer 1976; Lydall 1979). However, it was not until the assembling of the cross-nationally comparable database of the Luxembourg Income Study (LIS) that the impact of these assumptions was fully understood (Smeeding 2004). Differences in methodology arise in the definition of income, the choice of the recipient unit, the quality of underlying sources, the treatment of individual data (O'Higgins et al. 1990; Atkinson et al. 1995; Gottschalk and Smeeding 1997, 2000; Atkinson and Brandolini 2001).

Income definitions differ in comprehensiveness, as certain income sources like capital gains, imputed rents on owner-occupied dwellings, or home production may or may not be included. There are also widespread differences in the treatment of taxes (and social security contributions), as income may be taken before taxes, before taxes but after allowing for tax deductions, or after taxes. The definition of income may be augmented to include the imputed value of public in-kind benefits for education, health care and housing or to deduct indirect taxes. Moreover, income may be measured over a variety of time periods: the reference is often the year, but in some cases it is some 'current' period (for example, the most recent pay period for earnings in household surveys for the United Kingdom) and then the annual amount must be estimated.

The *reference unit* may be the household, the related or extended family, the tax unit, or the individual income earner. Information obtained from income tax records typically relates to the tax unit only, while sample surveys generally provide data for all members of a household. The total income may be adjusted for the size and the composition of the reference unit by dividing by an *equivalence scale.* Indeed, not adjusting income implies that the welfare achievable in a household with a certain income is independent of the number of its occupants. At the other extreme, taking income per capita amounts to an assumption that no economies of scale arise from cohabitation and that people do not differ in their needs. The *welfare unit* may be the person (person-weighted) or the household (household-weighted): in the former case the welfare indicator

represented by (equivalent) income is counted as many times as there are persons in the household, while in the latter it is counted only once. This welfare weighting is a separate issue from that of the equivalence scale: for instance, the European Commission (2002) typically reports statistics for the distribution of *equivalent disposable incomes* among *persons,* while the U.S. Census Bureau (2005) presents figures for the distribution of *unadjusted money incomes before taxes* among *households.*

Diversity in definitions is not the only factor that affects the comparability of income inequality statistics. There are also differences in the *nature of the data source*, the most important distinction being between sample surveys and administrative archives. Data may cover the whole population or only the household population, excluding people living permanently in institutions like boarding houses, nursing homes for the elderly, prisons, or military bases. Administrative data reflect the purposes for which they were collected. Even when sources have the same nature, they may considerably vary in quality, through differences in the response rate, the under-reporting of certain income components, or the coverage of the bottom and the top of the distribution. Lastly, significant differences can originate in the way data are processed. For example, the Gini index may be computed from micro-data or from observations grouped by income classes. When the ranking of observations is based on a variable different from that of concern, say before-tax income instead of after-tax income, measures of inequality are understated.

All these factors influence international comparisons of income inequality, as shown for instance by Buhmann et al. (1988) with regard to equivalence scales and by Smeeding et al. (1993) with regard to the inclusion of in-kind public benefits. These differences need to be kept in mind when making international comparisons. While perfect comparability is not achievable, it is important to raise the ratio of signal to noise by minimizing data and methodological differences across nations (Gottschalk and Smeeding 2000).

Relative Inequality Levels

Figure 1 compares the distribution of equivalent disposable income among persons in 32 nations for various years around the turn of the 21st century, or for the most recent year available in the LIS database. Disposable income is defined as the sum of wages, salaries and earnings from self-employment, cash receipts from property, private pension schemes, alimony and child support, public transfer payments (retirement pensions, family allowances, unemployment compensation, and welfare benefits) less income taxes and social security contributions. Observations are top- and bottom-coded in order to reduce the influence of anomalous income values. Total household income, the sum over all household members, is divided by a simple equivalence coefficient (the square root of the household size) and then attributed to each person in the household.

Figure 1 reports, for each country, the ratio to the median of the income of a person at the tenth percentile (P10 or 'low income') and a person at the 90th percentile (P90 or 'high income'). P10 and P90 provide some indication of how far below or above the middle of the distribution the poor and the rich are on the continuum of income. The ratio between P90 and P10, the 'decile ratio', is a measure of the gap between the rich and the poor. While these statistics refer to specific points of the distribution, the Gini index measures inequality across the entire distribution. For non-negative values, it varies between zero (perfect equality) and one (maximum inequality).

There is a wide range of income inequality among the nations of Fig. 1. The United States is an outlier among rich nations, and only Russia and Mexico, two middle-income economies, have higher levels of inequality. A low-income American at the 10th percentile in 2000 had an income that was only 37 per cent of the median income. By contrast, in most countries of central, northern and eastern Europe the income of the poor exceeded 50 per cent of the income of middle-income person; in the other English-speaking nations and in the southern European countries, plus Israel, it was above 40 per cent. Only in Russia and Mexico did the poor fare relatively

Inequality (International Evidence), Fig. 1 The distribution of disposable income in 32 high- and middle-income economies. *Notes*: P10 and P90 are the ratios to the median of the tenth and 90th percentiles, respectively. Observations are bottom-coded at 1% of the mean of equivalent disposable income and top-coded at ten times the median of unadjusted disposable income. Incomes are adjusted for household size by the square-root equivalence scale. See note to Table 1 for the definition of high- and middle-income economy. (*Sources*: Authors' calculations from the Luxembourg Income Study database, as of 10 March 2007 (figures coincide with those reported in http://www.lisproject.org/keyfigures/ineqtable.htm) and the European Community Household Panel database, Waves 1–8, December 2003 for Portugal; statistics for Japan were computed according to the same methodology as all other figures by Tsuneo Ishikawa for Gottschalk and Smeeding (2000))

worse than in the United States. In Greece, Portugal, Spain, Israel as well as the United States and the United Kingdom the rich persons earn more than twice the national median incomes. In poorer countries the 90th percentile can also be very high in relative terms, for example in Mexico, Russia, and Estonia.

The countries in Fig. 1 fall into distinctive clusters. Inequality, as measured by the decile ratio, is least in Nordic countries, the Netherlands and the Czech and Slovak Republics with values of 3 or less. The two other Benelux countries (Belgium and Luxembourg), Central Europe (France, Switzerland, Germany, Austria, Slovenia) and three other Eastern European countries (Hungary, Poland, Romania) come next at 3.2–3.6. These precede four English-speaking nations (Canada, Australia, Ireland and the United Kingdom), which have decile ratios comprised between 3.9 and 4.6, and the southern European

countries (Italy, Spain, Greece and Portugal) and Israel, whose ratios fall between 4.5 and 5.0. Only the United States, Estonia, Mexico and Russia have values in excess of 5. With decile ratios around 4, the two Asian countries, Taiwan and Japan, are in an intermediate position.

Inequality differs much more across middle-income than high-income economies. While Estonia, Russia and Mexico show a very unequal distribution of income, the other five countries, all from eastern Europe, exhibit moderate or low levels of inequality. The shape of the income distribution was noticeably different even in the mid-1980s across these formerly planned economies, with Czechoslovakia showing the least inequality and the Soviet Union the highest (Atkinson and Micklewright 1992).

In Fig. 1 countries are arranged, within the two categories of high-income and middle-income, by the decile ratio, from lowest to highest. This country rank order does not need to coincide with that based on the other statistics reported: P10, P90 and the Gini index. For instance, Sweden shows the second highest P10 but the seventh lowest Gini index. This follows from the fact that the Swedish at the 90th percentile is less closer to the middle than the equivalent person in Denmark, Finland or the Slovak Republic. (-These differences should not be overstressed as they are small and likely to be within the bounds of sampling error.) The rankings of countries in international comparisons depends on which part of the distribution is analysed, for example, the bottom with P10 or the top with P90, or in the way single observations are weighted by a summary measure of inequality like the Gini index, or the Theil and Atkinson indices. Different summary measures may produce different results reflecting differences at the top and bottom of the distribution. More robust, but partial, rankings are obtained by comparing the entire distributions by 'Lorenz dominance', whereby inequality is assessed to be unequivocally higher in country *A* than in country *B* if the Lorenz curve of country *A* lies everywhere below that of country *B*, but no unambiguous conclusion is achieved if the two curves intersect. Although countries may switch their relative positions, indices are still in general highly correlated: for instance, the correlation between decile ratio and Gini index in Fig. 1 is 0.97. The basic patterns of international inequality are clear regardless of the measure of inequality employed.

Redistribution

Every nation's tax and benefit system reduces market income inequality, but not all are equally effective in doing so. The efficiency with which nations accomplish this redistribution may vary over time as well as space. A common measure of the level of redistribution is represented by the difference between the Gini index for market incomes, that is, before public transfers are added and taxes and social security contributions are deducted, and the Gini index for disposable incomes. This difference provides only a first estimate of the actual impact of public redistribution, as it ignores how market income inequality would be different if there were no taxes and benefits. Table 2 shows the extent of redistribution in 16 countries using LIS data.

In all nations disposable incomes are more equally distributed than market incomes, suggesting that the tax and benefit system narrows the overall distribution. On average, inequality falls by about a third, from a Gini index of 44 to one of 29 per cent. Cross-country variation in original inequality is wider than after redistribution: the Gini index ranges from 33 to 52 per cent for market incomes, and from 23 to 37 per cent for disposable incomes. The United States has the highest inequality of disposable incomes, although the dispersion of market incomes is on the high side but not far from most other countries; it is as high as in Germany and Australia and below the values recorded for the United Kingdom, Poland and Israel. The fact is that the percentage reduction in before-tax-and-benefit inequality in the United States is a mere 23 per cent. If we exclude Taiwan, where redistribution has a tiny impact, only Switzerland shows a reduction as low as the United States, but the Swiss start from a much more equal distribution and end with a Gini index below the average.

Inequality (International Evidence), Table 2 Gini indices of market income and disposable income in 16 countries (per cent)

Country	Year Gini index for market income [1]	Gini index for disposable income [2]	Absolute reduction [3] = [1] − [2]	Percentage reduction [4] = [3]/[1]
High-income economies				
Denmark	2000 42	23	20	47

Middle-income economies				
Czech Republic	1996 44	26	18	41
Romania	1997 38	28	10	27
Poland	1999 50	29	21	41

Notes: Observations for disposable income are bottom-coded at 1% of the mean of equivalent disposable income and top-coded at ten times the median of unadjusted disposable income. Changes in disposable incomes due to bottom- and top-coding are entirely attributed to market incomes. Both market and disposable incomes are adjusted for household size by the square-root equivalence scale. (*Source*: Authors' calculations from the Luxembourg Income Study database, as of 10 March 2007)

These percentage reductions are very consistent with the patterns of aggregate public spending. High-spending northern and central European nations have the highest degree of inequality reduction, from 36 to 47 per cent; the English-speaking Anglo-Saxon (excluding the United States) nations and Israel are next with 28 to 33 per cent reductions; the United States and Switzerland are, as just seen, at the bottom of the scale. The degree of redistribution in southern Europe is lower than in Ireland and the United Kingdom, especially if public pensions are not included among transfers, according to the EUROMOD estimates based on micro-simulations rather than the records of the original micro-data sources (Immervoll et al. 2005). The nations that redistribute the most are not necessarily those with the greatest degree of market income inequality: before-tax-and-benefit incomes in Finland and the Netherlands are far more equally distributed than in the United States.

Absolute Inequality Levels

The comparisons in Fig. 1 relate to *relative* inequality. The income of the poor at the tenth percentile is compared with the income of the person at the middle of the distribution in the same country. When average standards of living differ across nations, results may look quite different if comparisons are made in terms of *real* income, that is, the amount of goods that a certain income can purchase.

The statistics in Fig. 2 on real incomes in 2000 international dollars are derived by adjusting the original incomes by the national consumer price indices (CPI) and converting them by means of the purchasing power parities (PPP) for gross domestic product (GDP). The real P10 and P90 are then recomputed as a fraction of the US median real income. These comparisons are very rough indicators of differences in 'real living standards'. First, the conversion to real income across countries and

Inequality (International Evidence), Fig. 2 The distribution of real disposable income in 32 high- and middle-income economies. *Notes*: Real P10 and P90 are the percentage ratios to the US median of the tenth and 90th percentiles, respectively; real median is expressed as a percentage ratio of the US median. Observations are bottom-coded at 1% of the mean of equivalent disposable income and top-coded at ten times the median of unadjusted disposable income. Incomes are adjusted for household size by the square-root equivalence scale. (*Sources*: Authors' calculations from the Luxembourg Income Study database, as of 10 March 2007, and the European Community Household Panel database, Waves 1–8, December 2003 for Portugal; statistics for Japan were computed according to the same methodology as all other figures by Tsuneo Ishikawa for Gottschalk and Smeeding (2000). Consumer price indices and purchasing power parity conversion factors from local currency units to international dollars are from International Monetary Fund (2006))

time is sensitive to the PPP and consumer price indices used. Second, the PPPs are computed for national accounts which are intrinsically different from survey data (Deaton 2005). For instance the ratios of total survey incomes to GDP aggregates vary considerably across these countries. Thus countries with surveys that capture less of national income appear to have much lower mean living standards than countries whose surveys or administrative records capture a larger share of that income. Third, it is questionable that the same conversion factor should be applied across the entire distribution. Lastly, real income does not account for goods and services such as education

and health care that are provided at different prices and under different financing schemes in different nations. As low-income citizens in some countries need to spend more out of pocket for these goods than do low- income citizens in other countries, their living standard is relatively lower than that measured by PPP-adjusted income.

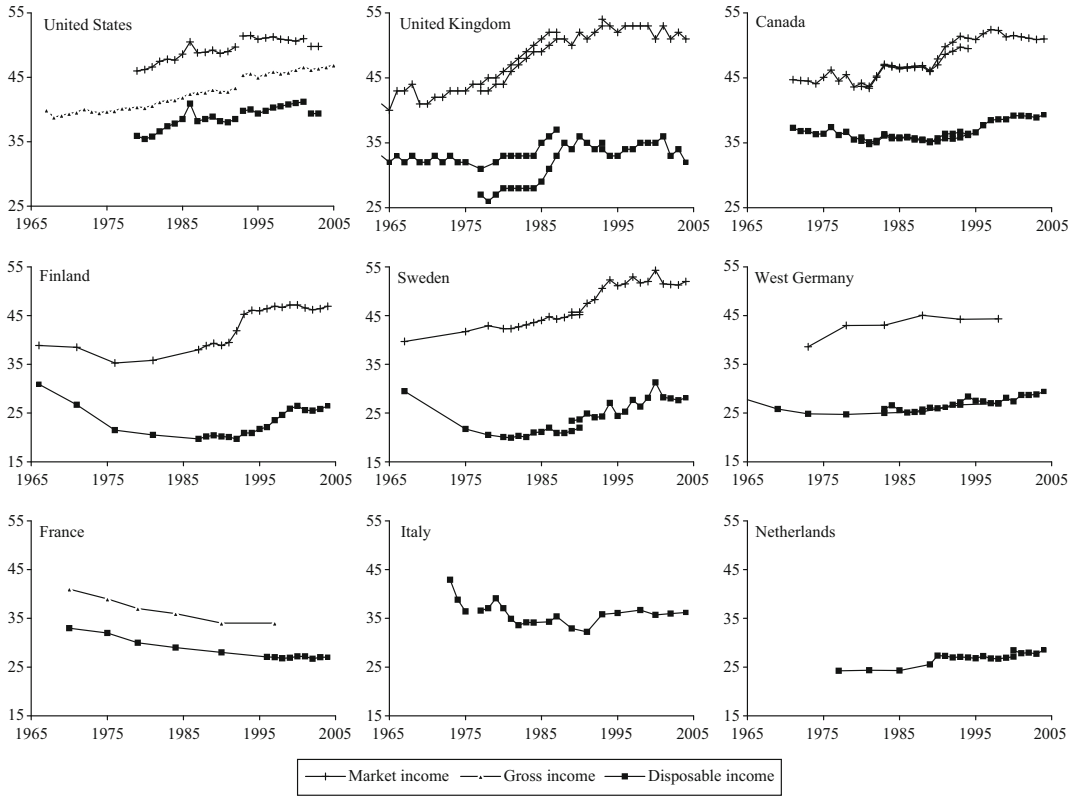
The living standard of the median German or Belgian appears to be 72 per cent of that of the median American; but the living standard of poor Germans and Belgians is just above that of their American counterparts, 38–39 per cent against 37 per cent of the US median. Low-income people in Denmark, Norway, Switzerland and, especially, Luxembourg are much better off than elsewhere. In all southern European countries but also, to a lesser extent, in Australia, Ireland and the United Kingdom, the living standards of low-income households were lower than in the United States. Of course, they are a great deal lower in all middle-income economies. At the other extreme, the rich Americans far surpass the rich in any other nation observed, save for the Luxembourgers.

Long-Run Trends in High-Income Economies

Movements of inequality over time follow irregular trajectories rather than smooth profiles, with more substantial changes often concentrated in few episodes (Atkinson 1997). Some causes are common to many countries, such as the spreading of skilled- biased technologies, the greater world economic integration, or the aging of population in more recent decades; some others are more specific to national experiences, typically changes in tax-and-benefit systems but also modifications in institutions such as wage setting policies. The evolution of inequality reflects the joint working of these factors, which sometimes balance out and sometimes reinforce each other, making it an arduous task to disentangle common trends from idiosyncratic variations. Moreover, changes in data collection and statistical methodology interrupt the continuity of time series. And so the interpretation of long-run movements needs to allow for the patchwork nature of the evidence.

The temporal patterns show some similarity in the United States and the United Kingdom, where inequality was considerably less in the 1940s than before the Second World War. It then moderately declined until the mid-1970s, when this trend abruptly reversed. But we have no consistent overall time series running this far back for other nations (see Gottschalk and Smeeding 2000, Figs. 6a and 6b, for the longer-term US and UK trends). The best we can do on a reasonably comparative basis is shown in Fig. 3, covering four decades from 1965 to 2005. (Estimates reflect national practices and are not to be compared across countries.) Indeed, the 1980s saw a substantial rise of inequality, more pronounced in Britain than in the United States, though the starting level was lower. In the 1990s the two nations parted: income distribution kept widening in the United States, while it broadly stabilized in the United Kingdom. Both Finland and Sweden experienced a fall in inequality until the early 1980s and then a modest rise afterwards, which has strengthened around the turn of the century. A tendency towards higher inequality followed by a period of stability seems to characterize the 1980s and the 1990s in the Netherlands and Norway as well as Australia and New Zealand. Canadian income inequality exhibited some variation but no clear trend from 1965 to the mid- 1990s, when it started to slowly rise. In the Federal Republic of Germany a sharp fall between 1962 and 1973 was followed by a period of stability and a modest rise over the 1990s. Income distribution narrowed in Italy from the 1970s to the 1980s; after a sharp widening at the beginning of the 1990s, there was virtually no change until 2004. In France alone, inequality steadily decreased between 1970 and the mid- 1990s, and remained stable afterwards.

In summary, national experiences vary and there is no one overarching common story. However, there was a general tendency for the disposable income distribution to narrow until the mid-1970s. Some increase in inequality was experienced by most nations in the 1980s to the 1990s, but its timing and magnitude differed widely across countries. In particular there was and is no regression to the mean pattern of change in the United States, which began with the most inequality in the late 1970s and has increasingly



Inequality (International Evidence), Fig. 3 Inequality trends in selected high-income economies (Gini index, per cent), 1965–2005. (*Source*: Authors' elaboration on national sources)

pulled away from the other nations through the early years of the twenty first century.

These observations mainly relate to disposable incomes. In the six countries for which data are available (Canada, the Federal Republic of Germany, Finland, Sweden, the United Kingdom and the United States), movements in market income inequality appear to be more synchronous, with a rise in the 1980s followed by stability thereafter. Changing public redistribution appears to be an important determinant of the time pattern of the inequality of disposable incomes. If we take, as before, the absolute difference between Gini indices, the redistributive impact of taxes and transfers initially increased and then stabilized or dropped in all countries except for the United States, where it remained quite stable over time. The United Kingdom stands out for having the most dramatic switch of regime, as in the early 1980s it apparently shifted from a situation not too different from the two Nordic countries to a model closer to that of the two North American countries. It is not possible to infer from this simple measure whether changes in redistribution are the automatic response of a progressive tax-and-benefit system to changes in the distribution of market incomes, or are instead the product of explicit policy choices (Atkinson 2004). Nevertheless, they confirm that a widening of the market income distribution need not result in a drastic increase in the inequality of disposable incomes.

Inequality (Measurement)

F. A. Cowell

Abstract

This article provides an overview of the key issues in inequality measurement and shows how theoretical concepts are related to practical judgements. The principal axioms of distributional analysis are used to show the social-welfare underpinnings of standard ranking principles and to derive families of inequality indices. Recent developments that focus on income differences and reference income levels are examined.

Introduction

Inequality measurement is principally concerned with the comparison of personal income distributions in quantitative terms. In its modern form it is a branch of welfare economics although it clearly derives some of its intellectual heritage from statistics. It is distinct from the measurement of poverty and relative deprivation, although there are close analytical links to these topics. The motivation for taking the subject of inequality seriously is both analytical and practical: the principal concepts reviewed in this article are of concern to theoretical economists and are also used by policymakers. The subject touches on questions addressed by philosophers and by social scientists.

The type of issue under consideration can be illustrated by a simple example as depicted in Tables 1 and 2. These tables do not pretend to be the most general or the most suitable representation of the facts, but they are from an easily accessible source and give a convenient snapshot of what happened to the distribution of income in the United States over a span of about 30 years. From Table 1 it is clear that the bottom decile income experienced a 12.2 per cent growth over the period (in real terms) while the median grew by half as much again (18.3 per cent) and the top decile grew by almost four times as much (44.8 per cent). Table 2 describes what happened to the average incomes of particular *groups*. The average income of households in the bottom fifth of the distribution grew by just 10.1 per cent over the 30 years while the average income of households

Inequality (Measurement), Table 1 Quantile incomes and growth, United States 1974–2004

	q-quantile		
q	1974	2004	Growth
10%	$9,741	$10,927	12.2%
20%	$16,285	$18,500	13.6%
50%	$37,519	$44,389	18.3%
80%	$64,781	$88,029	35.9%
90%	$83,532	$120,924	44.8%
95%	$102,534	$157,185	53.3%

Inequality (Measurement), Table 2 Growth in average incomes for the five quintile groups and overall. United States, 1974–2004

	Average income		
Group	1974	2004	Growth
1st	$9,324	$10,264	10.1%
2nd	$23,176	$26,241	13.2%
3rd	$37,353	$44,455	19.0%
4th	$53,944	$70,085	29.9%
Top	$95,576	$151,593	58.6%
Overall	*$43,875*	*$60,528*	*38.0%*

Note: Columns 2, 3 give the average incomes of the bottom fifth, second fifth, ... Incomes are in 2004 dollars; the income-receiving unit is the household. *Source*: as for Table 1.

in the top fifth grew by 58.6 per cent. We return to the use of the concepts of quantiles and shares after introducing some of the technical equipment needed for analysing income distributions.

The thumbnail sketch suggests a substantial increase in inequality in the United States over the last quarter of the 20th century. But how much did inequality increase? In what ways can the impressionistic method of inequality comparisons suggested in the example be made precise and interpreted within the context of standard economic analysis? The purpose of this article is to provide a succinct overview of the role played by economic theory and other abstract principles in this class of problem and how to make sense of inequality comparisons such as those suggested in the example.

The sketch example in Tables 1 and 2 also illustrates some of the essential practicalities that have to be taken into account when implementing the principles of inequality measurement. Should we be focusing on households or individuals? What is the appropriate definition of income?

To follow the analysis there are few prerequisites: an understanding of utility and preference analysis is helpful but not essential to grasping the basic points that will be discussed.

Basics

Components of the Problem

The framework adopted here is not the most general approach, but one that is suitable for setting out the key ideas. We begin by considering the basic building blocks and then show how to assemble the constituent parts.

Income and Income Distribution

At the heart of the problem there is some scalar entity to be called 'income', but in practice this entity could be wealth, expenditure or some other economic quantity, the distribution of which is of particular interest. Income is distributed among a number of 'income receivers', which we will refer to as 'persons' (although the income receiver in practice may be a family or household). Suppose that there is a known number of income receivers n and that person i has income x_i. The *income distribution* is then simply the vector

$$\mathbf{x} = (x_1, x_2, \ldots, x_n). \tag{1}$$

The set of all possible income distributions X is a subset of $\mathbb{R}^n$. The nature of X is going to depend in practice upon the precise definition of 'income': is it logically possible to have a zero value of x_i, for example? Or a negative value? As a working assumption we will take it that X consists of all vectors (1) such that $x_i \geq \underline{x}$ and leave open the specification of the lower bound $\underline{x}$ for particular instances of the inequalitymeasurement problem. Representations of the income distribution other than (1) will appear later in the discussion.

Indices

The topic of inequality measurement presumes that there is an inequality measure. An obvious interpretation of this is that there is some index I that, given a particular income distribution $\mathbf{x}$, yields a real number that is taken to be the amount of inequality exhibited by the distribution. In some ways the index I works like other well-known summary statistics of distributions, such as the mean

$$\mu(\mathbf{x}) := \frac{1}{n}\sum_{i=1}^{n} x_i \tag{2}$$

and the variance

$$\mathrm{var}(\mathbf{x}) := \frac{1}{n}\sum_{i=1}^{n} [x_i - \mu(\mathbf{x})]^2. \tag{3}$$

Indeed, the variance itself is sometimes used as an inequality index, although it is more common to use a transformed version of it known as the *coefficient of variation*:

$$I_{\mathrm{CV}}(\mathbf{x}) := \frac{\sqrt{\mathrm{var}(\mathbf{x})}}{\mu(\mathbf{x})}. \tag{4}$$

One of the most commonly used indices in practice is the *Gini coefficient* defined as

$$I_{\mathrm{Gini}}(\mathbf{x}) := \frac{1}{2n^2\mu(\mathbf{x})}\sum_{i=1}^{n}\sum_{j=1}^{n} |x_i - x_j|. \tag{5}$$

There are many more. However, rather than running through an exhaustive list of candidate

indices it is more useful to examine the principles that have usually been applied to construct indices; this we do by considering a priori what constitutes a 'suitable' inequality measure, the issue addressed in section "Axioms".

Ranking and Dominance

An apparently more flexible interpretation of the idea of inequality measurement is the idea of an inequality *ranking*. This is a partial ordering that picks up the general flavour of the kind of comparisons that we suggested in the introduction; the partial ordering is typically captured by a simple representational tool. Consider three of these.

The first of these tools is *Pen's parade* (named after the famous parable introduced by Pen 1974, ch. 3), which is simply the inverse of the empirical distribution function. To depict it let $x_{[i]}$ denote the ith smallest component in the vector (1) – the ith smallest income. Then take the collection of points

$$\left(\frac{1}{n}, x_{[i]}\right), \quad i = 1, 2, \ldots, n. \tag{6}$$

From this simple definition we can also introduce the idea of dominance. Take two distributions $\mathbf{x}'$ and $\mathbf{x}''$ in X where $\mathbf{x}' = (x'_1, x'_2, \ldots, x'_n)$ and $\mathbf{x}'' = (x''_1, x''_2, \ldots, x''_n)$. If it is true that $x'_{[i]} > x''_{[i]}$ for all $i = 1, 2, \ldots, n$ then we say that $\mathbf{x}'$ strictly Parade-dominates $\mathbf{x}''$.

The resulting graph plots income quantiles against population proportions: $x_{[i]}$ is the quantile corresponding to the bottom q per cent of the population where $q = 100\frac{i}{n}$. To illustrate the concept we use the information in Table 1 to produce a graph that looks like Fig. 1. In Pen's parable we imagine the whole population (seen as individuals rather than households) arranged in order on the [0,1] interval where each person's height has been altered in proportion to his/her income; the average-height income recipient in 1974 is located at position 0.57 in Fig. 1 (in other words, at a point 57 per cent along the horizontal axis the height of the Parade is exactly mean income) but in 2004 the average-height income recipient is located at position 0.61. Although the distribution of 2004 Parade-dominates the distribution in 1974, it is clear from Table 1 that overall the Parade shifted upwards in a lopsided fashion over the 30 years with the incomes of the very rich (95 per cent quantile) growing more than four times faster than those of the poor (10 per cent quantile); this shift suggests increased inequality over the period. However, by itself the Parade does not tell us much about inequality directly, although concepts closely related to it are widely used to characterize inequality comparisons. It is common to use *quantile ratios* for distributional comparisons: for example the popular '90–10 ratio' is given by $x_{[k]}/x_{[j]}$ where j and k are, respectively, the smallest integers satisfying $j/n \geq 10\%$ and $k/n \geq 90\%$: in the example above this ratio increased from 8.6 to 11.1. Furthermore, there is an important welfare-economic interpretation of the Parade that is discussed in section "Ranking Distributions" below.

For the second and third concepts we use the $x_{[i]}$ to derive the normalized income cumulations; for any $i = 1, 2, \ldots, a$ these are

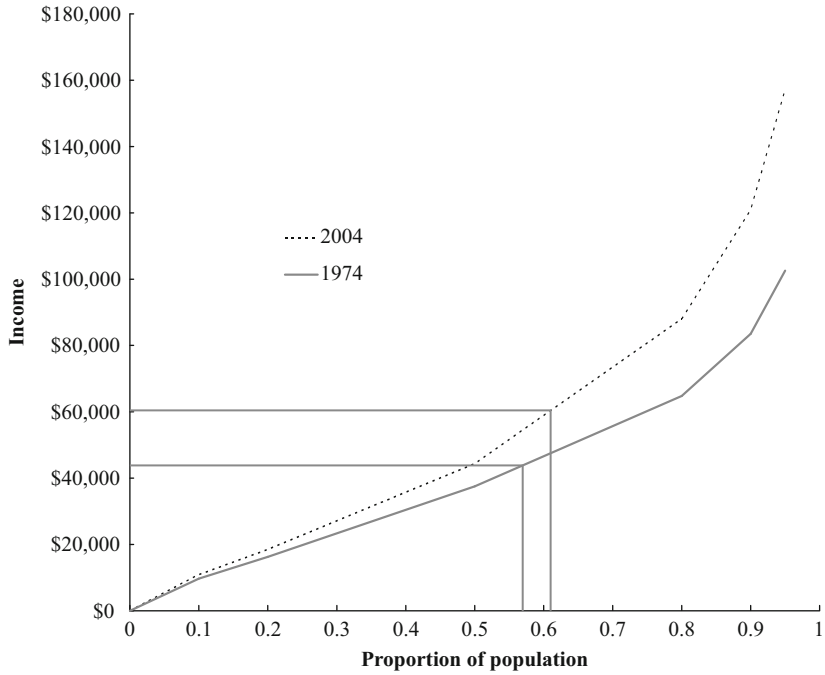
$$c_i := \frac{1}{n}\sum_{j=1}^{i} x_{[j]}. \tag{7}$$

Then the *generalized Lorenz curve* (GLC) is given by the graph of

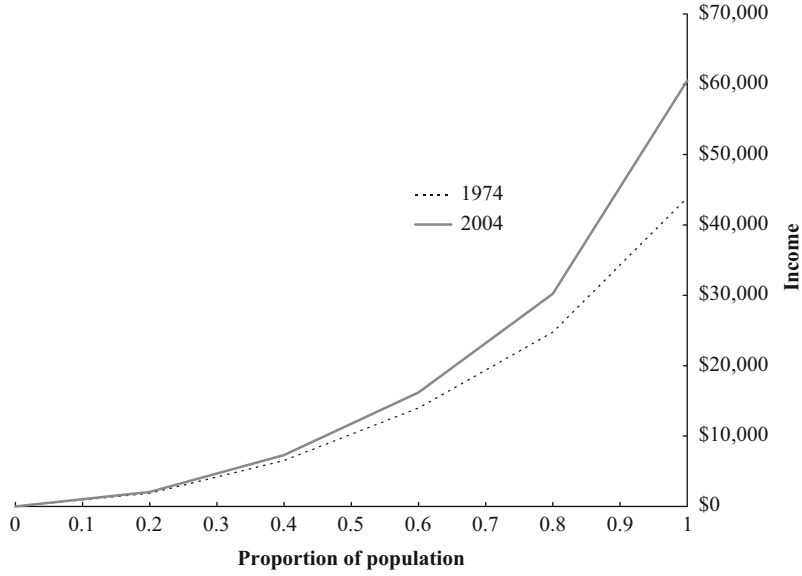
$$\left(\frac{i}{n}, c_i\right), i = 1, 2, \ldots, n. \tag{8}$$

Again we have a natural definition of dominance: for two distributions $\mathbf{x}'$ and $\mathbf{x}''$ in X if it is true that $c'_i > c''_i$ for all $i = 1, 2, \ldots, n$ then we say that $\mathbf{x}'$ strictly GLC-dominates $\mathbf{x}''$. For the example we used earlier the GLC is illustrated in Fig. 2, derived from Table 2. (Note that the definitions of Parade- and GLC-dominance can be extended to cases where the two distributions do not have the same number of incomes – this step makes use of the 'population principle' defined in section "Axioms". In some cases it is useful to consider the weak – non-strict – versions of the dominance criteria introduced here.)

The GLC plots the normalized income of the bottom $100q$ per cent of the population against q and, although the 2004 distribution GLC-dominates 1974, it is clear that over the period the growth of these group averages was not evenly distributed – the higher was q, the higher was the



Inequality (Measurement), Fig. 1 Parade diagram corresponding to Table 1 (*Source*: As for Table 1)



Inequality (Measurement), Fig. 2 Generalized Lorenz curve (*Source*: As for Table 1)

growth over 1974 to 2004. (This is easily inferred from Table 2: for example, the average income of the top 20 per cent grew almost six times as fast as the average income of the bottom 20 per cent.) Once again, although the GLC does not give information about inequality comparisons directly, there is an important welfare-economic interpretation (in section "Ranking Distributions"). In addition, a small modification of the GLC yields one of the central concepts of distributional analysis. Dividing c_i in (7)

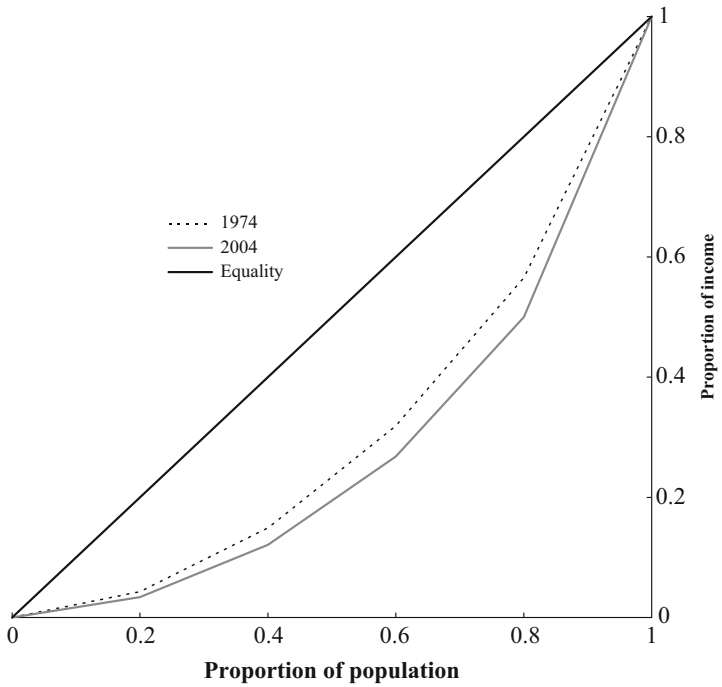
by the mean $\mu(\mathbf{x})$ gives the income share of the bottom $100\frac{i}{n}$ per cent of the population. The graph of the (population-proportion, income-share) pairs

$$\left(\frac{i}{n}, \frac{c_i}{\mu(\mathbf{x})}\right), i = 1, 2, \ldots, n \tag{9}$$

gives the *Lorenz curve*. Also, for two distributions $\mathbf{x}'$ and $\mathbf{x}''$, if it is true that, $c_i'/\mu(\mathbf{x}') > c_i''/\mu(\mathbf{x}'')$ for all $i = 1, 2, \ldots, n-1$ then we say that $\mathbf{x}'$ strictly Lorenz-dominates $\mathbf{x}''$. In the case of the example using US data this is illustrated in Fig. 3: the Lorenz curve plots the income share of the bottom $100q$ per cent of the population against q and the diagonal line depicts a hypothetical distribution of perfect equality. (Take the area trapped between the Lorenz curve and the equality diagonal. Using (7) and (9) we can show that the ratio of this area to the area of the whole triangle is given by the weighted sum $\sum_{i=1}^{n} \kappa_i x_{[i]}$ where the weights are $\kappa_i := [2i - 1 - n]/[n\mu(\mathbf{x})]$. This is exactly the Gini coefficient (5).) It is clear that for each q the share was smaller in 2004 than it was in 1974 – the 1974 distribution Lorenz-dominates that for 2004. This simple intuitive notion of greater inequality conforms exactly with a fundamental principle to be explained below.

Axioms

An inequality index I is in some ways like a utility function in consumer theory: it is a representation of an inequality ordering on the members of X and is usually taken to be continuous and ordinal – although there is often a 'natural' cardinal representation of a particular index, a formal argument for one representation rather than another is not usually provided (why not use the square or the log of the Gini coefficient?). Ordinality is sufficient for making comparing income distributions, the primary task of inequality analysis. Axioms are essentially formal statements of the principles of assessment that are used to give meaning to the ordering represented by I. The treatment here does not claim to generality; rather, it focuses on those principles that are central to modern approaches to inequality. Rather than presenting the axioms as formal statements, however, it is more useful here to introduce the underlying key principles discursively.



Inequality (Measurement), Fig. 3 Lorenz curve (*Source*: As for Table 1)

Assume that everywhere in the following discussion the vector **x** in (1) is any arbitrary member of the set X.

- First, it seems reasonable that the labelling of the components of **x** be irrelevant: it does not matter which income receiver gets which income. This means that I has the *symmetry* property:

$$\begin{aligned} I(x_1, x_2, \ldots, x_n) &= I(x_2, x_1, \ldots, x_n) \\ &= I(x_3, x_1, \ldots, x_n) = \ldots \end{aligned} \tag{10}$$

- We will always assume that this holds and we may therefore adopt the convention that incomes have been labelled such that $x_1 \leq x_2 \leq \ldots \leq x_{n\text{-}1} \leq x_n$.
- Second, we need some coherent way of characterizing inequality in differentsized populations. Perhaps the most obvious assumption is that simple replications of an income vector (1) leave inequality unchanged. This is the *population principle*:

$$\begin{aligned} I(x_1, x_2, \ldots, x_n) &= I(x_1, x_1, x_2, x_2, \ldots, x_n, x_n) \\ &= I(x_1, x_1, x_1, x_2, x_2, x_2, \ldots, x_n, x_n, x_n) = \ldots \end{aligned} \tag{11}$$

Taken in conjunction with symmetry this allows one to represent distributions purely in terms of a distribution function.

A key assumption that is commonly invoked focuses on the effect on inequality of a hypothetical small income transfer. Suppose $x_i < x_j$ and consider some positive number δ such that $x_i - \delta \geq \underline{x}$, then the *principle of transfers* (Dalton 1920) requires that:

$$\begin{aligned} &I(x_1, \ldots, x_i, \ldots, x_j, \ldots, x_n) \\ &\times < I(x_1, \ldots, x_i - \delta, \ldots, x_j + \delta, \ldots, x_n) \end{aligned} \tag{12}$$

  - a poorer-to-richer income transfer will always increase inequality.

As a counterpart to the assumption relating to different sizes of population (eq. 11) it is useful to have an assumption relating to different amounts of total income. The standard assumption is that of *scale independence*. This requires that, for any scalar $\lambda > 0$:

$$I(\lambda x_1, \lambda x_2, \ldots, \lambda x_n) = I(x_1, x_2, \ldots, x_n) \tag{13}$$

  - double all incomes or halve all incomes and inequality is left unaltered.

An alternative assumption that is sometimes used is *translation independence*. Take any real number δ such that $x_1 + \delta \geq \underline{x}$; then

$$\begin{aligned} &I(x_1 + \delta, x_2 + \delta, \ldots, x_n + \delta) \\ &= I(x_1, x_2, \ldots, x_n) \end{aligned} \tag{14}$$

  - add or subtract one dollar from every income and inequality is left unaltered.

Clearly this brief list raises some important questions. Why use these particular axioms? Some of them appear to be quite strong; for example, although scale independence seems attractive if the 'incomes' x_i here are measured in dollars and we consider just dividing through by some rate of exchange so as to work with incomes in some other monetary units, it may seem less attractive if we want to consider the impact on inequality of redistribution policies at different stages of economic growth: a rearrangement of income shares that constitutes a reduction in inequality in a low-income society might not be considered as a reduction in inequality if the whole population is prosperous. Furthermore, the axioms captured by Eqs. (10), (11), (12), and (13), for example, are satisfied by both (4) and (5) as well as other important classes of inequality measures; on the other hand, the axioms captured by Eqs. (10), (11), (12) and (14) are satisfied by (3) and another rich class of inequality measures. Following on from this question, what more is required to get a specific index or well-defined family of indices that is both theoretically appropriate and practical to implement?

To answer this we need to be precise about what it means to say that one distribution is more unequal than another and the intellectual basis used for making such comparisons. The meaning of inequality can be further clarified through one of several routes: this article will analyse three of these in turn, namely, social welfare, decomposition, income differences.

Social Welfare and Inequality

The welfare-economic approach to the subject starts from the position that inequality is about 'illfare' – the opposite of welfare. If we adopt this approach then the definition of inequality follows almost immediately. The idea is similar to the conventional measurement of economic waste and the basis for a simple model can be laid with only a little more theorizing.

The *social-welfare function* (SWF) is a real-valued function W defined on the space of distributions X. The social welfare associated with a particular income distribution (1), given by

$$W(x_1, x_2, \ldots, x_n), \tag{15}$$

is to be interpreted as follows: suppose we are given a specific SWF $W(\,)$ and that for two separate income distributions $\mathbf{x}'$ and $\mathbf{x}''$ we have $W(\mathbf{x}') > W(\mathbf{x}'')$; then social welfare associated with the distribution $\mathbf{x}'$ is higher than the social welfare associated with the distribution $\mathbf{x}''$. In principle W is an ordinal function so that the scale of measurement of welfare levels can be subjected to arbitrary monotonic-increasing transformations.

This basic specification raises a number of important questions:

Why express social welfare as a function of income? Income defined how?

What particular form should W take?

What is the relation between the functions I and W?

The answer to the first question helps to pin down the relationship between inequality measurement as conventionally practised and standard welfare economics – see section "Introduction". The answers to the last two questions will determine the form of a class of inequality measures and permit us to establish some important welfare-economic results: these are addressed in sections "Basics" and "Social Welfare and Inequality".

Welfare and Income

We need to rectify a point that was fudged in the discussion of the US example: how to do the trick of passing from a distribution of dollar income among households to a standard welfare analysis that is typically concerned with the levels of economic well-being of individuals. The standard approach is as follows. We require a method of appropriately capturing the relationship between the living standard that is attainable by an individual and the income that he/she is presumed to have access to within the household. This is conventionally done by defining a function $v(.)$ that has as its argument a list of non-income attributes $\mathbf{a}$ that might include household size, age and sex of household members and health status; $v(\mathbf{a})$ determines the number of *equivalent adults* in the household with attributes $\mathbf{a}$ such that

$$x = \frac{y}{v(\mathbf{a})}, \tag{16}$$

where y is nominal income and x is *equivalized income* that is taken to be comparable across different household types. Note that the equivalization function v is typically specified as independent of income although this simplification is not essential; of course, the way in which the function v is determined – from ethical considerations or econometric studies – is an important issue in its own right, but one that lies outside the present discussion. The function v transforms a distribution of dollar incomes among n households

$$\mathbf{y} = (y_1, y_2, \ldots, y_n) \tag{17}$$

into a distribution of equivalized incomes by households given by (1). In order to complete the welfare interpretation we need to recognize that social-welfare considerations are usually represented in terms of individuals rather than households, and so, for example, households consisting of couples should receive more weight in social-welfare evaluations than households consisting of single individuals. Therefore, if the income-receiving units consist of households of differing size, we might want to represent this by introducing a corresponding set of population weights w_i for the observations, so that the distribution becomes an ordered list of pairs:

$$((w_1, x_1), (w_2, x_2), \ldots, (w_n, x_n)) \tag{18}$$

I

where w_i is the number of persons in household i divided by the number of persons in the whole population. There is little analytical complication in using (18) rather than (1) as a representation of the distribution of equivalized incomes by individuals. Typically it is just a matter of a minor redefinition of formulas for inequality measures and the like: for example, the coefficient of variation (4) would now be written

$$\sqrt{\sum_{i=1}^{n} w_i \left[\frac{x_i}{\mu} - 1\right]^2} \tag{19}$$

where μ is the appropriately redefined mean $\sum_{i=1}^{n} w_i x_i$. (More generally: all measures that can be written in the form $\Phi\left(\frac{1}{n}\sum_{i=1}^{n}\varphi(x_i), \mu\right)$ just need to be rewritten in the form $\Phi\left(\sum_{i=1}^{n} w_i\varphi(x_i), \mu\right)$. A similar modification applies to the Gini coefficient.)

However, having introduced this important theoretical qualification we will now neglect it – for expositional purposes it is convenient to assume (*a*) that the population consists of isolated individuals that are identical in every relevant respect other than income and (*b*) that income appropriately represents individual welfare. So, from here on, i indexes individuals or households and the distinction between x and y is dropped.

Social Welfare and Inequality Measures

The idea of the SWF was introduced without discussing specific properties of the function W. Some properties must be imposed on W if we require there to be a specific relationship between social welfare and inequality and we impose specific assumptions on the function I. However, in addition it is particularly important to be explicit about how W should respond to an increase in one or more incomes. This is the usual principle that is applied:

Suppose we consider any income distribution $(x_1, x_2, \ldots, x_n)$ and some positive number δ. Then *monotonicity* requires that:

$$W(x_1, x_2, \ldots, x_i + \delta, \ldots, x_n) > W(x_1, x_2, \ldots, x_i, \ldots, x_n) \tag{20}$$

On the assumption that monotonicity holds and that W is a continuous function, the SWF can itself be used to derive a family of inequality measures. There are several ways of doing this, but a standard approach is to represent social welfare using a money metric: we can always do this in view of the ordinal nature of W and the requirement that it be monotonic and continuous. The *equally distributed equivalent* (EDE) income is a real number ξ such that for any $(x_1, x_2, \ldots, x_n)$ in X:

$$W(\xi, \xi, \ldots, \xi) = W(x_1, x_2, \ldots, x_n). \tag{21}$$

(Note that monotonocity is unnecessarily strong for this step: for example one could define ξ in cases where one required only that W is increasing if *all* incomes are increased by δ, not just if *some* income is increased by δ. However, the assumption of monotonicity is useful for other results that follow.)

Clearly the relationship (21) can be used to derive EDE as a function of the income distribution, $\xi(\mathbf{x})$ and the function $\xi(\ )$ is a valid way of representing social welfare.

Suppose we require that the principle of transfers apply to W; this by analogy with (12) means that a mean-preserving poorer-to-richer income transfer will *decrease* social welfare. Then it is always true that $\xi(\mathbf{x}) \leq \mu(\mathbf{x})$ and the normalized gap between ξ and μ provides a natural basis for an inequality index

$$1 - \frac{\xi(\mathbf{x})}{\mu(\mathbf{x})}. \tag{22}$$

It is clear that this index is bounded between zero and 1 and that if there were perfect equality then we would have $\xi(\mathbf{x}) = \mu(\mathbf{x})$ and inequality in (22) would be zero.

Furthermore, if the scale-independence property (13) is also satisfied, then EDE income takes the form of a generalized mean:

$$\xi(\mathbf{x}) = \left[\frac{1}{n}\sum_{i=1}^{n} x_i^{1-\varepsilon}\right]^{\frac{1}{1-\varepsilon}}, \varepsilon > 0 \tag{23}$$

and (22) gives the class of *Atkinson indices*:

Inequality (Measurement), Table 3 Inequality indices for the example in Table 1

	1974	2004
$I_{\mathrm{A}}^{0.25}$	0.067	0.097
$I_{\mathrm{A}}^{0.5}$	0.134	0.190
$I_{\mathrm{A}}^{0.75}$	0.207	0.286
I_{A}^{1}	0.297	0.418
I_{Gini}	0.395	0.466
I_{GE}^{0}	0.352	0.542
I_{GE}^{1}	0.267	0.406

$$I_A^{\varepsilon}(\mathbf{x}) := 1 - \left[\frac{1}{n}\sum_{i=1}^{n}\left[\frac{x_i}{\mu(\mathbf{x})}\right]^{1-\varepsilon}\right]^{\frac{1}{1-\varepsilon}}. \qquad (24)$$

(The limiting forms of (23) and (24) as $\varepsilon \to 1$ are, respectively,

$$\xi(\mathbf{x}) = \exp\left(\frac{1}{n}\sum\nolimits_{i=1}^{n}\log(x_i)\right) \text{ and } I_A^1(\mathbf{x}) = 1 - \exp\left(\frac{1}{n}\sum\nolimits_{i=1}^{n}\log(x_i)\right)/\mu(\mathbf{x}).)$$

The number ε– the degree of (relative) inequality aversion – is a parameter that characterizes individual members of the class of inequality measures. For any given unequal income distribution, the larger is ε the larger is the Atkinson inequality index – there is an example of this in Table 3 above. There is a close analogy with a class of risk indices in the case of constant relative risk aversion. This is unsurprising since this approach was explicitly founded on the formal similarity between distributional comparisons in terms of inequality and of risk (Atkinson 1970).

If, instead of the scale-independence property, we required I to satisfy translation independence (14), then we would obtain a different class of indices

$$I_{\mathrm{K}}^{\beta}(\mathbf{x}) := \frac{1}{\beta}\log\left(\frac{1}{n}\sum_{i=1}^{n}e^{\beta[x_i-\mu(\mathbf{x})]}\right) \qquad (25)$$

where $\beta > 0$ is a sensitivity parameter indexing members of the class (Kolm 1976). The connection of (25) with constant absolute risk aversion is evident. (One could also use 'regularity' assumptions other than scale- or translation-independence – see Bossert and Pfingsten 1990.)

Ranking Distributions

As noted earlier, there are important results available about welfare and inequality comparisons that do not require the usage of specific indices. They follow from standard first- and second-order dominance results that are familiar from finance and other disciplines. Take the special class of *additive* welfare functions where W in (15) can be written in the form $\sum_{i=1}^{n} u(x_i)$ for some function u. If W is additive and satisfies the monotonicity axiom, then u must be a strictly increasing function; if, furthermore, W satisfies the principle of transfers then u must be strictly concave. Then the following powerful results are available for any two distributions $\mathbf{x}'$ and $\mathbf{x}'' \in X$:

- *First-order*: $\mathbf{x}'$ strictly Parade-dominates $\mathbf{x}''$ if and only if $W(\mathbf{x}') > W(\mathbf{x}'')$ for any additive W that satisfies the principle of monotonicity.
- *Second-order*: $\mathbf{x}'$ strictly GLC-dominates $\mathbf{x}''$ if and only if $W(\mathbf{x}') > W(\mathbf{x}'')$ for any additive W that satisfies monotonicity and the principle of transfers (Shorrocks 1983).

(From the statement of these results it is clear that the Parade-dominance and GLC-dominance criteria are formally equivalent to first-order and second-order stochastic dominance in the analysis of probability distributions – see stochastic dominance.)

A version of the second-order result applies to the conventional Lorenz curve and it accords with the intuitive argument presented in the introduction. Take the class of SWFs that satisfy the principle of transfers (they do not have to be additive). Then, for two distributions $\mathbf{x}'$ and $\mathbf{x}''$ that have the same mean, the statement '$W(\mathbf{x}') > W(\mathbf{x}'')$ for any W in this class' is true if and only if $\mathbf{x}'$ strictly Lorenz-dominates $\mathbf{x}''$. Furthermore, under these circumstances for any inequality index I that satisfies the principle of transfers it must be the case that $I(\mathbf{x}') < I(\mathbf{x}'')$. The implication of this is that all inequality measures that satisfy the principle of transfers 'go the same way' if one distribution

Lorenz-dominates the other. This is illustrated in Table 3 (which again uses the distribution of household income by households). Rows 1 to 4 give the results for the Atkinson indices: notice that in each case measured inequality is closer to 1 (the maximum) the higher is the degree of inequality aversion. The indices in the last two rows of Table 3 are discussed in the next section.

Decomposition

The axioms discussed in section "Axioms" induced some structure on inequality measures. By introducing the idea of *decomposing* inequality we can impose more structure and thereby obtain a useful class of indices. There are two principal types of decomposition: by subgroups of the population (regions, age groups,...) and by components of income (labour income, income from capital,...). Here we focus just on the population-subgroup issue.

Imagine that the population of n persons can be partitioned into a collection of m groups so that any individual falls into just one of these m groups. Each group j could be considered as a sub-population of size n_j in its own right (where $\sum_{j=1}^{m} n_j = n$) and one could compute inequality within this subpopulation as

$$\iota_j = I(\mathbf{x}_j) \tag{26}$$

where $\mathbf{x}_j$ is the income distribution consisting of just the members of subgroup j. The essence of the decomposition problem is to represent inequality overall as a function of inequality in each group $j = 1, \ldots, m$

$$I(\mathbf{x}) = F(\iota_1, \iota_2, \ldots, \iota_m; \pi_1, \ldots, \pi_m, s_1, \ldots, s_m) \tag{27}$$

where F is an aggregation function and the terms after the ';' show that aggregation may depend on the groups' shares of the population $\pi_j := n_j/n$ and the groups' shares of total income $s_j := n_j\mu(\mathbf{x}_j)/n\mu(\mathbf{x})$. A consistency requirement on (27) is that, if the income distribution within subgroup j changes so as to increase ι_j in (26), all other things remaining the same, then inequality overall should increase. Insisting on this requirement on F for all logically possible partitions induces a type of separability on the function $I(\,)$ so that the index must be of the general form mentioned just after Eq. (19) above. If we also require that scale-independence hold, then the inequality index must take the specific form

$$I^{\alpha}_{\mathrm{GE}}(\mathbf{x}) = \frac{1}{\alpha^2 - \alpha}\left[\frac{1}{n}\sum_{i=1}^{n}\left[\frac{x_i}{\mu(\mathbf{x})}\right]^{\alpha} - 1\right] \tag{28}$$

or some monotonic transform of it, where α is a real number. The 'GE' used in the labelling of (28) stands for the *generalized entropy* class, which is a generalization of the two indices introduced by Theil (1967). (Theil's two indices are those corresponding to the special forms in the cases $\alpha = 0, 1 : I^{0}_{\mathrm{GE}}(\mathbf{x}) := -\frac{1}{n}\sum_{i=1}^{n}\log(x_i/\mu(\mathbf{x}))$ and $I^{1}_{\mathrm{GE}}(\mathbf{x}) = \frac{1}{n}\sum_{i=1}^{n}[x_i/\mu(\mathbf{x})]\log(x_i/\mu(\mathbf{x}))$. The values of these indices for the US example are given in the last two rows of Table 3.) The α in (28) is a parameter that characterizes different members of the GE class: a high positive value of α yields an index that is very sensitive to income transfers at the top of the distribution; specifying a negative value will produce an index that is sensitive to income transfers among the poor. (There is a functional relationship between the class (24) and the class (28). For any $\alpha < 1$ we have $I^{\varepsilon}_{A}(\mathbf{x}) = 1 - \left[1 + \alpha[\alpha - 1]I^{\alpha}_{\mathrm{GE}}(\mathbf{x})\right]^{1/\alpha}$ where $\varepsilon = 1 - \alpha$.)

Income Differences

The third way forward from the basic argument outlined in section "Axioms" focuses on fundamental income differences. This is one of the key ways in which one can motivate usage of the very well-known inequality indices mentioned in section "Indices". The variance and the coefficient of variation (4) can be thought of as a representation of the averaged squared difference between each income x_i and the mean. A compelling argument for the Gini coefficient is that it is the (normalized) expected value of the absolute difference between any two randomly selected incomes in the population.

However, there are other types of income difference that are of special relevance to inequality measurement. Just as some poverty indices can be characterized as a kind of average distance of individual incomes from a reference income level – the poverty line (many poverty indices can be written in the form $\frac{1}{n}\sum_{i=1}^{n} p(z - x_i)$ where z is the poverty line and $p(\ )$ is a non-decreasing function that is zero for all $x_i \geq z$) – so also some inequality measures use the idea of a reference level income. In the case of inequality the reference income level has been suggested as either that of the best-off person in society, or of the average income of all those who are better off than any given person i (Temkin 1993). In each of these cases application of standard axioms about the structure of inequality orderings leads to a class of inequality indices that bears a functional similarity to poverty indices and to indices of relative deprivation (Cowell and Ebert 2004).

Implementation

The practical issues associated with the exposition of the example in Tables 1 and 2 highlight some of the problems in implementing inequality measures and associated tools – the definition of income, income receiver, and so on. Given the way in which income data are usually obtained, issues of sampling and measurement error usually need to be treated carefully. Furthermore, the special nature of income and wealth distributions and the sensitivity of inequality indices to very high or very low incomes usually require that particular attention be paid to the problem of outliers. Finally, it should be noted that it is still sometimes the case that the data required for estimating inequality indices are made available only in grouped form rather than as microdata so that special techniques may be required for interpolation within income intervals and for modelling the tails of the distribution.

I

Inequality Between Nations

François Bourguignon

Abstract

Inequalities between nations are large but determining their magnitude and whether they have increased or decreased over time is not a simple matter. The conclusions that one reaches depend on the concept of inequality that one uses and on the point of view that one adopts.

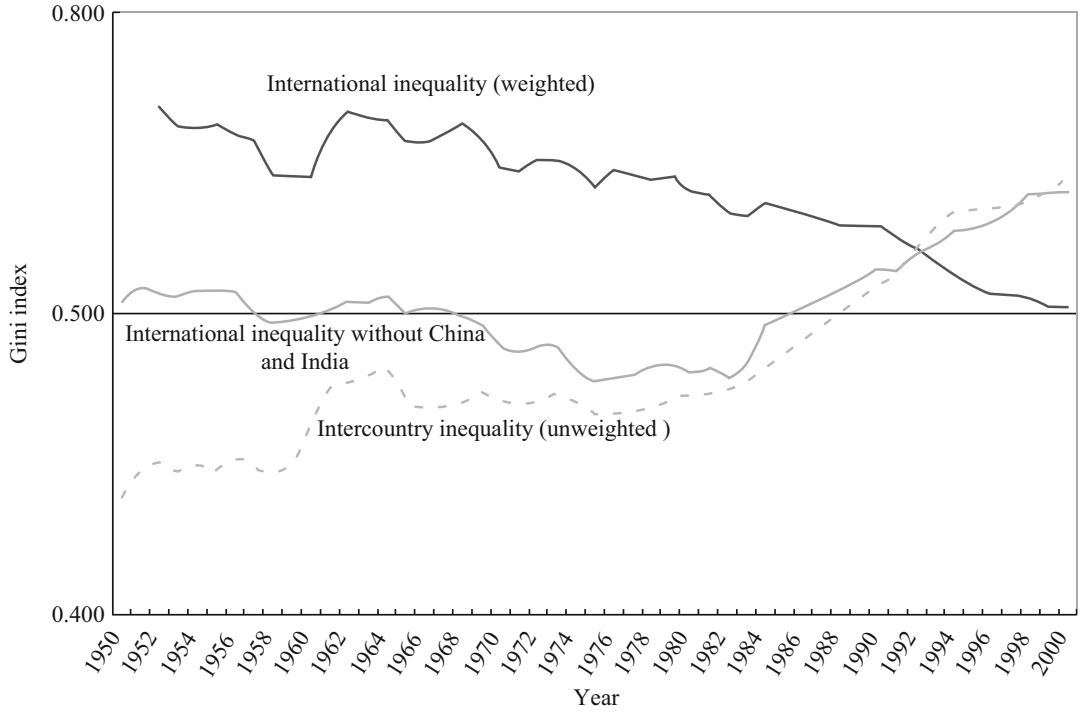
It is useful to distinguish three different concepts of world inequality (see Milanovic 2005; Bourguignon et al. 2004). The *inter-country* distribution measures the level of inequality across representative citizens of each country in the world. This is a distribution of unweighted gross national income (GNI) per capita. The *international* distribution uses country GNI per capita *weighted* by their population size: it measures the inequality in the distribution of the world's citizens if each citizen were assigned the average income of the country in which he or she resides, adjusted for purchasing power parity, instead of his or her own income.

Finally, there is the *global* distribution of individual incomes. This third concept lines up all citizens of the world (not countries) and calculates the distribution of their actual incomes, adjusted for purchasing power parity. *Global* inequality can be decomposed into inequality attributable to inequalities *within country* – that is, among persons within each country – and the differences of mean income *between countries*, that is *international* inequality.

The first section of this article describes the evolution of world inequality according to these various definitions and shows that they lead to somewhat contradictory conclusions, with inter-country inequality rising more or less continuously since the 1950s, international inequality declining, and global inequality increasing until the late 1980s and falling somewhat afterwards. The reason for these differences is easily understood, and has to do with population weights and the role played by giant developing countries like India or China and, to a lesser extent, with the evolution of inequality within countries. The second section tries to reconcile these various views on the evolution of world inequality by considering the mobility of world citizens within the income scale – this is similar to watching a movie rather than photographs of the world distribution of income at various points of time. The final section extends the income framework by providing some information on the evolution of world inequalities in a few non-income dimensions.

Evolution of World Inequality According to Alternative Definitions

The evolution of inter-country and international inequality between 1950 and 2000 is shown in Fig. 1, which shows that world income inequality, as measured by the Gini index, has been a story of increasing inter-country inequality and declining international inequality. (The Gini index is probably the most widely used measure of inequality. In theory it varies between 0 – perfect equality – and 1 – perfect inequality. Practically, it ranges from .20 to .25 in most egalitarian countries like the Nordic countries, and .6 or slightly more for the most inegalitarian countries in the world (for instance, Brazil or South Africa). Other measures are used below because of their decomposability property. But the evolution of the various definitions of world inequality is the same whatever the



Inequality Between Nations, Fig. 1 Inter-country and international distribution of income, 1950–2000 (*Source*: Milanovic 2005)

inequality measure being used.) A 20-year plateau was reached for inter-country inequality starting in the early 1960s, but the unequalizing trend resumed with the crisis of the world economy in the early 1980s. Due to differential demographic growth, no plateau is observed in the decline of the international inequality, but it can be seen that, since the 1987 or so, this decline is essentially fuelled by the fast growth of the two giant developing countries, namely, China and – to a lesser extent – India.

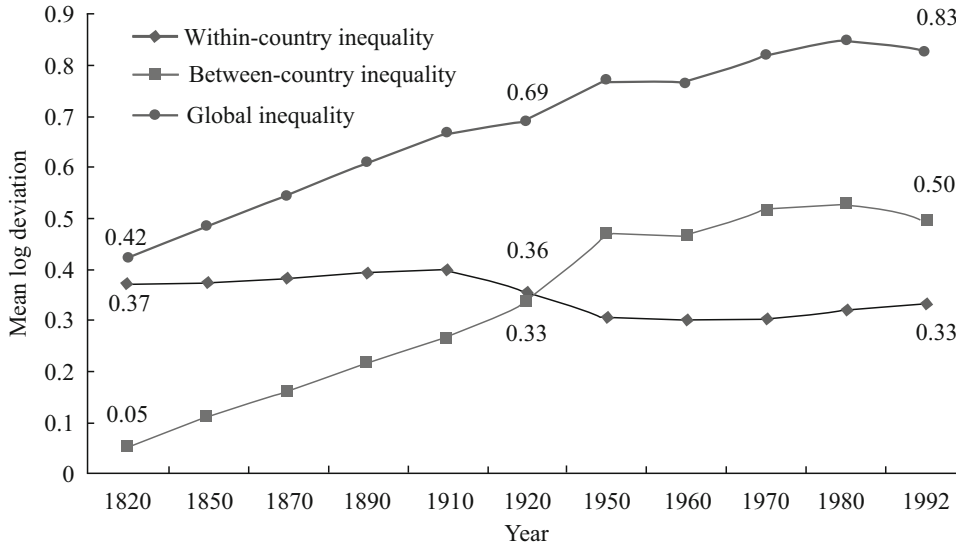
As China and India catch up to the world average, their equalizing effect on the international distribution of income will diminish. If they continue to develop at similar rates than in the past two decades, the effect of their growth will soon be unequalizing (Sala-i-Martin 2002c). Both inter-country and international inequality will then most likely increase unless countries at the bottom of the two distributions – sub-Saharan African economies in particular – begin to experience healthy growth. This suggests that, in the future, whether the world income distribution is equalizing or unequalizing will increasingly be a function of economic growth in Africa (and some other low-income countries), especially if population growth rates in Africa remain above world average.

To estimate *global* inequality, some knowledge of the distribution of inequality within each country is necessary. Producing estimates for long periods requires strong assumptions. Bourguignon and Morrison (2002) measure global inequality over 1820–1992 using historical estimates of countries' GDP per capita and rough figures on the distribution of income by deciles within countries to estimate the global distribution of income. They use income distribution information for a limited number of countries and assume that geographically and culturally similar countries or groups of countries have the same distributions. They then reconstitute the global distribution by assuming that individuals in each decile of a country's distribution have the same

income. With this method they estimate that the Gini coefficient for the global distribution increased from approximately 5 in 1820 to 66 in 1992, making today's world more probably more unequal than any single country. The mean logarithmic deviation shows the same dramatic evolution of global inequality in Fig. 2. But, because, this measure is decomposable into *within* and *between- country* inequality, it permits a better understanding of the forces behind that evolution. In particular, it turns out that *international* inequality was negligible at the turn of the 19th century (accounting for roughly 12 per cent of global inequality) but increased very rapidly until the Second World War. It then stabilized and started to decline after 1980. (The difference with Fig. 1 where international inequality declines more or less continuously after 1960 is due to the definition of countries – 33 'country groups' in Bourguignon and Morrisson as against 120 countries in Milanovic – and to the fact that Bourguignon and Morrisson considered discrete years rather than the whole annual series – for instance, 1960 is a 'low' point in the series shown in Fig. 1). Within country inequality, however, reached its peak around 1910 and declined dramatically (mainly due to equalizing forces in the now developed countries) between the two world wars, and started creeping back up only after the 1970s. The combined effect of these changes is an increase in the share of international inequality from roughly ten per cent in 1820 to more than 60 per cent by 1992.

For the recent past, trends in global inequality can be estimated using information from household surveys – which, for developing countries, have been available at regular time intervals only since the 1980s. Inequality within a country cannot increase drastically and indefinitely over the long term. Therefore, even though strong assumptions have to be made, Fig. 2, in which the evolution of the international inequality dominates, probably approximates rather well actual long- term trends. The same cannot be said for shorter periods. At the same time, estimates of global inequality become more uncertain over short time intervals because of problems of measurement and comparability between surveys for different countries or at different points of time.

What happened to global inequality in the recent past has been the subject of fierce debate in the context of globalization. In terms of method, Sala-i-Martin (2002a, b) uses an

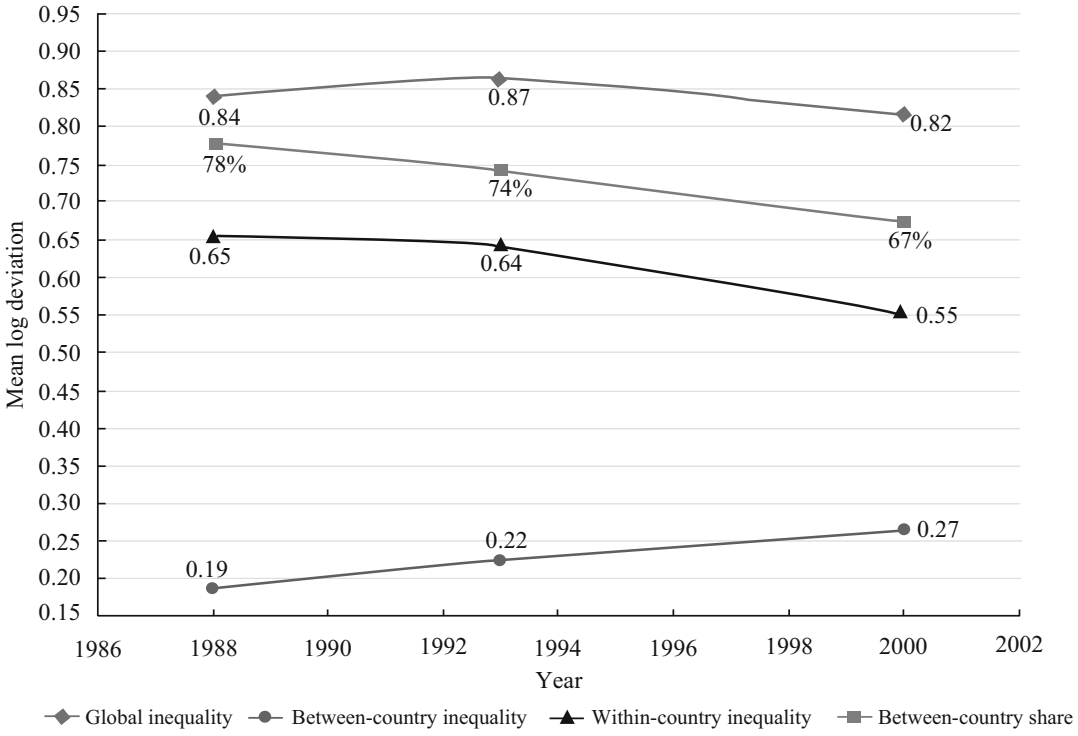


Inequality Between Nations, Fig. 2 Decomposition of global inequality into within-country and between- country inequality over a long period, 1820–1992 (*Sources*: Bourguignon and Morrison 2002; World Bank 2005)

approach that is similar to Bourguignon and Morrison (2002), combining GDP per capita figures and a constant rough continuous approximation of the distribution of income. Milanovic (2005) uses another method, estimating the parameters of country distributions on the basis of some predetermined functional form and grouped data from all available (comparable) household surveys over the 1980s and 1990s (which cover more than 90 per cent of the world population and world GNI). The sample of countries also differs non- marginally between the two studies.

In a three year comparison, Milanovic (2005) finds that global inequality increased slightly between 1988 and 1993 and then declined between 1993 and 1998. Sala-i-Martin (2002b, c) and others (see, for example, Bhalla 2002; Firebaugh and Goesling 2004) argue that it has declined. By and large, however, global inequality did not change much in 1988–2000. In all existing studies, variations of inequality do not exceed a few percentage points, whatever the inequality measure being used. This is in strong contrast with what was observed historically until the Second World War.

The latest and probably the most comprehensive estimate in terms of income distribution data being used is the World Bank (2005) – see Fig. 3. It confirms the evolution found by Milanovic. In agreement with Fig. 1, it also indicates that the share of global inequality that can be attributed to inequality between countries or *international* inequality declined steadily from 77 per cent around 1988 to 72 per cent around 1993 and to 67 per cent by around 2000. As global inequality stayed roughly the same during this time period, within-group inequality increased at a somewhat steady pace. These results are consistent with international inequality decreasing due to fast income growth in China and India – and with the



Inequality Between Nations, Fig. 3 Decomposition of global inequality into within-country inequality and between-country inequality using household survey data, 1980–2002 (*Source*: World Bank 2005)

evidence that inequality in China and in many other countries, including OECD countries, has been increasing over this period (see Ravallion and Chen 2007, for China; Atkinson and Brandolini 2004; Cornia 2004; Katz and Autor 1999; Gottschalk and Smeeding 1997). Interestingly enough, this evolution is the opposite of what was observed earlier in history. Does this evolution bring some support to the view derived from standard theoretical models of trade that globalization should tend to substitute inequality across countries by inequality within countries (see Bourguignon and Guesnerie 1999)?

What should we conclude from this review of evidence on the evolution of the world inequality of income? There is no doubt that the world has been increasingly unequal from the beginning of the industrial revolution until the end of the Second World War. But has it become more or less unequal afterwards? Should we rely on the *inter-country* definition and conclude for more inequality, or should we rely on the *international* – and *global* – definitions and conclude for less inequality? Should we give the same weight to China and the Liechtenstein, or should we have the world distribution of income depend on the relative performances of a few giant countries? It is argued in what follows that there is no right or wrong answer to these questions. Alternative definitions of world inequality correspond to different perspectives about the same evidence. The issue is to know whether this evidence is sufficient to form a final judgement or whether more is needed. The next section suggests that the common approach behind the figures reviewed so far may be misleading. Considering the income dynamics of countries, and country citizens, rather than viewing the 'anonymous' distribution at two points of time is more informative and somehow allows this apparent contradiction to be resolved.

Mobility on the World Income Scale

The approach of inequality in the preceding section focuses only on final outcomes and disregards initial starting positions. A better approach would be to track mobility. It departs from the conventional 'anonymous' view behind inequality measurement and can explain divergent opinions on changes in inequality between nations. If mobility itself forms part of the welfare criterion behind distributional judgements, then one is led to a conclusion about the change in the world distribution of income that is more nuanced and is consistent with both increasing and decreasing inequality. The main point is simply that the evolution of the distribution of income in the world since the 1980s has not been Pareto improving.

Some countries among the poorest and their inhabitants have lost income whereas the majority of world citizens have gained. Putting more emphasis on the former would then lead one to conclude that world welfare has fallen, that is, inequality has increased, whereas giving more weight to the latter leads to the opposite conclusion.

A simple way of tracking changes in the international distribution of income is to create 'mobility matrices' of world citizens moving over time from one income range to another (Bourguignon et al. 2004; Milanovic 2005). Such a mobility matrix is shown in Table 1. In the calculations behind this table, within- country inequality is

Inequality Between Nations, Table 1 Mobility matrix in absolute country per capita annual income levels (US dollars), 1980–2002

	Income in 2002				
Income in 1980	<710	711–1,100	1,101–2,890	2,890–10,000	10,001>
<710	1.28%	1.64%	0.00%	97.08%	0.00%
711–1,100	8.23%	3.89%	87.88%	0.00%	0.00%
1101–2,890	8.09%	0.56%	59.08%	32.28%	0.00%
2,890–10,000	0.00%	0.00%	0.98%	90.84%	8.17%
10,001>	0.00%	0.00%	0.00%	3.99%	96.01%

Source: Bourguignon et al. (2004)

assumed away and all citizens within a country are assumed to receive the same income. But there would be little difference if within country inequality were taken into account. In all cases, the world inhabitants that occupied the bottom range of the world income scale (less than 710 US dollars annually after correction for purchasing power parity (PPP), approximately the limit of the first quintile of the international distribution) in 1980 lived mostly in China and a few sub-Saharan African countries. In 2002, however, the Chinese had moved to an upper-income range whereas some sub-Saharan Africans who were initially in the second and third income range had fallen back to the first range. In other words, some poor people with income initially above 710 dollars in 1980 had fallen below that threshold by 2002.

Even though only eight per cent of each of the second and third income ranges fell into the bottom range over these two decades, this evolution clearly shows that no Pareto improvement has taken place in the world income distribution between 1980 and 2002. When considered in an anonymous way, as in the previous section, it may be the case that the average income of people in the poorest deciles of the international distribution of income has increased and may have even become closer to the mean world income. Yet this hides the fact that the composition of these deciles was very much modified. Chinese went out and were replaced by people from poor countries, initially richer than China, whose income fell after 1980.

Overall, whether the world distribution of income is judged as improving or worsening depends essentially on whether one considers that the increase in income of the Chinese and other poor people who climbed the income scale between 1980 and 2002 over- or under-compensates for the drop in the income of those people whose income fell. Looking at *international* inequality with population weights is equivalent to taking the former view, whereas focusing on *inter-country* inequality leads to the second conclusion. If the initial income position matters in assessing the social welfare of a population observed at a given point of time, then the social cost of falling incomes is not necessarily compensated for by the social gain of increasing incomes even if these changes take place towards and from the same income range. Deciding whether such a change increases or decreases social welfare requires some value judgements. The difference between those who feel that the world distribution of income has become worse and those who feel the opposite may simply be due to such differences in their value judgements.

Non-income Dimensions of World Inequalities

Most of the existing empirical evidence on inequality between nations concerns income, but recent studies have examined inequality in other dimensions of well- being, mainly health and education (see for example, Araujo et al. 2004; Deaton 2004; Goesling and Firebaugh 2004; Sala-i-Martin 2002c; Schady 2005). These studies indicate convergence in health and education indicators but divergence (or at least lack of convergence) in income. International inequalities in educational attainment and child mortality have been steadily declining, though improvements in life expectancy at birth have been set back since the early 1990s due to the devastating effects of HIV/AIDS and the difficult circumstances facing the former USSR and other transitions economies. Unlike global inequalities in income, global inequalities in educational attainments are attributable mostly to inequalities within countries.

What explains that there is convergence for health and education indicators and divergence for incomes? Deaton (2004, p. 109) points out that, while gains in income were undoubtedly important for improving nutrition and for funding better water and sanitation schemes, some countries made progress in reducing child mortality even in the absence of economic growth. These improvements came from the globalization of knowledge, facilitated by local political, economic and educational conditions. A possible explanation for the disconnect between the convergence in education and the divergence in

incomes is that education is not the only determinant of income and that the rise in per-worker schooling explains only a small part of the growth in output per worker.

Finally, it is worth insisting that there are major inequalities in voice and power between nations in participating to international decisions. These are discussed in detail in World Bank (2005). As Deaton (2004) puts it, poor countries lack the financial and human resources that would allow them to be equal participants in the international bodies in which decisions are taken that affect them and, beyond that, in setting the rules under which the international system operates.

Equity at the global level means that people should face the same opportunities for living the life they want regardless of where they are born. Income inequality among nations is only a sign that we are far from such a goal. Convergence in some non-income dimensions is an encouraging sign. Global action is possible in a number of areas to promote world equity, from improvements in international law and human rights, to promoting fairness in global markets, allowing free trade and free migration of labour, to more aid to the poorest, to a more equitable management of the environment and the global commons.

Inequality Between Persons

Anthony F. Shorrocks

Although inequality between persons can refer to a great variety of issues concerned with the disparate treatment and circumstances of individuals, economic discussion has focused on those aspects that relate to the acquisition and expenditure of income. As a consequence, the study of personal inequality has become largely synonymous with the distribution of income among individuals or households. Early contributors to this subject tended to provide an overall perspective on personal income distribution. In recent years, however, more attention has been paid to the particular dimension of inequality under investigation. Consideration has also been given to the precise way in which 'inequality' should be interpreted and measured, a trend most evident in the adjustments applied to observed incomes in order that the 'true' degree of inequality is revealed.

An initial distinction may be made between those studies which examine the origins of income dispersion and those which are interested in its consequences. The principal concern of the latter is inequality in living standards, or levels of well-being, and here the appropriate methodology is well established. For each household we require a measure of the level of its resources relative to its needs. The resource variable is typically identified with income, so that income distribution is the traditional point of departure in the study of unequal living standards. Ideally, however, income should be interpreted in a broad sense to include not only monetary receipts, but also unrealised capital gains, non-pecuniary benefits and household production which is not marketed. In addition, a long run income concept such as 'permanent income' or 'lifetime income' is preferred to the short run concept (weekly, monthly or annual) which applies to most of the readily available data. These incomes should then be adjusted to allow for different household circumstances. One type of adjustment concerns family characteristics, such as the number and ages of family members, and is accomplished by the use of household equivalence scales. A second type of adjustment relates to the environment in which the household operates and covers such factors as the prevailing level of commodity prices; the shelter, heating and transportation requirements associated with household location; and the level of provision of public goods and services. The aim, as before, is to achieve comparability between households in different circumstances. Needless to say, while this programme of adjustments may be generally accepted as the ideal, most empirical studies of living standards fall a long way short of the target.

A much larger body of literature is concerned with the causes of income inequality. This work focuses on the experience of individuals in factor markets and covers a wide range of issues on which opinions seldom agree. It will be helpful to begin by splitting the income y of an individual into components and writing

$$y = y_1 + y_2 + \ldots + y_n \tag{1}$$

$$y = r_1 x_1 + r_2 x_2 + \ldots + r_n x_n, \tag{2}$$

where r_i and x_i are the 'price' and 'quantity' associated with the ith component of income. A decomposition of this form would be appropriate if the x_i denoted the individual's endowments of productive factors, such as labour, capital and land, and the r_i represented the corresponding factor prices. This immediately suggests two principal causes of income inequality: differences in the endowments of productive resources which individuals own; and the structure of factor prices determined by the combination of institutional, market and social forces which we will call the *common environment* of individuals. Further refinement of this line of reasoning can be achieved by extending the coverage of the x_i to include a variety of other characteristics, and by looking back towards the source of the characteristics: to inheritance, in the form of genetic traits, material wealth and family advantage; to innate and acquired skills; and to the choices individuals make in respect of occupation, location and

workhours. There is also, inevitably, a portion of income, often attributed to 'chance' or 'luck', which is not systematically related to any of these factors.

Theories of income distribution differ not only in the particular influences and mechanisms that are stressed, but also in their view of what a theory of income distribution should set out to accomplish. One aim is to account for the overall degree of inequality at any date, and the pattern of changes in aggregate inequality that take place over time. Another topic of interest is the characteristic shape of the frequency distribution which incomes tend to follow. A third objective is to explain why different individuals happen to have different incomes. All three of these issues are valid concerns, and all would be addressed in a satisfactory general theory. On the whole, however, a distinct literature has developed on each of the questions. These are reviewed in turn below.

Changes in Income Dispersion Over Time

Explanations of changes in income inequality over time have typically drawn attention to the features of the common environment and to the consequent pattern of factor prices. Factor prices play a significant role in most of the discussion of income distribution prior to 1900, and even up to the middle of this century, as indicated by the selection of papers published by the American Economic Association in 1946. This is perhaps a reflection of the rigid social structure in the 19th century, which made it natural to assume that the resource endowments of individuals remained relatively constant over time. In those circumstances the first priority was to account for the level of factor prices or factor shares. Once this was done, aggregate factor payments could be allocated among individuals according to a prearranged pattern of entitlement. A theory of factor prices was, in effect, a sufficient explanation for the distribution of personal income.

The tendency to submerge the theory of personal income distribution within the grander themes of Labour, Capital and Land was not without its critics. Cannan (1905) was prompted to suggest that a student seeking an explanation for the riches and poverty surrounding him would return home in disgust from a typical lecture on the subject. He argued that more attention should be paid to the way that aggregate factor payments were shared between individuals, a suggestion taken up with enthusiasm by Dalton (1920) in one of the earliest and most outstanding volumes devoted to personal income distribution. The ideas of Cannan and Dalton had little immediate impact. But the importance they attributed to inheritance has certainly been echoed in subsequent research, most notably in connection with the sources of wealth inequality.

More recently, the explanation of long-run trends in income dispersion has been particularly associated with the work of Kuznets and Tinbergen, and again regards the common environment as the ultimate source of change. The programme of research that has developed from Kuznets (1955) is concerned with the relationship between economic growth and the distribution of income within countries, and sees demographic movements as a major influence on inequality. Countries begin with a fairly homogeneous population, largely employed in the traditional sector. In the course of development, individuals transfer into the modern sector causing income inequality to first rise and then fall, as the modern sector becomes dominant. Inequality within both the traditional and modern sectors may, however, remain constant. This suggests that observed variations in inequality could be spurious, reflecting the way in which data is recorded rather than a real change in the relative income positions of individuals. Other demographic factors, such as shifts in the age structure and household composition have also been cited as having a similar impact.

Tinbergen (1975) appeals to the common environment influences that determine the relative earnings of skilled and unskilled workers. In his view, the observed trend in income inequality is the outcome of a race between technology and education. Technological progress creates additional demand for skilled workers, while improved educational opportunities increases the supply. The direction of movement of the skilled–unskilled wage differential depends on

the relative strength of these two forces. Over the course of this century, education has advanced faster than technology, driving down the relative earnings in professional and skilled occupations with notable consequences for income dispersion. The distinguishing characteristic of Tinbergen's argument is the attention given to the operation of factor markets. Many other studies have been concerned with the role of education and training, but they tend to emphasize the process of skill acquisition and treat factor prices as exogenous data.

The Pattern of Income Frequencies

It has long been recognized that the density function for incomes has a characteristic shape, sufficiently regular and well documented to merit special attention. The major early contribution to this line of enquiry was undoubtedly Pareto, who, in a series of publications, including his *Cours d'économie politique* (1896), assembled evidence on personal incomes spanning more than four centuries and expounded his universal law of income distribution. Pareto noted that the data were closely matched by the formula

$$\text{In } N = \text{In } A - \alpha \text{ In } y, \tag{3}$$

where y is a given level of income and N is the number of people with incomes above y. Furthermore, the slope coefficient α was always approximately 1.5. This, he argued, could not be a coincidence. The statistical regularity must indicate a natural state of affairs which would tend to reassert itself if, for any reason, the income distribution departed temporarily from its stable equilibrium.

Pareto's results, and the inefficacy of redistributive policies which they seemed to imply, soon attracted both dedicated support and hostile opposition. The increasing availability of data eventually undermined the strong version of Pareto's law. However the tendency for the upper tail of incomes to follow the Pareto curve (3) is well established, and remains one of the 'stylized facts' concerning the distribution of both income and wealth. Pareto also had a profound influence on many of the methodological developments that have subsequently taken place. His interest in the collection and summary of data, the parametric description of income frequencies, and the identification and investigation of observed statistical regularities, are all strongly echoed in later research.

Although high incomes tend to follow the Pareto relationship the Lognormal distribution is a better representation over the whole income range. This provides a clue as to how the observed pattern of incomes could arise. For just as normal distributions result from a large number of small and statistically independent effects which combine additively, so lognormal distributions emerge when the effects combine multiplicatively. More formally, if we replace income in (1) with the logarithm of income to obtain

$$\text{In } y = y_1 + y_2 + \ldots + y_n, \tag{4}$$

and assume, say, that the y_i are identically and independently distributed variables, then the income pattern will be approximately lognormal when n is sufficiently large. In this argument it is the statistical properties, rather than the origins, of the components y_i that are significant. They may, therefore, be treated as unspecified random effects.

The notion that income distribution can be viewed as the outcome of a process governed by a large number of small random influences was developed by a number of authors, most notably Gibrat (1931) who formulated his 'law of proportionate effect', and Champernowne (1953) who demonstrated how the Pareto upper tail could emerge as a feature of the equilibrium distribution of a Markov Chain. Further modifications to these models were later shown to be capable of generating, as the limit of a stochastic process, a variety of other functional forms which have features in common with the lognormal and Pareto distributions, and which may be regarded as reasonable descriptions of the frequency distribution of income. As explanations of income inequality they have been criticized on the grounds that chance or luck, rather than systematic personal

or market forces, appears to be the principal determinant of income differences. But the significance attached to this complaint depends on the question that is being addressed. If we are primarily interested in accounting for the overall features of the density function of incomes, it may be appropriate from an aggregate perspective to treat the incidence of personal success and failure as a random event, while simultaneously accepting that success and failure may be rationalized at the level of specific individuals.

Income Differentials

The dominant theme of recent research on personal income inequality is the explanation of income differentials – the reasons why particular individuals have different incomes. This work has several distinctive features. One is an increasing concern with empirical issues, and with the empirical evaluation of competing theories, facilitated by the availability of large-scale survey data and the means to process the information. Nowadays the question is not so often which factors have an impact on income distribution, but which factors have the most quantitative significance as explanations of observed income differences. Another distinctive feature is the emphasis placed on the distribution of earnings, again partly a result of the quantity and quality of earnings data. Earnings inequality is important, not only because wages and salaries form such a large proportion of income, but also because it reflects the extent to which labour markets operate fairly. As a consequence the explanation of the inequality of pay has become the main battleground for opposing views on the origins of personal inequality.

One method of approaching the question of earnings differentials is to regard the labour market as being composed of a set of individuals with different personal traits P, and a set of job opportunities offering various combinations of characteristics J. The process of matching people to jobs then generates a relation between personal traits, job characteristics and pay which is typically captured in an earnings equation of the form

$$\ln\ w = \alpha_1 P + \alpha_2 J + R, \tag{5}$$

where w denotes earnings or hourly wage rates, and R is a non-systematic or random effect. In this formulation, the coefficients α_1 and α_2 may be interpreted as the 'prices' which the market imputes to the various characteristics. Their values are often estimated from empirical data. Notice that equation (5) has similarities with (2) and, more especially, with (4). This indicates that the separate influences combine multiplicatively, rather than additively, as Gibrat had suggested earlier.

Many different views on the determinants of earnings can be accommodated within equation (5). One common argument claims that earnings are related to the ability or productivity embodied in individuals. Certain personal traits may therefore be valued because they indicate the actual productive performance that derives from either natural ability or the skills acquired as a result of education, training and work experience. Furthermore since perceived, rather than actual, productivity is rewarded in the market place, other characteristics may also be valued if firms believe them to be correlated with relevant variables that cannot be observed. This can account for the 'prices' imputed to educational credentials, family background, gender and race. There are, however, alternative explanations for sex and race discrimination: consumer and employer prejudice towards the goods and services provided by disadvantaged groups; and exploitation by firms of the different supply elasticities that arise from personal circumstances and role specialization within the family.

The structure of job opportunities and the prices imputed to job characteristics lead to a different set of considerations. One line of argument, associated with segmented labour market models and the Job Competition model (Thurow 1976), stresses the significance of the distribution of jobs across occupations and industries, which depends on the state of technology, the structure of markets and the other social and institutional factors contained in the common environment. It is this job distribution, together with customary wage and salary differentials, which is the

principal determinant of earnings inequality. Personal characteristics appear to be important only because they are used by firms to ration entry into the more attractive jobs.

This argument suggests that the desirability of any given occupation is directly related to its imputed price. Exactly the opposite conclusion applies if the prices of the characteristics are interpreted in terms of Adam Smith's (1776, Book 1, ch. X) concept of compensating differentials. For if individuals can choose to trade-off income against job characteristics such as occupation, location and working conditions, it is precisely those jobs with the least desirable features that need to pay more in order to attract an adequate workforce.

The notion that some part of earnings may compensate for other job features, and that the process of choice may help to explain observed income variations, has special significance in the analysis of personal inequality. This may be seen by considering a situation in which people are faced with a set of employment prospects each of which offers a level of income and a combination of other characteristics. If all individuals select from the same set of options, there is clearly no 'true' inequality in the sense of unequal opportunity. Yet people with different tastes will choose different alternatives, so observed incomes will typically vary. It follows that observed income dispersion may well exaggerate the true degree of inequality if some income differences are attributable to choice.

Individuals do not, of course, all face the same set of options. So different opportunities, as well as different choices, contribute to observed inequality. Much of the discussion of the determinants of earnings can be viewed in the context of the distinction between these two factors. Indeed, the most controversial aspects of the study of income distribution often reflect conflicting opinions on the relative importance of the 'true' component of inequality arising from different opportunities and the 'spurious' element of inequality that results from choice. Notice that choice is not the only mechanism that separates opportunities from outcomes. Chance also has a role to play if uncertain prospects are among the set of available options. It is therefore most appropriate to decompose inequality into three components: choice, chance and unequal opportunity. The influence of chance will, however, tend to disappear when we examine the typical experience of a group of individuals.

Those who stress the importance of unequal opportunity tend to focus attention on the contribution of natural ability, family background and discrimination. Here we might, perhaps, distinguish between two aspects of unequal opportunity: the unequal inherited endowments associated with natural ability and family background; and the unequal market treatment associated with discrimination. In contrast, the impact of choice is most clearly seen in the decisions relating to hours of work and geographical location. Individual preferences can also explain the choice of occupation and length of training. Thus, for example, a naive version of the Human Capital model suggests that the level of acquired ability is freely chosen under conditions of equal opportunity, so that the earnings differentials corresponding to education and training are purely compensatory. Refinements of the model, however, allow training opportunities to be influenced by ability and family background, and these factors, together with discrimination, are important elements of those arguments which emphasize the lack of equal and open access to training programmes. The impact of choice on skill levels depends, therefore, on the precise process by which skills are acquired and augmented.

The debate on the relative importance of unequal opportunity and choice for earnings inequality has its counterpart in the study of investment income, via the determinants of wealth distribution. Here, individual preferences are captured in the motives for saving: a desire to provide for retirement, to make bequests, or simply to practice thrift. Choices based on these preferences then determine savings behaviour and can account for some wealth differences in terms of past accumulation. Unequal opportunity, on the other hand, appears principally in the guise of material inheritance, but may also arise from the differences in incomes and family circumstances that affect the opportunities for saving.

Inequality Between the Sexes

E. Boserup

Economic theory concerning inequality between the sexes focuses upon inequality in wages, job recruitment, promotion and dismissal, for women and men with similar qualifications and availability. Neoclassical theory explains these inequalities as a result of free and rational choice, based upon the biological differences between the sexes. According to Becker (1981), women's role in reproduction makes it rational for women to specialize more in family skills, and men more in labour market skills, and parents make a rational choice for their children by preparing them for different careers. When women's reproductive role is reduced due to the decline of birth rates, women's availability for the labour market increases, and they begin to invest more in labour market skills than is the case in countries with continued high fertility. So sex-related differences in level and types of human investment and availability provide the explanation for the differences in wages, types of work and promotion.

By focusing upon the biological differences between the sexes, neoclassical theory selects the features which distinguish inequality between sexes from inequality between other discriminated groups, that is the young versus the old, or foreigners versus members of the dominant ethnic or national group. All these inequalities have been characteristic features of human societies since prehistoric times. The basic principle in the organization of societies is that only members of the superior group have adult status or civic rights, while the members of the inferior groups depend upon the benevolence of the 'adults'. In most societies, economic and social development have reduced the inequalities, but nowhere have they been completely eliminated, and the traditional power of the superior male group over the inferior female group cannot be ignored in the economic analysis of inequality between sexes. The power of the male group over the female one is supported by access to the best technology and a monopoly in learning how to use it (Boserup 1970). Men's monopoly in the use of weapons, superior hunting equipment, and animal-drawn agricultural equipment, is of ancient origin. But even in societies where men have shifted to tractors and other industrial inputs, women often continue to use primitive hand tools for the operations assigned to them, and even in modern mechanized industries, men distribute the tasks and assign the unskilled, routine operations to the female workers.

In primitive subsistence economies, woman's reproductive role does not prevent her being assigned the most onerous tasks with incessant daily toil, and if the mother's work prevents her from taking care of young children, these are

cared for by older sisters or other members of the group. At a later stage of development, when specialization of labour leads to the transfer of an increasing share of the labour power of the family to outside work, the reproductive role of women contributes to explaining why more women than men continue to work in the family and for the family, either as unpaid family members or as domestic servants. However, due to their superior status, men have the right to dispose of money incomes earned by female family members within or outside the family enterprise. There may be regional and local differences in women's status, but in most traditional societies women cannot dispose of money or undertake monetary transactions, accept employment or move away from the locality where they live and work, without the permission of a male guardian who decides all these matters, as well as family matters, like marriage, divorce and the fate of the children. The right to take part in decisions on public matters is reserved for members of the male sex.

Gradually, as technological development transfers an increasing number of products and services from family production to production in specialized enterprises and institutions private or public, there is no need for the full labour power of all female family members in the household. Through the same process the family economy becomes more and more dependent upon money income to purchase the products and services which the family no longer produces, and to pay the taxes which finance the growing public sector. As a result, increasing numbers of women become money earners. At this stage, women's ability to engage independently in economic and other transactions, and their lack of responsibility, becomes a handicap not only to themselves but also to their employers, creditors, customers and guardians, as well as to public authorities and male family members who must support them, if they are unable to support themselves and their dependents because of economic disabilities.

In some European countries, 'market women', who were often middle-aged women with dependents, attained adult status many centuries ago. Later, when it became customary for young girls to work for wages before their marriage, and for other single, divorced and widowed women to support themselves and their dependents by wage labour, or by self employment, these categories of women were granted 'adult' status in economic affairs; but married women continued to be denied adult status. In most industrialized countries, married women first attained adult status when further reduction of the domestic sector, together with the decline of birth rates, radically increased their participation in the labour market and made their work in the labour market an important part of the national economy. In most developing countries, women, whether married or not, are still denied adult status in economic affairs; in some countries it severely limits their labour market participation, in other cases it limits the business activities they are able to accomplish.

Human capital investment in 'market skills' becomes more and more important with economic and social development, while investment in family skills loses in importance when more and more activities are transferred from the family setting to private enterprises or public institutions. When the responsibility for physical protection is transferred from the family to the government, and formal education is introduced, educational level may replace the ability to use weapons as a status symbol for male youth. The priority given to boys over girls in formal education is not only a result of their larger labour market participation, as suggested by Becker, but also a means to preserve a higher male status, by letting men reach higher educational levels than women.

The status of parents may require that their daughters be educated as well, but that boys should not lose status by receiving less schooling than their sisters, while to preserve the superior status of the husband, the wife must not be more educated than he is. Universities were long closed to women, and in many countries the difficulties of obtaining marriage partners for educated women make both parents and daughters afraid of continuing their education. The low marriage age for girls, another means to preserve male status in the family, may also prevent continuation of the education of girls. The differences between the sexes in educational levels serve to reinforce inequality not only in the family, but also in the labour market. With

economic development the difference becomes limited to the highest educational levels but it has not disappeared, even in countries with very high and uninterrupted female labour force participation.

Usually, differences in access to technical training for girls are much larger than differences in access to formal education. From the day women began to work for wages in urban activities, men have insisted on their priority right to skilled, supervisory, and other better paid work. Both in guilds, and later in industries and public service, men became apprentices and skilled workers while women remained assistants to the male workers, unskilled or semiskilled, working under male supervision. In most cases, male trade unions continued the fight of the guild members against rights for women to training, and even to membership of the organization and right to work in the trade. The inferior position of women was defended by the short stay in the labour market of young girls before they married, with no account taken of the large number of spinsters, poor married women and female heads of households, who were permanent members of the labour force both in European and in many non-European countries.

In addition to the lower position of women in the job hierarchy, female wage rates are usually much lower than male wage rates for similar work. Only in periods of great shortage of labour, for instance in wartime or in agricultural peak seasons, may female wages temporarily rise to the level of male wages. The fact that these wage differences are related to sex, and not to the burden of dependency, belies the usual explanation for them. They are a result of the principle of male superiority, and neoclassical theory has helped to make the principle acceptable. Since the theory assumes that differentials in wages equal differentials in marginal productivity of labour, the lower wage rates for women could be taken as a confirmation of the general assumption of female inferiority, which also applied to women as workers.

The superior status of men is supported when women doing similar work get lower wages; when a wife is prevented from earning as much as her husband, he preserves his superior status as principal breadwinner, even if he is too poor to enjoy the even higher status of being the only breadwinner in the family. Training girls in low-wage occupations and discriminating against women in recruitment for 'on the job training' or access to 'learning by doing' supervisory work, reduces the risk that male staff will lose status by being supervised by women.

When employers in private enterprises and public service pay males higher wages than females for similar work, they include the higher male wages in their production costs, even if that reduces the demand for products made primarily by male labour. If an enterprise or a trade has difficulties in competing, due to the payment of high male wages, employers will not reduce the wage differential, but will instead try to get the workers and the trade unions to accept the recruitment, or additional recruitment, of women. If they succeed, the trade will become less attractive to men, and the labour force will gradually become female as has happened to many trades in which trade unions were weak. The separation of the labour market into masculine and feminine trades and jobs becomes even more pronounced if the principle of equal pay for equal work is introduced by law or labour contract, since sex specialization makes it more difficult to prove that the work paid at different rates is 'equal'.

Inequalities between men and women in the labour market and in the family reinforce each other. While Becker assumes a harmony of interests between the marriage partners and an equal distribution of consumption and leisure between them, Sen (1985) uses bargaining theory to explain the observed inequalities in consumption and leisure, which in some countries include differences in coverage of calorie requirements and in access to health care between husband and wife, and between boys and girls. The wife's bargaining position is directly related to her access to the labour market and position in it, but her bargaining position is also weakened because women are likely to perceive inequalities as natural, and make no objections against them. This feature is due to the family socialization of girls from a young age. In many societies, girls are taught that they are less valuable human beings than their brothers, and virtually everywhere girls

must help their mothers to provide domestic and personal services for their brothers, who are allowed much more freedom and leisure.

Even in countries with high and perpetual labour force participation by women, girls' education and training within the family focus on child care and domestic activities, and on beautifying themselves to be able to make a good match and reduce the risk of divorce and abandonment, while boys' interests are stimulated in all other fields. Usually, girls are taught to be obedient, to be modest and to do routine jobs without protest, while boys are encouraged to be enterprising, even aggressive, and more self-confident. The inferiority feelings of the girls may induce them to invest less in education and training than boys, as suggested by Arrow (1973), but even if they have the same formal education and training as male competitors, women are likely to lose in competition with males in the labour market. Girls, who are socialized to accept routine jobs and to be modest and obedient, are unlikely to demand good jobs and advancement, or in other ways to fight actively for their interests in the labour market, even when there are few prejudices against them. Much female aptitude for routine and precision work, unsuitability for leadership and unwillingness to take responsibility results from family socialization in the first years of life. Most often, the schools continue in the same vein, but even when schools aim at abolishing inequality between the sexes, the teachers may be powerless, due to family socialization of pupils of both sexes.

In industrialized countries, the last few decades have seen an acceleration of related and mutually reinforcing changes in technology, labour participation by married women with small children, and birth rates. Decline of birth rates to below replacement level, and increasing female labour force participation provide an inducement to the improvement of household technologies, and the introduction of new products and services as substitutes for women's traditional activities and child care. These technological and social changes further induce increasing female labour force participation. A rapidly increasing proportion of married women continue their money-earning activities without reducing work hours during the period when they have small children. But the traditional sex hierarchy is dying very slowly, and although birth rates are low, female levels of education and professional training fairly high, and labour market participation high and continuous, reductions in sex differentials in earnings have been moderate, if any. Earnings in female occupations, including those requiring professional training, are lower than in male occupations with similar requirements. Except for a small female elite, women continue to occupy the positions at the bottom of the labour market within each occupation, as assistants to men, and often supervised by men even in otherwise female occupations.

Married women with full-time work and young children have much longer working hours than men and little leisure because male patterns of work have changed very little, in spite of reduced working hours and the increasing amount of money wives contribute to family expenditure, and also because of the lack of child-care facilities in many countries. However, in spite of the differences between male and female earnings, most women in the industrialized countries have become less dependent upon male support because of the general increase of all wages and the reduction of working hours in the labour market. Therefore, women can support themselves by work in the labour market, if they choose to, and with the aid of obligatory contributions from the father, and public support to female-headed households, they can support children, although the living standards of female-headed households are usually much lower than those of male-headed households. Consequently, many young women react against unequal work burdens by demanding divorce or leaving the home, or by not entering into a formal marriage or cohabitation. Others react by reducing birth rates even further. Contrary to earlier patterns, female applications for divorce have become more numerous than male ones in some industrialized countries. These social and demographic changes serve to make young men, and public opinion in general, more inclined to consider women's demands for more equality.

I

In many developing countries, economic and social development are producing changes in female labour force participation and birth rates which resemble earlier changes in industrialized countries. Family legislation has been modernized, there is legal equality or less legal inequality between the sexes, access to divorce has become less easy for men and easier for women, and better access to the labour market provides women with some possibilities for self-support in case of divorce and widowhood. Age differences between the spouses are declining due to higher female marriage age, birth rates are declining, and women's position is gradually improving.

But in many other developing countries, either economic changes are few, or male resistance to changes in the traditional status of women is strong. Except for voting rights to parliaments with little influence, women continue to be legally minor, and in many cases their situation has deteriorated because technological changes, or changes in land tenure, have deprived them of traditional means of self-support. In some countries, the labour market continues to be closed not only to married women, but also to deserted women, divorcees and widows, and if labour market shortages occur, they are met by large scale imports of male labour. In these countries birth rates remain high in spite of economic development. For women, economic support from sons is the only alternative to destitution, when the husband dies or ceases to support his wife, and women also desire to have many sons as a means to reduce the risk of abandonment and divorce.

Inequality of Pay

Henry Phelps Brown

The difference between the hourly rates of pay for two jobs might be seen in the same way as that between the prices of a ton of copper and a ton of steel: there is a common unit of quantity, but the conditions of supply and demand for the two articles are largely independent, and the difference between their prices is only an arithmetic by-product. But people do attach significance to the differences between rates of pay, and their ideas about what these should be help to fix particular rates. The relations between the rates of pay for different jobs are termed *differentials* when the jobs compared lie at different grades within the same occupation or industry, and *relativities* when they are in different ones. Both sorts of comparison are possible because jobs are defined by their requirements – what physical and mental ability, length of training, experience, tolerance of adverse working conditions, and the like, they demand from anyone who is to do them adequately; and these requirements are regarded as being common to jobs of all kinds, but present in different amounts and proportions. The requirements of given jobs are assessed intuitively by those who make practical judgements about the fairness of differentials and relativities, and are set out explicitly in the procedure known as job

evaluation. The rate for a job is regarded as made up of the shadow prices of the capacities to meet the several job requirements, together with the extent of each requirement in the given job.

The question then arises, how those shadow prices are determined: how comes it about that skill commands a higher price than muscle? Two answers have been given – convention, and supply and demand. The case for convention opens with an appeal to everyday knowledge of how people insist on the maintenance of customary relations. They require that relative pay conform with status. That the labourer's rate stood at two-thirds of the craftsman's in the building industry of Southern England over more than six centuries (Phelps Brown and Hopkins 1981) can be attributed only to convention. If women's rates had been simply proportioned to productivity, it is hard to account for their relative rise when the rule of 'equal pay for equal work' was enforced in the UK and the Netherlands. Here convention had been keeping pay down, but John Stuart Mill remarked long ago (1848, II, xiv, 2) that it was keeping the relative pay of clerks up, after the increase of supply of clerical capacity through extended education had tended to lower it. These observations are all consistent with differences of pay being set to match accepted gradations of status. But on the other hand there are all the instances of market forces moving a particular rate, and so changing a relativity, when there has been no question of an antecedent change in status. Differentials that have long remained constant have changed when an upheaval has loosened the hold of custom, and the way in which they have changed can be explained by market forces. The Soviet-type economies use the differentials and relativities in their pay structure as incentives to attract and deflect the supply of labour to particular employments. In the West, competition of employers for a new skill such as computer technology opens up a differential over the pay commanded by other qualifications at the same level. A mental experiment indicates that if those who need a long and costly training before they can meet a job's requirements – say surgeons – were to be paid no more than the unskilled, then though a certain number would still enter the profession out of interest in the work or a sense of social responsibility, it would not be possible to maintain the numbers for which consumers have shown themselves willing to pay at actual rates.

We conclude that the basic reason for the inequality of pay is that, on the side of demand, users are willing to pay different amounts for the capacity to meet the requirements of different jobs; and on the side of supply, that unless a certain rate of pay is provided, labour capable of doing the job will not eventually be forthcoming in the amount that users wish to employ at that rate. If status and pay commonly agree, that is because the personal capacity that confers status also commands a higher price because of its productivity. But there are zones of tolerance within which market forces do not fix rates closely, and here convention may prevail.

On this view, the major obstacle to the reduction of inequality lies in the limitations of the supply of labour to the better-paid jobs. These are to be found in the genetic distribution of personal potential, and next in the distribution of the factors moulding capacity in early childhood, from the homes that foster development to those that thwart it. The quality and extent of education are then limited by the availability of institutions, and the cost of maintenance of students that falls on their families. Similar limitations restrict the numbers obtaining training following education. Readier access to education and training should lower the supply price of labour to the jobs with more exacting requirements and higher pay; but the limitations imposed by heredity and early upbringing will remain (Rutter and Madge 1976; Phelps Brown 1977, chs. 6, 7 and 9).

So far the discussion has concerned the pay of different occupations, but the differences between the earnings of individuals in the same occupation also demand consideration. These are commonly wide. Some of the range arises from short-period fluctuations in bonus and overtime. Earnings also vary with age, and the inequality of lifetime pay is much less than that of pay at any one time. But a great part of the range is due to differences of individual performance. There are also some systematic forms of differentiation. Regional

differences in the rate of pay for the same work are often substantial. In local labour markets quite large differences are found between the pay for a given occupation in different firms. It is generally higher, the bigger the firm. There may be discimination against ethnic minorities or women. Discrimination 'before the market' occurs when the victims are denied equal access to the means of acquiring capacity. Discrimination 'within the market' occurs when some persons receive lower pay than others by reason of their ascriptive characteristics and not because of, or in proportion to, their lower capacity. It appears likely that discrimination 'within the market' is much less considerable than discrimination 'before the market'.

The combined outcome of differences of pay between jobs and among individuals in the same job is a distribution of individual earnings. The form of this distribution confronts us with a striking social regularity. When Lydall (1968) brought together comparable data of earnings from more than thirty countries, he found a common form of distribution. This was unimodal, with a long upper tail. The central part was closer to a log-normal than a normal distribution, but both tails were thicker or longer than in the log-normal, and in particular the upper tail was fitted closely by Pareto's formula. Generally, distributions of earnings are now taken to be log-normal but with a Paretean upper tail. Soviet planners are understood to treat the distribution of earnings as log-normal.

The common form does not imply an equal measure of inequality, though there are some striking instances of this. The distribution of the earnings of manual men found in the British wage census of 1886 agrees closely with that found in the 1970s. Bergson (1984) found 'a rather striking similarity in equality, as measured, between the USSR and Western countries,' though the USSR distribution lacks the Paretean tail. But differences appear among European countries. 'Britain, France and Italy show the greatest inequality, and the West German structure is the most egalitarian; Belgium and the Netherlands lie between', and the relative pay of women varies greatly among these countries (Saunders and Marsden 1981, pp. 61, 238). Dispersion has also varied over time. Kuznets (1963) found a systematic relation between the extent of dispersion and the stage of development of the economy, dispersion increasing in the earlier stages of growth and then decreasing in the developed economy. Williamson and Lindert (1980) found that the course of change in the American pay structure agreed with this. The differential for skill was small before 1816, and then came a rapid widening, down to 1856. A further surge from 1899 brought the differential to its peak in 1916; but after 1929 a process of contraction set in and was maintained until the Korean war. The authors ascribed the change to three major factors. A high rate of investment displaced unskilled more than skilled labour, and was linked with a movement of labour out of agriculture. The uneven advance of productivity in different sectors affected the demand for skilled and unskilled labour differentially. Variations in immigration and fertility affected the relative supply of the unskilled. Elsewhere it has been pointed out that it is differences of pay between occupations that make up the greater part of dispersion, except in Great Britain, and attention has been directed to the impact on these differences of changes in demand and supply (Douty 1980, ch. 5, for USA). In particular, the extension of education has increased the relative supply of professional and technical qualifications. Trade union policy has taken effect, in Great Britain to reduce or eliminate the formerly very wide regional differences (Hunt 1973) and in Sweden, in pursuance of solidarity, to reduce the lead of builders' pay, raise the relative pay of women, and reduce the gap between white-collar and manual rates. Government policy has endeavoured to raise the lowest paid, as by the national minimum rate in France, Wages Councils in Great Britain, and the Fair Labor Standards Act in the USA, though the long-run effect on dispersion is uncertain. Incomes policies have affected differentials markedly in the short run. Other short-run changes arise from the trade cycle: rising activity has raised the lower rates relatively, and conversely.

Despite the variability of the pay structure in these ways, the regularity of its main features over

space and time remains outstanding. It challenges explanation, but remains a matter of discussion. Theories that have been advanced to account for the distribution of income are relevant here (Sahota 1978), as is the analysis of the log-normal form (Aitchison and Brown 1957). We may take it that pay is based on capacity. That the distribution of some measures of capacity such as IQ is normal and not log-normal is no bar to believing this, for it is understandable that as we go up the scale of capacity, what users are willing to pay rises more than proportionately, until we reach the vast earnings of those 'at the top of their profession'. We have then to explain why the distribution of capacity should take a common form in diverse societies. It seems likely that the explanation lies in the life-chances of the individual, and the impact of the myriad forces, beginning with conception, that shape body, mind, personality, training and experience. Though these forces have many different features in different societies, they share a stochastic property that gives a common form to the distribution of capacity, and hence to the inequality of pay.

Infant Industry

Gerald M. Meier

Opposing arguments for free trade and protection constitute the longest-standing policy debate in the history of economic thought. In this debate the infant-industry argument has acquired pride of place as an exception to free trade – especially as trade theory now gives more attention to explicitly dynamic analysis instead of being confined to comparative statics. But the argument must be carefully stated, and when expressed in its precise modern form its applicability is narrowly limited.

During the period of mercantilism the argument was used to justify the granting of trade monopolies in new and hazardous trades and to inventions (Viner 1937, p. 71). Alexander Hamilton (1791), Friedrich List (1841) and J.S. Mill (1848) were also early prominent exponents of the argument. Since World War II it has acquired increasing emphasis for less developed countries.

The nature and scope of the infant-industry argument has been refined in modern times by the theory of domestic distortions and the application of welfare economics, with their concern for conditions of Pareto efficiency and determination of the cost of protection. It has also been delimited by considering the benefits and costs of alternative policy instruments – a subsidy, tariff

or quantitative restriction – in the context of the hierarchy of policy making (Bhagwati and Ramaswami 1963; Johnson 1965; Bhagwati 1971; Corden 1974).

The essence of the infant-industry argument rests on 'dynamic learning effects', so that the economy's transformation curve shifts outwards over time, and an industry that is not currently competitive may achieve comparative advantage after a temporary period of protection. Properly stated, the conditions necessary for infant-industry protection are: (1) irreversible technological external economies are generated that cannot be captured by the protected industry; (2) the protection is limited in time; and (3) the protection allows the industry to generate a sufficient decrease in economic costs such that the initial excess costs of the industry will be repaid with an economic rate of return equal to that earned on other investments.

If condition (1) is not fulfilled, the private market should be able to yield an efficient allocation unless capital markets are imperfect or there is imperfect information, so that risks are overestimated. Infant-industry protection is justified not by the fact that there are losses until the infant grows up – but by the fact of external economies associated with the learning process, so that there is underproduction from the social point of view. Condition (2) guarantees that the industry is not protected from infancy to geriatric or even senile stages. And condition (3) guarantees that the expected benefit must be sufficiently great to offset, in present value terms, the current costs of the policy required to produce the benefit (Kemp 1960).

If free trade is not optimal because of the presence of externalities and the possibility of lower costs over time, what then are the optimal policy instruments for protecting the infant industry? The normative theory of international trade policy has established that the first-best policy would be a production subsidy aimed at the source of the distortion (Corden 1974, pp. 28–31). This would be preferable to a tariff, which would lead to a by-product, consumption distortion. Although the tariff could restore equality between the marginal rate of domestic transformation and the marginal rate of transformation through foreign trade, it also would drive a wedge between the marginal rate of substitution in consumption and that of transformation. A tariff in turn would be preferable to a quantitative restriction, which would yield quota profits instead of customs revenue and would entail the cost of rent-seeking if there are import licences (Krueger 1974).

Although it is a domestic market failure that justifies the protection, nonetheless under certain types of market failure the first-best policy may not be a production subsidy (Corden 1984, pp. 91–2). If the learning experience results in dynamic internal economies in which the learning benefits remain wholly within the firm, the market failure may be in the imperfection of the capital market that makes the financing of such investment difficult or too expensive because the capital market is biased against this type of 'invisible' investment in human capital, or because the rate of interest for all long-term investment is too high owing to private myopia. In this case the first-best policy is to improve the capital market directly; a subsidy to that element of factor input or output that gives rise to the learning benefits would be second best, while further down the hierarchy there would be a general output subsidy to the industry, and then a tariff (Corden 1984, pp. 91–2).

Another case might involve dynamic external economies created by the labour training of a firm, but the firm is not able to retain the workers it has trained. In a perfect market situation the learning effects would be internalized: the workers would accept low wages during the learning stage, financing themselves by borrowing, with recoupment through subsequent mobility. But if the capital market is imperfect, or if there are rigidities in wage determination, this may not be possible. Again, the first-best policy is to improve the capital market; the second-best policy is to provide financing for, or subsidization to, the labour training; while subsidization of the firm's output would be further down the policy hierarchy.

Baldwin (1969) has indicated that a protective duty is no guarantee that individual entrepreneurs will undertake greater investments in acquiring technological knowledge. As long as the learning-

by-experience costs are higher than those which other firms must pay to acquire the knowledge, it cannot be assumed that firms will generally be prepared to incur the initial direct learning costs, even if the government imposes a tariff on the product. The duty will tend merely to encourage socially inefficient production as long as the state is willing to provide protection. A production subsidy on an industry-wide basis will have the same effect. What is needed is a direct and selective policy of subsidies to the initial entrants into the industry for discovering better productive techniques.

The infant-industry argument is also sometimes generalized to an 'infant economy' argument in which it is claimed that the entire industrial sector must go through an infancy stage, that the learning by each firm generates benefits for the whole sector and that by their mutual expansion all firms will enjoy a reduction in their production costs. Such a belief may underlie a broad import-substitution strategy with a uniform rate of effective protection to all manufacturing activities (Krueger 1984, p. 525). But import-substitution strategies beyond the first easy stage have proved excessively costly in developing countries, and their adverse effects on agricultural development and on export promotion have limited the rates of development in countries that have practised import-substitution protection (Balassa 1980).

In contrast to import substitution, it should be recognized that an export industry may also be an infant industry. Free trade may fail to bring about socially optimal levels of knowledge and factor endowment in new export industries. Policy interventions are then justified. Another possibility is that actual consumption experiences may be required to learn about an export commodity's qualities, but each firm's efforts at overcoming foreign-buyer resistance benefit not only itself but also all other firms that try to sell the same product in the same new market. The social returns of investments in market cultivation exceed the private returns, and subsidization is then justified (Mayer 1984). The higher rates of economic growth enjoyed by many countries that have promoted exports suggest that it is possible that the infant-industry proponents are correct in their basic argument that there is a period of learning and of relatively high costs, and that an export-promotion strategy is a more efficient way of developing an efficient, low-cost industrial structure (Krueger 1981, p. 16; Westphal 1981, p. 22).

Empirical evidence on infant-industry protection, however, is not as extensive as theoretical developments. Taussig (1888) concluded that there was legitimate application of protection 'for young industries' in the United States during the early period of 1789 to 1838. Marshall (1919), however, saw no clear evidence in support of intervention by the state in favour of nascent manufactures. For contemporary economies the empirical evidence with respect to infant industry protection is not definitive on its costs, benefits and duration of protection over time. Krueger and Tuncer (1982) showed that in Turkey there was no evidence to suggest that more protected industries experienced a higher rate of declining costs than less protected industries. The industries did not pass the necessary condition for an economic justification of protection, namely that they experienced more rapid gains in efficiency as judged by comparing domestic resource costs against foreign-exchange savings at shadow prices that properly reflect relative scarcities. Even though a protected industry may grow, the question remains whether it would not have grown in the absence of intervention. And the empirical question of potential benefits being greater than earlier costs must also be examined.

A major study concluded that productivity growth in infant industries appears to be highly variable and that few of the infant enterprises studied in less developed economies have demonstrated the high and continual productivity growth needed to achieve and maintain international competitiveness (Bell et al. 1984, p. 114). Moreover, high levels of protection have also tended to persist beyond a temporary learning period (ibid. p. 117), and there is little evidence that higher rates of protection have been given to industries with greater externalities.

Finally, regarding the degree of protection, Westphal (1981, p. 12) has suggested that – even for an 'efficient' infant industry, and evaluated at

prices that properly reflect relative scarcities – the domestic resource costs might initially be as much as twice the value of the foreign exchange saved or earned, with up to a decade being required to bring costs down to competitive levels. If production subsidies are given, the implied starting rate of subsidy in relation to value added is as much as 50 per cent. If, however, tariff protection is utilized, the rate of effective protection implied at the start of production is as high as 100 per cent.

Clearly the empirical justification for infant-industry protection will remain ambiguous until more research is done in quantifying the costs and benefits of protection, and its magnitude and duration. Such research is still in its own infancy.

Infant Mortality

K. Wolpin

There is extensive variation in the level of infant mortality (deaths under 1 year of age) across countries, over time within countries, and across subgroups within countries or regions. Social scientists, and demographers in particular, have devoted a great deal of research effort towards identifying the underlying sources of variation, biological and genetic, environmental and behavioural, and their relative importance.

To gain perspective on the degree of cross-sectional and temporal variation in infant mortality rates, the following data are useful. According to World Fertility Survey statistics obtained in the mid-1970s, in Bangladesh 13.5% of all children ever born died before the age of one, in Mexico 7.2% of infants died, and in Malaysia 3.6%. Comparable figures were approximately 1.9% for the USA, 1.3% for Japan, and 1.2% for Sweden. Around 1900 the USA had an infant mortality rate equal to that cited for present-day Bangladesh; around 1925 it was equal to that of present-day Mexico; and directly after World War II to that in present-day Malaysia. Further, within the region of West Africa, a high mortality area, the infant mortality rate in 1972 varied from 12.2% in Ghana to 21.6% in Guinea.

It is not my intention to review the evidence on the relative importance of the various factors thought to influence the level of infant mortality, for in my view that literature has serious methodological flaws stemming from the lack of a consistent theoretical paradigm. Suffice it to say that there is still much debate even among those who would not hold this view. I wish instead to present an economic perspective which has a critical bearing on the methodological approach used to resolve this debate. This perspective draws heavily on the notion of household production (Becker 1965).

The essence of this approach is that infant health, survival being one albeit very important aspect of health, is produced according to some technological function which includes as inputs the resources devoted to the child (during pregnancy and after birth), such as prenatal care, breastfeeding, parental time devoted to child care, vaccinations, etc.; environmental conditions, such as sanitation and weather; biological conditions, such as the interval between births, the age of the mother at birth, and the genetic endowment of the child. More precisely, these inputs yield a probability distribution over health outcomes. Infant mortality differs systematically among individuals within a society, across societies, and over time within societies because of the differences in the levels and mix of these inputs and because of differences in the characteristics of the technology. In order to estimate the production function from data of any kind, it is necessary to postulate a mechanism which accounts for the input variation in the data.

From the economist's perspective it is natural to think of individuals as optimizing subject to constraints. Inputs have prices, monetary and/or psychic; faced with a given health technology, input levels are chosen depending upon the array of input prices both currently and the distribution expected to prevail in the future, wage rates (current and future), other income sources (current and future), preferences, and family and child endowments not subject to choice to the extent that they are known by the household. Much of the empirical literature can be seen as attempting to estimate technology, although in most of that literature technology is confounded with preferences through the introduction of income or prices. Further, few studies have estimated technology, accounting for the fact that, within an optimization framework, input choices would be conditioned on family or child endowments and on exogenous environmental factors. For example, because an infant's intake of breast milk depends on its ability to suckle, immature or ill infants may thus be breastfed less or not at all,

leading to an upward bias in the estimation of the effect of breastfeeding on infant health or survival. A number of recent papers which adopt this household production framework using both micro-level data from developed (Rosenzweig and Schultz 1983) and less developed (Olsen and Wolpin 1983) countries have demonstrated the importance of the assumptions about the process generating input variation in estimating input effects.

It is plausible that infant mortality is linked behaviourally to other demographic decisions, such as the number, timing, and spacing of children. Indeed, there is a large literature which has posed the question about the impact of infant deaths on fertility, presuming the variation in infant mortality at the individual level to arise solely or mostly from stochastic events not subject to control. Two distinct fertility strategies have been discussed – replacement and hoarding. Replacement refers to the fertility reaction to a realized death, while hoarding refers to a strategy of acquiring an inventory of children in anticipation of future deaths (Ben-Porath 1976; Schultz 1976). Replacement behaviour would arise in the simplest of dynamic models with infant survival uncertainty because an infant death must increase the marginal benefits of an additional child. Hoarding behaviour, which is a response to the *ex ante* survival uncertainty, will arise only if mortality of older children is significant and/or surviving children are desired early in the life cycle. Although it is recognized that this behaviour, if rigorously modelled, would require solving a complicated dynamic stochastic optimization problem, most attempts to estimate these effects have been statistical in nature (Olsen 1980) and only loosely based on theory. Some estimates of replacement based explicitly on a behavioural formulation have been obtained (Wolpin 1984), but solving and estimating such models is computationally burdensome. Formulating and estimating a dynamic model with hoarding is a more ambitious undertaking than has yet been accomplished. Incorporating health investment decisions in children in a dynamic choice setting has yet to be implemented, although that is where this literature is and ought to be moving.

But, what does the household choice theoretical framework have to do with the enormous differentials in infant mortality we observe between countries and the historically extraordinary decline in infant mortality throughout the world? Surely the individuals in Bangladesh cannot choose to have an infant mortality rate equal to that in the USA. One can view this question in two ways. At a superficial level, it is clear from the figures cited above that infant mortality is inversely related to per-capita income in the cross-section and the time series. For example, using data from the World Fertility Survey countries, the per-capita income for countries with an infant mortality rate above 10% was around $350, for countries with an infant mortality of between 7.5 and 10%, it was $600, for countries with an infant mortality rate between 5.0 and 7.5%, $1302, and for countries with infant mortality rates between 2.5 and 5.0%, $2168. Of course, it is not income per se which causes reductions in infant mortality, but the improved preventive medicine and eradication of disease, the introduction of modern sanitation, and the improved food distribution, which come with economic development. Even ignoring the fact that the relationship between infant mortality and income is far from perfect – for example, Turkey had in the 1970s an infant mortality rate similar to that in Bangladesh but a per-capita income level ten times as large – the relationship between infant mortality and income is not fundamental. To the extent that innovations in medicine and the like parallel changes in economic circumstances of the population as a whole and are intertwined with the fundamental desires of the population, they too require explanation in the context of overall economic and social development. What one learns from the household choice framework is that to understand the cross-section and time-series aggregate data, what is needed is a model of economic growth which incorporates endogenous demographics, by which I mean conscious choice about investments in human capital (infant health, for example) and family size, in addition to investments in physical capital. Introducing modern sanitation, for example, requires real resources in research and implementation and some decision process must be responsible for the diversion of resources to that use.

To Malthus (1798), mortality played a crucial role as a positive check on population growth. One can always argue about what Malthus really meant, but stripped to essentials the argument was that the fixed capacity of land coupled with exogenous population growth causes consumption per capita to fall to the subsistence level. Although Malthus recognized that fertility might respond to falling living standards, this preventive check was in his view weak. The equilibrium mortality rate is that rate which constrains population size to remain at the level consistent with steady state subsistence consumption.

The standard neoclassical growth model, e.g. Solow (1956), takes net population growth (fertility net of mortality) as exogenous. Per-capita consumption is maximized when the marginal product of capital is equal to the net reproduction rate. This model leads to the result that the 'optimal' mortality rate is equal to the excess of the fertility rate over the replacement fertility rate. Samuelson (1975) noticed that in an overlapping generations growth model, the optimal rate of growth of population is infinite because welfare rises continously the more young there are to support the old. Samuelson conjectured that there would be a deterministic optimum for population in a model which combined the neoclassical and overlapping generations approaches. Unfortunately, an overlapping generations model with capital (Diamond 1965) does not yield an interior solution for the optimal population growth rate for any unbounded production function (Deardorff 1976); again, population growth should optimally be zero. Because the overlapping generations framework is based on individual optimization, it allows for a broadening of the choice set. It does not make a great deal of sense to discuss optimal population issues in models where there exists no mechanism to achieve the optimum. There have been some attempts to allow for endogenous population in such models by adopting the notion from the microeconomic literature on fertility that households can choose their fertility, where children are consumption goods requiring expenditures (Eckstein and Wolpin 1985; Nerlove et al. 1984). These models are capable of describing the time path of output, consumption and population, and can yield insights as to the impact of technology, taste and endowments on those time paths. Incorporating infant mortality into overlapping generations growth models as a choice outcome, in the sense of allowing for investment in the human and physical capital necessary to affect it, would seem to be a logical and important step forward in understanding the economic and demographic development process. In particular, in many now developed countries, infant mortality decline preceded the decline in fertility so that population growth increased during the transition. Can an economic growth model in which fertility and investments in child survival are explicitly chosen by economic agents account for such a demographic pattern, and can this be fit into the observed timing of economic growth?

The notion that infant mortality, more broadly infant health and even more broadly child human capital, is and has always been an economic decision in a fundamental sense forces one to think more carefully about the determinants of aggregate cross-sectional and time-series demographic and economic variables. Much of this work is itself in an infant stage; its health and survival is also subject to choice.

Infant-Industry Protection

Douglas A. Irwin

Abstract

The infant industry argument for protection holds that new industries in developing countries should be promoted through trade or industrial policy measures to allow them to mature and compete successfully against established foreign rivals. This article assesses the theory and evidence behind this qualification to the case for free trade.

The infant industry argument for trade protection is one of the oldest and most widely debated qualifications to the case for free trade. The argument holds that certain new industries should be protected from foreign competition in the expectation that they will eventually mature and successfully compete against more experienced foreign rivals. The case for infant industry protection involves temporary and selective, not permanent and across-the-board, government assistance and is often discussed in the context of trade policies that might promote economic development.

The idea of infant industries can be traced back as far as the 17th century (Irwin 1996). In Book IV of the *Wealth of Nations* (1776), Adam Smith was sceptical that trade restrictions would create new wealth, arguing that they would just divert scarce resources into less productive endeavours. Other writers, such as Alexander Hamilton (1791) and Friedrich List (1841), believed that policies to promote manufacturing industries would be beneficial in encouraging economic diversification and growth in developing countries. The classical economist John Stuart Mill (1848, p. 922) lent his authority to the case by endorsing it in this way:

> The only case in which, on mere principles of political economy, protecting duties can be defensible, is when they are imposed temporarily (especially in a young and rising nation) in hopes of naturalizing a foreign industry, in itself perfectly suitable to the circumstances of the country. The superiority of one country over another in a branch of production, often arises only from having begun it sooner. There may be no inherent advantage on one part, or disadvantage on the other, but only a present superiority of acquired skill and experience. A country which has this skill and experience yet to acquire, may in other respects be better adapted to

> the production than those which were earlier in the field.... But it cannot be expected that individuals should, at their own risk, or rather to their certain loss, introduce a new manufacture, and bear the burthen of carrying it on until the producers have been educated up to the level of those with whom the processes are traditional. A protecting duty, continued for a reasonable time, will [*changed to* '*might*' *in later editions*] sometimes be the least inconvenient mode in which the nation can tax itself for the support of such an experiment. But ['*it is essential that*' *added in later editions*] the protection should be confined to cases in which there is good ground of assurance that the industry which it fosters will after a time be able to dispense with it; nor should the domestic producers ever be allowed to expect that it will be continued to them beyond the time necessary for a fair trial of what they are capable of accomplishing.

In the 19th century, the debate over infant industry protection centred on whether such protection would (*a*) create new wealth and capital, or merely divert it from other more profitable activities, (*b*) stimulate domestic producers to acquire new technology and skills, or just stifle the incentive for such efforts, and (*c*) generate long-term net benefits, or simply foster costly industries that would require ongoing government support. Unfortunately, economic analysis proved to be of little assistance in evaluating these claims, as one could envision the successful maturation of an infant industry but also see the possibility of protection breeding inefficiencies; a priori, neither outcome could be dismissed.

In the modern literature, the infant industry argument hinges on dynamic learning effects, which allow an industry that is not currently competitive to become so after a temporary period of protection. As such, the conditions for infant industry protection include the following: (*a*) irreversible technological external economies that cannot be captured by the protected industry, (*b*) a limited period of protection, and (*c*) sufficient long-run economic benefits (lower production costs that generate producer surplus) that will more than compensate for the costs associated with protection, with a rate of return at least equal to that on other investments (Kemp 1960).

If condition (*a*) is not fulfilled, the private market should deliver an efficient outcome unless there is some other market imperfection (poorly functioning capital markets, imperfect information) so that risks to starting the industry are overestimated by private agents and there is underproduction from the social point of view. Condition (*b*) states that protection must be time-limited, and not persist indefinitely. Condition (*c*) requires an intertemporal cost–benefit analysis, wherein the initial costs of protecting the industry will be more than offset by long-run benefits.

The modern literature on infant industries also focuses on identifying the specific market failure or distortion that makes government intervention necessary as well as the ranking of alternative policy instruments in terms of their ability to correct the market failure or distortion. If an industry is characterized by learning-by-doing spillovers, wherein production costs for any firm fall as a result of production experience by anyone in the industry (that is, the learning benefits are external to the firm), then this dynamic economy of scale may lead to a divergence between private and social costs of production. The knowledge generated by research and development expenditures can also create external benefits which could lead to underinvestment by the private market. And if there are capital market failures, such that firms cannot acquire credit (Flam and Staiger 1991; Bond 1993), or informational barriers to entry (Grossman and Horn 1988), there may be a case for selective interventions.

Once the specific obstacle facing the infant industry is identified (that is, related to production experience, technology transfer, or imperfect capital markets), then the policy recommendation can be specifically targeted to address the problem. In general, trade protection will not be the first-best policy intervention to correct the distortion that hinders the development of an infant industry. Baldwin's (1969) classic critique of the infant industry argument stresses that import protection fails to provide the right incentive for an infant firm to make additional investments in acquiring technological knowledge and does not necessarily solve a firm's appropriability problem of securing the benefits of investments in knowledge or production experience. But, by reducing foreign competition and raising the domestic price, it does make the status quo more profitable.

If the economic conditions giving rise to infant industries are difficult to assess, the implementation of a welfare-improving policy also poses difficulties for governments. The government must differentiate among various industries (ignoring the lobbying of firms for government assistance), pick those to support with preferential policies, select the proper policies to ensure that firms have the incentive to respond the right way, and be able to resist pressure from firms to maintain protection indefinitely (Tornell 1991).

Despite many theoretical articles on infant industry protection, Krueger and Tuncer (1982, p. 1142) wrote that 'there has been virtually no systematic examination of the empirical relevance of the infant industry argument' through *ex post* evaluations or other studies. They found little correlation between various measures of the effective rate of protection and industry productivity growth in Turkey, but did not perform counterfactual simulation or cost–benefit analysis (see Harrison 1994).

To date, there are still relatively few evaluations of infant industry policies. Luzio and Greenstein (1995) studied performance of the Brazilian microcomputer industry under protection that started in the early 1990s. They found that the rates of technological advance in Brazil were rapid but lower than that of potential international competition. As a result, the technical frontier in Brazil lagged that best performance practices in international markets by three to five years, and forgone consumer surplus due to protection approached 20 per cent of domestic expenditure on microcomputers.

Hansen et al. (2003) examined the welfare effects of subsidies in Denmark for the production of electricity from wind power. They found strong learning-by-doing productivity growth in the Danish windmill industry, and the industry achieved a dominant position in the world market. By their calculation, these subsidies passed a cost–benefit test: the costs consist of the efficiency loss from diverting electricity production from using fossil fuels to utilizing wind power, but the benefits include reductions in the environmental damage of using fossil fuels and the emergence of a new export sector. They concluded that the subsidies pass a cost–benefit test because the value of the windmill firms at the stock exchange far exceeds the accumulated distorted losses in electricity production.

Economists have also looked at historical cases of infant industry protection, as it is commonly contended that high-income countries such as the United States, Japan and Germany rose to industrial prominence by protecting infant industries in the late 19th and early 20th centuries (Chang 2003). Two studies examined the US iron and steel industry in the late 19th century. Head (1994) sought to account for the individual roles of learning-by-doing, changing resource endowments, and tariff protection in the emergence of the steel rail industry. In a counterfactual simulation of what would have happened under free trade, he concluded that learning effects were very strong and that, even though the steel rail tariff hurt rail users in both short and long runs, the tariff's overall effect on welfare was positive but fairly small. Irwin (1998) studied the US tinplate industry which, after earlier failures, flourished after receiving tariff protection in 1890. His counterfactual simulation indicated that, without the additional duties, domestic tinplate production would have arisen about a decade later as US iron and steel input prices converged to those in Britain. Although the tariff accelerated the industry's development, welfare calculations suggest that protection did not pass a cost–benefit test.

In general, however, economists have been sceptical about the relevance of the infant industry argument for current developing countries, and for the ability of governments to implement the policy wisely. For example, reviewing the empirical literature on manufacturing establishments in developing countries, Tybout (2000) found that unexploited economies of scale in developing countries are insignificant and that protection tends to reduces average efficiency levels by allowing lower-productivity, higher-cost firms to survive in the market. He concluded that 'although the econometric evidence on technology diffusion in [developing countries] is limited, it does suggest that protecting "learning" industries is unlikely to foster productivity growth' (2000, p. 39).

Inflation

Michael Parkin

Abstract

This article essay reviews the theoretical and empirical literature on the causes and consequences of inflation – of a continuously rising price level and falling value of money. It describes the research agendas using the analytical distinction between anticipated inflation – an idealized situation in which prices are rising at a rate at which all economic agents expect them to rise – and unanticipated inflation. The literature on the effects of inflation on economic growth and unemployment, inflation in open economies, positive theories of central bank behavior, inflation and fiscal policy, and policies towards inflation including interest rate and inflation targeting receives particular attention.

'Inflation is a process of continuously rising prices, or equivalently, of a continuously falling value of money' (Laidler and Parkin 1975, p. 741). Because there are several ways of measuring prices, there are also several different measures of inflation. The most commonly used measures in the modern world are the percentage rate of change in a country's Consumer Price Index or in its Gross Domestic Product deflator. Measures of inflation in earlier periods are based on fragmentary samples of prices, such as those of corn and other staple commodities, or of labour.

Inflation has been a feature of human history for as long as money has been used as a means of payment, and as Milton Friedman (1970, p. 24) famously wrote, 'inflation is always and everywhere a monetary phenomenon, in the sense that it cannot occur without a more rapid increase in the quantity of money than in output'.

Anna J. Schwartz (1973) provides a compact account of the history of inflation from antiquity to modern times. One of the earliest documented inflations in the ancient world occurred following Alexander the Great's conquest of the Persian Kingdom (330 BC); the Roman Empire experienced rapid inflation under Diocletian at the end of the third century AD. We have no knowledge of inflation for the thousand years that followed the fall of the Roman Empire. But we do have data from the Middle Ages onwards. The inflation episodes during the Middle Ages were modest, and during those years there was a tendency for periods of rising prices to be interspersed by periods of falling prices. This pattern of intermittent inflation and deflation persisted all the way through to the Great Depression of the 1930s. Since the Great Depression, there has been a general tendency for prices to rise every year (with trivial exceptions). In the 1970s and early 1980s, serious inflations – of more than ten per cent a year – gripped most of the industrial world. But this 'double-digit' inflation era was short-lived, and by the mid-1980s inflation rates had returned to the more modest levels experienced in the late 1960s. In the early 2000s, there was little sign of high inflation returning in the major economies. Individual inflations of spectacular dimensions occurred in inter-war Europe, during the fall of Nationalist China (1948–9), and in modern times in some Latin American nations, Israel, and Zimbabwe. Some of these were episodes were hyperinflations – inflation rates that exceeded 50 per cent per month.

It is the fact that inflation has been so variable over time and across countries that gives rise to the question: what are the causes and the consequences of inflation? It is the enormously rich variation in inflationary experience that also provides the data which makes progress in answering those questions possible.

The literature on inflation is large, and several comprehensive, if dated, surveys of it are available (see Bronfenbrenner and Holzman 1963; Johnson 1963; Laidler and Parkin 1975). No up-to-date survey of the literature on inflation was available as of 2006.

Attempts to understand inflation have been aided by the insight that anticipated inflation has different effects from unanticipated inflation. It is convenient to use that distinction in organizing this article. But it must be borne in mind that the distinction between anticipated and unanticipated inflation is analytical. It is not a distinction that

has an immediate or direct correspondence with actual historical inflations.

Anticipated Inflation

Anticipated inflation is an idealized situation in which prices are rising at a rate at which all economic agents expect them to rise. No one is caught by surprise. What are the effects of a fully anticipated inflation?

There is little disagreement on the answer to this question concerning the effects on nominal variables – on such things as nominal interest rates, wages and foreign-exchange rates. Other things equal, the higher the expected rate of inflation, the higher the *level* of nominal interest rates, the higher is the rate at which wages rise, and the faster the rate of currency depreciation. Furthermore, these effects are one for one. An x per cent higher anticipated inflation raises nominal interest rates by x per cent, makes wage rates rise x per cent faster, and makes the currency depreciate x per cent faster.

There is less than complete agreement about the effects of anticipated inflation on *real* economic variables. Abstracting from transitory adjustment paths, all economic theories predict monetary neutrality: a one-shot change in the quantity of money leads to a proportionate change in the levels of all prices (and wages) and has no real effects. But not all economic theories predict monetary superneutrality – that real variables are neutral with respect to changes in the growth rate of the quantity of money.

There are three alternative views in the literature concerning money's superneutrality. One view is that money is superneutral – a change in the anticipated inflation rate has no effects on output (or economic welfare). A second view is that in increase in the anticipated inflation rate increases output (and economic welfare). Yet a third view is that a higher anticipated inflation rate lowers output (and economic welfare).

The superneutrality result has been most elegantly and clearly stated by Sidrauski (1967). The result also is present in some modern theories of money that pay detailed attention to the physical environment in which monetary exchange arises (see, for example, Townsend 1980). The essential feature of models that generate superneutrality is that the real rate of interest is imposed by the structure of preferences (intertemporally additive with a constant rate of time preference). In equilibrium, the marginal product of capital is equal to this fixed rate of time preference so that, regardless of what happens to money, the capital stock and output rate are unaffected.

The natural rate hypothesis is a variant of the superneutrality proposition. This hypothesis, advanced by Friedman (1968) and Phelps (1968), states that money is superneutral in the particular sense that there is a unique natural unemployment rate that is independent of the anticipated rate of inflation. Any trade-off between inflation and unemployment is temporary and best thought of as a trade-off between unanticipated inflation and unemployment.

The second view that a higher anticipated rate of inflation increases output and improves economic welfare arises in two classes of models. The first is the so-called Mundell–Tobin effect (Mundell 1963, 1965; Tobin 1965). A higher anticipated inflation rate results in an increase in the opportunity cost of holding real money balances. According to the Mundell–Tobin view, this higher opportunity cost of holding money leads to a portfolio reallocation away from money and towards physical capital. The higher holdings of physical capital result in a higher stock of capital and therefore in a higher capital–labour ratio, which in turn leads to a higher level of output. A rise in the anticipated rate of inflation would put the economy on an adjustment path towards the new higher capital stock that would be associated with a transitory rise in the growth rate and a permanent rise in the level of output. A restatement of the Mundell–Tobin position couched in a modern rational expectations terms has been provided by Fischer (1979). The second type of model is one in which an asymmetry in price and wage adjustment – a downward rigidity – creates a long-run trade-off between inflation and the level of economic activity – a downward-sloping long-run Phillips curve.

The third view that a higher anticipated rate of inflation lowers output and economic welfare also arises in two classes of models. First in an overlapping-generations framework (Samuelson 1958; Wallace 1980) a rise in the anticipated rate of inflation leads agents to economize on their holdings of money which, in turn, leads them to save less and transact on a lower scale with the succeeding generation. Second, Clower's (1967) suggested technological basis for money – the cash-in-advance constraint – generates super-non-neutrality. Using Clower's assumption, Stockman (1981) shows that, because a higher anticipated inflation rate raises the opportunity cost of holding money, this, in effect, raises the opportunity cost of undertaking all transactions and, therefore, in equilibrium lowers the scale of transactions undertaken. In Stockman's model, this results in a lower investment rate and lower capital stock. Thus a higher expected inflation rate leads to a lower level of output. A rise in the anticipated inflation rate will place the economy on an adjustment path that would result in a lower transitory growth rate and a lower permanent level of income.

Some of the above results can be thought of in terms of the substitute/complement relation between money and capital. If money and capital are substitutes in portfolios, then the Mundell–Tobin result arises. If money and capital are complements, as they implicitly are in the overlapping generations and cash-in-advance models, then higher anticipated inflation leads to lower output.

There is an abundance of empirical evidence on the alternative hypotheses about the effects of fully anticipated inflation. But the evidence is not entirely unambiguous. Because the very concept of anticipated inflation is analytical and not historical, in examining inflationary experience assumptions must be made concerning the extent to which inflations have been anticipated.

Comprehensive and systematic attempts that have addressed the question in the context of economic growth are those by Kormendi and Meguire (1985), Barro (1997), and Sala-i-Martin et al. (2004).

Using post-war data for 47 countries, Kormendi and Meguire analyse the effects of a change in the anticipated rate of inflation on output growth in a multivariate regression framework. Anticipated inflation was measured as simply the mean growth rate of inflation over the sample period (which went from the late 1940s to 1977). The finding of that study solidly rejects the Tobin–Mundell hypothesis and, in some formulations, fails to reject the opposite view.

Using data for about 100 countries between 1960 and 1990, Robert Barro finds that inflation has a negative effect on growth. The effect is small but significant and implies that maintained for a number of years, in inflation rate that exceeds ten per cent per year has a large cumulative effect on output. Barro is careful in his analysis of the endogeneity of inflation and growth to establish that causation runs from inflation to growth.

Barro's finding is challenged by Sala-i-Martin, Doppelhofer and Miller. Using data from 1960 to 1996 for 88 countries and 67 variables considered candidates for influencing the rate of economic growth, and using a Bayesian averaging of classical estimates approach, they find that neither average inflation rate nor the square of the inflation rate has a significant effect on the growth rate.

The work just summarized takes a reduced form and linear approach, and these features limit its utility. Future work on the effects of inflation on growth should be directed toward looking at structural accounts of the linkages and seeking highly nonlinear and perhaps nonparametric relationships between these two variables.

Investigations of the neutrality of unemployment (and output) with respect to anticipated inflation has been the subject of innumerable studies, and Laidler and Parkin (1975) review the state of this literature up to the mid-1970s. The conclusions that emerged from this work were mixed, and most of the results generated on data-sets that ended around 1970 showed the existence of a trade-off. But as the data for the 1970s (with its high inflation rate) were added, the picture changed and Laidler and Parkin concluded that it was not possible to reject the view that the unemployment rate is neutral with respect to anticipated inflation.

This conclusion is challenged in three different ways. First, the classic Sargent (1976) shows that reduced-form equations estimated for a given sampling interval over a given sampling period cannot distinguish among alternative theories, even though the theories have radically different policy implications. The implication of this result for Phillips curve trade-offs is that useful inferences can be made but only by estimating reduced forms over different sub-periods or countries across which policy rules differed systematically. As of 1976, Sargent thought that not much of this type of work had been done, so that little was known.

Second, further empirical work seemed to be consistent with the view that a permanent trade-off exists. King and Watson (1994) study the US Phillips correlations and Phillips trade-offs in a bivariate time-series analysis. They use the unit root (I(1)) inflation process to get around the Sargent (1976) problem (see Fisher and Seater 1993; King and Watson 1997, for details), and estimate structural models to interpret the data and compute the long-run trade-offs and sacrifice ratios (cost of lowering inflation) associated with each model. Except for the extreme case of a real business cycle model, they find long-run trade-offs between inflation and unemployment.

The same conclusion is reached by Akerlof et al. (1996), but for a different reason. They report evidence of permanent downward wage stickiness, which implies a long-run trade-off. This evidence comes from four sources: ethnographic surveys, Bureau of Labor Studies data on the distribution of wage changes in manufacturing establishments, union settlements (in both the United States and Canada), and the authors' own survey of individuals in the Washington DC area. The authors' were aware that Panel Study of Income Dynamics (PSID) data showed evidence of extensive downward wage flexibility, but argue that individual reporting errors are large, and when corrected for using data from the Current Population Survey, downward rigidity is present. The presence of downward wage rigidity would constitute a serious challenge to the natural rate hypothesis – the neutrality of the unemployment rate with respect to the anticipated inflation rate. And not surprisingly, much work has been done to check the conclusion reached by Akerlof, Dickens and Perry. Parkin (2000) summarizes this work, which concludes that the money wage rate is not downwardly rigid and that the appearance of downward rigidity results from three sources of bias; measurement error, rounding error and long-term contracts. Controlling and correcting for these sources of bias points towards wage flexibility. Clearly more work is needed to settle this issue.

The third challenge to monetary neutrality comes from a series of papers by Barro (1977, 1978) and Mishkin (1982a, b). Decomposing money growth into anticipated and unanticipated components, Barro reports that only unanticipated money growth influences unemployment and real GDP and (as predicted) both anticipated and unanticipated money growth influences the price level. Mishkin shows that Barro's estimation procedure, while providing consistent parameter estimates, delivers incorrect standard errors. When Mishkin replicates Barro's exercises with valid tests, he rejects the restrictions implied by neutrality. (He does not reject the restrictions implied by rationality.)

The literature just reviewed deals with the consequences of anticipated inflation and not its causes. Questions concerning causality are more naturally addressed in the context of an investigation of unanticipated inflation.

Unanticipated Inflation

It is not possible to analyse unanticipated inflation in isolation, independently of other aspects of aggregate economic performance. Fluctuations (at the business cycle frequency) in the general level of economic activity and in inflation, though far from perfectly correlated, share some common features. There is, for example, a general positive correlation between inflation and real income (or equivalently, a negative correlation between inflation and unemployment). There is also a positive correlation between money and income as well as between the velocity of circulation of money and income.

The 'stylized facts' about the business cycle (shared by all economies) raise difficult questions about cause and effect. Of the four variables – the price level, real output, the money supply and the velocity of circulation – which, if any, is the prime mover? Do fluctuations in the growth rate of the money supply cause fluctuations in the other variables? Do autonomous movements in the price level, perhaps stemming from wage-push pressure, initiate the fluctuations in money, velocity and output? Does the business cycle have its origin in real factors that initiate fluctuations in output, which in turn lead to induced fluctuations in money supply growth, inflation and velocity?

At one level questions such as these are statistical and are capable of being investigated using econometric methods that detect causality, such as those proposed by Granger (1969). Studies based on such methods have not, however, delivered decisive results.

Most investigations of the possible causes of inflation have sought to understand the phenomenon by identifying the sources of inflation and studying the transmission mechanism whereby those sources are translated into variations in the rate of inflation and in other economic aggregates. This approach is one which seeks to understand both inflation and the business cycle as an integrated phenomenon.

There are three broad classes of theories that have been proposed for understanding the unanticipated and cyclical aspects of inflation. The first of these stems from the work of Keynes (1936) and emphasizes both price stickiness and the potential for autonomous movements in prices. On this view, the normal state of affairs would be one in which wages and prices are relatively sticky, responding only gradually to aggregate demand shocks. Shocks to aggregate demand arise from a variety of sources. One possibility is that autonomous fluctuations in investment produce fluctuations in aggregate demand. Other possible sources of aggregate demand fluctuations are fluctuations in wealth and interest rates which in turn are induced by fluctuations in the growth rate of the money supply. Fluctuations in wealth and interest rates can induce fluctuations in investment and consumption. All of these potential sources of variation in aggregate demand lead to cycles in both output and the price level. Initially, a change in demand will have bigger output effects than price-level effects, but eventually prices and wages will adjust to reflect fully the change in aggregate demand. The resulting co-movements in output and prices will be positively, though not strongly, correlated.

From time to time this normal state of affairs is disturbed by autonomous price shocks. The most commonly hypothesized source of price shocks is wage-push. It is suggested that, at times of substantial industrial or social unrest, movements in the level of money wages will act as a type of social safety mechanism. The idea that wage-push results from sociological phenomena was particularly popular amongst economists in the UK in the early 1970s (see, in particular, Balogh 1970; Jones 1972; Wiles 1973; Hicks 1974. By the time the first oil shock occurred (late 1973), 'wage-push' gave way to 'oil-push' as the most commonly identified source of autonomous movement in inflation.

When autonomous movements in the price level occur, the phenomenon that came to be known as 'stagflation' quickly follows. The autonomous price rise raises the inflation rate and lowers output (raising unemployment). If the higher unemployment and lower output induces an increase in the growth rate of the money supply, then even further price-level rises occur.

This traditional version of the Keynesian theory of inflation and the business cycle, together with some of the sociological embellishments that have been briefly reviewed above, is very thoroughly explained and elaborated in Laidler and Parkin (1975).

More recent and sophisticated versions of the Keynesian theory of cycles and inflation may be found in papers by Fischer (1977), Phelps and Taylor (1977), and Taylor (1979, 1980). The essence of these 'New Keynesian' theories is the existence of long-term contractual arrangements in labour markets. Such arrangements result in wages, the major element of costs, being predetermined. This stickiness of wages and costs

results in a stickiness of prices, even if the expectations of prices that form the basis for the long-term labour market contracts are formed rationally.

A second approach to understanding cyclical fluctuations is one based on incomplete contemporaneous information about aggregate demand. This approach, sometimes called the 'New Classical Theory', was first suggested in the early 1970s by Lucas (1972, 1973). The approach is broadly consistent with the Keynesian mechanism of aggregate demand determination but proposes an alternative theory of aggregate supply. Individual economic agents are assumed to operate in informationally isolated 'islands' and to be incapable of distinguishing relative from absolute price level changes. The resulting confusion causes them to respond to absolute price changes as if they were relative price changes. This response results in positive co-movements in output and the price level.

In both the Keynesian and New Classical approaches, the key driving variable generating the cycle – fluctuations in both real output and the inflation rate – is a fluctuating growth rate in the money supply. This is not to deny that other things might, from time to time, shock the economy. Rather, it is a proposition about the major ongoing source of cyclical variation. Within both of the theories, positive co-movements of velocity are explained by appealing to the idea that to some degree the cycle itself is forecastable. To the extent that it is, higher rates of inflation at the cyclical peak will in part be anticipated and, therefore, reacted to. It is always efficient to reduce money holdings when the opportunity cost of holding money increases. Higher expected inflation rates, leading to higher nominal interest rates, induce such economizing and are, therefore, the major source of procyclical fluctuations in velocity.

A third approach to understanding aggregate fluctuations denies the primacy of variations in the money supply growth rate, or in any other sources of aggregate demand fluctuation in generating the cycle. This approach, known as 'real business cycle theory', has yet to gain a major following but has, in recent years, begun to spawn a growing and important literature (see, in particular, King and Plosser 1984; Kydland and Prescott 1982; Long and Plosser 1983; Nelson and Plosser 1982). Though differing in details, the essential proposition of the new real business cycle theories is that aggregate fluctuations emanate from technological shocks to the aggregate production function or, in some versions, from sector-specific shocks and from the interactions between sectors of the economy – although a large literature has now incorporated Calvo (1983) price stickiness or monopolistic competition.

Technological shocks that generate fluctuations in full-employment output would, other things equal, generate negative co-movements in prices, and, presumably, to the extent that such movements were forecastable, countercyclical movements in velocity. Since such co-movements do not occur, it seems as if the real cycle theories are in substantial trouble. King and Plosser (1984) address this problem directly by proposing that technological shocks which affect real output induce responses in money and credit that accommodate – indeed over-accommodate – the real fluctuations. Thus, when there is a positive shock to aggregate supply, this induces an even bigger rise in the total volume of money and credit and, therefore, induces procyclical co-movements in money, prices and output. To the extent that these are forecastable, economizing on real balances generates procyclical velocity.

There is not, at the present time, any definitive and systematic evidence capable of disposing convincingly of any of these three alternative approaches; nor is there any overwhelming evidence suggesting that any of them is clearly in the lead.

Inflation in Open Economies

The alternative approaches to understanding inflation that have been reviewed so far have (implicitly) examined inflation in a closed economy. Most practical concerns about inflation arise in individual countries which are open economies.

The international trade and international capital market transactions undertaken by such countries have an important bearing on their inflation performance. Also, the foreign-exchange rate regime – fixed or flexible – has an important influence upon a country's inflation performance. It was during the period of rapidly accelerating inflation in the 1970s that open economy theories and the international transmission mechanism gained in prominence (see Parkin and Zis 1976a, b).

The main feature of the analysis of inflation in an open economy is the emphasis on the limited potency of domestic monetary policy under fixed exchange rates. In a country, or more interestingly in a world, operating on fixed exchange rates, individual countries' monetary policies have no effect on the country's rate of inflation. Instead, monetary policy influences the country's balance of payments. In such a world, inflation is a world phenomenon, not a national phenomenon. It is the growth rate of the world money supply that determines the world average rate of inflation. Theorizing along this line had, in fact, made good progress even as early as the middle of the 18th century at the hands of David Hume (1752). It was rediscovered and popularized in the 1960s and early 1970s by Mundell (1971) and Johnson (1973).

The rediscovery of David Hume's analysis provided interesting insights into the resurgence of world inflation at the end of the 1960s. An attempt on the part of the United States to finance its Great Society programme and the Vietnam War with limited tax increases and with an increase in the growth rate of the money supply – with an increase in the inflation tax – became the engine of an inflation that engulfed the entire fixed exchange-rate world.

Understanding the international generation and transmission of inflation in a flexible exchange rate world, such as that which had emerged by the mid-1970s, is still far from settled. At the centre of the problem of understanding inflation is the problem of understanding the determination of foreign exchange rates. Large and rapid movements in foreign-exchange rates are seen as having a potentially powerful and rapid effect on domestic price levels. The forces that determine exchange rates are still, however, far from well understood. Viewing the foreign exchange rate as following a random walk is as precise as any structural theories of the exchange rate that have so far been proposed and tested.

Despite the absence of a convincing theory of inflation in an open economy, the effects of policy coordination (or its absence) have been studied. A central question addressed by Oudiz and Sachs (1984) and Obstfeld and Rogoff (2002) is whether unilateral national monetary policy rules are inferior to international monetary coordination. The answer is that they are not.

Positive Theories of Central Bank Behaviour

Recent developments in understanding inflation have been dominated by the rational expectations revolution and the related and more far-reaching revolution that has uses rigorous dynamic general equilibrium analysis. Some of the implications of that revolution have been discussed above and have been to strengthen and refine the theories of inflation that emphasize fluctuations in the growth rate of the money supply as the principal source of fluctuations in inflation and other economic aggregates.

The rational expectations hypothesis holds that expectations are formed by making predictions of future inflation on the basis of the mechanisms that generate actual inflation. If inflation is indeed caused by rapid monetary expansion, then forecasting future inflation is the same thing as forecasting future monetary policy. But monetary policy itself emerges from an ill-understood political process. In most countries the task of formulating monetary policy has been delegated to a central bank. Yet, in determining monetary policy, central banks are often influenced by the economic and political environment in which they operate and must also take account of the consequences of their actions for the behaviour of the economy as a whole.

In order to understand the inflationary process, with people forming expectations rationally, it becomes necessary to understand the

policymaking mechanisms and the forces that generate varying monetary growth rates. The first serious analysis of this problem was that by Kydland and Prescott (1977) and the problem has been investigated more recently by Barro and Gordon (1983a, b) and Cukierman (1992). In the models proposed by these writers, a central bank's goal is to achieve an optimal combination of inflation and unemployment. Lower inflation and lower unemployment are seen by the central bank as desirable objectives. The bank is constrained, however, by a short-run trade-off between inflation and unemployment – a trade-off arising from the considerations described above. A surprise rise in inflation would produce a cut in unemployment while a surprise drop in inflation would produce a rise in unemployment. The precise way in which the short-run trade-off between inflation and unemployment constrains the central bank depends on the expectations of private agents concerning the bank's behaviour. A central bank that can credibly precommit to a particular rule about inflation – perhaps a zero-inflation rule – would be a bank that could engender rational expectations of zero inflation. It would be optimal for such a bank to in fact precommit to a zero rate of inflation and then deliver that rate.

The ability to precommit and with credibility seems to require some mechanism for binding the central bank that does not have a readily identifiable counterpart in the real world. Central banks are, in fact, free to pursue whatever policies they wish at their discretion. Since this fact is known to all private economic agents, it will be rational for them to take it into account when forming expectations about central bank behaviour. The equilibrium that results in this case will be such as to ensure that the actual inflation rate chosen by the bank is one that removes any temptation for the bank to depart from that rate and further exploit the short-run trade-off. Put differently, the inflation rate chosen will be the best available at the natural rate of unemployment. Only in such a situation would the central bank have no further temptation to attempt to exploit the short-run trade-off. Thus without the ability to precommit to a fixed (and presumably zero) rate of inflation, a central bank will end up delivering a higher rate of inflation than that which is socially desirable.

One feature of the positive theories of inflation developed by Kydland–Prescott and Barro–Gordon that some people find disquieting is the time inconsistency. (In game theory language, the equilibrium concept is Nash rather than sub-game perfection.) Attempts to develop positive analyses that do not have this feature have been based on reputation. One such approach, in Barro and Gordon (1983a), uses the so-called 'trigger strategy' model of reputation suggested by James Friedman (1971). A model is proposed in which the central bank would be punished if it delivered too high a rate of inflation and in which it takes time to restore the bank's reputation. In equilibrium, the bank never does inflate at a rate that requires the punishment to be inflicted.

An alternative approach by Barro (1986) uses the reputation analysis developed by Kreps and Wilson (1982). In this model there are two potential 'types' of central banker, one that likes inflation and one that dislikes it. The inflationary central banker has an incentive to masquerade as a non-inflationary type in order to induce low inflation expectations. By inducing low inflation expectations, the inflationary central bank will, at some point, be able to exploit those low expectations and produce a surprise inflation; it will do this by following initially a strategy of inflating at exactly the same rate as would be chosen by a non-inflationary central bank. At some later point it will pursue a mixed strategy – a strategy analogous to choosing an inflation rate by drawing numbers from an urn. Once this mixed strategy has resulted in a high rate of inflation, the inflationary central banker is revealed, and expectations about inflation as well as actual inflation will rise.

Another feature of the Kydland–Prescott and Barro–Gordon models that is objectionable is that the central bank targets an unemployment rate below the natural rate. If it were to target the natural rate, there is no tension between its inflation and real goals. Cukierman overcomes this objection by replacing the symmetric loss function of the standard model with an asymmetric loss function: the central bank weighs positive

deviations from the natural unemployment rate more heavily than deviations below the natural rate.

Backus and Driffill (1985) and Cukierman (see Cukierman 1992, ch. 3), have suggested another modification to the standard model: the possible interactions between labour unions (working as a unified wage-setting institution) and the central banks. In this case, inflation (and money supply growth) is determined as the outcome of a game between the central bank and the economy-wide labour union.

Empirical tests of the alternative positive theories of central bank behaviour have been conducted by Ruge-Murcia (2003) and by Cukierman and Gerlach (2003). Ruge-Murcia uses US time-series data and rejects the Barro–Gordon formulation but does not reject the Cukierman asymmetric loss function formulation. Cukierman and Gerlach use data for 22 OECD countries and reach a similar conclusion.

Other recent developments in understanding central bank behaviour arise from the normative analysis of monetary policy to achieve an inflation target, and it is convenient to discuss this topic in the context of inflation policy below. But, before that, it is convenient to consider the links between monetary policy and fiscal policy.

Inflation and Fiscal Policy

A further consequence of the rational expectations and dynamic general equilibrium revolutions has been to force attention back to the connection between fiscal and monetary policy. The simple accounting fact that government expenditure must be financed, either by taxation, by borrowing or by money creation, implies that any analysis of the determination of money growth must at the same time make consistent propositions about fiscal policy and deficit financing. Of course, variations in the growth rate of interest-bearing debt can provide a good deal of insulation of money growth from the deficit. Nevertheless, large and persistent deficits may give rise to rational expectations of future money growth, even in the face of currently firm monetary policies. Sargent and Wallace (1981) have shown that, if the fiscal authority is the prime mover and follows taxation and spending policies that are independent of monetary policy, then, essentially, inflation and, ultimately, money growth are fiscal phenomena. Whether these findings are of practical importance is a matter of some controversy. Sargent (1982), studying the ends of four big inflations, has argued that adjustments in fiscal policy have been crucial to ending inflation. By implication, the emergence of a large and apparently uncontrolled deficit would be seen as the origin of serious inflation. Work by Dornbusch and Fisher (1986) offers a different interpretation, however, placing major importance on the behaviour of the foreign exchange rate.

The link between fiscal policy and inflation is most complete in Woodford's (1995) fiscal theory of the price level. Because the quantity of money demanded depends on the opportunity cost of holding money, which in turn depends on the rational expectation of the inflation rate, there is a large number (infinite) of equilibrium price level paths. The standard (mostly unstated) approach rules out all the purely speculative equilibria and selects the unique equilibrium based on the monetary fundamentals. In which the government's choice of how to finance its debt determines the inflation rate. The fiscal theory of the price level rejects this approach and rules out equilibria by the government's selection of its debt financing regime. As an example, Kocherlakota and Phelan (1999) show that, with a policy of constant taxes and constant money, the fiscal theory predicts that a one-time cut in the quantity of money generates a speculative hyperinflation (in contrast to the standard model prediction of a one-time fall in the price level).

Policy Towards Inflation

Analyses of policies towards inflation have changed over the years. Advocacy of gradually slowing down the growth rate of the money supply and advocacy of controls on wages and prices were the most commonly heard policy

suggestions for controlling inflation in the 1960s and early 1970s. Those who saw autonomous wage and price movements as the principal source of inflation saw prices and incomes policies as the major weapon to control it. Those who saw money growth as the source of inflation embraced monetary gradualism as the most obvious cure. A prodigious amount of work attempting to evaluate alternative policies was undertaken, much of which is surveyed by Laidler and Parkin (1975).

As a consequence of the rational expectations and dynamic general equilibrium revolutions, the focus of the policy debate has shifted markedly from that of seeking to manipulate variables such as key wage settlements (the prices-and-incomes policy solution) or the growth rate of the quantity of money (the monetarist solution). Instead, attention has turned to thinking about the way in which different institutional arrangements interact to produce different inflation rates. And the emphasis has shifted from policy as an action to policy as a process or set of rules.

One line of research has examined the consequences of alternative monetary systems, including the adoption of alternative forms of commodity money (see, in particular, 'Conference on Alternative Monetary Standards' 1983). Another research direction has been the investigation of targeting nominal income growth as a means of conquering and avoiding inflation (Tobin 1983; Taylor 1985).

But the idea that has attracted most attention both in the research community and among central banks is the use of a monetary policy rule that seeks to achieve either an inflation rate target or a price level target. The study of inflation or price level targeting has both a positive and a normative dimension and sometimes the two are not explicitly distinguished.

Svensson (1999) has provided a nice distinction between what he calls 'instrument rules' and 'targeting rules' for monetary policy. In the context of inflation targeting (and that is the context of most of the recent literature on monetary policy) an instrument rule specifies how the policy instrument responds to the current state of the economy. The current state can include current forecasts of future variables. A targeting rule, in contrast, states that the policy instrument shall be set at the level that makes for forecast inflation rate equal the inflation target.

The policy instrument that features in instrument rules is either the overnight interest rate on inter-bank loans or the monetary base. Woodford (2003) provides the authoritative account and discussion of the interest rate instrument rule and shows that such a rule can, in principle, deliver low and stable inflation provided that it incorporates the 'Taylor principle', which states that the interest rate must change in the same direction as a change in the inflation rate but by more than the change in the inflation rate (Taylor 1993, 1999).

McCallum (1988) has explored the use of a monetary base rule and compared the robustness of interest rate and monetary base rules.

It is a curious fact about the models that explore the use of an interest rate rule that money plays either no role or no essential role in the inflation process. The models in which money plays no role are typically specified as reduced forms in which inflation is generated by expected inflation and the output gap; the output gap responds to the real interest rate, which equals the nominal interest rate set by the central bank minus the inflation rate; and expectations are rational. Other models are specified at a deeper structural level with consumers maximizing intertemporal utility of consumption and leisure and monopolistically competitive firms setting prices according to a Calvo (1983) formula.

In some models, money enters through a 'shopping time' function (King and Wolman 1996). But whether present in the model or not, money plays no essential role in the inflation process. This fact is emphasized in Woodford (2003) by his exploration of the cashless economy and is seen as a virtue because it might provide insights on inflation in a future economy when technological change has driven money, as we know it, out of existence.

It is also a curious fact that inflation targeting amounts to targeting a variable whose value cannot be influenced by a central bank's current actions until well beyond the bank's forecast horizon. It is the long and variable lags in the response

of inflation (and output) to monetary policy that led Friedman to his original advocacy of a money stock growth rate target.

The evolution of inflation over the coming years will provide valuable evidence on both the inflation process, the currently out-of-favour monetarist ideas, and the wisdom of the current policy regimes.

Conclusion

Macroeconomics in general, and the theory of inflation in particular, is in a fluid state. The foregoing has attempted to review that state and provide a picture of the path that we have taken in getting to it. We have broad agreement on the facts to be explained and broad agreement on the behaviour of nominal variables (for given real variables) in an inflationary economy in which the path of inflation is anticipated. We also have broad agreement that fully anticipated inflations, though in many theoretical models capable of generating non-neutralities, are nevertheless to a good approximation neutral. Beyond that there is little in the way of firm knowledge. We have a variety of models of macroeconomics and inflation, and many clear theoretical results. We do not have much, however, in the way of solidly based rejections of any of the available models. Uncertainty surrounds both the issue of the impulse (or impulses) that generate inflation and other fluctuations and the issue of the propagation mechanisms that translate those impulses into movements in output and the price level.

Inflation Accounting

G. Whittington

The adjustment of the accounts of business enterprises to reflect the consequences of inflation has been the subject of considerable theoretical controversy and practical experimentation in recent years, as a result of historically high inflation rates. The traditional valuation basis of accounts is historical cost, and the gap between historical values and current values tends to be widened by inflation. Furthermore, historical cost accounting does not reflect the gain on borrowing, which arises from having a liability which is fixed in nominal monetary units, in a period of inflation, or its counterpart, the loss on holding money, or assets denominated in nominal monetary units (such as trade debts).

Two apparently competing systems have been proposed to deal with the inflation accounting problem. The first is Current Purchasing Power Accounting, CPP. This applies general price indices to his torical cost in order to allow for the decline in the value of money due to inflation. The second system is current value accounting, which revalues assets and liabilities at their current values, or, alternatively, restates historical cost by reference to a specific price index relating to the specific asset type, rather than a general price index. The current value accounting system found most commonly in practice, and featuring most prominently in the theoretical debate, is current cost accounting, CCA, which revalues assets at current cost, that is, replacement cost (typically) or recoverable amount (the higher of net selling price or net present value of future services to its present owners), whichever is the lower. A third system, which combines current valuation with CPP adjustments, and therefore eliminates the need to choose between CPP and CCA, is the real terms system, RT.

The principles of the three systems may be illustrated by a simple numerical example. Suppose an asset is bought at time *O* for £10,000 when the retail price index is 100. By time *1*, the current cost of the asset is £15,000, by which time, the retail price index is 120. CPP accounting would restate the historical cost (£10,000 at time *O form of physical cap*) as £12,000 (= £10,000 × 120/100) at time *1*, because it would take 1.2 time *1* £s to buy the equivalent of 1 time *0* £. On the other hand, the proprietor's capital also needs to be restated in an exactly equivalent manner, so no gain or loss is shown by CPP, unless the asset was financed by borrowing in nominal money units (which would not require

restatement, leading to a gain on borrowing) or had a value fixed in nominal money units (which would also not require restatement, leading to a loss on holding monetary assets). Current value accounting, on the other hand, would restate the asset at its current market value, £15,000 at time *1*. If we retained the unindexed money capital maintenance convention, this would lead to the recognition of a gain of £5000 (= £15,000–£10,000). Alternatively, if we used a form of physical capital maintenance convention, such as is commonly found in CCA systems, we would restate capital also by reference to the specific price change of the physical assets, so no gain would be shown. Real Terms, RT, accounting, on the other hand, would restate the asset at current value (£15,000 at time *1*) but would restate the proprietor's capital by reference to the retail price index (£12,000 at time *1*), showing a 'real gain' of £3000 (= £15,000–£12,000), which is the amount by which the asset has appreciated in excess of the fictitious element due to inflation. There are many detailed variations on the simple systems illustrated here. These are explained and illustrated in Whittington (1983).

The CPP system deals only with the effects of general price level changes and ignores relative changes in the prices of specific assets. It is thus a pure inflation accounting system which would be adequate if all prices changed in the same proportion. The system was developed in Germany during the hyperinflation of the early 1920s. It was developed further and introduced into the North American literature by H.W. Sweeney (1936). During the past two decades, similar systems have been adopted by leading Latin American countries (notably Brazil, Chile and Argentina) under the pressure of very high inflation rates. In practice, CPP seems to be adopted only when pure inflation is seen as an important and urgent problem.

The CCA system owes its origins to the replacement cost accounting systems proposed by American, Dutch and German writers in the first three decades of the 20th century. CCA became prominent in the inflation accounting debate in the English-speaking world in the mid-1970s, with the aid of support from government agencies (such as the Securities and Exchange Commission in the USA and the Sandilands Committee in the UK). An account of this 'CCA counter-revolution' (and other aspects of the history of inflation accounting) will be found in Tweedie and Whittington (1984). The probable motivation for government support for CCA was that this system avoids the use of general indices and that any form of general indexation was regarded, at the time, as reinforcing the process of inflation. The obvious strength of CCA is that it attempts to record the assets held and used by the business at their specific current prices (although the precise definition of current cost is a controversial issue), thus measuring the current performance (in the profit and loss account) and state of the business (in the balance sheet) in terms of economic opportunities currently available in the market place. The weakness of the system is in its treatment of assets and liabilities which are of fixed nominal money value. The two capital maintenance concepts which are naturally associated with CCA are physical capital maintenance (as in the Sandilands Committee's operating profit measure) and nominal money capital maintenance (as in the Sandilands Committee's statement of total gains). Neither of these is capable, in its simplest form, of reflecting the gain on borrowing or loss on holding money which occurs in a period of inflation: indeed, some supporters of CCA would deny that such gains and losses occur. In order to capture these effects, recent British CCA systems (as in the Accounting Standard SSAP16 1980) have adopted the gearing adjustment and the monetary working capital adjustment. These attempt to capture the gain on borrowing and loss on holding money, respectively, by using specific rather than general price indices. They have proved difficult to implement in practice as well as being difficult to justify theoretically, and are currently under review. They have been proposed but not implemented in a number of other countries (Australia, Canada, Germany, New Zealand, and Sweden). A clear account of the debate surrounding the introduction of CCA in the United Kingdom will be found in Kennedy (1978).

The RT system owes its origins to the work of Sweeney (1936), who pointed out that stabilization of the monetary unit by the use of general indices could be applied to any valuation base. The term CPP is normally restricted to stabilization of a historical cost base, so we use the term RT for stabilization of a current cost or other current value base. Since a CCA system already records assets at their current values, which are denominated in current currency units, the stabilization of such a system to convert it to an RT system requires no further indexation of asset values. The proprietor's capital is, however, adjusted by a general index, so that initial capital is maintained in terms of real purchasing power before a profit or gain is recognized. Thus, the RT system recognizes only real gains on assets (as illustrated earlier): it also recognizes the real gain on borrowing and loss on holding monetary assets in a period of inflation. This system was developed in considerable detail by Edwards and Bell (1961), who showed that it was possible, within the RT framework, to calculate CCA operating profit and then, by adding real gains and losses on holding assets and liabilities (which Edwards and Bell describe as 'real holding gains' or losses) to derive a final total of real profit or gain (which they describe as 'real business profit').

In many ways, the RT system seems to be a logical and consistent means of recognizing the effects of general inflation in eroding the purchasing power of proprietor's capital, while also recognizing the effects of changing individual prices on the value or cost of the specific assets held and used by the business. It thus deals with the problems dealt with by both CPP and CCA, while avoiding the weaknesses of these two systems. There are strong elements of the RT system in the current USA standard on accounting for changing prices (FAS33), and it may be the system which will ultimately prevail in practice. Its slow emergence has much to do with the fact that CPP and CCA have been espoused by groups which see their particular interests being served by one of these systems; for example, professional accountants tend to be attracted by the relative objectivity (and therefore lower risk of professional liability for error) of CPP, which avoids subjective estimates of current values.

Finally, it should be noted that this essay has dealt only with business accounting. Inflation accounting is also an important problem in national accounts. The traditional adjustments for price changes are replacement cost of capital consumed and the elimination of stock appreciation (see Stone and Stone 1977). This is analogous to CCA adjustment of business accounts. National accounts are also often restated in constant price terms, but this is a crude transformation rather than CPP or RT adjustment which would require restatement of opening capital figures to reveal real holding gains and losses (including those on monetary items) in various sectors. This issue is explored in Godley and Cripps (1983).

Inflation and Growth

John Cornwall

Although the relationship between inflation and economic growth has interested economists for some time, the nature of this association is still not well understood. Early discussions deliberated on the relative merits of a rising compared to a falling price level on profits, confidence, investment and other macro variables as these affected the growth of the economy, especially productivity. No noticeable consensus emerged from these deliberations. In more recent times, in particular the post World War II period up until the early 1970s, the historical record gives ambiguous if not misleading clues. For example, cross-country comparisons of rates of inflation and productivity growth in the developed capitalist economies reveal virtually no association between the two. And if the period of rapid growth of productivity of the 1950s and 1960s is compared with the period of stagnation since the early 1970s, over time a negative correlation between inflation and productivity growth is found in each of the economies. The rise in inflation rates is associated with a slowdown in productivity growth.

The Political Economy of Inflation and Growth

Conventional economic theory is equally inconclusive on the causal connection between the two. However, since the early 1970s, activist government intervention in the various economies has introduced a connecting link, resulting in a definite causal connection between inflation and growth that is likely to persist for some time to come. As a result, a correct understanding of this relationship involves a conceptual framework that is broader than that assumed by conventional economic theory. The causal relationship between inflation and growth must be seen as a problem in political economy, for it is the response of governments to inflation, both actual and predicted, that has and will determine the ultimate impact of inflation on the growth of productivity and output.

To put the matter in its simplest form, inflation leads to slow growth or stagnation because in those countries in which inflation cannot be brought under control by other means (e.g. an incomes policy) governments respond by implementing restrictive aggregate demand policies. Such responses lead, as they have since the early 1970s, to high rates of unemployment and low rates of capacity utilization, investment and productivity growth.

Taking the analysis one step further, in studying the mechanism by which inflation leads to stagnation under existing institutions it is useful to divide the developed capitalist economies into two groups. First, there are economies that experience accelerating rates of inflation under conditions of sustained high employment. To put the matter differently, there are countries in which the non-accelerating inflation rate of unemployment (NAIRU) is greater than the rate of unemployment at which all unemployment is voluntary.

No successful incomes policy can be implemented that would allow involuntary unemployment to be reduced to a minimum without the strong demand conditions leading to accelerating rates of inflation. As a result these countries will adopt restrictive aggregate demand policies in order to increase unemployment enough to reduce the rate of inflation. The fear that stimulative fiscal policies will lead to greater budget deficits and the fear of increased power of labour under full employment conditions, partly because it is believed that each causes inflation rates to accelerate, will reinforce this trend towards restrictive aggregate demand policies.

These economies can be said to suffer from an inflationary bias (Cornwall, 1983, ch. 6). Because of the policy response to this bias, inflation (or even the fear of inflation) will lead to high rates of unemployment and low rates of growth of productivity, that is, economic stagnation.

In contrast there is a second group of economies which, because of favourable institutional arrangements, could achieve full employment

without accelerating rates of inflation *if restrictive aggregate demand policies were not adopted by the first group of economies*. These countries would be likely to adopt full employment policies if restrictive policies were not in effect elsewhere. But when they are, this group of economies is also forced to pursue restrictive aggregate demand policies but for quite different reasons than the first group. However, the effect of policy on the growth of output and productivity is the same; it will be greatly reduced.

Pluralist Economies

Thus the first step in understanding the relation between inflation and productivity growth is a recognition that the simultaneous achievement of full employment and non-accelerating rates of inflation is not an automatic feature of capitalist economies. Moreover any failure to achieve these goals is not to be attributed to a failure of the authorities to follow some monetary or fiscal rule. Instead, the failure of an economy to handle inflationary pressures while maintaining full employment must be attributed to existing institutional and political arrangements. These make the coordination of wage and price settings in individual markets with the national goal of overall wage and price stability impossible.

These institutions can be said to act as constraints limiting the number and kinds of policy instruments available to the authorities for combating inflation. Going further, since the authorities in these economies respond to accelerating inflation by creating whatever unemployment is politically tolerable in an attempt to reduce inflation, the use of aggregate demand policies as an instrument for realizing desirable employment goals is, therefore, severely constrained by an inflationary bias. The authorities in these economies can be expected to pursue stagnationist policies under existing institutional and political arrangements.

The relation between inflation, the political response to inflation, and growth just described is similar to that seen by Kalecki (1977). However, it is more accurate to limit the kind of 'political theory of the business cycle' foreseen by Kalecki to a special group of capitalist economies which will be referred to as 'pluralist' economies. Pluralist economies share certain features in common. Governments play an essentially passive role in governing, primarily reacting to demands by special interest groups; there is a widespread belief among the powerful economic and political groups that an invisible hand or system of countervailing power exists that guarantees some kind of social optimum; the industrial relations system can be characterized as adversarial; and decision-making within the trade-union movement is decentralized.

The countries today that suffer from an inflationary bias and whose institutional features most clearly coincide with those just mentioned are the developed English-speaking countries, particularly Canada, the United Kingdom and the United States. Very likely, other countries with somewhat different institutions suffer from an inflationary bias, for example, France and Italy, and for the purposes at hand could be included in this group (Barber and McCallum, 1982; Crouch, 1984; McCallum, 1983).

Corporatist Economies

There is a second group of economies which will be referred to as 'corporatist economies'.

Corporatist economies are characterized by a tradition of state intervention in the economy, a high degree of cooperation and collaboration between the major economic groups in policy formation, a disbelief in invisible hands, and a system of industrial relations that can be described as cooperative. Primarily because of these institutions, these economies have been able in one form or another to implement relatively successful voluntary incomes policies in the past. Inflation has not been eliminated to be sure but has been kept at rates lower than would likely have resulted had union and managament been unwilling to cooperate with government in the interests of achieving wage and price stability. More certainly, as Table 1 reveals, economies with these characteristics and with powerful trade union movements as well, for

Inflation and Growth, Table 1 Annual average rates of unemployment (U) and inflation ($\dot{p}$), 1963–73 for selected capitalist economies

Source: OECD, *Economic Outlook*, Paris, various issues; and OECD, *Labour Force Statistics*, Paris, various issues

example, Austria and Sweden, have been able to reduce unemployment to extremely low levels without experiencing inflation rates much higher (if higher) than those in the pluralist economies.

Unfortunately given the high degree of economic interdependence between economies, most of those economies best able to contain inflation at full employment can no longer do so when the pluralist economies adopt restrictive policies. The economic importance of the pluralist bloc in the world economy forces restrictive policies on the second group of countries. Their importance guarantees that by restricting aggregate demand in their own countries, depressed conditions in the pluralist countries will be exported to the others in the form of a decrease in demand for their exports. Furthermore any attempt by any of the corporatist economies to offset declining exports through stimulative demand policies will lead to current account deficit that cannot be sustained through continuous borrowing (Thirlwall and Hussain, 1982). As a result, the full employment goal must be sacrificed.

Basic to this argument is the assumption that in the face of depressed demand conditions in the pluralist bloc, any corporatist economy acting on its own is not able to offset the adverse effects of a full employment policy on its payments position through an exchange rate policy. Unfortunately changes in the exchange rate are not sufficient to induce the kind of expenditure switching needed to bring the current account of the corporatist economies more or less into balance at full employment. These economies can be said to be limited or constrained in their use of aggregate demand policies for attaining full employment because of a payment constraint.

It is useful for pedagogical reasons to divide the capitalist world into two mutually exclusive groups, pluralist and corporatist. With this simplification in mind, the stagnating capitalist economies fall into one or the other of two groups: those in which restrictive demand policies are employed out of a fear of inflation and those in which a fear of payments problems at full employment caused by the restrictive policies of the first group leads to the same policies. The causal mechanism at work today, whereby inflation (or merely the fear of inflation) in one group of countries leads to worldwide stagnation, now becomes clear. As long as the pluralist group restricts aggregate demand because of an inflationary bias, less than full employment conditions are forced upon the rest of the world. As a result, an inflationary bias in the pluralist group, that is, a tendency for inflation rates to accelerate at or before full employment, leads not just to breakdown in those countries but to worldwide stagnation.

The Failure of Conventional Policies

As just argued, worldwide stagnation can be attributed to an inflationary bias in a group of key countries. Seen in another way, the difficulties or sources of stagnation can be traced to a failure of the traditional policy instruments, that is, monetary, fiscal and exchange rate policies, to work successfully in realizing full employment, price stability and external balance. Underlying this failure are certain structural and institutional changes that develop over a prolonged period of full employment such as the quarter of a century following World War II. Simply put, in

democratic capitalist societies the rising affluence attributable to a long period of full employment is accompanied by the extension of the welfare state. This greatly increases the relative power of labour. As a result wages (and prices) are no longer determined primarily by the traditional market forces of demand and supply (Hicks, 1974; Okun, 1981; Scitovsky, 1978). This makes aggregate demand policy a highly inefficient means of fighting inflation. While wages and prices may respond eventually if restrictive policies are pushed far enough, the quantity effects on output and employment are substantial and immediate and persist while the policy is in effect. Futhermore, any implementation of an expansionary demand policy following a 'successful' restrictive policy that has brought down inflation rates will merely bring back the inflation in the pluralist economies. Restrictive policies whose aim is to permanently reduce inflation will fail in these countries because they fail to attack the sources of the inflationary bias.

Increased affluence and greater labour power also contribute to the ineffectiveness of exchange rate policy. First, consider that the trend in international trade has been increasingly towards the more highly fabricated goods that are desired for their non-price qualities, for example, design, durability, reliability, delivery dates, etc. This trend can, to a large extent, be attributed to affluence. It results in a downward trend in price elasticities of traded goods making it increasingly unlikely that the Marshall–Lerner conditions will be satisfied. When they are not, devaluation leads to a worsening of the trade deficit, other things being equal.

Second, the successful use of the exchange rate as an instrument for relieving a payments constraint is severely compromised by the existence of real wage resistance. A cheapening of exports relative to imports following devaluation likely leads to a decline in real wages. Under full employment conditions labour will have a strong incentive to press for higher money wage increases in an effort to protect their real wages. The resulting wage–price spiral can lead to the real exchange rate returning to its previous level. Like the inflationary bias, this difficulty arises out of the increased power of labour under full employment conditions and the affluence full employment brings.

Real wage resistance can be a real problem even in corporatist economies that may have had success in the use of income policies in the past. In earlier times the incentive for acceptance by labour of a voluntary incomes policy was provided by a promise of full employment and the rising real wages that full employment encourages. Unfortunately a devaluation of the currency, forced upon the authorities in their pursuit of full employment by restrictive policies in the pluralist bloc, may lead to non-compliance with the incomes policy.

If the reduction in real wages can be limited, real wage resistance might be avoided. However, the international interdependence of capital markets can and has lead to situations in which the local authorities have little control over the magnitude of the actual depreciation of the exchange rate. A deliberate devaluation generates fears of accelerated inflation in the minds of managers of exceedingly large and mobile capital funds. This leads to large withdrawal of funds from the country, a further depreciation of the currency, greater fears of inflation, etc. As the experience of several countries in the recent past make clear, governments are soon forced to reverse their employment policies in order to protect the exchange rate.

Conclusions

In order to break the causal chain leading from inflation to restrictive policy to stagnation that prevails under modern capitalist conditions, major structural-institutional changes are required. Most important are changes that would relieve the pluralist economies of their inflationary bias. A different conception of the role of the state in the economy, the development of a cooperative industrial relations system and possibly of centralized collective bargaining would be extremely helpful because these changes increase the possibility that a successful incomes policy could be implemented. The benefits of its success for the rest of the world are apparent.

A second programme for recovery is more limited in that it is restricted to the corporatist bloc. This would take the form of the corporatist economies adopting coordinated trade and lending policies that discriminate against the pluralist group, in order to ease possible payments difficulties from full employment policies.

There are other possibilities involving one or more countries, but, however much they differ in detail, they share one thing in common: all require radical and basic structural changes in key economic and political institutions. Without these adaptations, the present political economy of inflation and stagnation will continue indefinitely and will be worldwide.

Inflation Dynamics

Timothy Cogley

Abstract

There have been a number of changes in monetary policy rules in the United States and UK since the early 1960s. The Lucas critique says that this should induce changes in the equilibrium law of motion. This article summarizes reduced-form evidence on the evolving law of motion for inflation in the USA and the UK. Since the 1970s, inflation has become lower on average, less volatile and less persistent. There is also less uncertainty about the central bank's long-run target for inflation.

As with other macroeconomic data series, economists have long been interested in the dynamics of inflation. This series is of particular interest because of its relationship to alternative theories of aggregate fluctuations and associated effects of alternative monetary policies. Indeed, for understanding the behaviour of inflation, it is important to take into account the alternative monetary policies that were in force during the period being studied. Shifts in monetary policy rules alter the

fundamentals that drive inflation and therefore also alter its dynamic properties. Accordingly, one must distinguish inflation variation arising within a stable monetary regime from movements that follow from shifts in policy rules.

For the United States, Taylor's (1993) rule is often used to describe Federal Reserve behaviour. Although his rule was originally intended as a normative proposal, Taylor and others soon discovered that it closely approximated Federal Reserve behaviour during the Volcker–Greenspan era (1979–2006). Shortly thereafter, a number of economists began to explore whether the Taylor rule also described Fed behaviour prior to that (for example, Clarida et al. 2000; Lubik and Shorfheide 2004). They found that it did, although with different coefficients. Prior to Volcker's term as chairman, the Fed reacted more strongly to fluctuations in output and was less sensitive to movements in inflation. In fact, although the Fed increased the nominal funds rate when inflation rose, it increased the funds rate by less than one for one, so that the real funds rate actually declined, thus amplifying the initial movement in inflation. According to Clarida, Gali and Gertler and Lubik and Schorfheide, this was an important factor behind the high and volatile inflation of the 1970s.

Important changes have also occurred in UK monetary policy. After the Second World War, the Bank of England at first operated under the Bretton Woods system of fixed exchange rates; the breakdown and float in the early 1970s was followed by attempts to re-establish fixed exchange rates in the 1980s, the decision to opt out of EMU after the foreign-exchange crisis of 1992, the adoption of inflation targeting in 1992, and finally central-bank independence from the Treasury in 1997. The last two steps in particular altered the way the Bank of England conducts monetary policy, with the Bank now placing a higher priority on controlling inflation.

The Lucas critique says that a change in a government policy rule should alter the equilibrium law of motion for endogenous variables. In this article I summarize research on changes in the dynamic properties of inflation since the early 1960s. I focus on the USA and the UK because they are the two economies studied most extensively in the literature.

Evolving Inflation Dynamics in the USA and the UK

I use a vector autoregression (VAR) to summarize the dynamic properties of inflation. For a historical period during which government and private decision rules are unchanged, one can estimate a time-invariant VAR. Here I am concerned about a period with changing monetary policy rules, however, so VAR parameters must be allowed to vary, in accordance with the Lucas critique. Consequently, much of the literature on evolving inflation dynamics studies Bayesian VARs with drifting conditional mean and variance parameters; for example, Benati and Mumtaz (2006), Canova and Gambetti (2006), Cogley and Sargent (2001, 2005a, b), Cogley et al. (2005), and Primiceri (2005a).

Cogley and Sargent (2005a, b) estimate VARs of the form

$$y_t = X_t'\theta_t + \mathrm{E}_t, \tag{1}$$

where y_t is a vector consisting of inflation, a short-term nominal interest rate, and a real activity variable such as unemployment or GDP. The right-hand variables X_t consist of a constant plus lags of y_t, and the conditional mean parameters θ_t evolve as a driftless random walk subject to reflecting barriers. The driftless random walk assumption makes θ_t vary as

$$\theta_t = \theta_{t-1} + v_t, \tag{2}$$

where v_t is $NID(0, Q)$. The reflecting barriers prevent θ_t from wandering into the region of the parameter space where the system has explosive autoregressive roots. This representation puts a unit root in inflation, because the reflecting barriers do not restrict drift in the VAR intercepts, but it prohibits more than one unit root in inflation.

The VAR innovations ε_t are assumed to be conditionally normal with mean zero and drifting variance

$$R_t = B^{-1} H_t B^{-1\prime}, \tag{3}$$

where H_t is diagonal and B is lower triangular:

$$H_t = \begin{pmatrix} h_{1t} & 0 & 0 \\ 0 & h_{2t} & 0 \\ 0 & 0 & h_{3t} \end{pmatrix}, \tag{4}$$

$$B = \begin{pmatrix} 1 & 0 & 0 \\ \beta_{21} & 1 & 0 \\ \beta_{31} & \beta_{32} & 1 \end{pmatrix}. \tag{5}$$

The diagonal elements of H_t are univariate stochastic volatilities that evolve as driftless, geometric random walks:

$$\ln h_{it} = \ln h_{it-1} + \sigma_i \eta_{it}. \tag{6}$$

The random-walk assumption is designed to fit permanent shifts in innovation variances such as those associated with the 'Great Moderation' in the USA (McConnell and Perez Quiros 2000). This formulation allows time-varying correlations among the VAR innovations, and it guarantees that R_t is positive definite. Primiceri (2005a) extends the model to allow for drifting covariances as well, $R_t = B_t^{-1} H_t B_t^{-1\prime}$.

The results reported below illustrate various aspects of the Bayesian posterior distribution for this model. Readers who are interested in the technical details should consult the original sources.

Trend Inflation

Figure 1 depicts trend inflation in the USA and the UK. Following Beveridge and Nelson (1981), I define trend inflation in terms of long-horizon forecasts. At date t, trend inflation is the level at which inflation is expected to settle after the transient variation dies out,

$$\overline{\pi}_t = \lim_{j \to \infty} E_t \pi_{t+j}. \tag{7}$$

To approximate $\overline{\pi}_t$, write the VAR in companion form as

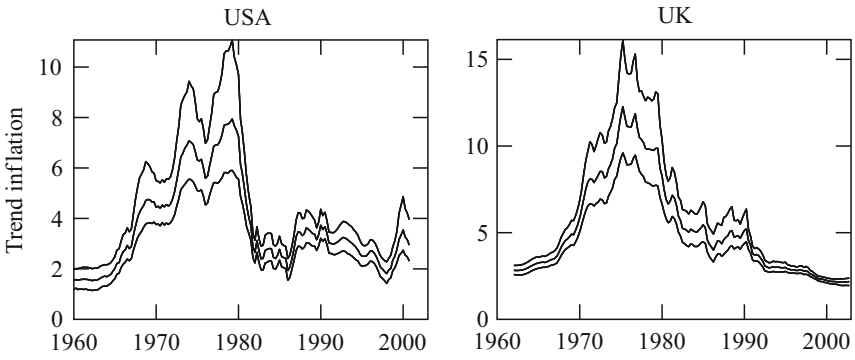
$$z_t = \mu_t + A_t z_{t-1} + \varepsilon_{zt}, \tag{8}$$

where μ_t contains the VAR intercepts and A_t the autoregressive parameters. Then trend inflation $\overline{\pi}_t$ can be approximated by the long-horizon VAR forecast,

$$\overline{\pi}_t \doteq \mu_t (I - A_t)^{-1}. \tag{9}$$

The figure portrays the posterior median of $\overline{\pi}_t$ at each date along with the interquartile range. (All the figures are based on the author's calculations.)

The median estimate of trend inflation was a bit below two per cent in the USA in the early 1960s, and it was just shy of three per cent in the UK. It increased sharply in both countries in the late 1960s and early 1970s and peaked in the mid- to late 1970s. In the UK, a peak of 12 per cent was



Inflation Dynamics, Fig. 1 Trend inflation in the USA and the UK (*Sources*: Federal Reserve Economic Database (USA), Bank of England (UK))

reached in 1975, and $\overline{\pi}_t$ remained in double digits until 1980. In the USA, trend inflation ratcheted to 4.5 percent in 1970, then to seven per cent in 1974, and finally to almost eight per cent in 1979. In the early 1980s, Paul Volcker's disinflation in the USA and Margaret Thatcher's monetarist experiment in the UK brought $\overline{\pi}_t$ quickly back down to more tolerable levels. In the USA, trend inflation has fluctuated around 2–3.5 per cent since 1985. In the UK, $\overline{\pi}_t$ settled in the neighbourhood of 2.5 per cent when the Bank of England adopted an explicit inflation target in 1992, and then declined gradually to around two per cent after 1997.

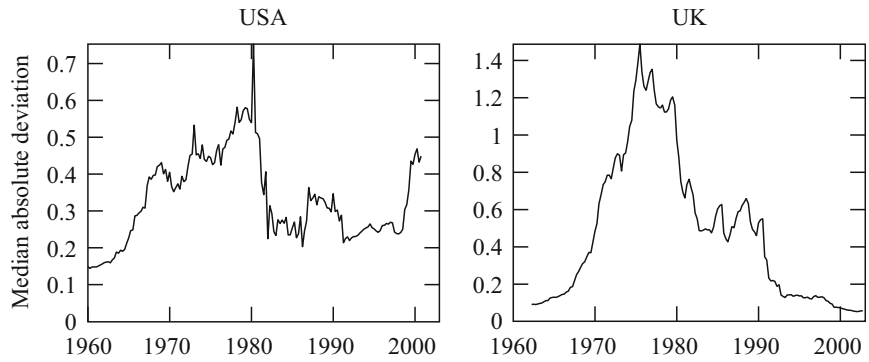
Measures of uncertainty about trend inflation also rise and then fall. The inter-quartile range for $\overline{\pi}_t$ is narrow at the beginning of the sample, widens substantially in the middle, and then narrows again at the end. Thus, the 1970s was not only a decade when trend inflation was high, but also a time of substantial uncertainty about its exact value. For example, in the USA, when the median estimate of $\overline{\pi}_t$ peaked at eight per cent, there was a fifty-fifty chance that it was somewhere outside the interval 5.75–12 per cent. Similarly, when the median estimate of UK trend inflation peaked at 12 per cent, there was a fifty-fifty chance that it could exceed 16 per cent or fall short of 12 per cent.

The inter-quartile range quantifies level uncertainty, that is, uncertainty about where $\overline{\pi}_t$ is at a particular date. One can also quantify how rapidly trend inflation drifts. Figure 2 portrays the median absolute deviation for $\Delta\overline{\pi}_t$. (I report this statistic instead of the standard deviation because of outliers.) Not only is there a lot of uncertainty about the level of $\overline{\pi}_t$ in the 1970s, but $\overline{\pi}_t$ was also drifting more rapidly then. The rate of drift fell considerably in both countries in the early 1980s, and in the UK it also declined sharply after 1992. Stock and Watson (2005) were the first to report a result like this in the context of an unobserved-components model of US inflation. The result also holds for our drifting-parameter VARs.

Uncertainty about $\overline{\pi}_t$ presumably reflects uncertainty about the central bank's long-run target for inflation, or doubt about its commitment to the target, or both. For the UK, it is interesting to note how the inter-quartile range narrowed and the rate of drift declined after the adoption of inflation targeting in 1992. In contrast, the inter-quartile range for the USA was about as wide in the 1990s as in the 1980s, and its width was also comparable to that of the UK for the 1980s. Similarly, the rate of drift in US trend inflation was considerably higher at the end of the sample than in the UK. The difference, of course, is that the USA has not adopted a formal inflation target. Taken at face value, these figures illustrate how an explicit inflation target can anchor long-run inflation expectations.

Inflation Gap Variability

Next I turn to changes in inflation volatility. To a first-order approximation, trend inflation is a random walk, which means that inflation itself has



Inflation Dynamics, Fig. 2 Median absolute deviation for $\Delta\overline{\pi}_t$ (*Sources*: Federal Reserve Economic Database (USA), Bank of England (UK))

infinite unconditional variance. Here I focus instead on the volatility of de-trended inflation, $\pi_t - \overline{\pi}_t$. A central bank that behaves as if minimizing an undiscounted quadratic loss function will adjust its policy instrument so that inflation eventually converges to its target. Thus, I interpret $\overline{\pi}_t$ as a measure of target inflation and $\pi_t - \overline{\pi}_t$ as the deviation from the target or 'inflation gap'. At each date in the sample, I approximate its instantaneous standard deviation as

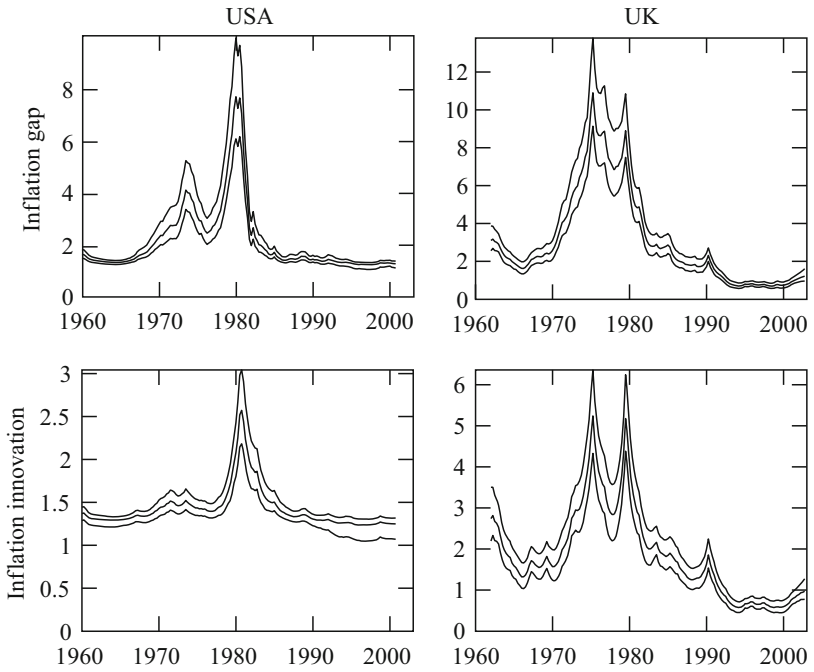
$$\sigma_t(\pi_t - \overline{\pi}_t) = \left[\sum_{j=0}^{\infty} e_\pi' A_t^j R_t A_t^{j\prime} e_\pi\right]^{1/2}, \qquad (10)$$

where e_π' is a selection vector that picks out π_t from the vector z_t. The top row of Fig. 3 portrays the evolution of the posterior median and interquartile range for σ_t.

Along with Fig. 1, Fig. 3 depicts a positive correlation between inflation gap volatility and trend inflation. Inflation volatility was low at the beginning and ends of the samples when trend inflation was low, and it was high during the great inflation of the 1970s. Thus, not only has average inflation declined since the 1970s, but so has inflation gap volatility. Moreover, this did not come at the expense of an increase in output or unemployment volatility, which follow much the same trajectory as for inflation. Sticky price models often predict a trade-off between the variability of inflation and real variables, but that trade-off is not apparent here. Instead we see a simultaneous decline in both after 1980.

Whether the greater stability of inflation and output is the result of better policy or better luck (that is, smaller shocks) is the subject of much current research. The absence of a volatility trade-off suggests that better luck is a promising candidate, however, for smaller shocks would deliver a simultaneous decline in both in standard models.

Inflation can be volatile either because shocks are volatile or because they are persistent. Thus, we can drill down by examining innovation variances and measures of persistence. In the bottom row of Fig. 3, I report the standard deviation of one-step ahead VAR prediction errors for inflation. For the UK, the pattern is the same as in the other figures:



Inflation Dynamics, Fig. 3 Standard deviation of inflation gaps and inflation innovations (*Sources*: Federal Reserve Economic Database (USA), Bank of England (UK))

prediction errors were large in magnitude during the 1970s and smaller before and after. For the USA, there was only a slight increase during much of the 1970s, but a sharp spike during the brief window in 1979–80 when the Federal Reserve was targeting monetary aggregates.

To the extent that monetary policy affects inflation with long and variable lags, these pictures also hint that good luck in the form of smaller shocks is part of the story. But the movements in innovation variances do not necessarily disprove the bad-policy story, for better policy can take the form of smaller policy shocks. It is also conceivable that better policy could damp the impact of non-policy shocks. Perhaps more importantly, if policy in the 1970s was so bad that sunspots affected equilibrium outcomes, then better policy could eliminate one of the shocks altogether (that is, the sunspot), and that would reduce the VAR prediction error variance for inflation and other variables.

Stock and Watson (2005) also report a decline in the prediction-error variance after the great inflation, but they point out another sense in which inflation has simultaneously become harder to forecast. Consider the R^2 statistic for the VAR forecast of inflation,

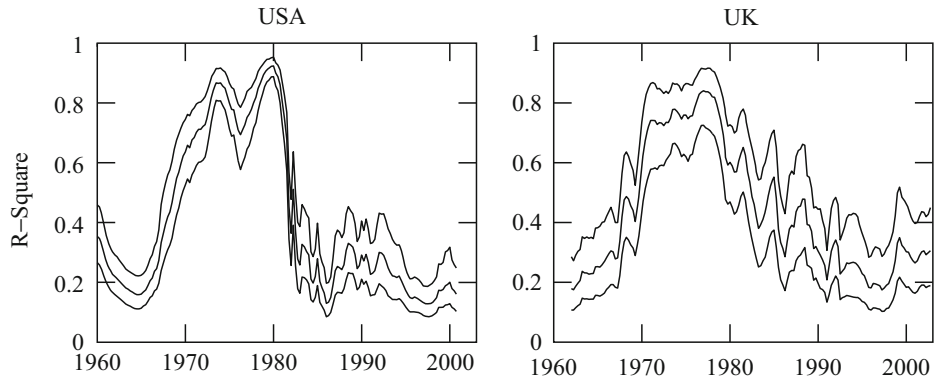
$$1 - R_t^2 = \frac{\sigma_t^2(\pi_t - E_{t-1}\pi_t)}{\sigma_t^2(\pi_t - \overline{\pi}_t)}. \qquad (11)$$

The numerator is the VAR innovation variance shown in the bottom row of Fig. 3, and the denominator is the total variance depicted in the top row. Since both terms of the ratio decline after the great inflation, it is not obvious whether the R^2 statistic has increased or decreased. One-step ahead prediction errors are smaller after 1980, but so is the total amount of transient variation that one hopes to predict.

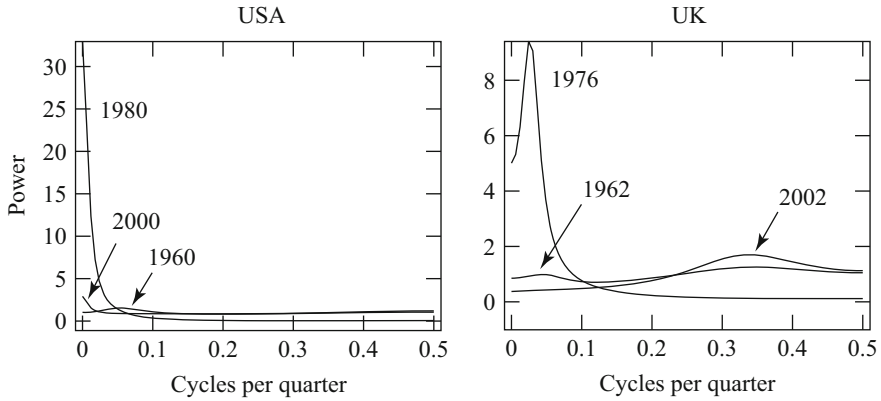
As shown in Fig. 4, for our time-varying VARs the denominator actually falls by more, so that the R^2 for inflation declines. Furthermore, this decline is statistically significant. For example, for the USA the posterior probability of a decline in R^2 between 1980 and 2000 is 0.998. Stock and Watson report a similar finding for an unobserved-components model of inflation. Thus, inflation has become both more and less predictable: inflation forecast errors are smaller in absolute value, but they account for a larger proportion of inflation-gap variability.

This means the inflation gap has become less autocorrelated and also less crosscorrelated with lags of other macroeconomic variables. In other words, it is closer to a martingale-difference variate. In Fig. 5, I summarize changes in inflation gap persistence by graphing its normalized spectrum,

$$g_{\pi\pi}(\omega, t) = \frac{2\pi f_{\pi\pi}(\omega, t)}{\int_{-\pi}^{\pi} f_{\pi\pi}(\omega, t) d\omega} \qquad (12)$$



Inflation Dynamics, Fig. 4 Predictability of the inflation gap (*Sources*: Federal Reserve Economic Database (USA), Bank of England (UK))



Inflation Dynamics, Fig. 5 Normalized spectrum for the inflation gap (*Sources*: Federal Reserve Economic Database (USA), Bank of England (UK))

In the numerator, $f_{\pi\pi}(\omega, t)$ represents the instantaneous power spectrum,

$$f_{\pi\pi}(\omega, t) = e_{\pi}'(I - A_t e^{-i\omega})^{-1} \frac{R_t}{2\pi} \left(I - A_t e^{i\omega}\right)^{-1\prime} e_{\pi}. \tag{13}$$

The denominator is the instantaneous variance of $\pi_t - \overline{\pi}_t$. Thus, $g_{\pi\pi}(\omega, t)$ measures autocorrelation rather than autocovariance. I also multiply by 2π so that the units are easy to interpret. In these units, a white noise variate has $g_{\pi\pi}(\omega, t) = 1$ at all frequencies. Relative to that benchmark, excess power at low frequencies represents positive autocorrelation, and excess power at high frequencies signifies negative autocorrelation. If the ordinate at frequency zero is less than 1, then the price level is partially mean reverting (Cochrane 1988).

In the early 1960s, the spectrum was relatively flat in both countries, and the inflation gap was not far from being white noise. The gap became more persistent by the mid- to late 1970s, however, with power concentrated at frequencies of eight years per cycle or longer. This signifies the presence of substantial transient fluctuations in inflation. Evidently, the monetary authorities were permitting inflation fluctuations to go unchecked for years at a time, only gradually bringing $\overline{\pi}_t$ back toward $\overline{\pi}_t$. These policies were reversed after the early 1980s, and by the end of the sample the spectrum had again become relatively flat. Thus, we also see a positive correlation between trend inflation and persistence of the inflation gap. Trend inflation was low and the gap was weakly persistent at the beginning and the end of the sample, and they were high and strongly persistent, respectively, in the middle.

For the USA, Cogley and Sargent (2005b) and Primiceri (2005b) explain this association in terms of changing Fed beliefs about the sacrifice ratio. In Cogley and Sargent's model, the central bank wants to reduce inflation in the 1970s, but it wants to move very slowly. Their hypothetical central bank prefers gradualism because it puts some weight on Keynesian Phillips-curve models which at that time predicted intolerable sacrifice ratios – much higher than the predictions of the same models in the 1980s or 1990s. Thus, when inflation was highest, optimal policy called for an extremely gradual adjustment towards the target, making the inflation gap highly persistent.

Cogley and Sargent's story gains credibility when one reviews the analyses of leading policy economists from the late 1970s. For example, Arthur Okun (1978, p. 284) wrote that 'recession will slow inflation, but only at the absurd cost in production of roughly $200 billion per point'. At that time, $200 billion amounted to roughly ten per cent of GDP, and, if we extrapolate Okun's estimate to zero inflation, the total cost amounts to three-quarters of a year's GDP. Like the central bank in Cogley and Sargent's model, Okun recommended gradualism in the 1970s because he thought the cost of aggressive actions would be exorbitant.

This explanation dovetails nicely with the work of Orphanides (2001, 2003), who demonstrates that the Fed overestimated the magnitude of the output gap in the 1970s because it was slow to detect the productivity slowdown. Because the estimated output gap was too big, they also initially exaggerated the amount of disinflation that would ensue. When that disinflation failed to materialize, they became pessimistic about the amount of slack needed to slow inflation, concluding that the sacrifice ratio was bigger than previously thought. Output gap misperceptions are not an element of Cogley and Sargent's model (their hypothetical central bank is better at filtering than the Fed was), but it may be an important part of the bigger picture.

In retrospect, the high estimates of sacrifice ratios in the 1970s may seem excessive because current estimates are quite a bit lower. Indeed, that is probably one reason why central banks now react more strongly to inflation. In any event, what matters for understanding monetary policy in the 1970s was what economists believed then, not what we believe now with the benefit of hindsight.

Finally, it is interesting to contrast the shape of the spectrum for the USA and the UK at the end of the sample. For the UK, the spectrum has a trough at frequency zero and a gentle positive slope, a shape that signifies partial mean reversion in the price level. For the USA, there is still a peak above 1 at frequency zero and a downward sloping spectrum, hence no mean reversion in the price level.

The contrast is noteworthy because it connects with questions about optimal monetary policy. In a textbook version of a dynamic New Keynesian model, the first-order condition for optimal policy is

$$\pi_t = -\frac{\lambda}{\kappa}(x_t - x_t - 1), \qquad (14)$$

where x_t is the output gap and λ and κ are parameters (Woodford 2003, ch. 7). Because x_t is a stationary random variable, the right-hand side is over-differenced, implying that optimal policy induces mean reversion in the price level. Woodford explains that a partially mean-reverting price level is a feature of optimal policy in many versions of the New Keynesian model, because a credible commitment on the part of the central bank to roll back future price increases restrains a firm's incentive to increase its price today. To make that promise credible, the central bank must follow through by taking actions to reverse realized movements in the price level. The end-of-sample UK inflation spectrum implies a partial rollback of the price level, but the US inflation spectrum does not.

Conclusion

During the great inflation of the 1970s, inflation outcomes worsened in many dimensions. Inflation was higher on average, more volatile and more persistent. There was more uncertainty about the central bank's long-run target for inflation and also more uncertainty about where inflation would be one quarter ahead. All of that has been reversed, possibly because of improved monetary policy rules, possibly because we have not experienced the severe adverse supply shocks that central bankers had to contend with in the 1970s. Sorting out the reasons behind the improvement in inflation outcomes is the subject of much ongoing research.

Inflation Expectations

Bennett T. McCallum

Abstract

Agents' expectations about future values of inflation play an important role in macroeconomic analysis. From a steady-state perspective, higher expected inflation rates induce agents to hold smaller real money balances and, in most models, to hold different amounts of capital. In dynamic analysis, inflationary expectations affect agents' decisions regarding saving and price adjustments, and affect monetary policy behaviour in ways that have become increasingly important. Over time, analysts' treatment of expectations evolved from distributed-lag, adaptive models to rational expectations, a change that had major analytical implications. Analysis of learning behaviour has become more prominent, supplementing or occasionally replacing rational expectations.

The concept of inflationary expectations came to the fore in the work of Chicago School economists during the 1950s, with notable contributions including those of Cagan (1956), Bailey (1956), and Friedman (1960, 1969) on hyperinflation experiences, the cost of inflation, and the optimal steady-state inflation rate. The upsurge of inflation experienced in many countries following the 1971–3 demise of the Bretton Woods System led to additional interest, which was increased again by the spread of rational expectations analysis

during the 1970s. Yet another boost in prominence came from the widespread influence of monetary policy strategies based on the notion of inflation targeting, beginning around 1990 and continuing unabated as of 2006. Major developments in technical analysis relating to monetary policy have lent additional interest to inflationary expectations in various ways that are touched upon below.

The following exposition begins by considering ways that inflationary expectations are important in terms of comparative steady-state analysis, pertaining to 'long-run' phenomena, before turning to expectations' role in dynamic analysis that corresponds to cyclical fluctuations. Next, the manner in which expectations are formed is discussed, with emphasis on the rational expectations hypothesis and also on recent attempts to depart in a disciplined manner from the strict rationality requirement. Finally, a brief historical note is included.

Steady-State Effects

From a steady-state perspective it is natural to presume that actual and expected rates of inflation (and other variables) coincide, so it is common to discuss the welfare cost of inflation, super-neutrality, and so on, in terms of actual rather than expected inflation. Most of the allocational effects are, however, attributable in principle to expected rather than realized inflation. Even in an economy in which the real rate of interest is invariant to expected inflation, the nominal interest rate – and therefore the quantity of real money balances held – will be influenced by these expectations. In particular, a relatively high expected inflation rate will induce individuals to hold *(ceteris paribus)* relatively small shares of their wealth in the form of money (which, as the medium of exchange, pays its holders interest at a lower rate – often assumed to be zero – than other assets). Consequently, since reduced real money balances entail reduced quantities of the transaction-facilitating services that are provided by the medium of exchange, agents are required to devote relatively more time and/or resources to the activity of 'shopping', that is, conducting transactions. In addition, the volume of transactions conducted may fall. A reduced level of utility is then the consequence for each individual agent, *ceteris paribus*, of an increased rate of expected inflation. In two classic contributions, Friedman (1960, 1969) argued that, on the assumption that there are virtually no resource costs associated with the creation and management of fiat money, overall efficiency requires a rate of expected inflation that drives the opportunity cost of holding money to zero and thereby satiates agents with the transaction-facilitating services of money. An exposition that extends the argument to models with finite-lived agents and considers the modification needed when lump-sum tax/transfers are not feasible is provided by McCallum (1990).

In many well-articulated models, expected inflation also has steady-state effects on other real macroeconomic variables – that is, money is not 'superneutral' (Barro and Fischer 1976). In models with finite-lived agents, for example, the steady-state real rate of interest will be affected by inflationary expectations and, consequently, so will the per capita stock of capital and rate of consumption. But, even if individuals are modelled as having infinite time horizons and a fixed rate of time preference – features which (together with exogenous growth rates) fully determine the steady- state real rate of interest – capital and consumption per capita will under most specifications depend (though probably weakly) on the expected inflation rate. (The well-known model of Sidrauski 1967, provides an exception, but only because it ignores individuals' desire for leisure.) In sum, the magnitude of inflationary expectations may have significant allocative consequences, even if one neglects the practically important effects of tax schedules that are set in nominal terms. Such allocative effects are in principle operative also at business-cycle frequencies, but the large magnitude of the capital stock/investment ratio in developed countries leads to the presumption that these effects are of quantitative significance only over longer spans of time.

Dynamic Effects

There are three main ways in which expectations of future inflation affect period-byperiod equilibria in dynamic analyses with typical macroeconomic models. First, intertemporal decisions depend significantly on *real* rates of interest, which are nominal rates adjusted for expected inflation. Second, expected inflation rates are important determinants of price-setting behaviour in most models in which there is some form of nominal price stickiness, reflecting a failure of prices to adjust immediately to values that would prevail under full flexibility. Third, monetary policy decisions may be based in substantial part on expected inflation rates, as with the strategy of 'inflation forecast targeting' that has been prominent in recent years (for example, Bernanke et al. 1999; Svensson and Woodford 2005).

With respect to the second of these, there has been much disagreement over the best way to represent departures from full price flexibility. (Indeed, an important school of macroeconomic thought adheres to the real-business-cycle view that it is best to assume full flexibility.) In recent years (for example, 1998–2006) variants of the Calvo (1983) price-adjustment scheme have been most prominent, but over the years specifications due to Lucas (1972a, 1973), Fischer (1977), Taylor (1980), Mankiw and Reis (2002), and others have also attracted significant support. Some of the models advanced in the 1970s imply that any real stimulus resulting from inflation will be smaller, the greater is the extent to which this inflation was previously expected. Indeed, a prominent and important line of thought originated by Friedman (1966, 1968) and Phelps (1967) contends that inflation will provide a stimulus to output and employment (via the so-called Phillips-curve relation) *only* to the extent that it is unexpected. As the validity of that viewpoint – that there is no long-lasting trade-off between unemployment and inflation – is highly relevant for stabilization policy, many attempts were made to conduct statistical tests. The appropriate design of such tests will, of course, depend significantly on the way in which expectations are formed, a matter discussed below.

Rational Expectations

As mentioned above, for steady states it is natural to presume that expected inflation rates will match those actually realized, and virtually all contemporary steady-state theorizing proceeds under that assumption. Analysis of quarter-to-quarter or year-to- year movements requires, however, some more ambitious formulation concerning expectational behaviour. From the time of Cagan's (1956) study of hyperinflations until the mid-1970s, the most widely used hypothesis was that of adaptive expectations – which makes each period's change in the relevant variable proportional to the most recent expectational error – with other autoregressive representations also used to some extent. During the 1970s it became clear, however, that adaptive and other fixed autoregressive specifications permit the occurrence of repeated, systematic expectational *errors.* But, since such errors are costly to the individual agents who make them, standard neoclassical reasoning suggests that it would be analytically fruitful to assume that agents typically eliminate any systematic source of expectational error, subject to available information. This hypothesis of rational expectations was introduced by Muth (1961) and developed in a macroeconomic context by Lucas (1972a, 1973) and Sargent (1973). It met with some initial resistance, perhaps because of a mistaken impression that it implies homogeneity of information and expectations across agents and/or that activist macroeconomic stabilization policy must necessarily be ineffective. Scepticism about agents' cognitive abilities also played a role, probably. But by the end of the 1970s the rational expectations hypothesis – implying that an agent's expectational errors are uncorrelated over time with all elements of his information set – had become dominant in both theoretical and applied macroeconomics.

The early development of techniques for the econometric implementation of rational expectations involved attempts to test the Friedman–Phelps no-trade-off hypothesis mentioned above. Various estimates of the crucial slope parameter attached to the expected-inflation variable in a Phillips-type relationship had been

obtained, during the late 1960s and early 1970s, with econometric procedures relying upon the assumption of adaptive expectations (or fixed autoregressive expectations with lag weights summing to 1.0). Typical estimates of the slope parameter obtained in these studies were in the vicinity of 0.4–0.6, well below the value of unity implied by the Friedman–Phelps theory (for example, Solow 1969). It was shown analytically by Sargent (1971) and Lucas (1972b), however, that the test strategy utilized would not identify the parameter at issue if expectations are in fact formed rationally. Instead, the estimate would tend to equal this parameter value times the sum of lag coefficients in a univariate forecasting equation for the inflation rate, a sum that need not equal the value of 1.0 presumed by the procedure in question. Estimates using similar (quarterly, US) data-sets but taking account of this insight were then found to yield values close to unity (McCallum 1976). The resulting interpretation – that the true parameter value is approximately unity and that expectations are at least approximately rational – subsequently received indirect support from additional estimates presuming fixed autoregressive expectations, as the values obtained rose over time during the 1970s (Gordon 1976). As the univariate autoregressive representation of actual inflation was also changing during this period, with the sum of lag coefficients rising from around 0.5 to nearly 1.0, these findings accorded well with the Sargent–Lucas interpretation of the evidence.

As important implication of the Sargent-Lucas analysis is that, if expectations are in fact rational, one cannot generally measure the 'long-run' effect (that is, comparative steady-state effect) of one variable on another by the sum of coefficients in a distributed-lag relationship. For example, since expected inflation affects interest rates to a different extent from unexpected inflation, the sum of coefficients in a distributed-lag regression of interest on inflation will depend on the stochastic properties of inflation (the variable being forecast) as well as the slope coefficient measuring the effect of expected inflation on interest. To test hypotheses about the latter effect, it is necessary to take some account of the type of process generating the variable being forecast. That this principle continues to obtain when frequency-domain statistical techniques are employed was emphasized by Whiteman (1984) and McCallum (1984), but King and Watson (1992) and Fisher and Seater (1993) developed procedures that can be used for model-free tests if the monetary policy rule in force (over the sample period) is such that it generates unit-root behaviour of the log of the money stock.

During the second half of the 1990s, expectations came to play an increasingly important role in monetary policy analysis as 'New Keynesian' or 'New Neoclassical Synthesis' models, firmly based on optimizing analysis while incorporating sluggish price adjustments, became the norm for researchers in academia and central banks alike (Goodfriend and King 1997; Rotemberg and Woodford 1997; Clarida et al. 1999; Woodford 2003). In these models with forward-looking expectations in the price-adjustment equations, optimal policy requires 'history- dependent' rules (Woodford 2003) that take account of expectations in a manner not recognized in traditional optimal-control analysis. Various developments, including consideration of issues implied by the zero lower bound on nominal interest rates, made policy analysis increasingly a matter of 'managing expectations' (Eggertsson and Woodford 2003). From the perspective of actual policy practice rather than theory, Goodfriend and King (2005) present documentation, based on Federal Open Market Committee transcripts, indicating that as early as November 1979 the committee was using long-term interest rates as an indicator of inflationary expectations, which were being used to help guide the disinflation of 1979–84. This episode has, more recently, come to be widely regarded as a major turning point in the remarkable worldwide reduction in inflationary difficulties that took place between the late 1970s and the early 1990s.

Issues Regarding Expectations

The principle mentioned above, involving distributed-lag coefficient sums, can remain true

even if expectations are not strictly rational. In particular, it will apply if expectations are formed in a manner that reflects full but delayed responsiveness to the properties of the generating system. Expectational behaviour of that type, which might be termed 'asymptotic rationality,' can be expressed analytically by the condition that the unconditional mean of the expectational error process equals zero, a weaker requirement than that the error must be uncorrelated with all information variables available at the time of expectation formation. This less stringent type of partial rationality has not been prominent to date, but may become important eventually. It is not analytically similar, it should be said, to hypotheses involving *learning* – that is, changing perceptions over time regarding the structure of the system.

During recent years, analysis of learning behaviour has developed into an important and influential ingredient in reasoning about expectations, in two different respects. First, it is a much-noted fact that in most monetary macro-models there is a multiplicity (that is, two or more) of rational expectations (RE) solutions that are dynamically stable, that is, non-explosive. (Dynamically unstable solutions can usually be ruled out by recognition of a transversality condition that is relevant in the explicit or implicit optimization problem solved by the model's agents.) A widely held point of view is that in cases of indeterminacy – that is, two or more stable RE solutions – there is a presumption of substantial non-optimality for that reason alone, so that (for example) a monetary policy rule that permits such indeterminacy should be strenuously avoided (see, for example, Benhabib and Farmer 1999; Woodford 2003.) An alternative possibility, expressed most explicitly by McCallum (2003), is that in such cases only a single stable RE solution may be economically relevant. From that perspective there is evidently good reason to believe that a necessary (not sufficient!) condition, for a particular RE solution to be plausible, is that it be *learnable* by some process that enables individual agents in an economy to obtain empirical information about the parameters that govern the behaviour of the economy. (It seems implausible that individuals could obtain such information by processes that do not involve inference from data generated by the economy.) Extensive study of such processes has been one feature of a large body of work summarized in the influential treatise of Evans and Honkapohja (2001). The leading contender for a learning process for this first purpose is recursive least squares learning, with the issue being whether such a learning process converges to a RE solution as time passes and an unlimited quantity of data is accumulated. There exist alternative learning algorithms, of course, but the one in question is in several respects specified so as to be highly conducive to learnability, so that if a RE solution is not learnable by this procedure then it should not be regarded as a plausible candidate for an economically relevant equilibrium. This point of view may, in some cases, eliminate concerns regarding solution multiplicity. In this first type of learning analysis, the concept of E-stability – due to DeCanio (1979), Evans (1986), Marcet and Sargent (1989), and Evans and Honkapohja (1992) – is used extensively, as it provides a convenient technique for determining the learnability status of particular RE solutions. A notable application to monetary policy rules is Bullard and Mitra (2002).

A second, quite different, and more ambitious application of learning algorithms is to represent distinct hypotheses, as alternatives to RE, concerning the formation of expectations. This line of work has been pursued extensively by Evans and Honkapohja (2001) and numerous other researchers including Sargent (1993) and Orphanides and Williams (2005). An attractive feature of this approach is that it views expectational behaviour as departing somewhat from full, strict expectational rationality, but nevertheless retaining much of the intellectual discipline imposed by the RE requirement that behaviour regarding expectation formation be governed by the same optimizing benchmark that characterizes neoclassical economics more generally. From the substantive perspective, the use of learning processes (such as constant-gain modifications of least-squares learning that have the effect of down-weighting older data) in place of RE in calibrated macroeconomic models often gives rise to additional serial correlation in endogenous variables,

thereby generating model properties that are viewed by many analysts as being more nearly consistent with actual macro time-series data.

Historical Considerations

The foregoing discussion is somewhat historical in nature yet includes no references to literature predating the Second World War. Is there some explanation for this absence? The most celebrated discussion of inflationary expectations in the 'pre-war' literature is, probably, that of Irving Fisher. In *Appreciation and Interest* (1896), Fisher emphasizes the real versus nominal interest rate distinction that is often associated with his name, and in *The Theory of Interest* (1930) he estimates a distributed-lag regression relating interest to current and past inflation rates (interpreting the long lags as due to 'delayed adjustment'). In addition, several other economists (such as Marshall 1890) devoted some attention to the effects of expected inflation, the contribution of Henry Thornton (1802) being perhaps the most prescient (on this topic, see Humphrey 1983). All in all, however, it seems that the subject attracted little attention in the pre-war literature. Even in Knut Wicksell's famous analysis of the 'cumulative process' of inflation, there is only brief passing mention (1898, pp. 96, 148) of the possibility that the inflation will be anticipated. Discussion of the effects of sustained inflationary expectations on capital formation seems to be entirely absent. This neglect may perhaps be satisfactorily explained by first noting that it is sustained inflation that is relevant and then recalling that during this earlier era the world's major economies normally adhered to some commodity- money standard, thereby sharply reducing the scope for substantial inflation to arise or to be sustained.

Inflation Measurement

David E. Lebow and Jeremy B. Rudd

Abstract

Inflation measurement is the process whereby changes in the prices of individual goods and services are combined to yield a measure of general price change. This article discusses the conceptual framework for thinking about

inflation measurement and considers practical issues associated with determining an inflation measure's scope; with measuring individual prices; and with combining these individual prices into a measure of aggregate inflation. We also discuss the concept of 'core inflation' and summarize the implications of inflation measurement for economic theory and policy.

Inflation measurement is the process whereby changes in the prices of individual goods and services are combined to yield a measure of general price change. In formal terms, we may specify the time-*t* rate of aggregate inflation *Pt* as

$$P_t = F\left(p_t^1, p_t^2, \ldots p_t^I\right), \tag{1}$$

where $F(.)$ is a function that aggregates a set of I individual time-t price changes p_t^i.Writing the problem in this manner highlights three basic issues associated with inflation measurement. First, we must decide what collection of price changes we wish to include (or, more generally, what should be the measure's *scope*); second, we must ensure that the *individual* price changes are correctly measured; and finally, we must choose a method for combining those changes into a measure of aggregate inflation.

While the problem of inflation measurement can be broadly described in these terms, dealing with the numerous complications that emerge in practice requires some explicit conceptual framework. Probably the simplest way to construct a measure of overall inflation involves defining the aggregate price level in terms of the cost of a fixed basket of goods and services. Such a measure – sometimes labeled a *cost-of-goods index* (COGI) – has several practical advantages; in particular, for a broad enough basket of goods, the change in a COGI comes very close to what most people intuitively mean by an inflation rate, and a COGI-type measure can easily be defined for any sub-component of expenditure or production (such as consumption, investment, or the output of intermediate goods). However, this simple measure of inflation faces an important practical difficulty. In a dynamic economy, the composition and nature of output will evolve as existing goods are consumed or produced in different quantities, as the characteristics of existing products change, or as entirely new goods are introduced; these changes make the COGI's fixed bundle of goods become less representative over time. The COGI approach provides no guidance as to how to address this problem, suggesting that a more comprehensive conceptual framework is needed.

If we confine our attention to consumption prices, then a natural guiding principle is provided by the concept of a *cost-of-living index* (COLI), which measures the expenditure needed for an optimizing consumer to maintain a specified level of utility as prices change. The strength of the COLI framework derives from its grounding in the theory of consumer behaviour, which can provide clear-cut suggestions (at least in principle) as to how to deal with such problems as changes in expenditure patterns or the introduction of new goods. That said, this feature of the COLI approach can also be a weakness to the extent that consumer theory provides an incorrect characterization of actual behaviour (NRC 2002,

pp. 53–8) or is insufficiently well developed to handle a particular practical situation. In addition, because the COLI concept pertains only to consumption, it provides little or no guidance about the construction of broader measures of inflation that include prices for other components of output (these might be of interest, for instance, to a monetary policymaker). The COLI framework therefore provides a natural guide to the construction of a consumer price index (CPI), which attempts to measure the prices of goods and services consumed by households; it will not, however, be able to inform the construction of a price index for overall GDP, which is defined to include the prices of *all* domestically produced final output – whether purchased by consumers, businesses, governments, or the rest of the world. (While a literature does exist on the measurement of price change from a *producer* perspective – see Diewert 1983, for an overview – it has generally received much less attention than the corresponding consumer-based approach.)

Despite these potential shortcomings, a COLI-based approach is commonly employed as a framework for informing inflation measurement – in the United States, for example, the CPI uses the COLI concept both as its explicit measurement objective and as a reference for making practical decisions about index construction (U.S. Bureau of Labor Statistics 2005). In much of what follows, therefore, we follow common practice in using the concept of a cost-of-living index to guide our discussion of the three basic issues – scope, individual price measurement, and aggregation – that are associated with the measurement of inflation. In addition, we discuss the concept of *core inflation*, which can be motivated and interpreted in terms of an alternative approach to inflation measurement. Finally, we conclude by considering the implications of these measurement issues for economic research and policy.

What Items Should Be Included in an Inflation Measure?

The scope or domain of a cost-of-goods index – whether it is defined for consumption goods or more broadly – is defined to include all items that are purchased and sold in market transactions, and, hence, that have well-defined prices. (In reality, of course, any inflation measure will include only a subset of goods consumed or produced in the economy, so sampling in order to provide a representative characterization of aggregate price change represents an important practical concern.) By contrast, the scope of a cost-of-living index is much broader than that of a corresponding COGI for consumption goods in as much as a COLI needs to account for *anything* that affects utility, including changes over time in 'background' or 'environmental' factors such as weather, pollution, crime, or the provision of public goods.

For a COLI-based measure of consumption price inflation, therefore, the relevant set of price changes $p_t^1, p_t^2, \ldots p_t^I$ should in principle include changes in both market prices and the 'shadow prices' of environmental factors (with the latter defined in the sense of Pollak 1989). In practice, however, it is almost impossible to correctly measure the effect on utility of these sorts of changes (even if we could do so, inclusion of such factors strays beyond what most people understand by the term 'inflation'). These considerations lead to the concept of a 'conditional' COLI, which (to follow Pollak 1989, again) is defined as the smallest change in expenditure that is required in order to maintain a reference utility level following a change in prices, *with the state of the environment fixed*. Although intuitive, the concept of a conditional COLI has its own conceptual difficulties. In particular, since preferences over market goods will likely depend on the environment (for example, demand for medical care depends on the incidence of disease), the rate of inflation implied by a conditional COLI will depend on the particular state of the environment that we condition on.

While the concept of a conditional COLI provides useful guidance regarding the relevant domain of a measure of consumption price inflation, it cannot unambiguously solve all questions about scope. For example, many households receive an implicit flow of services from owner-occupied housing. On the assumption that the 'price' of these services could be measured, it is

unclear whether they should enter a COLI given that they are not generated by a market transaction or explicit expenditure (and are not closely related to a conventional notion of a price); of course, the initial home purchase does meet these criteria. A similar problem extends to a number of other goods that are consumed by households but not directly purchased by them (one example is banking services furnished without explicit charge, which are included in most national accounts' definitions of consumption). And, again, once one moves outside of the realm of private consumption, the conditional COLI framework provides no practical guidance regarding the construction of inflation measures for other components of production or spending (such as investment) or for broader measures of inflation (such as the GDP price index).

Finally, a particularly difficult and controversial issue concerns the proper role of asset prices in inflation measures. If we extend the theory of a cost-of-living index to an intertemporal or multiperiod context (see Pollak 1975), then expected changes in the price of future consumption streams can affect current inflation through their impact on *lifetime* utility. We can therefore consider a cost-of-living index that is defined to include current and future prices of consumption goods; furthermore, to the extent that information about future consumption prices is contained in current asset prices, an argument can be made for including these prices in a COLI-based inflation measure (Alchian and Klein 1973). In practice, however, the volatility of asset prices – as well as the related fact that observed movements in asset prices can stem from sources unrelated to expected future consumption-price changes – typically precludes their inclusion in conventional inflation measures. (The current purchase prices of durable goods, which *are* often included, provide a partial exception.)

How Should Individual Price Changes Be Measured?

A number of practical problems complicate the measurement of individual price changes. First, in a modern economy the characteristics of existing goods can change over time; likewise, new goods and services will constantly be entering – and old goods leaving – production and consumption. Left unaddressed, these problems will render it impossible to track the price changes for an identical set of goods and will cause the set of goods being priced to become increasingly less representative of actual consumption and production. This will obviously affect COGI-based measures of inflation, and it will also affect COLI-based measures to the extent that changes in the characteristics or variety of available goods have an effect on the utility that is realized from their consumption.

Several techniques exist for dealing with non-trivial changes in the characteristics (loosely speaking, the 'quality') of existing products; all of these involve some procedure for dividing the observed price change into a component that reflects changes in the good's characteristics and a component that reflects 'pure' price change, where only this latter component is appropriate for inclusion in an inflation measure. (Moulton and Moses 1997 and NRC 2002, provide a detailed description and assessment of these various methods of quality adjustment in the context of the US CPI; see also ILO et al. 2004.) For example, when the original and modified products exist in the same period, any difference in their prices can be attributed to differences in the goods' characteristics. Alternatively, in the more common case where a good exists in one form in period t and in another in period $t + 1$, the 'pure' price change over the intervening period can be imputed from the observed average price change for a similar group of goods. (A 'matched model' index, which only includes price changes for goods that remain in the sample without change – and so implicitly assigns that average price change to other items – is a common example.) Finally, additional information may be brought to bear on the problem: under certain assumptions, for example, data on the cost to manufacturers of modifying the characteristics of a product can be used to compute the effect of these modifications on the good's price.

When detailed information about a product's characteristics is available, so-called 'hedonic' methods may be used. The hedonic approach relates the observed price of a good to its characteristics; any change in characteristics can then be explicitly controlled for and removed from the good's total price change. Specifically, when the individual effects of a good's characteristics on its price are stable over time, a measure of pure price change can be obtained by permitting the level of the price-characteristics relation to shift in each period. In the more realistic case where different hedonic functions exist for each period, a measure of pure price change between periods t and $t + 1$ can be defined as $h^{t+1}(z_t)/h^t(z_t)$ *or* $h^{t+1}(z_{t+1})/h^t(z_{t+1})$, where $h^i(z)$ denotes the hedonic function in period i relating the good's price to its set of characteristics z. (Here, the first expression yields a 'Laspeyres-like' price measure as the hedonic function is evaluated with the set of characteristics from the variety that is purchased in the base period; similarly, the second expression yields a 'Paasche-like' measure.)

An important advantage of the hedonic approach to dealing with quality change is that it can be explicitly grounded in cost-of-living theory. Under relatively weak conditions, $h^{t+1}(z^t) - h^t(z_t)$ provides an upper bound for the compensating variation associated with a given price change; likewise, $h^{t+1}(z_{t+1}) - h^t(z_{t+1})$ gives a lower bound for the equivalent variation (NRC 2002, pp. 153–4). It is unknown, however, whether these bounds are particularly tight. In addition, statistical agencies typically find real-time production of measures like these too difficult, and instead produce quality-adjusted price changes by scaling the observed price change for a good by the ratio $h^{t-j}(z_t)/h^{t-j}(z_{t+1})$, where the $t-j$ superscript makes apparent the dependence of the estimated hedonic function on an earlier period's data. Such a procedure cannot, in general, be justified in terms of a COLI-based approach (Pakes 2002).

The 'new goods' problem can be thought of as a more difficult variant of the quality-adjustment problem in which the new good contains features or characteristics that have never existed before (in a sense, the dimension of the 'characteristics space' has increased): examples include the introduction of the video cassette recorder or cellular telephone. In this case, one needs a method for imputing the price of a newly introduced good in the period prior to its first appearance in the economy; as was suggested by Hicks (1940, pp. 114–15), one logical imputation involves setting this pre-introduction price equal to the price at which the demand for the good is just equal to zero. While such an approach can be explicitly motivated in terms of a COLI-based framework, its implementation requires a degree of information about consumer preferences that is unlikely to be realized in practice (see Hausman 1997, for a representative example). It is therefore common for statistical agencies to attempt to mitigate the new goods problem through the more rapid addition of new items into the set of price changes being tracked over time; while intuitive, this approach may not always ameliorate the effects of new-goods introduction (Pakes 2002).

Another problem that arises in measuring individual price changes relates to the fact that even identical goods can sell for different prices across different sellers. These differentials could reflect true price differences – a particular outlet might simply be able to charge a lower price – but they could also reflect characteristics of the outlet itself, such as customer service or convenience. In the latter case, two otherwise identical goods should be treated as different products if they are sold at different outlets; similarly, when the outlet used to price a particular good changes, some adjustment – akin to the sorts of quality adjustments discussed above – must be made to the good's price.

One final issue relating to the measurement of individual price changes is that a good's purchase price need not be related to its effect on current-period utility if it provides consumption services in more than one period (as is the case for a durable good) or if it can be stored for later consumption. For a durable good, the conceptually relevant measure of the change in the good's price in a given period is the change in its user cost. In practice, the user cost turns out to be difficult to estimate and often implies erratic price movements. In the presence of a well-functioning rental

market, the cost of hiring a good can serve as a proxy for its user cost; this 'rental equivalence' procedure is used in the US CPI for owner-occupied housing. However, the absence of rental markets for most durable goods limits the usefulness of this technique, and in practice the purchase prices of many durable goods are directly included in most inflation measures.

How Should the Individual Price Changes Be Combined?

The combination of individual price changes into an aggregate measure of inflation falls into the domain of the theory of *index numbers*, a full discussion of which is beyond the scope of this survey. We therefore focus on some of the practical issues that arise in choosing and implementing an aggregation formula.

A natural way to construct a cost-of-goods index involves weighting the individual price changes for the components of the fixed market basket by their shares in overall expenditures. When the initial period of the index is the same as the period used to specify the expenditure weights, the resulting measure corresponds to a Laspeyres index. As is well known, however, a Laspeyres index overstates changes in the cost of living when consumer substitution occurs in response to changes in relative prices; hence, alternative formulas that do capture substitution behaviour can provide a more accurate approximation to a COLI. Examples include the Törnqvist and Fisher ideal indexes (both members of the 'superlative' class of index numbers defined by Diewert 1976), which employ aggregation weights derived from quantities purchased in both the initial and final periods of the comparison. Although the theory is not as well developed as that for consumer expenditures, similar justifications for commonly employed superlative aggregation formulas may exist for broader measures of output prices as well (for example, see Diewert 1983, for a production-based interpretation of a Törnqvist index).

In addition, statistical agencies often make use of 'chaining' (Fisher 1911, ch. 10; Forsyth and Fowler 1981) when constructing long time series of inflation rates; with this procedure, the price changes implied by a sequence of indexes defined over various sub-periods are 'chained' or cumulated together. In the COGI context, chaining carries an intuitive or pragmatic appeal in as much as it ensures that the basket being priced will remain reasonably representative of actual consumption patterns over time. However, chaining by itself cannot correctly capture consumer substitution. (Feenstra and Shapiro 2003, and Szulc 1983, consider other problems that can arise with chained indexes.)

In many circumstances, price indexes must be constructed in the absence of timely data on expenditures. A superlative aggregation formula cannot be used in real time in these cases (indeed, the fact that the Laspeyres index requires only expenditures from an earlier base period accounts for much of its appeal). A compromise procedure, which requires only base-period expenditure data, involves using a weighted constant elasticity of substitution (CES) aggregator (this includes the weighted geometric mean – which measures the cost of living when utility takes a Cobb–Douglas form – as a special case). Based on historical evidence, one could form a judgement about the likely degree of substitutability across items and then use an appropriately calibrated CES formula (Shapiro and Wilcox 1997). Such a procedure is now employed by the US CPI to aggregate *individual* prices (that is, prices *within* item-area strata), with a geometric means formula used for the majority of cases and a Laspeyres formula reserved for strata where substitution is deemed unlikely a priori.

Accurately capturing substitution behaviour is not the only relevant issue for choosing an aggregation formula. Statistical agencies typically measure a sample of prices (where the number of price quotes for a given sub-index may be quite small), and commonly used formulas can differ in their susceptibility to small-sample biases. Indeed, Bradley (2001) has argued that

small-sample bias in Laspeyres indexes – not a failure to capture substitution across categories of goods – accounts for most of the observed difference between the published (Laspeyres) version of the US CPI and a superlative (Törnqvist) variant.

At least two other issues arise in choosing how to combine individual price changes into a measure of overall inflation. First, the weights selected for use in aggregation can reflect explicit or implicit judgements as to which agents are to be represented in the index. By employing aggregate expenditure weights, the typical consumer price measure in effect gives a larger weight to the inflation rates faced by richer households – a so-called 'plutocratic' weighting scheme. (Alternatively, we could compute the simple average of each household-specific inflation rate; this 'democratic' weighting scheme might be more representative of a 'typical' household's experience.) For some purposes, one might also explicitly choose to measure the inflation rate faced by a particular segment of the population, such as wage earners, the poor, or the elderly.

Second, correct measurement of the quantities used in aggregation is critical. To the extent that these are subject to measurement error (as might occur if they are estimated from survey data), and to the extent that mismeasured weights are systematically associated with items that display above-or below-average price changes, the resulting aggregate inflation rate will be mismeasured. (Lebow and Rudd 2003, present evidence of this in the US CPI.)

The Concept of Core Inflation

Core inflation was originally defined as 'the trend rate of increase' of either 'the price of aggregate supply' or 'the cost of the factors of production' (Eckstein 1981). More commonly, however, core inflation is understood in a statistical sense as corresponding either to 'underlying inflation' (the portion of overall inflation that is free from transitory influences) or to a measure of the common trend in all prices. In line with its various definitions, core inflation can be measured in a variety of ways.

The most prevalent core inflation measures are 'exclusion' measures that omit certain items, such as food and energy, from the calculation of overall inflation. The popularity of excluding food and energy derives in part from the experience of the 1970s and early 1980s, which saw sizable supply-driven price hikes for these items. Many prices other than food and energy may move erratically as well, however (indeed, some countries publish exclusion-based measures of core consumer price inflation that omit housing, the effects of changes in indirect taxes, or other items). Thus, a variant on the exclusion approach involves adjusting the weight of items in inverse proportion to their variability (sometimes termed a 'neo-Edgeworthian' index), so that items with erratic prices are downweighted rather than omitted entirely.

A second category of core inflation measures includes limited-influence measures such as medians or trimmed means (Bryan and Cecchetti 1994). These measures exclude a certain proportion of the largest and smallest price changes each period (in the extreme case of the median, all items but one are excluded each period). In contrast to standard exclusion measures, however, the omitted items will vary period by period. Limited-influence measures sometimes do well in statistical exercises aimed at finding measures that are well correlated with long moving averages of headline inflation, or measures that can serve as good univariate predictors of headline inflation. However, for these limited-influence measures to capture underlying inflation well, true relative price changes must be smaller than transitory fluctuations (which will not always be the case). In addition, construction of these measures is often sensitive to the degree of disaggregation employed and to the length of time over which the individual price changes are measured.

A third set of approaches uses econometric techniques to estimate core inflation (variously

defined). For example, in an econometric reduced-form Phillips curve (as was employed in Eckstein's original study), lagged inflation terms can proxy for the persistent component of inflation once one controls for supply shocks and aggregate demand (the univariate analogue would involve taking simple or weighted averages of past inflation as the core inflation measure). Another approach is to use a dynamic factor model to extract a common component or 'signal' from a set of disaggregated inflation rates (Bryan and Cecchetti 1993). Other econometric approaches have been proposed as well (often invoking economic theory to provide their rationale) – for example, core inflation may be defined as the component of inflation that is uncorrelated with long-run economic activity (Quah and Vahey 1995), or best correlated with money growth. Of course, these theory-based underpinnings might be controversial; more generally, econometric approaches might be difficult to understand or communicate.

The neo-Edgeworthian, limited-influence, and dynamic factor approaches to measuring core inflation exemplify an alternative 'statistical' or 'stochastic' approach to inflation measurement that has garnered increased interest in recent years (Wynne 1997). Wynne contends that the economic basis for these inflation concepts is 'some concept of "monetary" inflation that...is not necessarily the same thing as changes in the cost of living'. If so, these alternative approaches will in principle imply different decisions about scope and aggregation relative to those implied by a COLI-based framework. In particular, to the extent that these measures seek to capture the portion of aggregate price movement that is attributable to changes in the supply of money, their relevant scope could be the price of *any* transaction that involves an exchange of money (including prices for financial assets and the purchase prices – not the user costs – for durable goods). In addition, the aggregation weights employed by these stochastic approaches are typically informed by purely statistical considerations, and so need not bear any resemblance to the weights implied by cost-of-living theory.

Implications for Research and Policy

Inflation measurement matters for at least three reasons. First, and most obviously, economic decisions often depend directly – even automatically – on published inflation measures. In the public sphere, many government programmes are indexed to inflation measures such as changes in a consumer price index: in the United States, for example, Social Security benefits, income tax schedules, and coupon payments on inflation-indexed government debt are all directly tied to changes in the CPI. Private contracts, including wage arrangements, are also indexed to changes in the CPI (although such indexation provisions are less common today than they were when inflation was higher and more uncertain).

The use of inflation measures in indexation arrangements, in principle, should help inform the details of inflation measurement. If indexation of a payment is intended to maintain its real purchasing power for a recipient, then this goal is best served by using an inflation measure tailored to that recipient. Thus, indexation of pension payments would utilize an inflation measure that reflects the consumption patterns of pensioners; income-support payments would use a measure reflecting the consumption of the poor; and so on. Such specialized price indexes can differ from an aggregate price index in both the choice of priced items and in the weights assigned to them.

Inflation measurement is also important because inflation affects economic welfare and therefore serves as a goal of public policy in its own right – in particular, a central objective of monetary policymakers is the maintenance of low and stable inflation. Problems measuring the average level of inflation will therefore affect a central bank's choice of inflation target (whether explicit or implicit). For example, many argue that the Federal Reserve should seek to stabilize *measured* inflation at some level higher than zero, in part because the US CPI tends to overstate changes in the cost of living (for example, Bernanke et al. 1999). More problematically, if measurement errors in inflation vary over time in unknown ways, central banks could respond inappropriately to movements in observed inflation rates.

Finally, because real quantities are typically estimated by deflating nominal values with a price index, inflation measurement directly affects the construction of other economic statistics (including real GDP and productivity). Thus, our ability to correctly assess the effects of technological progress, the sources of economic growth and changes in living standards over time hinges in an obvious way on the accurate measurement of individual and aggregate price movements. Furthermore, if the extent of measurement error in inflation varies over time and across items or places, then growth comparisons could be affected; examples include measuring changes in living standards over long periods (Gordon 2005) and comparing growth and productivity performance in the United States and Europe (Ahmad et al. 2003).

Inflation Targeting

Lars E. O. Svensson

Abstract

Inflation targeting is a monetary-policy strategy that was introduced in New Zealand in 1990, has been very successful in terms of stabilizing both inflation and the real economy, and as of 2007 had been adopted by more than 20 industrialized and nonindustrialized countries. It is characterized by an announced numerical inflation target, an implementation of monetary policy that gives a major role to an inflation forecast and has been called 'inflation-forecast targeting', and a high degree of transparency and accountability.

Inflation targeting is a monetary-policy strategy that was introduced in New Zealand in 1990, has been very successful, and as of 2007 had been adopted by more than 20 industrialized and non-industrialized countries. It is characterized by (a) an announced numerical inflation target, (b) an implementation of monetary policy that gives a major role to an inflation forecast and has been called 'inflation-forecast targeting', and (c) a high degree of transparency and accountability.

The *numerical inflation target* is typically around two per cent at an annual rate for the Consumer Price Index (CPI) or a core CPI, in the form of a range, such as one to three per cent in New Zealand; or a point target with a range, such as a two per cent point target with a range/tolerance interval of plus/minus one percentage points in Canada and Sweden; or a point target without any explicit range, such as two per cent in the UK and 2.5 per cent in Norway. The difference between these forms does not seem to matter in practice: a central bank with a target range seems to aim for the middle of the range, and the edges of the range are normally interpreted as 'soft edges' in the sense that they do not trigger discrete policy changes, and being just outside the range is not considered much different from being just inside.

In practice, inflation targeting is never 'strict' inflation targeting but always 'flexible' inflation targeting, in the sense that all inflation-targeting central banks ('central bank' is used as the generic name for monetary authority) not only aim at stabilizing inflation around the inflation target but also put some weight on stabilizing the real economy, for instance, implicitly or explicitly stabilizing a measure of resource utilization such as the output gap between actual output and 'potential' output. Thus, the 'target variables' of the central bank include not only inflation but other variables as well, such as the output gap. The objectives under flexible inflation targeting seem well approximated by a quadratic loss function consisting of the sum of the square of inflation deviations from target and a weight times the square of the output gap, and possibly also a weight times the square of instrument-rate changes (the last part corresponding to a preference for interest-rate smoothing). (The instrument rate is the short nominal interest rate that the central bank sets to implement monetary policy.) However, for new inflation-targeting regimes, where the establishment of 'credibility' is a priority, stabilizing the real economy probably has less

weight than when credibility has been established (more on credibility below).

Because there is a lag between monetary-policy actions (such an instrument-rate change) and its impact on the central bank's target variables, monetary policy is more effective if it is guided by forecasts. The implementation of inflation targeting therefore gives a main role to forecasts of inflation and other target variables. It can be described as *forecast targeting,* that is, setting the instrument rate (more precisely, deciding on an instrument-rate path) such that the forecasts of the target variables conditional on that instrument-rate path 'look good', where 'look good', for instance, means that the inflation forecast approaches the inflation target and the output-gap forecast approaches zero at an appropriate pace.

Inflation targeting is characterized by a high degree of *transparency.* Typically, an inflation-targeting central bank publishes a regular monetary-policy report which includes the bank's forecast of inflation and other variables, a summary of its analysis behind the forecasts, and the motivation for its policy decisions. Some inflation-targeting central banks also provide some information on, or even forecasts of, their likely future policy decisions.

This high degree of transparency is exceptional in view of the history of central banking. Traditionally, central-bank objectives, deliberations, and even policy decisions have been subject to considerable secrecy. It is difficult to find any reasons for that secrecy beyond central bankers' desire not to be subject to public scrutiny (including scrutiny and possible pressure from governments or legislative bodies). The current emphasis on transparency is based on the insight that monetary policy to a very large extent is 'management of expectations'. Monetary policy has an impact on the economy mostly through the private-sector expectations that current monetary-policy actions and announcements give rise to. The level of the instrument rate for the next few weeks matter very little to most economic agents. What matters is the expectations of future instrument settings, which expectations affect longer interest rates that do matter for economic decisions and activity.

Furthermore, private-sector expectations of inflation for the next one or two years affect current pricing decisions and inflation for the next few quarters. Therefore, the anchoring of private-sector inflation expectations on the inflation target is a crucial precondition for the stability of actual inflation. The proximity of private-sector inflation expectations to the inflation target is often referred to as the 'credibility' of the inflation-targeting regime. Inflation-targeting central banks sometimes appear to be obsessed by such credibility, there are good reasons for this obsession. If a central bank succeeds in achieving credibility, a good part of the battle to control inflation is already won. A high degree of transparency and high-quality and convincing monetary-policy reports are often considered essential to establishing and maintaining credibility. Furthermore, a high degree of credibility gives the central bank more freedom to be 'flexible' and also stabilize the real economy.

Whereas many central banks in the past seem to have actively avoided *accountability*, for instance by not having explicit objectives and by being very secretive, inflation targeting is normally associated with a high degree of accountability. A high degree of accountability is now considered generic to inflation targeting and an important component in strengthening the incentives faced by inflation-targeting central banks to achieve their objectives. The explicit objectives and the transparency of monetary-policy reporting contribute to increased public scrutiny of monetary policy. In several countries inflation-targeting central banks are subject to more explicit accountability. In New Zealand, the Governor of the Reserve Bank of New Zealand is subject to a Policy Target Agreement, an explicit agreement between the Governor and the government on the Governor's responsibilities. In the UK, the Chancellor of the Exchequer's remit to the Bank of England instructs the Bank to write a public letter explaining any deviation from the target larger than one percentage point and what actions the Bank is taking in response to the deviation. In several countries, central-bank officials are subject to public hearings in the Parliament where monetary policy is scrutinized; and in several countries, monetary policy is regularly or occasionally subject to extensive

reviews by independent experts (for instance, New Zealand, the UK, Norway, and Sweden).

So far, since its inception in the early 1990s, inflation targeting has been a considerable *success*, as measured by the stability of inflation and the stability of the real economy. There is no evidence that inflation targeting has been detrimental to growth, productivity, employment, or other measures of economic performance. The success is both absolute and relative to alternative monetary-policy strategies, such as exchange-rate targeting or money-growth targeting. No country has so far abandoned inflation targeting after adopting it, or even expressed any regrets. For both industrial and non-industrial countries, inflation targeting has proved to be a most flexible and resilient monetary-policy regime, and has succeeded in surviving a number of large shocks and disturbances. As of 2007, a long list of non-industrial countries were asking the International Monetary Fund for assistance in introducing inflation targeting. Although inflation targeting has been an unqualified success in all the small- and medium-sized industrial countries that have introduced it, the United States, the eurozone and Japan have not yet adopted all the explicit characteristics of inflation targeting, but they are all moving in that direction. Reservations about inflation targeting have mainly suggested that it might give too much weight on inflation stabilization to the detriment of the stability of the real economy or other possible monetary-policy objectives; the fact that real-world inflation targeting is flexible rather than strict and the empirical success of inflation targeting in the countries where it has been implemented seem to confound those reservations.

A possible alternative to inflation targeting is *money-growth targeting,* whereby the central bank has an explicit target for the growth of the money supply. Money-growth targeting has been tried in several countries but been abandoned, since practical experience has consistently shown that the relation between money growth and inflation is too unstable and unreliable for money-growth targeting to provide successful inflation stabilization. Although Germany's Bundesbank paid lip service to money-growth targeting for many years, it often deliberately missed its money-growth target in order to achieve its inflation target, and is therefore arguably better described as an implicit inflation targeter. Many small and medium-sized countries have tried exchange-rate targeting in the form of a *fixed exchange rate,* that is, fixing the exchange rate relative to a centre country with an independent monetary policy. For several reasons, including increased international capital flows and difficulties defending misaligned fixed exchange rates against speculative attacks, fixed exchange rates have become less viable and less successful in stabilizing inflation. This has led many countries to instead pursue inflation targeting with flexible exchange rates.

A current much-debated issue concerning the further development of inflation targeting is the appropriate *assumption about the instrument-rate path* that underlies the forecasts of inflation and other target variables and the *information provided about future policy actions.* Traditionally, inflation-targeting central banks have assumed a constant interest rate underlying its inflation forecasts, with the implication that a constant-interest-rate inflation forecasts that overshoots (undershoots) the inflation target at some horizon such as two years indicates that the instrument rate needs to increased (decreased). Increasingly, central banks have become aware of a number of serious problems with the assumption of constant interest rates. These problems include that the assumption may often be unrealistic and therefore imply biased forecasts, imply either explosive or indeterminate behaviour of standard models of the transmission mechanism of monetary policy, and on closer scrutiny be shown to combine inconsistent inputs in the forecasting process (such as some inputs such as asset prices that are conditional on market expectations of future interest rates rather than constant interest rates) and therefore produce inconsistent and difficult-to-interpret forecasts. Some central banks have moved to an instrument-rate assumption equal to market expectations at some recent date of future interest rates, as they can be extracted from the yield curve. This reduces the number of problems mentioned above but does not eliminate them. For

instance, the central bank may have a view about the appropriate future interest-rate path that differs from the market's view. A few central banks (notably in New Zealand, Norway, and Sweden – the last probably within the next few months) have moved to deciding on and announcing an optimal instrument-rate path; this approach solves all the above problems, is the most consistent way of implementing inflation targeting, and provides the best information for the private sector. The practice of deciding on and announcing optimal instrument-rate paths is now likely to be gradually adopted by other central banks in other countries, in spite of being considered more or less impossible, or even dangerous, only a few years ago.

Another issue is whether flexible inflation targeting should eventually be transformed into flexible *price-level targeting*. Inflation targeting as practised implies that past deviations of inflation from target are not undone. This introduces a unit root in the price level and makes the price level non-stationary. That is, the conditional variance of the future price level increases without bound with the horizon. In spite of this, inflation targeting with a low inflation rate is referred to as 'price stability'. An alternative monetary-policy regime would be 'price-level targeting', where the objective is to stabilize the price level around a price-level target. That price-level target need not be constant but could follow a deterministic path corresponding to a steady inflation of two per cent, for instance. Stability of the price level around such a price-level target would imply that the price level becomes trend stationary, that is, the conditional variance of the price level becomes constant and independent of the horizon. One benefit of this compared with inflation targeting is that long-run uncertainty about the price level is smaller. Another benefit is that, if the price level falls below a credible price-level target, inflation expectations would rise and reduce the real interest rate even if the nominal interest rate is unchanged. The reduced real interest rate would stimulate the economy and bring the price level back to the target. Thus, price-level targeting may imply some automatic stabilization. This may be highly desirable, especially in situations when the zero lower bound on nominal interest rates is binding, the nominal interest rate cannot be further reduced, and the economy is in a liquidity trap, as has been the case for several years until recently in Japan. Whether price-level targeting would have any negative effects on the real economy remains a topic for current debate and research.

Inflationary Gap

David Vines

This term originates from the analysis of inflation put forward by Keynes in *How to Pay for the War* (1940). If there is a gap between the level of aggregate demand for goods and services and the quantity of available supply, then this will cause inflation.

The 'inflation gap' has been used as a basis for straightforward demand pull theories of inflation. But in *How to Pay for the War* Keynes used his concept of the inflation gap to build a strikingly novel theory of the inflationary process in the UK during World War I, which foreshadowed both the demand pull and the cost push concepts developed later, and which also made a particular use of the effects of inflation on income distribution. First of all, Keynes embodied the assumption of flexible rather than administered prices of produced goods and services; any excess demand associated with the inflation gap causes the prices of goods to rise relative to their costs of production, to the extent necessary to choke off the excess demand. The second distinctive part of the theory is as follows. The rise in prices of goods will be effective in choking off the excess demand – i.e. it will close the inflation gap – for the following two reasons. First, if there is a tax on profits bigger than any tax on wages then profit incomes will leak out of circulation to the government thereby diminishing the consumption of rentiers. Second, if the propensity to consume out of profit incomes is lower than that out of wage incomes – as assumed by Keynes – then a redistribution away from wages will, of itself, lower the propensity to consume. Notice that, the fall in real wages required to close the inflation gap may be large, since it depends upon the existence of the profits tax or upon the difference between the two consumption propensities. The third distinctive element in Keynes's theory is that the resulting reduction of real wages will cause pressure for an increase in money-wages. But if the inflation gap is not to reappear, then the prices of goods must run ahead of the increases in money-wages again. The speed of the inflation depends upon the lag with which wages chase prices, and inflation accelerates if this lag shortens.

The novelty of Keynes theory may be apparent when it is realised that the dominant inflation theory of the time derived from the quantity theory of money, in which the rate of inflation is determined by the rate of monetary growth (Keynes 1940). Keynes's own theory has remained popular with Latin American structuralist writers; the inflation gap originates both because of chronic supply side ('structural') problems and because of a failure of policy to control demand, and changes in the distribution of income away from wages are thought to play an important role in stabilizing the overall process, as in Keynes's theory. (See Kaldor 1964; Cardoso 1980, presents a formal model but without the stabilizing role of lower real wages on demand.)

Orthodox demand pull theories of inflation see an inflation gap as leading to a rather different kind of inflationary process. Again they begin with an excess of aggregate demand over supply. In one version this excess demand will increase the prices of goods relative to wages, since firms are assumed to be price taking profit maximizers, who only increase supplies in the face of an extra demand if the profit margin per unit rises at the same time (Friedman 1968, 1975; Phelps 1970). In this case, wages again chase prices as wage earners begin to learn that real wages have fallen, and the process so far is very similar to that presented by Keynes. Or, in another version, the excess demand may not of itself raise prices until it percolates directly through to the labour market and causes money-wages to rise, subsequently inducing increases in prices, and then in turn inducing wages to chase the higher prices (Laidler and Parkin 1975). But in both of these more conventional demand pull theories, the extent of the inflation which ultimately emerges depends on how demand management policy (i.e. fiscal and monetary policy) responds to dampen down the inflation gap, by curtailing economic activity. Indeed, in the hands of monetarist economists, under the assumption of a constant velocity of circulation of money, the extent of the inflation comes to depend directly on the rate of growth of the money supply, the very view which Keynes had earlier criticized. Crucially, these orthodox theories do not, like Keynes, see changes in the distribution of income away from wages as serving the function of regulating the excess demand, and of thereby determining the severity of the inflationary process which emerges.

Keynes himself did not foreshadow another possibility, almost the reverse of what he analysed. This is that a cost push inflation process could be engendered by a social conflict over the distribution of income, quite independently of any inflationary stimulus coming from the inflation gap (see Rowthorn 1977; Meade 1982; and Marglin 1984).

Informal Economy

Keith Hart

Abstract

The informal economy or sector has become the preferred term for unregulated economic activities, in both rich and poor countries. Based on Weber's theory of rationalization, it was coined during the early 1970s in response to proliferating self- employment and casual labour in Third World cities. Now its range of reference is very wide, embracing everything from high-level political corruption to home improvement. The phenomenon is real enough and of some antiquity, but its definition remains elusive. Operating beyond the rules of bureaucracy, the informal economy may be understood dialectically as division, content, negation or residue.

The term 'informal economy' became current in the 1970s as a label for economic activities that take place outside the framework of bureaucratic public and private sector establishments. It arose in response to the proliferation of self-employment and casual labour in Third World cities; but later the expression came to be used with reference to societies like Britain, where it competed with epithets of deindustrialization – the 'hidden', 'underground', 'black' economy, and so on.

The social phenomenon is real enough and of some antiquity. London's East End in the mid-19th century is a stark example of informal economic organization which rivals in scale any of today's tropical slum areas (Davis 2006). Nevertheless, the empirical referents of the 'informal economy' remain elusive, ranging as they do between the extremes of corrupt public finance in Congo and do-it-yourself in a London suburb. The intellectual history of the concept is clearer. It was provoked by the failure of prevalent economic models to address a large part of the world that they claimed to offer prescriptions for. Sociologists, anthropologists, geographers and historians have grasped the opportunity to embarrass economists by pointing out this deficiency. More remarkably, many economists, including employees of bureaucracies such as the World

Bank and the International Labour Organization (ILO), have identified the 'informal sector' as something they must deal with. Whereas once the effects of 'informality' were thought to be palliative, they are now often seen as a threat to legitimate businesses.

Some notable attempts have been made to document the economy of the streets. Henry Mayhew's investigations for the *Morning Chronicle* in the 1850s, published as *London Labour and the London Poor* (1861–2), are a classic source, as are Oscar Lewis's several accounts of the 'culture of poverty' (for example, *La Vida,* 1964). Very little of all this impinged on the world of development economists. The dualistic models of economic development that prevailed in the 1960s took their lead from W. Arthur Lewis's (1954) theory of development with unlimited supplies of labour, whereby underemployed rural workers migrated to find wage employment in a higher productivity urban economy.

In *Peddlers and Princes* (1963), Clifford Geertz identified two economic ideal types in a Javanese town. The majority were occupied in a street economy that he labelled 'bazaar-type'. Opposed to this was the 'firm-type' economy consisting largely of Western corporations that benefited from the protection of state law. These had *form* in Weber's (1981) sense of 'rational enterprise' based on calculation and the avoidance of risk. National bureaucracy lent these firms a measure of protection from competition, thereby allowing the systematic accumulation of capital. The 'bazaar', on the other hand, was individualistic and competitive, so that accumulation was well-nigh impossible. Geertz considered what it would take for a group of reform Muslim entrepreneurs to join the modern 'firm' economy. They were rational and calculating enough; but they were denied the institutional protection of state bureaucracy, which was the preserve of the existing corporations.

A decade later and in the context of growing unease over Third World urban unemployment, Keith Hart (1973, based on a conference paper of 1971) argued that the masses who were surplus to the requirements for wage labour in African cities were not 'unemployed' but rather were positively employed, even if often for erratic and low returns. He proposed that these activities be contrasted with the 'formal' economy of government and organized capitalism as 'informal income opportunities'. Moreover, he suggested that the aggregate inter-sectoral relationship between the two sources of employment might be of some significance for models of economic development in the long run. In particular, the informal economy might be a passive adjunct of growth originating elsewhere or its dynamism might be a crucial ingredient of economic transformation in some cases.

The dualism (formal–informal) and some of the thinking behind it received immediate publicity through its adoption in an influential ILO (1972) report on incomes and employment in Kenya, which elevated the 'informal sector' to the status of a major source for national development by the bootstraps, as it were. This was enough to encourage legions of researchers to adopt the term. Before long a substantial critique of the 'informal sector' concept had emerged. Marxists claimed that its proponents mystified the essentially regressive and exploitative nature of this economic zone, which they preferred to call 'petty commodity production'. The study of Third World urban poverty rapidly became a new segment of the academic division of labour; as a key term in its discourse, the informal economy attracted an unusual volume of debate (Bromley 1978). Later, sociologists applied the term to industrial societies (Pahl 1984).

Hernando De Soto argued that Peru was a mercantilist state whose overregulated and impenetrable national bureaucracy excluded the vast majority from effective participation in development. The latter were an entrepreneurial peasantry flocking in ever-larger numbers to the main cities. They were forced to operate informally, that is, outside the law, in sectors such as housing, trade and transport. Later, he portrayed poor countries like Peru as being trapped in a world economy dominated by the first industrial nations (De Soto 2000). Red tape is mainly an effect of a global regime that forces marginal states to adopt inappropriate institutional practices. The result is the same: migrants pile up in the cities and are

forced to work outside the law. Countries like the USA, which dominates this global financial bureaucracy, made the transition to modern capitalism by giving informal practices and decentralized violence full rein in their own development. Similar flexibility has to be shown today if the poor urban masses are to have a chance of joining global development on less unequal terms.

The idea of an 'informal economy' is entailed by the institutional effort to organize society along formal lines (Hart 2006). 'Form' is *the rule,* an idea of what ought to be universal in social life; and for most of the 20th century the dominant forms have been those of bureaucracy, particularly of national bureaucracy, since society has become identified to a large extent with nation states. This identity may now be weakening in the face of the neoliberal world economy and a digital revolution in communications. Popularity as a jargon word has not helped the informal economy acquire a measure of analytical precision. For many it is a convenient name for an unambiguous empirical phenomenon – what you find in the slums of Manila. Others refer to size (large-scale–small-scale), productivity (high–low), visibility (enumerated–unenumerated), pattern of rewards (wages–self-employment), market conditions (monopoly–competitive) and much else. Hart (1973), like Geertz, explicitly derived his analysis from Weber's theory of rationalization. Much that goes on in developing countries today is only marginally the product of state regulation: it is thus 'informal' relative to the forms of publicly organized economic life. This is a qualitative distinction.

'Form' is the rule, the invariant in the variable. Idealist philosophers from Plato onwards thought the general idea of something was more real than the thing itself. The 'formal sector' is likewise an idea, a collection of people, things and activities that share an idea; but we should not mistake the idea for the reality that it partially identifies. What makes something 'formal' is its conformity with such an idea or rule. Thus formal dress in some societies means that the men will come dressed like penguins, but the women are free to wear something extravagant that suits them personally – they come as variegated butterflies. Formality endows a class of people with universal qualities, with being the same and equal. What makes dress 'informal' is therefore the absence of such a shared code. But informality is relative to the eye of the beholder. Any observer of an informally dressed crowd will notice that the clothing styles are not random. We might ask what these informal forms are and how to account for them. The world's ruling elite can be identified as 'the men in suits', because they choose to wear a style invented in the 1920s as an informal alternative to formal evening dress.

What the public and private sectors share is conformity to the rule of law at the national and increasingly international levels. How then might non-conformist economic activities, 'the informal economy', relate to this formal order? They may be related in any of four ways: as *division,* as *content,* as *negation* and as *residue.* The first two imply a positive relationship of interdependence, the third is antagonistic and the last relatively autonomous. The moral economy of capitalist societies is based on an attempt to keep separate impersonal and personal spheres of social life. The establishment of a formal public sphere entailed another based on domestic privacy. Most people, traditionally men more than women, divide themselves every day between production and consumption, paid and unpaid work, submission to impersonal rules in the office and the free play of personality at home. Money is the means whereby the two sides are brought together, so that their interaction is an endless process of separation and integration that I call *division.*

For any rule to be translated into human action, something else must be brought into play, such as personal judgement. So informality is built into bureaucratic forms as unspecified *content.* Take a chain of commodities from their production by a transnational corporation to their final consumption in a Third World city. At several points invisible actors appear filling the gaps that the bureaucracy cannot handle directly, from the factories to the docks to the supermarkets and street traders who supply the cigarettes to smokers. Informal processes are indispensable to the trade, as variable content to the universal form. Of course, some of

these activities may break the law, through a breach of health and safety regulations, tax evasion, smuggling, the use of child labour, selling without a licence, and so on. The third way that informal activities relate to formal organization is thus as its *negation.* Rule breaking takes place both within bureaucracy and outside it; and so the informal is often illegal. The informalization of the world economy is to a large extent criminal and this includes white-collar crime.

The fourth category is not so obviously related to the formal order as the rest. Some 'informal' activities exist parallel to it, as *residue.* They are just separate from the bureaucracy. It would be stretching the logic of the formal–informal pair to include peasant economy, traditional institutions and much else besides within the rubric of the 'informal'. Yet the social forms endemic to these often shape informal economic practices.

It is inconsistent to claim that the urban poor have an informal economy but their rich masters do not; or that the Third World has an informal sector but not the industrialized West. As long as there is formal economic analysis and the *partial* institutionalization of economies around the globe along capitalist lines, there will be a need for some such remedial concept as the informal economy. Its application to concrete conditions is stimulated by palpable discrepancies between prevalent models and observed realities. Such a discrepancy provoked the emergence of the concept in the 1970s, when Third World economies bore the brunt of the depression that marked the end of the West's post-war miracle. Later the accelerating decline of the British economy encouraged some social scientists to adopt the term there. The common strand is the growing inability of modern states to control the wider economic environment that sustains them. Hence the need for a dualistic model, such as that offered by the 'informal economy' concept.

Information Aggregation and Prices

James Jordan

Abstract

Economists commonly interpret market-clearing prices as the signals that competitive markets transmit to economic agents to facilitate the efficient allocation of resources. Informational decentralization theory formalizes this interpretation by characterizing the market mechanism as the unique decentralized mechanism that achieves efficient allocation with the minimal required communication. Rational expectations equilibrium theory formalizes a different aspect of the interpretation, showing

that markets transmit to each trader all of the decision-relevant information in the market.

Market-clearing prices aggregate decision-relevant information that is initially dispersed throughout the economic environment. Hayek (1945) asserts that competitive markets economize on the communication needed to achieve efficient allocations by embedding in prices all that any individual needs to know about the rest of the economy. During the 1970s and 80s, Hayek's famous assertion was interpreted and formalized by two distinct literatures in economic theory. Hurwicz's (1960) model of decentralized allocation mechanisms stimulated a literature on *informational decentralization theory* that led to the characterization of the market as the unique informationally decentralized allocation mechanism that minimizes the communication needed to achieve Pareto-efficient allocations. This result verifies Hayek's assertion, although the minimal message communicated by the market mechanism necessarily includes the market clearing trades as well as prices.

Hayek's assertion has a second connotation in financial asset markets and other markets involving trade under uncertainty, where the dispersed information may be of direct interest to all traders. In this setting Hayek's assertion can be interpreted as a version of the *strong form* of the *efficient market hypothesis* (for example, Fama 1970), which states that market prices constitute a sufficient statistic for all of the decision-relevant information in the market. Adding *rational expectations* (Muth 1961) to models of general equilibrium under uncertainty makes it possible to formalize Hayek's assertion as follows. If all information in the market is directly communicated to all traders, the resulting equilibrium is also a rational expectations equilibrium. That is, each trader would find the market-clearing prices statistically sufficient for all of the decision-relevant private information of others. This version of Hayek's assertion is also verified, again provided that the market clearing trades are added to the prices in forming the sufficient statistic. There are also interesting cases in which the prices alone form a sufficient statistic.

Informational Decentralization

Mount and Reiter (1974) formalized the general model of informationally decentralized allocation as follows. There are n agents, indexed $1 \leq i \leq n$. The private information, or environment, of agent i is an element e^i of a set E^i. The set of economic environments is the Cartesian product $E = E^1 \times \ldots \times E^n$, with generic element $e = (e^1,\ldots,e^n)$. Let Y denote a set of outcomes or allocations. The desired performance is modelled by a *performance correspondence* $g : E \rightarrow\!\!\!\!\rightarrow Y$, which associates with each environment e a set of desired allocations $g(e)$, where the double arrow is used to denote that g is set-valued. The communication among agents is embodied in messages $m \in M$, where M is the *message space*. Each message is associated with an allocation via an *outcome* function $h : M \rightarrow Y$. Finally, each environment is associated with a set of messages via a *message correspondence* $\mu : E \rightarrow\!\!\!\!\rightarrow M$. An allocation mechanism (μ,M,h) *realizes* the performance correspondence g if for all $e \in E$,

$$\mu(e) \neq \varnothing; \tag{1}$$

and

$$h(m) \in g(e) \text{ for all } m \in \mu(e). \tag{2}$$

An allocation mechanism (μ,M,h) is *informationally decentralized* if there are individual message correspondences $\mu^i : E^i \rightarrow\!\!\!\!\rightarrow M$ such that for each $e \in E$,

$$\mu(e) = \cap_{i=1}^{n} \mu^i(e^i). \quad (3)$$

This rather abstract definition can be interpreted by imagining that a computer chooses a message m at random and displays it to all agents. If for some agent i, $m \notin u^i(e^i)$ then agent i vetoes this message and another is chosen at random, until a message m is found that is accepted by all agents, that is, $m \in \cap_i \mu^i(e^i)$, at which point the allocation $h(m)$ is chosen. The message m embodies the communication needed to achieve the allocation $h(m) \in g(e)$, because each agent i makes the veto/ accept decision based only on e^i and m. An informationally decentralized allocation mechanism (μ,M,h) that realizes a given g is *informationally efficient* if there is no other such mechanism that uses a message space that is smaller, in an appropriate sense, than M. If E and Y are finite, then the cardinality of M is the appropriate measure of size. In this case, the minimum required size agrees with the *communication complexity* of g, as that measure is defined in the computer science literature (for example, Karchmer 1989). In models with continua of environments and allocations, it is more common to require that M be a manifold and interpret its dimension as its size. In this case, informational efficiency has the interpretation of using messages with the minimum number of real variables.

The application of this model to competitive markets is direct. Let E denote the set of pure exchange environments with l commodities. Assume that each trader's consumption set is the non-negative orthant R^l_+, so that trader i's private information is $e^i = (u^i,\omega^i)$, where $u^i : \mathrm{R}^l_+ \to \mathrm{R}$ is trader i's utility function and ω^i is an initial endowment bundle in R^l_+. Let Y be the set of all net trades that balance in the aggregate, $Y = \{y = (y^1, \ldots, y^n) \in \mathrm{R}^{nl} : \sum_i y^i = 0\}$. The desired allocations are simply the Pareto efficient allocations that are also non-coercive, in the sense that traders are not forced below the utility level of their initial endowments. Formally, define $g : E \to\!\!\!\!\to Y$ as $g(e) = \{y \in Y : (\omega^1 + y^1, \ldots, \omega^n + y^n)$ is a Pareto-efficient allocation satisfying $u^i(\omega^i + y^i) \geq u^i(\omega^i)$ for all $i\}$. Non-coerciveness, which is sometimes called 'individual rationality', excludes the possibility of achieving Pareto efficiency by giving everything to one trader.

The *competitive allocation mechanism* is defined as follows. Let P denote the interior of the unit simplex in R^l_+, and define the *competitive message space* $M_c = \{(p, y) \in P \times Y : py^j = 0$ for all $i\}$ The outcome function $hc : Mc \to Y$ is the projection $h_c(p, y) = y$, and the individual message correspondence $\mu^i_c : E^i \to\!\!\!\!\to M_c$ is defined as $\mu^i_c(u^i, \omega^i) = \{(p, y) \in M_c. : \omega^i + y^i \in \mathrm{R}^l_+$ and $u^i(\omega^i + y^i) \geq u^i(x^i)$ for all $x_i \in \mathrm{R}^l_+$ satisfying $px^i \leq p\omega^i\}$. In effect, $\mu^i_c(e^i)$ is trader i's offer curve, and the *competitive message correspondence* μ_c, defined as $\mu_c(e) = \cap_i \mu^i_c(e^i)$, is the intersection of the offer curves.

The competitive allocation mechanism (μ_c,M_c, h_c) is informationally decentralized by construction. If the sets E^i are restricted by conventional assumptions (for example, utility functions are continuous, quasi-concave and strictly increasing, and endowments are strictly positive) then $\mu_c(e)$ is equal to the nonempty set of competitive equilibria for e, and the First Fundamental Welfare Theorem implies that the competitive allocation mechanism realizes g.

The informational efficiency of the competitive allocation mechanism was established by Hurwicz (1977) and Mount and Reiter (1974). The dimension of the competitive message space, M_c, is $n(l\text{-}1)$, so the informational efficiency of (μ_c,M_c,h_c) means that any other allocation mechanism (μ,M,h) which is informationally decentralized and realizes g must have $\dim M \geq n(l - 1)$. This requires imposing sufficient mathematical regularity on (μ,M,h) so that dim M is well-defined and μ cannot behave as a Peano curve, encoding multi-dimensional information into the unit interval, for example. In particular, it is sufficient to require that M be (homeomorphic to) an open subset of a Euclidean space and that, on the set of exchange environments in which all traders have Cobb–Douglas utility *functions*, the correspondence μ admits a continuous selection on some open subset (on Cobb–Douglas environments, μ_c is itself single-valued and continuous). More general conditions are given by Mount and

Reiter (1974), where the non-coerciveness requirement on g is also relaxed to require merely that for Cobb–Douglas environments, $g(e)$ includes only interior Pareto-efficient allocations. This excludes the mechanism that gives everything to trader 1 by using a message space of dimension $(n - 1)$l to enable traders 2,..., n to communicate their endowments.

The informational efficiency of competitive markets leaves open the possibility that other allocation mechanisms are also informationally efficient. This possibility is excluded by Jordan (1982b), albeit under stronger mathematical regularity conditions. In particular, the message correspondence μ is required to be single-valued and continuous on Cobb–Douglas environments, as opposed to merely having a local continuous selection. The non-coerciveness assumption is also much less dispensable for this result.

The informational decentralization literature verifies Hayek's assertion by characterizing the market mechanism as the unique informationally efficient mechanism that achieves non-coercive Pareto-efficient allocations. However, the competitive message is more than just the 1 - 1 relative prices that are the focus of Hayek's insight. The realization of non-coercive Pareto-efficient allocations requires $n(1–1)$-dimensional messages because of the need to communicate the equilibrium trades as well as the prices.

Rational Expectations Equilibrium

A simple version of the rational expectations equilibrium model can be described as follows. Before trade, each trader i observes her endowment, $\omega^i \in \mathrm{R}^1_+$, and a private signal, z_i, which is jointly distributed with the future state s, which is common to all traders, that determines her utility function $u^i(\cdot, s) : \mathrm{R}^1_+ \to \mathrm{R}$. Assume for simplicity that there is only a finite number of possible private signal values, each of which has positive probability. In a rational expectations equilibrium, each trader i maximizes her expected utility conditional on her private signal z^i and any endogenous market variables she observes. To formulate the information aggregation condition, suppose that all private signals were publicly observable. Then every trader would observe all of the information in the market, so there would be no need to infer information from market variables. The appropriate equilibrium concept would be a *full communication equilibrium* (FCE), defined as associating with each profile of signals $z = (z^i)_i$, a price vector $p(z)$ and net trades $y(z) = (y^i(z))_i$ satisfying, for each z,

$$\sum\nolimits_i y^i(z) = 0, \tag{4}$$

and for each trader i,

$$\begin{aligned} &\omega^i + y^i(z) \text{ maximizes } E\{u^i(x^i,\cdot)\,|\,z\} \\ &\quad \text{subject to } p(z)\ x^i \le p(z)\omega^i, \end{aligned} \tag{5}$$

where the expectation is taken over s with respect to the conditional distribution over s given z. Thus, an FCE allocation is an allocation that would result if every trader possessed all of the information in the market. The information aggregation question is thus whether an FCE can be supported if traders are given only their private information and, for example, the equilibrium price vector. More precisely, does an FCE $(p(\cdot), (y^i(\cdot))_i)$ also satisfy

$$\begin{aligned} &\omega^i + y^i(z) \text{ maximizes } E\{u^i(x^i,\cdot)\,|\,z^i, p(z)\} \\ &\quad \text{subject to } p(z)x^i \le p(z)\omega^i, \end{aligned} \tag{6}$$

for each z and each trader i? Functions $p(\cdot)$, $(y^i(\cdot))_i$ that satisfy Eqs. (4) and (6) constitute a *rational expectations equilibrium* (REE). Thus the information aggregation question is whether an FCE is also an REE.

Kreps (1977) provides a simple example showing not only that the answer is 'no', but that an REE can easily fail to exist. In the Kreps example, there are two traders, two commodities and two equiprobable states of the world, $s \in \{a, b\}$ The traders' endowments are $\omega^1 = \omega^2 = (3, 3)$ and their state-dependent utility functions are given by

$$\begin{aligned} u^1(x,a) &= 2lnx_1 + lnx_2,\ u^1(x,b) \\ &= lnx_1 + 2lnx_2, \end{aligned}$$

$u^2(x,a) = lnx_1 + 2lnx_2$, $u^2(x,b) = 2lnx_1 + lnx_2$.

Trader 1's signal is the state itself, $z^1 = s$, so trader 1 is fully informed; and trader 2's signal is a constant, $z^2 = \overline{z}^2$, so trader 2 is uninformed. Suppose by way of contradiction that $p(\cdot)$ is an REE price function. There are two possible cases. If $p(a,\overline{z}^2) \neq p(b,\overline{z}^2)$, then the price reveals the state to trader 2, and both traders are fully informed. However, it is easily seen that the (fully informed) environments $(\omega^i, u^i(\cdot, a))_i$ and $(\omega^i, u^i(\cdot, b))_i$ have the same unique equilibrium price $p = \left(\frac{1}{2}, \frac{1}{2}\right)$ There remains only the case that $p(a,\overline{z}^2) = p(b,\overline{z}^2)$, in which trader 1 is fully informed but trader 2 remains uninformed. However, the exchange environments $(\omega^1, u^1(\cdot,a)), (\omega^2, \frac{1}{2}u^2(\cdot,a) + \frac{1}{2}u^2(\cdot,b)))$ and $(\omega^1, u^1(\cdot,b)), (\omega^2, \frac{1}{2}u^2(\cdot,a) + \frac{1}{2}u^2(\cdot,b)))$ have unique and distinct equilibrium prices, thus eliminating this case as well. Thus market prices cannot always aggregate all the information in the market, and the use of market prices as information signals as well as rates of exchange can prevent even the existence of equilibrium.

If traders condition their expectations on the entire competitive message, however, full information aggregation occurs. In fact, for each trader i, conditioning on $p(z)$ and $y^i(z)$ is enough. More precisely, every FCE also satisfies Eq. (6)

$$\omega^i + y^i(z) \text{ maximizes } E\left\{u^i\left(x^i,\cdot\right) \middle| p(z), y^i(z)\right\}$$
$$\text{subject to } p(z)x^i \leq p(z)\omega^i, \qquad (7)$$

for each z and every trader i. It follows from the FCE property Eq. (5) that for any observed p and y^i, $\omega^i + y^i$ maximizes $E\{u^i(x^i, \cdot)| z\}$ subject to $px^i \leq p\omega^i$ for every z in the observed event $\{z : (p(z), y^i(z)) = (p, y^i)\}$. Thus the conditional expected utility function in Eq. (7) is a convex combination of expected utility functions, each of which is maximized by $\omega^i + y^i(z)$ subject to $p(z)x^i \leq p(z)\omega^i$. Therefore, the convex combination has the same maximum at the same constraint. Moreover, $(p(z), y^i(z))$ is the minimal market data needed for full information aggregation. Jordan (1982a) shows that, if traders condition expectations on non-constant functions of the competitive message $(p(z), (y^i(z))_i)$, then each trader's data must be sufficient to reveal $(p(z), y^i(z))$ to each trader i, not only to ensure full information aggregation but even to avoid examples of nonexistence of equilibrium.

The simultaneous determination of expectations, prices and trades in a rational expectations equilibrium begs the question of how the private information z becomes embedded in the prices and trades, from which each trader can infer the private information of others. A dynamic interpretation is given by Jordan (1982c). Suppose that, initially, each trader i conditions expectations on the private signal z^i alone. This leads to an initial equilibrium price vector $p_1(z)$, but suppose that, before the equilibrium trades are executed, traders update their expectations using the information revealed by $p_1(z)$. This leads to a second equilibrium price vector $p_2(z)$, and so on, until a price vector $p_T(z)$ is reached that reveals no new information that changes any trader's demand. This process may fail to reveal all decision-relevant information to every trader. For example, if the only trader with a non-constant signal has state-independent preferences, no information will be revealed and the process will terminate at the first step. However, for each trader i, the final price and net trade $\left(p_T(z), y^i_T(z)\right)$ is a sufficient statistic for all of the decision-relevant information trader i has learned from z^i and the temporary equilibrium prices. In this sense, the final prices and net trades summarize all of the private information revealed by prices along the temporary equilibrium path. The sequence of temporary equilibria is virtual in the sense that the temporary equilibrium trades are never executed. If they were, expectations of interim capital gains and losses could lead to nonexistence of temporary equilibrium, which is shown by an example in Jordan (1982c).

The Kreps (1977) example described above shows that prices alone cannot always support full information aggregation. However, the example is non-generic in the sense that a slight

perturbation of the state-dependent utility functions can make the full communication equilibrium prices different in the two states, resulting in full revelation. Radner (1979) develops a financial asset market model in which the FCE price function p(·) is generically 1–1. In Radner's model, the set of future states and current signal values are both finite. Each future state corresponds to a vector of values for the assets that are currently traded. Each signal z is associated with a conditional probability vector over the future states, and thus the future asset values. Radner shows that the set of signal-conditional probability arrays that give rise to FCE price functions that are not 1 - 1 is a closed nowhere dense set of Lebesgue measure zero. This line of research was greatly extended in a series of papers by Allen (see Allen and Jordan 1998, for a more detailed survey). Let Z denote the range of possible signal values z, and suppose that the relation between the signal z and conditional expected utility functions is sufficiently regular that the set of full communication environments $(E\{u^i(\cdot)|\ z\},\ \omega^i)_i$ has dimension no larger than the dimension of Z. If Z is finite, as in Radner's model, both sets have dimension zero.

Allen (1981) shows that, if $dimZ < \frac{1}{2}dimP$, then an FCE price function p(·) is generically 1-1. Allen (1982b) shows that, if $dimZ < dimP$, then an FCE price function is generically 1 - 1 except on a subset of Z having Lebesgue measure zero. This implies that, if the probability distribution over signals has a density function on Z, then an FCE price function is 1 - 1 on a set of signals having probability one, so that prices are again fully informative. The dimensional inequality is crucial. Jordan and Radner (1982) provide a robust example of the nonexistence of price-conditional rational expectations equilibrium with $dimZ = dimP = 1$.

Most of the results described above do not substantially restrict the way in which traders' preferences depend on the unknown future state of the world. Financial asset market models, in contrast, typically involve special kinds of state-dependent preferences that give rise to some interesting cases in which market prices are fully revealing. The earliest full revelation result was obtained by Jerry Green (1973) in an Arrow-securities markets model. In this case, the securities traded are wealth claims contingent on each future state, and traders have private signals about the probability distribution over the future states. Green (1973) shows that the derivative of market excess demand with respect to the state probabilities has a dominant diagonal property that ensures that the function from the full communication probabilities to the FCE price vector is 1-1. Grossman (1981) generalizes Green's model to obtain the full revelation of decision-relevant information even when the FCE prices are not 1-1. However, Green (1977) shows that, if 'noise' is included in the environment in the form of random endowments, rational expectations equilibrium can fail to exist.

The Green–Grossman full revelation result depends on the completeness of the securities markets. In the absence of complete markets, full revelation through prices can be obtained under restrictions on the nature of the uncertainty or on traders' utility-of-wealth functions. Grossman (1978) considers a model with a single riskless asset and several risky assets. The future values of the risky assets have a joint normal distribution. Traders have private signals about the mean of this distribution, but the covariance matrix is fixed. Grossman (1978) shows that, if traders' utility-of-wealth functions exhibit non-increasing absolute risk-aversion, then the FCE price vector is a 1 - 1 function of the full communication mean, and thus reveals all decision-relevant information. The same asset markets are studied by Jordan (1983), but arbitrary small perturbations are allowed in traders' endowments and the joint probability distribution over private signals and future risky asset values. In this case, if the number of private signal variables exceeds the number of risky assets ($dimZ > dimP$), full revelation by prices is assured only for three special classes of utility-of-wealth functions: linear, exponential, and constant relative risk aversion with the same constant for all traders.

I

The full revelation of private information by the market seems inconsistent with the acquisition of costly private information. For this reason, Grossman and Stiglitz (1980) introduced a financial asset market model, generalized by Hellwig (1980), which has a price-conditional rational expectations equilibrium that is only partially revealing. This model assumes that traders have exponential utility, and that future risky asset values are normally distributed. Full revelation is prevented by adding noise to the model in the form of randomness in the aggregate supply of the risky asset. Unfortunately, the existence of rational expectations depends on the special parametric assumptions of the model. Allen (1982a, 1985a, b) and Anderson and Sonnenschein (1982) develop general models of partially revealing approximate rational expectations equilibria, but the rational expectations equilibrium literature has not produced a general model of partially revealing equilibrium.

Cascade experiments test the theory that conformity can result from individuals receiving private imperfect information and making public decisions in a sequence (see ▶ Information Cascades).

Cascade theories provide a rational explanation for imitation even when people receive different private information. If a person gathers additional information by observing others' decisions, then a sequence of decisions that matches one alternative might be strong enough to outweigh that person's contrary private information. When the initial decisions in a sequence are correct, cascades can lead to better overall decision-making than private information alone. However, information cascades are problematic when the initial decision-makers in a queue receive incorrect information and convey it to others through their public (incorrect) decisions.

Anderson and Holt (1997) designed the first laboratory cascade experiment to test the theory described in Bikhchandani et al. (1992). Participants were shown two cups labelled A and B. Cup A contained two light marbles and one dark marble. Cup B contained two dark marbles and one light marble. A six-sided die was used to determine whether Cup A or Cup B was selected at the start of each decision-making round. The cups were equally likely to be selected by the die throw. Once a cup was selected, each person saw one private draw from the cup, with the marble being returned to the cup after each draw. Each participant made a public prediction about which cup (A or B) was being used for the draws in a randomly determined sequence that changed from round to round. Sessions included six decision-makers who were paid two dollars for a correct prediction and nothing otherwise for each of 15 rounds.

In any given round, if the first two public predictions matched (AA or BB) it was rational (based on Bayes' rule) for all subsequent decision-makers to follow, regardless of which marble they saw drawn from the cup (see ▶ Bayesian Statistics). Starting with prior probabilities of 1/2 for each cup, if the first decision-maker predicted cup A, others could rationally infer that he saw a light marble, since there were more light marbles than dark marbles in Cup A. With this new information, the probability of Cup A should have been updated to 2/3. If the second decision-maker predicted Cup A, others could infer that he also saw a light marble, and the probability of Cup A being used for the draws should have been updated to 4/5. Even if the third person observed a dark marble, it was still more likely that Cup A was being used for the draws, and a cascade should start with the third decision-maker. Alternatively, if the first two decision-makers cancelled each other out (AB or BA) and the next two matched, then a cascade could start with the fifth person in the sequence.

Cascades were possible, based on the private draws and the decision-making sequence, in about half the Anderson and Holt (1997) experiments and actually formed in about 70 per cent of these cases. Almost all the people who did not join rational cascades were following private information that conflicted with the cascade. This type of deviation is explained by cascade models with small amounts of noisy behaviour, as described in Anderson and Holt (1997) and Goeree et al. (2007), who showed that incorrect cascades are not likely to persist in experiments with long sequences of decisions.

From a policy perspective, cascades are a concern because they hide information, since the private information of cascade followers is not revealed by their decisions. Kübluer and Weizsäcker (2004) studied whether or not

people recognized the lack of information in conforming decisions by making participants pay a fee to see a private signal. In one version of their experiment, it was rational for only the first person in the sequence to purchase information, but the authors found that many people made irrational purchases. Some of this behaviour can be explained by a model with error, since it is rational to buy information if one cannot completely trust the quality of public decisions.

In addition to the studies discussed above, laboratory experiments have been used to test other variations of the seminal cascade theory including applications to voting (Hung and Plott 2001), investment (Alsopp and Hey 2000), markets (Drehmann et al. 2005; Cipriani and Guarino 2005) and advice-giving (Çelen et al. 2005).

Information Cascades

Sushil Bikhchandani, David Hirshleifer and Ivo Welch

Abstract

An information cascade occurs when individuals, having observed the actions and possibly payoffs of those ahead of them, take the same action regardless of their own information signals. Informational cascades may realize only a fraction of the potential gains from aggregating the diverse information of many individuals, which helps explain some otherwise puzzling aspects of human and animal behaviour. For example, why do individuals tend to converge on similar behaviour? Why is mass behaviour prone to error and fads? The theory of observational learning, and particularly of information cascades, has much to offer economics and other social sciences.

An *information cascade* is a situation in which an individual makes a decision based on observation of others without regard to his own private information.

Social observers have long recognized that human beings have a deep-rooted proclivity to imitate. According to Machiavelli (1514, p. 152), 'Men nearly always follow the tracks made by others and proceed in their affairs by imitation.' Even animals imitate in choices of mate and territories. A common view among social scientists equates the conformity of individuals in large groups with irrationality – 'fads', 'mass psychology', or the 'madness of crowds'.

However, there has also been recent recognition of the benefits of social influence. For example, zoologists have argued that, despite its possible disadvantages, imitation is an evolutionary adaptation that has promoted survival over thousands of generations by allowing individuals to take advantage of the hard-won knowledge of others (Gibson and Hoglund 1992).

Nevertheless, as this article discusses, even when individuals are entirely rational, observational influence helps surprisingly little, leading to social outcomes that are inefficient and superficially may seem irrational. Irrationality undoubtedly affects social behaviour. Recent developments in the theory of observational learning, however, give reason to be sceptical about casual attributions of perverse social outcomes to irrational passions.

Why do people tend to 'herd' on similar actions? Why is mass behaviour prone to error and fads? The theory of observational learning helps explain some otherwise puzzling phenomena about human behaviour, and offers a vantage point for treating issues in economics and business strategy.

We call influence resulting from rational processing of information gained by observing others *observational learning* or *social learning*. Observational learning is only one of several possible causes of convergent behaviour. The simplest reason is that individuals can have identical beliefs and decision problems. Alternative reasons for conformity include positive payoff externalities, which lead to conventions such as driving on the right-hand side of the road; preference interactions, as with everyone desiring to wear the more 'fashionable' clothing as determined by what others are wearing; and sanctions against deviants, as with a dictator punishing opposition.

Among these theories, however, only observational learning explains why mass behaviour is error-prone, idiosyncratic, and often fragile in the sense that small shocks might lead to large shifts in behaviour. To understand how these effects arise, consider a sequence of rational individuals who take identical decisions under uncertainty. Each individual makes use of all relevant information – his own private signal and any inferences drawn from observing the choices of preceding individuals. As soon as the information gleaned from publicly observable choices of others is even slightly more informative than the individual's private signal, he imitates his immediate predecessor without regard to his private information. Therefore, this individual's choice is uninformative about his signal, and at that point an information cascade starts. His immediate successor finds herself in an identical position; she imitates him (her immediate predecessor) and ignores her private signal. Based on the information conveyed by the actions of the first few individuals – the ones not in a cascade – every succeeding individual takes the same action. This action may be an incorrect one, so even small shocks such as the possible arrival of a different type of individual or a little new information can overturn it. Thus, observational learning explains not only conformity but also rapid and short-lived fluctuations such as fads, fashions, booms and crashes.

The social outcome is highly error-prone because there is an information externality. If an individual selects an action that depends on his information signal, his action provides useful information to later decision-makers. However, it is in the self-interest of an individual in a cascade to ignore his signal; therefore, later individuals do not get the benefit of learning his private signal. Thus, the failure of individuals to take into account the welfare of later decision-makers leads to inefficient information aggregation.

This entry focuses on the situation where individuals with diverse private information learn by observing the actions of others or the consequences of these actions. (Previous surveys of this literature include Bikhchandani et al. 1998, and Chamley 2004.)

Observable Actions Versus Observable Signals

Consider a setting in which individuals choose an action in a chronological order. Each individual starts with some private information, obtains some information from predecessors, and then decides on a particular action. We consider two scenarios. In the *observable actions* scenario, individuals can observe the actions but not the signals (that is, private information) of their predecessors. As demonstrated below, cascades will arise in this model. We compare this with a benchmark *observable signals* scenario in which individuals can observe both the actions and the signals of predecessors. (See Welch 1992; Bikhchandani et al. 1992; Banerjee 1992.)

The main ideas are seen in the following simple example. Several risk-neutral individuals decide in sequence whether to *adopt* or *reject* a possible action. The payoff to adopting, V, is either 1 or -1 with equal probability; the payoff to rejecting is 0. In the absence of further information, the two alternatives are equally desirable. The order in which individuals decide is given and known to all.

Each individual's signal is either High (H) or Low (L). It is H with probability $p > 1 = 2$ if $V = 1$, and with probability $1-p$ if $V = -1$. Bayes' rule implies that, after observing one H, an individual's posterior probability that $V = 1$ is p; if instead one L is observed the probability that $V = 1$ is $1-p$. All private signals are identically distributed and independent conditional on V. Naturally, an individual's posterior belief about V also depends on information derived from predecessors. All this is common knowledge among the individuals.

In the observable signals scenario, each individual observes predecessors' information signals. As the pool of public information keeps increasing, later individuals will settle on the correct choice (adopt if $V = 1$, reject if $V = -1$) and thus behave alike.

Because actions reflect information, it is tempting to infer that, if only the actions of predecessors are observable, the public information set will also gradually improve until the true value is revealed almost perfectly. But that is not the case. In the observable actions case, individuals often converge fixedly on the same wrong action – that is, the choice that yields a lower payoff, *ex post*. Furthermore, behaviour is *idiosyncratic* in that the choices of a few early individuals determine the choices of all successors.

To return to our example, the first individual, Asterix, adopts if his signal is H and rejects if it is L. All successors can infer Asterix's signal perfectly from his decision. If Asterix adopted, then Beatrix, the second individual, should also adopt if her private signal is H; as Beatrix sees it, there have now been two H signals, the one she inferred from Asterix's actions and the one she observed privately. However, if Beatrix's private signal is L, it exactly offsets Asterix's signal H. She is indifferent between adopting and rejecting. We assume, for expositional simplicity, that, as Beatrix is indifferent between the two alternatives, she tosses a coin to decide. (By similar reasoning, if Asterix rejected, then Beatrix should reject if she observes L, and toss a coin if her signal is H.)

The third individual, Cade, faces one of three possible situations: both predecessors adopted (AA), both rejected (RR), or one adopted and the other rejected (AR or RA). In case AA, Cade also adopts. He knows that Asterix observed H and that more likely than not Beatrix observed H too (although she may have seen L and flipped a coin). Thus, even if Cade sees a signal L, he adopts. Consequently, Cade's decision to adopt provides no information to his successors about the desirability of adopting. Cade is therefore in an *information cascade*; his optimal action does not depend on his private information. The uninformativeness of Cade's action means that no further information accumulates. Everyone after Cade faces the same decision and also adopts based only on the observed actions of Asterix and Beatrix. By similar reasoning, RR leads to a cascade of rejection starting with Cade.

In the remaining case where Asterix adopted and Beatrix rejected (or vice versa), Cade knows that Asterix observed H and Beatrix observed L (or vice versa). Thus, Cade's belief based on the actions of the first two individuals is that the $V = 1$ and $V = -1$ are equally likely. He finds himself in a situation identical to that of Asterix, so Cade's

decision is based only on his private signal. Then, the decision problem of the fourth individual, Daisy, is the same as Beatrix's. Asterix's and Beatrix's actions have offset and thus carry no information to Eeyore. And if Cade and Daisy both take the same action – say, adopt – then an adoption cascade starts with Eeyore.

An individual's optimal decision rule is as follows. Let d be the difference between the number of predecessors who adopted and the number who rejected. If $d > 1$, then adopt regardless of private signal. If $d = 1$, then adopt if private signal is H and toss a coin if signal is L. If $d = 0$, then follow private signal. The decisions for $d = -1$ and $d < -1$ are symmetric. The difference between adoptions over rejections evolves randomly, and very quickly hits either the upper barrier of + 2 and triggers an adoption cascade, or the lower barrier of − 2 to trigger a rejection cascade. With virtual certainty, all but the first few individuals end up doing the same thing.

Order of Information, Noise, and Information Externalities

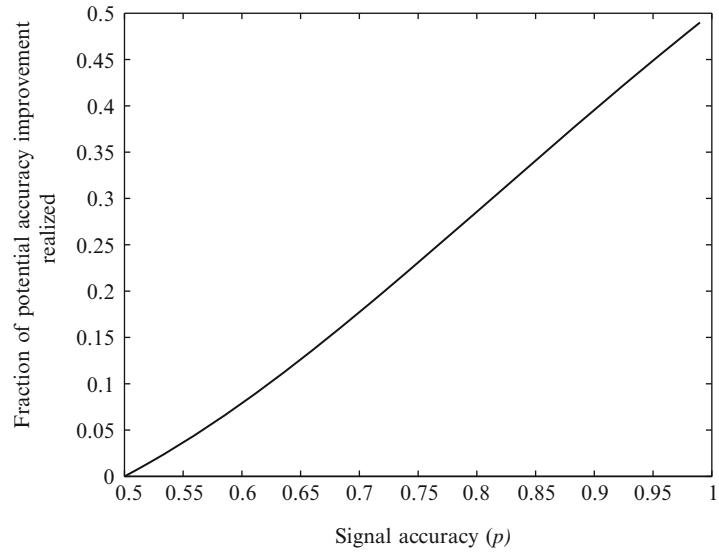
The reason the outcome with observable actions is so different from the observable signals benchmark is that, once a cascade starts, public information stops accumulating. An early preponderance towards adoption or rejection causes all subsequent individuals to ignore their private signals, which thus never join the public pool of knowledge. Nor does the public pool of knowledge have to be very informative to cause individuals to disregard their private signals. As soon as the public pool becomes slightly more informative than the signal of a single individual, individuals defer to the actions of predecessors and a cascade begins.

Furthermore, the type of cascade depends not just on how many H and L signals arrive, but on the order in which they arrive. For example, if signals arrive in the order HHLL. . ., then all individuals adopt, because Cade begins an adoption cascade. If, instead, the same set of signals arrive in the order LLHH. . ., all individuals reject, as Cade begins a rejection cascade. Thus, in the observable actions scenario, whether individuals on the whole adopt or reject is *path dependent*.

A cascade is likely even when private signals are noisy. Specifically, in the above example, let the probability that the signal is correct be $p = 0{:}51$. The probability that an adoption or rejection cascade forms after the first two individuals is close to 75%! (The signal sequences HH – that is, Asterix observes H and Beatrix observes H – and LL cause adoption and rejection cascades respectively, starting with Cade. Similarly, HL and LH each lead to adoption and rejection cascades with probability 0.5 each, if the action chosen by Beatrix after a coin flip is the same as Asterix's. The sum of the probabilities of these events is about 0.75.) After eight players the probability is only 0.004 that the individuals are not in a cascade. (This is the probability $|d| < 2$ for each of individuals 3 through 8.)

Although a cascade starts eventually with probability one, the probability of being in a correct cascade (that is, an adoption cascade when $V = 1$ and a rejection cascade when $V = -1$) is only 0.5133. (The calculation can be found in Bikhchandani et al. 1992.) If individuals do not observe their predecessors' choices (or information), then they would choose an action based only on the private signal; the probability that an individual's choice is correct is 0.51. Thus, the increase in accuracy from observing the actions of predecessors is small. Contrast this with the observable signals scenario, where after many individuals the publicly observed information signals of predecessors are virtually conclusive as to the right action.

More generally, even when individuals have more accurate signals (p is much greater than 0.5), the information contained in a cascade is substantially short of efficient information aggregation. Consider the benchmark observable signals scenario. Individuals far enough out would know the true state almost perfectly. The correctness of these individuals' actions increases from p to 1 due to information revelation. Figure 1 graphs, as a function of the signal accuracy p, the fraction of potential accuracy improvement realized in the observable actions scenario. (The fraction of potential accuracy improvement realized is (Pr[correct



Information Cascades, Fig. 1 Gains from action observability (Note: Fraction of potential accuracy improvement realized $\left(\left[\frac{p(p+1)}{2(1-p+p^2)} - p\right]/(1-p)\right)$ as a function of signal accuracy (p is the probability that the signal is high given that the true value is high))

cascade]-p)(1 -p). From (3) in Bikhchandani et al. 1992, Pr[correct cascade] = $p(p)$ 1) = 2(1 -p) p^2). This fraction increases from 0 for very noisy signals to 0.50 for very informative signals. Thus, in the basic model, at most half of the potential gains are realized.

An individual's private information is useful to others. However, in choosing the optimal action, the individual ignores this benefit: with the onset of a cascade in the observable actions scenario, individuals rationally take uninformative imitative actions. This information externality reduces information aggregation. To see this, consider an alternative benchmark scenario in which (*a*) each individual maximizes a discounted sum of payoffs to all individuals and (*b*) no individual can directly reveal his private information; others learn of his information only through this individual's choice of action. The onset of cascades in this scenario is delayed (compared with the observational actions scenario); information aggregation is efficient subject to the constraint that private information is revealed only through actions.

Fragility

Of course, in reality we do not expect a cascade to last for ever. The arrival of better-informed individuals or the release of new public information can easily dislodge a cascade. Indeed, participants in a cascade know that the cascade is based on information that is only slightly more accurate than the private information of an individual. Thus, a key prediction of the theory is that behaviour in cascades is *fragile* with respect to small shocks. (In some models in which conformity is enforced by the threat of sanctions upon defectors, rare shifts occur when the system crosses a critical value that shifts the outcome from one equilibrium to another; Kuran 1989.)

How robust are the conclusions that cascades are born quickly and idiosyncratically, and shatter easily? When some assumptions in the example are relaxed, is the aggregation of information still inefficient or delayed?

Robustness of the Basic Model

The conclusions of the basic model remain robust along a number of dimensions. We discuss here alternative assumptions about the action space and the signal, which affect the conclusions to some extent.

The Action Space

In the basic model, players make inferences about others' signals from observed choices. When there

are many possible actions, the action choice can convey more information. If the set of actions is continuous and unbounded, then actions fully reveal players' information and cascades do not arise (Lee 1993). (If the action space is a continuous but bounded interval, then when an individual optimally chooses one of the end points of the interval, the value of his signal is not revealed by his action. In consequence, incorrect cascades can form at the end points of the interval.) For example, if a set of firms cannot invest less than zero, they may incorrectly cascade on zero investment.

However, if players are even slightly unsure of the payoff functions of other players, then there is a discontinuous shift to a slower learning process in which information aggregation is inefficient (Vives 1993). In many real-world settings, the action space is bounded or partly discrete: investment projects that have a minimum efficient scale, elections amongst a discrete set of alternatives, a car purchase of a Ford or a Toyota, a takeover decision of whether to bid or not bid for a target firm, and a decision to hire or fire a worker.

The Signal Space

As in the simple two signal example presented above, in settings with a large but discrete set of signal values cascades occur with probability close to one and are sometimes incorrect. In some continuous signal settings cascades do not form (Smith and Sorensen 2000), but an informational externality remains and information aggregation is inefficient. Furthermore, with substantial probability individuals soon follow the behaviour of recent predecessors, and with some probability that action is incorrect. Indeed, with any finite number of individuals, a continuous signal setting is observationally similar to a discrete signal setting that approximates the continuous model. In other words, in a continuous signals setting herds tend to form in which an individual follows the behaviour of his predecessor with high probability, even though this action is not necessarily correct. Thus, the welfare inefficiencies of the discrete cascades model are also present in continuous settings (Chamley 2004, ch. 4).

Observability of Payoffs or Signals

Several papers consider the inefficiency of social learning when there is some degree of observability of payoffs (Caplin and Leahy 1994). Furthermore, even if individuals can observe the payoffs of predecessors, inefficient cascades can form and with positively probability last for ever, because a cascade can lock into an inferior choice before sufficient trials have been performed on the other alternative to persuade later individuals that this alternative is superior (Cao and Hirshleifer 2002). Indeed, if individuals can observe a subset of past signals, such as the past k signals, inefficient cascades can form.

Other Assumptions of Basic Model

When individuals have the freedom to delay their action choice, in equilibrium there is delay, followed by a sudden onset of cascades when an individual commits to an action (Chamley and Gale 1994; Zhang 1997). The existence, idiosyncrasy and fragility of cascades are robust to relaxing other assumptions as well, including allowing for differing information precision, costly information acquisition, and heterogeneous observable tastes (see Bikhchandani et al. 1998, and the references therein). Inefficient cascades still form when individuals have reputational as well as informational motives to herd (Ottaviani and Sorensen 2000). When individuals are imperfectly rational, inefficient cascades still form, but overconfident individuals provide social value when their impetuous choices shatter incorrect cascades (Bernardo and Welch 2001).

Applications

There has been extensive testing of information cascades models in the laboratory. Experiments provide some support for information cascades and observational learning (Anderson and Holt 1997).

Demand for Goods and Securities

The information cascades theory implies not just that consumer purchase decisions will be influenced by others, as occurs, for example, in

automobile purchases in Finland (Grinblatt et al. 2004), but that the source of this influence is informational. In consequence, the cascades approach implies that the incorrect cascades arise in settings in which individuals observe summary statistics of others' behaviour, such as whether one product is outselling another. Golder and Tellis (2004) provide evidence that information cascades play a role in the dynamics of product life cycles. The cascades theory also implies that individuals who are viewed by others as being better informed will be fashion leaders, in the sense that their decisions can trigger immediate cascades. This can explain the effectiveness of a star basketball player's endorsement of a brand of sneakers, but not of his or her endorsement of a brand of beer.

Even without fashion leaders, there are ways for individuals to have disproportionate effects on the onset of information cascades. In a salient 1995 episode, management gurus Michael Treacy and Fred Wiersema secretly purchased 50,000 copies of their business strategy book in order to inflate the sales measures used to construct the *New York Times* best-seller list. Despite mediocre reviews, their book not only made the best-seller list but subsequently sold well enough to continue as a best-seller without further demand intervention by the authors.

The ubiquitous and legitimate marketing method of offering a low initial price may be a successful scheme for introducing an experience good: early adoptions induced by the low price help start a positive cascade. This idea was first analysed by Welch (1992) to explain why initial public offerings of equity are on average severely underpriced by issuing firms. Indeed, a seller may be tempted to cut price secretly for early buyers, so that later buyers will attribute the popularity of the product to high quality rather than low price.

Medicine

Most doctors cannot stay fully abreast of relevant medical advances in their specialties, suggesting that they may select among new treatments based primarily on observation of choices made by other doctors. The cascades approach implies that medical treatments will be characterized by localized conformity and occasional reversals triggered by limited information, and that doctors perceived as having special expertise will have disproportionate influence. It has indeed been claimed that a blind reliance by physicians upon their colleagues' medical decisions commonly leads to surgical fads and even to treatment-caused illnesses (Robin 1984). Many dubious practices seem to have been adopted initially based on weak information (elective hysterectomy, ileal bypass and tonsillectomy), and then later abandoned. A few decades ago, differences in tonsillectomy frequencies in different countries and regions were extreme.

Politics

People learn about others' political beliefs by observing how they vote and from opinion and exit polls. Several studies of political momentum show that early respondents carry disproportionate weight (see Bartels 1988). A possible non-informational explanation is that individuals have a direct preference to conform, but we would expect such an effect to be stronger when an individual is personally exposed to acquaintances with strong views than when the individual observes a polling statistic. Furthermore, polling numbers influence not just preference between candidates, but 'thermometer score' ratings of the perceived quality of candidates. Iowa voters gave an obscure candidate named Jimmy Carter a conspicuous early success in the 1976 US presidential campaign. Many southern states have coordinated their primaries early in the election cycle on the same date ('Super Tuesday') in order to increase their influence on the presidential election. The expanding turnout of protestors in Leipzig in 1989, which triggered the fall of communism in East Germany, has been modelled as an information cascade (Lohmann 1994). More broadly, a recent literature on the social diffusion of ideas emphasizes that individual signals are sometimes not reflected in public discourse, leading to poor information aggregation in public policy decisions (Kuran and Sunstein 1999).

Finance

The decision of individual investors to participate in the stock market and the buying and selling decisions of mutual fund managers are influenced by their peers' decisions (Hong et al. 2005), and there is some indication that herding by mutual funds influences prices (Wermers 1999). The rise in popularity of investment clubs and of day-trading in the 1990s was probably due in part to a self-feeding effect in which individuals learned from the media or word of mouth that many others were day trading. Several theoretical models of securities market trading (Avery and Zemsky 1998) and market crashes (Lee 1998) have been developed which embody either cascade or cascade-like features. Hirshleifer and Teoh (2003) review the theory and evidence of social learning and cascades in finance.

Zoology

Zoologists have documented observational learning, and proposed that information cascades are exhibited in a variety of animal behaviours, including 'false alarm' flights from possible predators, selection of night roosts by birds, and mate-choice copying in various animal species (Giraldeau et al. 2002).

Information Sharing Among Firms

Xavier Vives

Abstract

Firms may have efficiency or strategic incentives to share information about current and past behaviour or intended future conduct. This article examines those incentives and the welfare consequences from the perspective of static oligopoly and monopolistic competition models. It concludes with a review of the available evidence.

Keywords

Antitrust; Bertrand competition; Collusion; Common values; Cournot competition; Disclosure; Disclosure rules; Hard information; Independent values; Information sharing among firms; Misrepresentation; Monopolistic competition; Private values; Product differentiation; Soft information; Trade associations

Information sharing (IS) among firms has been a contentious topic in antitrust and has received substantial attention from researchers. Firms may share information about current and past behaviour of, for example, customers, orders and prices, as well as cost and demand conditions. This type of information exchange typically involves hard or verifiable information. Firms may also exchange information about intended future conduct – for example, planned prices, production, new products or capacity expansion. This typically involves soft information. Firms may have incentives to share information for efficiency or strategic reasons. The latter include influencing the behaviour of rivals or sustaining collusion. We will discuss here the results of static models, leaving out dynamic models of collusion and information signalling (see for those models Vives 1999, sects. 8.4, 8.5 and 9.1.5; Kühn and Vives 1995, sect. 8).

Firms may exchange cost or demand information in order to better adapt their output and pricing decisions to uncertainty. From the firm's point of view, the main effects of IS are the increased precision of information to be used by itself and rivals, and the corresponding impact on firms' strategies. In general, increased precision has a positive effect on a firm's expected profits, while the effect of increased precision of rivals and the induced strategy correlation depends on the nature of competition and shocks.

Information exchange is typically modelled as a two-stage game in which firms first unilaterally decide whether to reveal their signals, and then, after receiving those signals and possibly revealing them, compete *à la* Cournot or Bertrand. It is assumed that firms report their signals truthfully if they decide to share information. The workhorse model has quadratic payoffs and normal distributions (or distributions yielding linear conditional expectations) for signals and uncertain parameters such as demand intercepts and marginal costs. The assumptions yield linear equilibria at the second

stage and explicitly computable payoffs. (See Vives 1999, sect. 8.3.1; Kühn and Vives 1995, sects 2–5.) A sample of the literature is Novshek and Sonnenschein (1982), Clarke (1983), Vives (1984), Fried (1984), Gal-Or (1985, 1986), Li (1985), Sakai (1985), Shapiro (1986), Kirby (1988), Sakai and Yamato (1989), Raith (1996), and the extensions in Malueg and Tsutsui (1996, 1998). In the subgame-perfect equilibria of the two-stage game (excepting Bertrand competition with cost uncertainty) unilaterally revealing information is a dominant strategy with independent values, private values (that is, where each firm receives a signal with no noise about its payoff-relevant parameter), or common values with strategic complements. With common value and strategic substitutes, not revealing is a dominant strategy.

If firms are able to enter into industry-wide agreements, the determining factor is whether the information pooling situation increases or reduces expected profits. With the exception of Bertrand competition under cost uncertainty, expected profits with IS are always larger than without, under independent values, private values, and common value and strategic complements. With (for example, Cournot with substitutes), IS yields higher (lower) expected profits for a high (low) degree of product differentiation or steeply (slowly) rising marginal costs. Note that since IS often raises profits under one-shot interaction, IS cannot be taken as prima facie evidence of collusion.

IS agreements are usually mediated by trade associations that typically disclose an aggregate statistic of firms' private signals. Monopolistic competition, where no firm has a significant impact on aggregate market outcomes, is suitable for examining the role of such associations' disclosure rules. A firm first decides whether or not to join the association and reveal its private information. Under non- exclusionary disclosure, information is made available to everyone in the market; under exclusionary disclosure, it is provided to members only. Obviously, with a non-exclusionary disclosure rule, IS will not ensue if the sharing is costly (by not joining, a firm, being negligible in terms of aggregate market impact, can free ride and obtain market information costlessly, with no effect on market aggregates). With an exclusionary disclosure rule, IS may occur if the membership fee is not too high (see Vives 1990).

The impact of IS on consumer surplus and total surplus depends on the type of competition and uncertainty, and on the number of firms. Three effects operate: output adjustment to information, output uniformity across varieties (given consumer preference for variety), and selection among firms of different efficiencies. IS may allow firms to better adjust to demand and/or costs shocks (output adjustment effect). This will tend to improve welfare except if the firm is a price setter and demand is uncertain. In this case, more information will give the firm greater scope to extract consumer surplus – an insight already valid for a monopolist. In monopolistic competition, where variety must be taken into account, IS tends to make the outputs of varieties more similar with common value uncertainty and less so with private value uncertainty, thus increasing (decreasing) expected total surplus under demand uncertainty and Cournot (Bertrand) competition (Vives 1990).

Analysis of the oligopoly case is complex, but several generalizations hold. Under demand uncertainty and Cournot competition, IS increases expected total surplus (ETS); under demand uncertainty and Bertrand competition, it decreases consumer surplus (as well as ETS, under monopolistic competition). With common values, IS always increases ETS, except under price competition, when goods are poor substitutes and/or there are many firms. (See Kühn and Vives 1995, sect. 5.2; Vives 1999, sect. 8.3.3.) There are potentially large efficiency benefits from information exchange. For example, the production rationalization effect of cost information exchange under Cournot can be very large and is of a larger order of magnitude than the market power effect (Vives 2002).

What happens when there is no trade association to provide a mechanism to share information truthfully? Assume private cost information that is exchangeable only at an interim stage, once each firm learns its own cost but does not know its rivals'. In this case, if information is not verifiable

and there are no other signalling possibilities, information revelation is impossible, since all firms would like to be perceived as being low-cost. With verifiable information, full revelation ensues if disclosure is costless and it is known whether firms have information (Okuno- Fujiwara et al. 1990; Van Zandt and Vives 2006). The lowest- cost firm will reveal its type and then all other types will unravel. Information could also be revealed through costly signalling in the form of wasteful advertising (for example, Ziv 1993), or via dynamic competition in which production levels are observable (Mailath 1989) or with sales reports (Jin 1994). In the latter case, sharing sales reports eliminates the incentive to misrepresent and changes the consequences of IS. If it is possible to verify information but not whether the firm is informed, then the unravelling result need not hold, and firms can selectively disclose acquired information (Jansen 2005).

Evidence on the effect of IS among firms is scant. Genesove and Mullin (1999) study information exchange in the Sugar Institute and find no misreporting, but some information withholding, suggesting that information can be verified. Doyle and Snyder (1999) study production plans announcements in the trade press in the automobile industry and find that a firm's announcement affects competitors' responses. Announcements of increased production are met by upward adjustments in production, which they interpret as consistent with announcements signalling a common demand parameter. Christensen and Caves (1997) study capacity announcements in the pulp and paper industry and find that unexpected announcements by rivals promote project abandonment in sub-industries with low concentration levels (and the opposite in concentrated sub-industries); they compare these results with IS models of cost information. Armantier and Richard (2003) examine exchange of cost information in the multi-market context of the airline industry. The authors account for entry decisions in a Cournot setting with complementary goods across markets, and simulate a hypothetical agreement to share cost information by American Airlines and United Airlines at Chicago O'Hare airport. They find that IS would improve airline profitability and moderately harm consumers (although, theoretically, cost IS need not necessarily hurt consumers in such a situation). The experimental results in Cason (1994) suggest that pricing behaviour is influenced by IS decisions. Ackert et al. (2000) find that in a Cournot game with cost uncertainty, where it cannot be verified whether a firm has received information, when a firm receives information about industry-wide cost unfavourable information is disclosed but favourable information is withheld. Contrary to theory, when information is about a cost-specific shock, disclosure is not affected by the favourableness of information.

Information Technology and the World Economy

Dale W. Jorgenson and Khuong Vu

Abstract

This article analyses the impact of investment in information technology (IT) on the recent resurgence of world economic growth. We describe the growth of the world economy, seven regions, and 14 major economies during the period 1989–2004. We allocate the growth of world output between input growth and productivity and find, surprisingly, that input growth greatly predominates. Moreover, differences in per capita output levels are explained by differences in per capita input rather than variations in productivity. The contributions of IT investment have increased in all regions, but especially in industrialized economies and Developing Asia.

Introduction

This article analyses the impact of investment in information technology (IT) equipment and software on the recent resurgence in world economic growth. The crucial role of IT investment in the growth of the US economy has been thoroughly documented and widely discussed. (See Jorgenson and Stiroh 2000, and Oliner and Sichel 2000. The growth accounting methodology employed in this literature is discussed by Jorgenson et al. 2005, and summarized by

Jorgenson, 2005.) Jorgenson (2001) has shown that the remarkable behaviour of IT prices is the key to understanding the resurgence of American economic growth. This behaviour can be traced to developments in semiconductor technology that are widely understood by technologists and economists.

Jorgenson (2003) has shown that the growth of IT investment jumped to double-digit levels after 1995 in all the G7 economies – Canada, France, Germany, Italy, Japan, and the United Kingdom, as well as the United States. (Ahmad et al. 2004, have analysed the impact of IT investment in OECD countries. van Ark et al. 2003; 2005), and Francesco Daveri 2002, have presented comparisons among European economies.) These economies account for nearly half of world output and a much larger share of world IT investment. The surge of IT investment after 1995 resulted from a sharp acceleration in the rate of decline of prices of IT equipment and software. Jorgenson (2001) has traced this to a drastic shortening of the product cycle for semiconductors from three years to two years, beginning in 1995.

In section "World Economic Growth, 1989–2003" we describe the growth of the world economy, seven economic regions, and 14 major economies given in Table 1 during the period 1989–2003. (We include 110 economies with more than one million in population and a complete set of national accounts for the period 1989–2003 from Penn World Table, 2002, and World Bank Development Indicators Online, 2004. These economies account for more that 96 per cent of world output.) The world economy is divided among the G7 and Non-G7 industrialized economies, Developing Asia, Latin America, Eastern Europe and the former Soviet Union, North Africa and the Middle East, and sub-Saharan Africa. The 14 major economies include the G7 economies listed above and the developing and transition economies of Brazil, China, India, Indonesia, Mexico, Russia, and South Korea.

We have sub-divided the period in 1995 in order to focus on the response of IT investment to the accelerated decline in IT prices. As shown in Table 1, world economic growth has undergone a powerful revival since 1995. The per capita growth rate jumped nearly a full percentage point from 2.50 per cent during 1989–95 to 3.45 per cent in 1995–2003. We can underline the significance of this difference by pointing out that per capita growth of 3.45 per cent doubles world output per capita in a little over two decades, while slower growth of 2.50 per cent doubles per capita output in slightly less than three decades.

In section "Sources of World Economic Growth" we allocate the growth of world output between input growth and productivity. Our most astonishing finding is that input growth greatly predominated! Productivity growth contributed only one-fifth of the total during 1989–95, while input growth accounted for almost four-fifths. Similarly, input growth contributed more than 70 per cent of growth after 1995, while productivity accounted for less than 30 per cent. The only important departure from this worldwide trend is the Asian miracle before 1995, when the rate of economic growth in Developing Asia far outstripped the rest of the world and productivity growth predominated.

In section "Sources of World Economic Growth" we distribute the growth of input per capita between investments in tangible assets, especially IT equipment and software, and investments in human capital. The world economy, all seven regions, and the 14 major economies, except Indonesia and Mexico, experienced a surge in investment in IT after 1995. The soaring level of US IT investment after 1995 was paralleled by jumps in IT investment throughout the industrialized world. The contributions of IT investment in Developing Asia, Latin America, Eastern Europe, North Africa and the Middle East, and sub-Saharan Africa more than doubled after 1995, beginning from much lower levels. By far the most dramatic increase took place in Developing Asia.

In section "World Output, Input and Productivity" we present levels of output per capita, input per capita and productivity for the world economy, the seven economic regions, and the 14 major economies. We find that differences in per capita output levels are primarily explained by

differences in per capita input, rather than variations in productivity. Taking US output per capita in 2000 as 100.0, world output per capita was a relatively modest 23.9 in 2003. If we use similar scales for input and productivity, world input per capita in 2003 was a substantial 42.4 and world productivity a robust 56.3. Section "Summary and Conclusions" concludes the paper.

World Economic Growth, 1989–2003

In order to set the stage for analysing the impact of IT investment on the growth of the world economy, we first consider the shares of world product and growth for each of the seven regions and the 14 major economies presented in Table 1. Following Jorgenson (2001), we have chosen GDP as a

Information Technology and the World Economy, Table 1 The world economy: shares in size and growth by group, region, and major economies. The measures for groups and the world are averages weighted by GDP (in PPP$) share

	Period 1989–1995			Period 1995–2003

measure of output. We employ the Penn World Table, generated by Heston et al. (2002), as the primary data source on GDP and purchasing power parities for economies outside the G7 and the European Union, as it existed prior to enlargement in May 2004. (Maddison 2001, provides estimates of national product and population for 134 countries for varying periods from 1820 to 1998 in his magisterial volume, *The World Economy: A Millennial Perspective*.)

We have revised and updated the US data presented by Jorgenson (2001) through 2003. Comparable data for Canada have been constructed by Statistics Canada (see Baldwin and Harchaoui 2003). Data for France, Germany, Italy, and the UK and the economies of the European Union before enlargement have been developed for the European Commission by Bart van Ark et al. (2003). Finally, data for Japan have been assembled by Jorgenson and Kazuyuki Motohashi (2005) for the Research Institute on Economy, Trade, and Industry. We have linked these data by means of the OECD's purchasing power parities for 1999 (OECD 2002).

The G7 economies accounted for slightly under half of world product from 1989 to 2003. The per capita growth rates of these economies – 2.18 per cent before 1995 and 2.56 per cent afterward – were considerably below world growth rates. The growth acceleration of 0.60 per cent for the G7 economies lagged behind the jump in world economic growth. The G7 shares in world growth were 41.3 per cent during 1989–95 and 33.6 per cent in 1995–2003, well below the G7 shares in world product of 47.4 per cent and 45.3 per cent, respectively.

During 1995–2003 the United States accounted for 21.8 per cent of world product and 48.2 per cent of G7 output. After 1995 Japan fell from its ranking as the world's second largest economy to third largest after China. Germany dropped from fourth place before 1995, following the United States, China and Japan, to fifth place during 1995–2003, ranking behind India as well. Japan remained the second largest of the G7 economies, while Germany retained its position as the leading European economy. France, Italy and the UK were similar in size, but less than half the size of Japan. Canada was the smallest of the G7 economies.

The US growth rate jumped from 2.43 per cent during 1989–95 to 3.56 per cent in 1995–2003. The period 1995–2003 included the shallow US recession of 2001 and the ensuing recovery, as well as the IT-generated investment boom of the last half of the 1990s. The United States accounted for more than half of G7 growth before 1995 and more than two-thirds afterward. The US share in world growth fell below its share in world product before 1995, but rose above the US product share after 1995. By contrast Japan's share in world economic growth before 1995 exceeded its share in world product, but fell short of the product share after 1995. The remaining G7 economies had lower shares of world growth than world product before and after 1995.

The 16 economies of Developing Asia generated slightly more than a fifth of world output before 1995 and more than a quarter afterward. The burgeoning economies of China and India accounted for more than 60 per cent of Asian output in both periods. (Our data for China are taken from the Penn World Table, 2002. Alwyn Young 2003, presents persuasive evidence that the official estimates given, for example, by the World Development Indicators, 2004, exaggerate the growth of output and productivity in China.) The economies of Developing Asia grew at 7.35 per cent before 1995 and 5.62 per cent afterward. These economies were responsible for an astounding 61 per cent of world growth during 1989–95! Slightly less than half of this took place in China, while a little less than a third occurred in India. Developing Asia's share in world growth declined to 43 per cent during 1995–2003, remaining well above the region's share of 26.1 per cent of world product. China accounted for more than half of this growth and India about a quarter.

The 15 Non-G7 industrialized economies generated more than eight per cent of world output during 1989–2003. These economies were responsible for lower shares in world growth than world product before and after 1995. Prior to the fall of the Berlin Wall and the collapse of the Soviet Union, the 14 economies of Eastern

Europe and the former Soviet Union were larger in size than the Non-G7, generating 9.3 per cent of world product. All of the economies of Eastern Europe experienced a decline in output during 1989–95. Collectively, these economies subtracted 26.8 per cent from world growth during 1989–95, dragging their share of world product down to 6.6 per cent. During 1989–1995 Russia's economy was comparable in size to Germany's, but from 1995 to 2003 the Russian economy was only slightly larger than the UK economy.

During 1989–95 the ten per cent share of the Latin American economies in world growth exceeded their eight-and-a-half percent share in world product. After 1995 these economies had a substantially smaller six per cent share in world growth, while retaining close to an eight-and-a-half share in world product with Brazil and Mexico responsible for more than 60 per cent of this. Brazil's share in world growth was below its three per cent share in world product before and after 1995, while Mexico's growth was lower than its product share before 1995 and higher afterward.

The 11 economies of North Africa and the Middle East, taken together, were comparable in size to France, Italy, or the UK, while the 30 economies of sub-Saharan Africa, as a group, ranked with Canada. The economies of North Africa and the Middle East had a share in world growth of 6.3 per cent during 1989–95, well above their 3.6 per cent share in world product. After 1995 their share in world growth fell to 4.6 per cent, still above the share in world product of 3.9 per cent. Growth in the economies of sub-Saharan Africa lagged behind their shares in world product during both periods.

Sources of World Economic Growth

We next allocate the sources of world economic growth during 1989–2003 between the contributions of capital and labour inputs and the growth of productivity. We find that productivity, frequently touted as the primary engine of economic growth, accounted for only 20–30 per cent of world growth. Nearly half of this growth can be attributed to the accumulation and deployment of capital and another a quarter to a third to the more effective use of labour. Our second objective is to explore the determinants of the growth of capital and labour inputs, emphasizing the role of investment in information technology equipment and software and the importance of investment in human capital.

We have derived estimates of capital input and property income from national accounting data for the G7 economies. We have constructed estimates of hours worked and labour compensation from labour force surveys for each of these economies. We measure the contribution of labour inputs, classified by age, sex, educational attainment, and employment status, by weighting the growth rate of each type of labour input by its share in the value of output. Finally, we employ purchasing power parities for capital and labour inputs constructed by Jorgenson (2003). (Purchasing power parities for inputs follow the methodology described in detail by Jorgenson and Yip 2000.)

We have extended these estimates of capital and labour inputs to the 103 Non-G7 countries using data sources and methods described in section "Methods and Data Sources". (We employ data on educational attainment from Barro and Lee 2001, and governance indicators constructed by Kaufmann et al. 2004, for the World Bank; for further details, see section "Methods and Data Sources".)

We have distinguished investments in information technology equipment and software from investments in other assets for all 110 economies in our study. We have derived estimates of IT investment from national accounting data for the G7 economies and those of the European Union before enlargement. We measure the contribution of IT investment to economic growth by weighting the growth rate of IT capital inputs by the shares of these inputs in the value of output. Similarly, the contribution of Non-IT investment is a share-weighted growth rate of Non-IT capital inputs. The contribution of capital input is the sum of these two components.

We have revised and updated the US data presented by Jorgenson (2001) on investment in information technology and equipment. (US data

on investment in IT equipment and software, provided by the Bureau of Economic Analysis, BEA, are the most comprehensive and detailed. The BEA data are described by Grimm et al. 2005.) Data on IT investment for Canada have been have been constructed by Statistics Canada (Baldwin and Harchaoui 2003). Data for the countries of the European Union have been developed for the European Commission by van Ark et al. (2003). Finally, data for Japan have been assembled by Jorgenson and Motohashi (2005). We have relied on the WITSA *Digital Planet Report* (2002/2004) as the starting point for estimates of IT investment for the remaining economies. (WITSA stands for the World Information Technology and Services Alliance. Other important sources of data include the International Telecommunication Union, ITU, telecommunications indicators, the UNDP *Human Development* reports, and the Business Software Alliance 2003. Additional details are given in section "Methods and Data Sources".)

We have divided labour input growth between the growth of hours worked and labour quality, where quality is defined as the ratio of labour input to hours worked. This reflects changes in the composition of labour input, for example, through increases in the education and experience of the labour force. The contribution of labour input is the rate of growth of this input, weighted by the share of labour in the value of output. Finally, productivity growth is the difference between the rate of growth of output and the contributions of capital and labour inputs.

The contribution of capital input to world economic growth before 1995 was 1.18 per cent, a little more than 47 per cent of the growth rate of 2.50 per cent. Labour input contributed 0.79 per cent or slightly less than 32 per cent, while productivity growth of 0.53 per cent or just over 21 per cent. After 1995 the contribution of capital input climbed to 1.56 per cent, around 45 per cent of output growth, while the contribution of labour input rose to 0.89 per cent, around 26 per cent. Productivity increased to 0.99 per cent or nearly 29 per cent of growth. We arrive at the astonishing conclusion that the contributions of capital and labour inputs greatly predominated over productivity as sources of world economic growth before and after 1995!

We have divided the contribution of capital input to world economic growth between IT equipment and software and Non-IT capital input. The contribution of IT almost doubled after 1995, less than a quarter to more than a third of the contribution of capital input. However, Non-IT was more important before and after 1995. We have divided the contribution of labour input between hours worked and labour quality. Hours rose from 0.39 per cent before 1995 to 0.62 per cent after 1995, while labour quality declined from 0.40 per cent to 0.27 per cent. Labour quality and hours worked were almost equal in importance before 1995, but hours worked became the major source of labour input growth after 1995.

The acceleration in the world growth rate after 1995 was 0.95 per cent, almost a full percentage point. The contribution of capital input explained 0.38 per cent of this increase, while the productivity accounted for 0.46 per cent. Labour input contributed a relatively modest 0.10 per cent. The jump in IT investment of 0.26 per cent was most important source of the increase in capital input. This can be traced to the stepped-up rate of decline of IT prices after 1995 analysed by Jorgenson (2001). The substantial increase of 0.23 per cent in the contribution of hours worked was the most important component of labour input growth.

Table 2 presents the contribution of capital input to economic growth for the G7 economies, divided between IT and Non-IT. Capital input was the most important source of growth before and after 1995. The contribution of capital input before 1995 was 1.28 or almost three-fifths of the G7 growth rate of 2.18 per cent, while the contribution of 1.43 per cent after 1995 was 55 per cent of the higher growth rate of 2.56 per cent. Labour input growth contributed 0.49 per cent before 1995 and 0.46 per cent afterward, about 22 per cent and 18 per cent of growth, respectively. Productivity accounted for 0.42 per cent before 1995 and 0.67 per cent after 1995 or less than a fifth and slightly more than a quarter of G7 growth, respectively.

The powerful surge of IT investment in the United States after 1995 is mirrored in jumps in

Information Technology and the World Economy, Table 2 Sources of output growth: 1995–2003 vs. 1989–1995. The measures for groups and the world are averages weighted by GDP (in PPP$) share GDP Sources of growth (% points per GDP Sources of growth (% points per Growth annum) Growth annum)

the growth rates of IT capital through the G7. The contribution of IT capital input for the G7 increased from 0.38 during the period 1989–95 to 0.69 per cent during 1995–2003, rising from 30 per cent of the contribution of capital input to more than 48 per cent. The contribution of Non-IT capital input predominated in both periods, but receded slightly from 0.90 per cent before 1995 to 0.74 per cent afterward. This reflected more rapid substitution of IT capital input for Non-IT capital input in response to swiftly declining prices of IT equipment and software after 1995.

The modest acceleration of 0.38 per cent in G7 output growth after 1995 was powered by investment in IT equipment and software, accounting for 0.31 per cent, while the contribution of Non-IT investment slipped by 0.16 per cent. Before 1995 the contribution of labour quality of 0.42 per cent accounted for more than 80 per cent of the contribution of G7 labour input, while the contribution of hours worked of 0.28 per cent explained more than 60 per cent after 1995. The rising contribution of hours worked was offset by the declining contribution of labour quality, while productivity growth rose by 0.25 per cent.

In Developing Asia the contribution of capital input increased from 1.88 per cent before 1995 to 2.70 per cent after 1995, while the contribution of labour input fell from 1.61 per cent to 1.19 per cent. These opposing trends had a slightly positive impact on growth. The significant slowdown in the Asian growth rate from 7.35 per cent to 5.62 per cent can be traced entirely to a sharp decline in productivity growth from 3.86 to 1.72 per cent. Productivity explained slightly over half of Asian growth before 1995, but only 30 per cent after 1995.

The first half of the 1990s was a continuation of the Asian Miracle, analysed by Krugman (1994), Lau (1999), and Young (1995). This period was dominated by the spectacular rise of China and India and the continuing emergence of the Gang of Four – Hong Kong, Singapore, South Korea, and Taiwan. However, all the Asian economies had growth rates considerably in excess of the world average of 2.50 per cent. The second half of the 1990s was dominated by the Asian financial crisis but, surprisingly, conforms much more closely to the 'Krugman thesis' attributing Asian growth to input growth rather than productivity.

The Krugman thesis was originally propounded to distinguish the Asian Miracle from growth in industrialized countries. According to this thesis, Asian growth was differentiated by high growth rates and a great predominance of inputs over productivity as the sources of high growth. In fact, productivity growth exceeded the growth of input during the Asian Miracle of the early 1990s! Moreover, growth in the world economy and the G7 economies was dominated by growth of capital and labour inputs before and after 1995. Productivity growth played a subordinate role and fell considerably short of the contributions of capital and labour inputs to world and G7 growth.

Developing Asia experienced a potent surge in investment in IT equipment and software after 1995. The contribution of IT investment more than doubled from 0.15 percent to 0.43 per cent, explaining less than eight per cent of the contribution of capital input before 1995, but almost 16 per cent afterward. The rush in IT investment was particularly powerful in China, rising from 0.17 per cent before 1995 to 0.63 per cent afterward. India fell substantially behind China, but outperformed the region as a whole, increasing the contribution of IT investment from 0.09 to 0.26 per cent.

Indonesia was the only major economy to experience a decline in the contribution of both IT and Non-IT investment after 1995. South Korea's IT investment increased from 0.29 before 1995 to 0.46 per cent afterward, while Non-IT investment dropped as a consequence of the Asian financial crisis. The contribution of Non-IT investment in Asia greatly predominated in both periods and also accounted for most of the increase in the contribution of capital input after 1995. The contributions of hours worked and labour quality declined after 1995 with hours worked dominating in both periods.

Economic growth in the 15 Non-G7 industrialized economies accelerated much more sharply than G7 growth after 1995. The contribution of labour input slightly predominated over capital

input before and after 1995. The contribution of labour input was 0.81 per cent before 1995, accounting for about 40 per cent of Non-G7 growth, and 1.26 after 1995, explaining 39 per cent of growth. The corresponding contributions of capital input were 0.75 per cent and 1.12 per cent, explaining 37 and 34 per cent of Non-G7 growth, respectively. Non-G7 productivity also rose from 0.47 before 1995 to 0.89 percent afterward; however, productivity accounted for only 23 and 27 per cent of growth in these two periods.

The impact of investment in IT equipment and software in the Non-G7 economies doubled after 1995, rising from 0.22 per cent to 0.44 per cent or from 29 per cent of the contribution of Non-G7 capital input to 39 per cent. This provided a substantial impetus to the acceleration in Non-G7 growth of 1.25 per cent. Non-IT investment explained another 0.14 per cent of the growth acceleration. However, the increased contribution of hours worked of 0.49 per cent and improved productivity growth of 0.42 per cent predominated.

The collapse of economic growth in Eastern Europe and the former Soviet Union before 1995 can be attributed almost entirely to a steep decline in productivity during the transition from socialism. This was followed by a modest revival in both growth and productivity after 1995, bringing many of the transition economies close to levels of output per capita that prevailed in 1989. The contribution of capital input declined both before and after 1995, even as the contribution of IT investment jumped from 0.09 to 0.26 per cent. Hour worked also declined in both periods, but labour quality improved substantially.

Latin America's growth decelerated slightly after 1995, falling from 2.95 to 2.52 per cent. The contribution of labour input was 1.92 per cent before 1995 and 1.89 per cent afterward, accounting for the lion's share of regional growth in both periods. The contribution of capital input rose after 1995 from 0.72 per cent to 0.99 per cent, but remained relatively weak. Mexico's IT investment declined slightly after 1995, while Non-IT investment increased. Nonetheless the contribution of IT investment in Latin America more than doubled, jumping from 0.15 per cent before 1995 to 0.34 per cent afterward or from 21 per cent of the contribution of capital input to 34 per cent. Productivity was essentially flat from 1989 to 2001, rising by 0.31 per cent before 1995 and falling by 0.36 per cent after 1995.

Productivity in sub-Saharan Africa collapsed during 1989–95 but recovered slightly, running at minus 1.63 per cent before 1995 and 0.36 per cent afterward. The contribution of labour input predominated in both periods, but fell from 2.77 per cent to 1.89 per cent, while the contribution of capital input rose from 0.52 per cent to 0.99 per cent. Productivity in North Africa and the Middle East, like that in Latin America, was essentially stationary from 1989 to 2001, falling from a positive rate of 0.50 per cent before 1995 to a negative rate of minus 0.46 per cent afterward.

World Output, Input and Productivity

The final step in our analysis of the world growth resurgence is to describe and characterize the levels of output, input, and productivity for the world economy, the seven economic regions, and the 14 major economies in Table 3. We present levels of output per capita for 1989, before the transition from socialism, 1995, the start of the worldwide IT investment boom, and 2003, the end of the period covered by our study. We also present input per capita and productivity for the years 1989, 1995 and 2003, where productivity is defined as the ratio of output to input.

The G7 economies led the seven economic regions in output per capita, input per capita, and productivity throughout the period 1989–2003. Output per capita in the G7 was, nonetheless, well below US levels. If we take US output per capita in 2000 as 100.0, G7 output per capita was 66.9 in 1989, 72.8 in 1995 and 85.5 in 2003. For comparison: US output per capita was 80.6, 86.3, and 106.4 in these years.

The output gap between the United States and the other G7 economies has widened considerably, especially after 1995. Canada was very close to the United States in output per capita in 1989, but dropped substantially behind by 1995. The United States–Canada gap widened further

Information Technology and the World Economy, Table 3 Levels of output and input per capita and productivity (US = 100 in 2000). The levels for groups and the world are averages weighted by population share

	Output per capita			Input per capita			Productivity

All GD7	**9.0**	**10.2**	**14.0**	**24.4**	**24.0**	**28.3**	**36.8**	**42.4**	**49.6**

during the last half of the 1990s. Germany, Japan, Italy, and the UK had similar levels of output per capita throughout 1989–2003, but remained considerably behind North America. France lagged the rest of the G7 in output per capita in 1989 and failed to make up lost ground.

The United States was the leader among the G7 economies in input per capita throughout the period 1989–2003. If we take the United States as 100.0 in 2000, G7 input per capita was 72.8 in 1989, 77.4 in 1995, and 86.4 in 2003, while US input per capita was 84.4, 89.1, and 101.4, respectively. Canada, Germany and Japan were closest to US levels of input per capita with Canada ranking second in 1989 and 2003 and Japan ranking second in 1995. France lagged behind the rest of the G7 in input per capita throughout the period with Italy and the UK only modestly higher.

Productivity in the G7 has remained close to US levels, rising from 91.7 in 1989 to 93.9 in 1995 and 96.7 in 2001, with the United States equal to 100.0 in 2000. Canada was the productivity leader throughout 1989–2003 with Italy and France close behind. The United States occupied fourth place in 1989 and 1995, but rose to second in 2003. Japan made substantial gains in productivity, but lagged behind the other members of the G7 in productivity, while Germany surpassed only Japan.

Differences among the G7 economies in output per capita can be largely explained by differences in input per capita rather than gaps in productivity. The range in output was from 64.7 for France to 106.4 for the United States, while the range in input was from 62.1 for France to 101.4 for the United States. Productivity varied more narrowly

from 86.7 for Japan to 109.5 for Canada with French productivity of 104.2 closely comparable to the United States.

In the economies of Developing Asia output per capita rose spectacularly from 6.0 in 1989 to 8.5 1995 and 12.1 in 2003 with the United States equal to 100.0 in 2000. Levels of output per capita in Asia's largest economies, China and India, remained at 13.4 and 8.6, respectively, in 2003. These vast shortfalls in output per capita relative to the industrialized economies are due mainly to differences in input per capita rather than variations in productivity. Developing Asia's levels of input per capita were 19.1 in 1989, 21.5 in 1995, and 26.2 in 2003, while Asian productivity levels were 31.7, 39.7, and 46.1, respectively.

China made extraordinary gains in output per capita, growing from 4.8 in 1989 to 8.1 in 1995 and 13.4 in 2003 with the United States equal to 100.0 in 2000. India had essentially the same output per capita as China in 1989, but grew less impressively to levels of only 6.0 in 1995 and 8.6 in 2003. China's input per capita – 17.9 in 1989, 20.7 in 1995, and 28.0 in 2001 – exceeded India's throughout the period. India's 31.2 productivity level in 1989 considerably surpassed China's 26.9. China's productivity swelled to 39.3 in 1995, outstripping India's 35.3. China expanded its lead with a productivity level of 48.0 in 2003 by comparison with India's 43.1.

Indonesia and South Korea grew impressively from 1989 to 1995, but fell victim to the Asian financial crisis during the period 1995–2003. Indonesia maintained its lead over India in output per capita, but dropped behind China in 2003. Indonesia led both China and India in input per capita during 1989–2003. Indonesia's productivity level led both China and India in 1995, but fell behind both economies by 2003. South Korea made substantial gains in productivity, achieving a level close to Japan in 2003, while falling considerably short of Japan's impressive input per capita.

The 15 Non-G7 industrialized economies, taken together, had levels of output per capita comparable to Germany, Italy, Japan, and the UK during 1989–2003. Input per capita for the 15 Non-G7 economies was also very close to these four G7 economies. However, productivity for the group was comparable to that of Germany, the second lowest in the G7.

Before the beginning of the transition from socialism in 1989, output per capita in Eastern Europe and the former Soviet Union was 34.3, well above the world economy level of 18.9, with the United States equal to 100.0 in 2000. The economic collapse that accompanied the transition reduced output per capita to 22.5 by 1995, only modestly higher than the world economy level of 20.0. A mild recovery between 1995 and 2003 brought the region back to 29.3, below the level of 1989, but well above the world economy average of 23.9. Input in the region was stagnant at 43.2 in 1989, 41.4 in 1995, and 42.6 in 2003. Productivity collapsed along with output per capita, declining from 79.4 in 1989 to 54.4 in 1995, before climbing back to 68.8 in 2003.

The downturn in output per capita and productivity was especially severe in the economies of the former Soviet Union. Russia's level of output per capita fell from 41.8 in 1989 to 25.1 in 1995 before recovering feebly to 33.5 in 2003. Russian input per capita remained essentially unchanged throughout the period 1989–2003, while productivity mirrored the decline and subsequent recovery in output, falling from a West European level of 83.6 in 1989 to 52.4 in 1995 before recovering to 70.6 in 2003. We conclude that the transition from socialism failed to restore Eastern Europe and the former Soviet Union to pre-transition levels of output and input per capita by 2003, while productivity remained weaker than before the transition.

For the Latin American region output per capita rose from 18.6 to 21.0 during 1989–2003, input per capita rose from 27.1 to 33.0, but productivity was essentially unchanged at about two-thirds of the US level in 2000. The stall in productivity from 1989 to 2003 was pervasive, contrasting sharply with the rise in productivity in the G7 economies, the Non-G7 industrialized economies, and Developing Asia. Nonetheless, Latin America's lagging output per capita was due chiefly to insufficient input per capita, rather than a shortfall in productivity.

Brazil's economic performance has been anaemic at best and has acted as a drag on the growth of Latin America and the world economy. Despite productivity levels comparable to the rest of Latin America, Brazil was unable to generate substantial growth in input per capita. Although Mexico lost ground in productivity between 1989 and 2003, rising input per capita produced gains in output per capita after 1995, despite a slight decline in the contribution of IT investment.

Output and input per capita in sub-Saharan Africa was the lowest in the world throughout the period 1989–2003, but the level of productivity was slightly higher than Developing Asia in 1989. All the economies of North Africa and the Middle East fell short of world average levels of output and input per capita. Output per capita grew slowly but steadily for the region as a whole during 1989–2003, powered by impressive gains in input per capita, but with stagnant productivity.

Methods and Data Sources

To measure capital and labour inputs and the sources of economic growth, we employ the production possibility frontier model of production and the index number methodology for input measurement presented by Jorgenson (2001). For the G7 economies we have updated and revised the data constructed by Jorgenson (2003). For the remaining 103 economies, we rely on two primary sources of data: the Penn World Table (2002) and *World Bank Development Indicators Online* (2004) provide national accounting data for 1950–2003 for all economies in the world except Taiwan. WITSA's *Digital Planet Report* (2002; 2004) gives data on expenditures on IT equipment and software for 70 economies, including the G7. (Other important sources of data include the International Telecommunication Union, ITU, telecommunications indicators, and the UNDP *Human Development* reports.)

US data on investment in IT equipment and software, provided by the Bureau of Economic Analysis (BEA), are the most comprehensive. (The BEA data are described by Grimm, Moulton and Wasshausen, 2004). We use these data as a benchmark in estimating IT investment data for other economies. For the economies included in the *Digital Planet Report* we estimate IT investment from IT expenditures. The *Digital Planet Report* provides expenditure data for computer hardware, software, and telecommunication equipment on an annual basis, beginning in 1992.

Expenditure data from the *Digital Planet Report* are given in current US dollars. However, data are not provided separately for investment and intermediate input and for business, household, and government sectors. We find that the ratio of BEA investment to WITSA expenditure data for the United States is fairly constant for the periods 1981–90 and 1991–2001 for each type of IT equipment and software. Further, data on the global market for telecommunication equipment for 1991–2001, reported by the ITU, confirms that the ratio of investment to total expenditure for the United States is representative of the global market.

We take the ratios of IT investment to IT expenditure for the United States as an estimate of the share of investment to expenditure from the *Digital Planet Report*. We use the penetration rate of IT in each economy to extrapolate the investment levels. This extrapolation is based on the assumption that the increase in real IT investment is proportional to the increase in IT penetration.

Investment in each type of IT equipment and software is calculated as follows:

$$I_{c,A,t} = \eta_{c,A,t} * E_{c,A,t}$$

where $I_{c,A,t}$, $\eta_{c,A,t}$, and $E_{c,A,t}$ are investment, the estimated investment-to-expenditure ratio, and the *Digital Planet Report* expenditures, respectively, for asset A in year t for country c.

The IT expenditures for years prior to 1992 are projected by means of the following model:

$$\ln(Ec_{i\ t-1}) = \beta_0 + \beta_1 \ln(Ec_{it}) + \beta_2 \ln(y_{it-1})$$

where Ec_{it} represents expenditure on IT asset c and the subscripts i and t indicate country i in year t, and y_{it} is GDP per capita. The model

specifies that, for a country i, spending on IT asset c in year $t-1$ can be projected from GDP per capita in that year and spending on asset c in period t.

Given the estimated IT investment flows, we use the perpetual inventory method to estimate IT capital stock. We assume that the geometric depreciation rate is 31.5 per cent and the service life is seven years for computer hardware, 31.5 per cent and five years for software, and 11 per cent and 11 years for telecommunication equipment. Investment in current US dollars for each asset is deflated by the US price index to obtain investment in constant US dollars.

To estimate IT investment for the 66 economies not covered by the *Digital Planet Reports*, we extrapolate the levels of IT capital stock per capita we have estimated for the 70 economies included in these *Reports.* We assume that IT capital stock per capita for the 40 additional economies is proportional to the level of IT penetration. The details are as follows:

For computers we divide the 70 economies included in the *Digital Planet Reports* into ten equal groups, based on the level of personal computer (PC) penetration in 2003. We estimate the current value s^i_{HW} of computer stock per capita in 2003 for an economy i as:

$$s^i_{HW} = s^{-I}_{HW} * \left(P^i_{HW}/\overline{P}^I_{HW}\right),$$

where $\overline{s}^I_{HW}$ is the average value of computer capital per capita in 2001 of Group I for countries included in the *Digital Planet Report,* P^i_{HW} and $\overline{P}^I_{HW}$ are the PC penetration rates of economy i and the average PC penetration of Group I, respectively.

For the economies with data on PC penetration for 1995, we use the growth rates of PC penetration over 1989–2003 to project the current value of computer capital stock per capita backwards. We estimate computer capital stock for each year by multiplying capital stock per capita by population. For economies lacking the data of PC penetration in 1995 and 1989, we estimate computer capital stock by assuming that the growth rates in the two periods, 1995–2003 and 1989–95, are the same as those for the group to which it belongs.

For software capital stock, we divide the 110 countries into ten categories by level of PC penetration in 2003. We subdivide each of these categories into three categories by degree of software piracy, generating 30 groups. (The information on software piracy is based on study conducted by the Business Software Alliance 2003.) We assume that the software capital stock-to-hardware capital stock ratio is constant in each year for each of the 30 groups:

$$s^i_{HW} = \overline{s}^I_{HW} * \left(s^i_{HW}/\overline{s}^I_{HW}\right)$$

where $\overline{s}^I_{HW}$ is the average software capital stock per capita of Subgroup I in 2003. Since the value of computer stock per capita has been estimated for 1995 and 1989, this enables us to estimate the software capital stock per capita for these two years.

Finally, we define the penetration rate for telecommunications equipment as the sum of mainline and mobile telephone penetration rates. These data are available for all 110 economies in all three years – 1989, 1995 and 2003. We have divided these into ten groups by the level of telecommunications equipment penetration for each year. The current value of telecommunications capital stock per capita is estimated as:

$$s^{it}_{TLC} = \overline{s}^{It}_{TLC} * \left(P^{it}_{TLC}/\overline{P}^{It}_{TLC}\right)$$

where $\overline{s}^{It}_{TLC}$ is the average current of telecommunications equipment capital stock per capita in year t of Group I for economies included in the *Digital Planet Reports* and P^{it}_{TLC} and $\overline{P}^{It}_{TLC}$ are the telecommunications equipment penetration rates of economy i and the average penetration rate of Group I in year t.

We employ Gross Fixed Capital Formation for each of the 103 economies provided by the Penn World Table, measured in current US dollars, as the flow of investment. We use the Penn World Table investment deflators to convert these flows into constant US dollars. The constant dollar value of capital stock is estimated by the perpetual inventory method for each of the 103 economies for 1989 and the following years. We assume a depreciation rate of seven per cent and a service life of 30 years.

The current value of the gross capital stock at a year is the product of its constant dollar value and the investment deflator for that year. We estimate the current value of Non-ICT capital stock of an economy for each year by subtracting the current value of IT stock from the current value of capital stock in that year. Given the estimates of the capital stock for each type of asset, we calculate capital input for this stock, using the methodology presented by Jorgenson (2001).

Finally, labour input is the product of hours worked and labour quality:

$$L_t = H_t * q_t$$

where L_t, H_t, and q_t, respectively, are the labour input, the hours worked, and labour quality. A labour quality index requires data on education and hours worked for each of category of workers.

We extrapolate the labour quality indexes for the G7 economies by means of the following model:

$$\begin{aligned} q_{i,t} = \quad & \beta_0 + \beta_1 \ \text{Education}_{i,t} \\ & + \beta_2 \ \text{Institution} \ 1_i + \beta_3 \ \text{Institution} \ 2_i \\ & + \beta_4 \ \text{Income} \ 1989_i + \beta_5 T \end{aligned}$$

where subscripts i and t indicate economy i in year t. Education is the educational attainment of the population aged 25 or over from the data-set constructed by Barro and Lee (2001). Institution 1 = 'Rule of Law' and Institution 2 = 'Regulatory Quality' are constructed by Kaufmann et al. (2004) for the World Bank; Income 1990 is GDP per capita for 1990 from the Penn World Table and T is a time dummy.

Labour quality is largely explained by educational attainment, institutional quality and living conditions. The model fits well ($R^2 = 0.973$) and all the explanatory variables are statistically significant. We assume that hours worked per worker is constant at 2000 hours per year, so that growth rates of hours worked are the same as employment.

Summary and Conclusions

World economic growth, led by the industrialized economies and Developing Asia, experienced a strong resurgence after 1995. Developing Asia accounted for an astonishing 60 per cent of world economic growth before 1995 and 40 per cent afterward, with China alone responsible for half of this, but output per capita remained well below the world average. Sub-Saharan Africa and North Africa and the Middle East languished far below the world average. Eastern Europe and the former Soviet Union lost enormous ground during the transition from socialism and have yet to recover completely.

The growth trends most apparent in the United States have counterparts throughout the world. Investment in tangible assets, including IT equipment and software, was the most important source of growth. However, Non-IT investment predominated. The contribution of labour input was next in magnitude with labour quality dominant before 1995 and hours worked afterward. Finally, productivity was the least important of the three sources of growth, except during the Asian Miracle before 1995.

The leading role of IT investment in the acceleration of growth in the G7 economies is especially pronounced in the United States, where IT is coming to dominate the contribution of capital input. The contribution of labour input predominated in the Non-G7 industrialized economies, as well as Latin America, Eastern Europe, sub-Saharan Africa, and North Africa and the Middle East. Productivity growth was the important source of growth in Developing Asia before 1995, but assumed a subordinate role after 1995. Productivity has been stagnant or declining in Latin America, Eastern Europe, sub-Saharan Africa, and North Africa and the Middle East.

All seven regions of the world economy experienced a surge in investment in IT equipment and software after 1995. The impact of IT investment on economic growth has been most striking in the G7 economies. The rush in IT investment was especially conspicuous in the United States, but jumps in the contribution of IT capital input in Canada, Japan, and the UK were only slightly lower. France, Germany and Italy also experienced a surge in IT investment, but lagged considerably behind the leaders. While IT investment

followed similar patterns in the G7 economies, Non-IT investment varied considerably and explains important differences among growth rates.

Although the surge in investment in IT equipment and software is a global phenomenon, the variation in the contribution of this investment has increased considerably since 1995. Following the G7, the next most important increase was in Developing Asia, led by China. The Non-G7 industrialized economies followed Developing Asia. The role of IT investment more than doubled after 1995 in Latin America, Eastern Europe, and North Africa and the Middle East, and sub-Saharan Africa.

Information Theory

Esfandiar Maasoumi

Information theory is a branch of mathematical statistics and probability theory. Thus, it can and has been applied in many fields, including economics, that rely on statistical analysis. As we are concerned with it, the technical concept of 'information' must be distinguished from the semantic concept in common parlance. The simplest and still the most widely used technical definitions of information were first introduced (independently) by Shannon and Wiener in 1948 in connection with communication theory. Though decisively and directly related, these definitions must also be distinguished from the definition of 'information' introduced by R.A. Fisher in 1925 for estimation theory.

Whenever observations are made or experiments conducted, we seek information about the underlying populations. Information theory provides concepts and definitions by means of which we may measure formally what can be inferred from the sampled data. More narrowly interpreted, we may view these concepts and definitions as summary statistics representing the associated (empirical) distributions, much like the moments of distributions. These concepts, however, also admit the intuitive meanings not unlike the notions of 'information' and 'uncertainty' in common parlance. One such concept, the *entropy* of a distribution, is central to information theory and is a measure of disorder or uncertainty. It was the definition of entropy that first caught the attention of Henri Theil and led to the use of information theory in *economics* in the 1960s. Following this discovery two measures of income inequality, measures of divergence and/or concentration in trade and industry, and many other economic applications were introduced in Theil (1967). Further applications in economic theory and other social sciences are discussed in Theil (1972, 1980).

A somewhat different but equally important set of developments of information theory have taken place in *econometrics*. Information criteria exist which measure the 'divergence' between populations. The use of such criteria helps to discriminate statistically between hypotheses, select models and evaluate their forecasting performance. These are essential steps in model evaluation and inference in econometrics.

Given a sample and (possibly) some prior information, a so-called 'maximum entropy (ME)' distribution of the underlying continuous process may be derived. This distribution and its quantiles and moments can be used in order to resolve a number of important problems including that of undersized samples. Theil and Laitinen (1980) formulated the ME distribution, and Theil and Fiebig (1984), give a complete coverage of this topic.

More general concepts of entropy and the associated measures of divergence can be used to develop a family of Generalized Entropy (GE) measures of inequality and in the area of 'multidimensional' welfare analysis. A by-product of this is the development of a 'summary welfare attribute' which serves as an index of several miscellaneous attributes such as income, wealth and physical quality of life indices. Another by-product is the development of 'information

efficient' functional forms when the regression function is unknown *a priori*.

Applications to the classical theory of consumer and producer demand equations is noteworthy. The feature of this theory that provides the connection with information theory is the concept of 'value shares', the expenditure on a given commodity (input factor) divided by total expenditure. Thus the value shares have the same mathematical properties as probabilities ($0 \leq p_i \leq 1$). Theil (1967) noted some of the first attempts by Lisman (1949) and Pikler (1951) to draw analogies between econometric and information theory concepts. Emphasizing a point elaborated upon by De Jongh (1952), Theil wrote: 'the reason information theory is nevertheless important in economics is that it is more than a theory dealing with information concepts. It is actually a general partitioning theory in the sense that it presents measures for the way in which some set is divided into subsets ….' And then, 'it may amount to dividing certainty (probability 1) into various possibilities none of which is certain, but it may also be an allocation problem in economics.'

Our account begins with the introduction of some basic concepts.

Central Definitions and Concepts

An extensive literature exists which treats information theory in an axiomatic manner, much of it stimulated by the work of Shannon (1948) and Wiener's suggestive remarks in Wiener (1948). Kullback (1959) provides a comprehensive bibliography. From Stumpers (1953) it is clear, however, that some important contributions had appeared prior to 1948. For our purposes it will suffice to note that the occurrence of an event contains (or conveys) information. Thus one needs 'information functions' that measure the amount of information conveyed. If, as is usual, we are concerned with random events, there usually exist prior probabilities of occurrence of events and posterior probabilities. Hence, given an information function, we may measure the 'information gain' as between the prior and the posterior probabilities. Further, given an experiment and a *set* of observations, we may measure the 'expected information gain'.

The most widely used information function is $-\log p_i$, where p_i denotes the probability of a random variable X taking a value x_i. This function is non-negative and satisfies the 'additivity axiom' for *independent events*. That is, the information that both of two independent events have occurred is equal to the sum of the information in the occurrence of each of the events. More general information functions will be discussed later. The base of the logarithm (usually e or 2) determines the desired 'information unit', 'bits' when 2 is the base, and 'nits' when the natural base is employed. It may be useful to list some of the axioms that are employed to restrict the form of information functions:

Let such functions be denoted by $h(\cdot)$.

Axiom 1 – $h(\cdot)$ is a function only of the probability of events (p, say).
Axiom 2 – $h(p)$ is continuous in p, $0 < p \leqslant 1$.
Axiom 3 – $h(p)$ is a monotonically decreasing function of p.

This last axiom is quite intuitive. For instance, when we receive a definite message (observation) that a most unlikely event (p close to zero) has occurred, we are more highly surprised (informed) than if the event had a high probability (p close to 1) of occurrence. Thus, we may impose the following restrictions:

$$h(0) = \infty, \quad h(1) = 0 \quad \text{and} \quad h(p_1) > h(p_2), \quad \text{if } 0 \leq p_1 < p_2 \leq 1.$$

There are many functions that satisfy these axioms. $\log 1/p = -\log p$ is uniquely identified (apart from its base) on the basis of a further axiom, the *additivity* of $h(.)$ in the case of independent events.

A generalization of the above definition is needed for general situations in which the messages received are not completely reliable. An important example is the case of forecasts of weather or economic conditions. Suppose p_1 is

the probability of occurrence of an event (perhaps calculated on the basis of frequency of occurrence in the past), and p_2 the probability of the same event *given that it had been predicted to occur* (calculated in the same manner). We may then enquire as to the merit or the 'information gain' of such predictions. Given the observation that the predicted event has occurred, this information gain is defined as follows:

$$h(p_1) - h(p_2) = \log p_2/p_1$$

More generally, the information content of data which may be used to 'update' prior probabilities is defined by:

Information gain (IG) = log (posterior probability/prior probability). Since typically, data are subject to sampling variability, the 'expected information gain' is the appropriate measure of information gain. Thus, the expected value of IG defined above may be obtained with respect to either the prior or the posterior distributions over the range of the possible values for the random event. This gain is the difference between the 'expected information' in the two distributions. Consider a set of n mutually exclusive and exhaustive events $E_1, \ldots, E_n$ with corresponding probabilities $p_1, \ldots, p_n$ ($\Sigma p_n = 1$, $p_i \geq 0$). Then occurrence of an event contains $h(p_i)$ information with probability p_i. *Before* any observation is made, the 'expected information' in the distribution $p = (p_1, \ldots, p_n)$ is given by:

$$0 \leq \sum_{i=1}^{n} p_i h(p_i) = H(p) \leq \log n. \qquad (1)$$

When $h(p_i) = -\log p_i$, the convention: $p_i \log p_i = 0$ if $p_i = 0$, is used. The maximum, $\log n$, occurs when $p_i = 1/n$ for all $i = 1, \ldots, n$. This is a situation of maximum prior 'uncertainty' or 'disorder' in the distribution p. Contrast this with $p_1 = 1, p_i = 0 \forall i \neq 1$, in which case $H(p) = 0$.

A dual concept to 'expected information' may be defined. This is the 'Entropy' which measures the 'uncertainty' or 'disorder' in a distribution p as defined by $H(p)$ in equation (1). Entropy is a central concept in information theory and its applications. It is also considered as an index of how close a distribution is to the uniform distribution. Note that an otherwise unknown distribution (p) may be determined by maximizing its entropy subject to any available restrictions. For instance the first few moments of the distribution may be specified *a priori*. The distribution so obtained is called the 'Maximum Entropy' (ME) distribution. In Theil and Laitinen (1980), *continuity* as well as the first moment of the observed data are utilized in order to obtain the ME distribution of the data and its higher moments.

The concept of 'divergence' or 'distance' between distributions naturally follows those of expected information gain and entropy. Instead of the prior and posterior distributions referred to earlier, it may be more suggestive to consider competing distributions (perhaps resulting from competing hypotheses), $f(x)$ and $g(x)$, which may generate a random variable x with the range denoted by R. There are two *directional* measures of divergence between $f(\cdot)$ and $g(\cdot)$. These are:

$$I(2,1) = \int_R g(x) \log \frac{g(x)}{f(x)} \mathrm{d}x$$

and

$$I(1,2) = \int_R f(x) \log \frac{f(x)}{g(x)} \mathrm{d}x.$$

A *non-directional* measure in the same context may be an average of the two directional criteria given above. For instance:

$$J(1,2) = \int_R [\log f(x) - \log g(x)][f(x) - g(x)]\mathrm{d}x$$
$$= (1,2) + I(2,1).$$

This is the well known Kullback–Leibler information criterion used extensively in many applications.

Various generalizations of these criteria are obtained either by generalizations of the form of the information function (which typically include the logarithmic form as a special case), or by generalizations of the *metrics* that include $J(1,2)$ above.

Some properties of these central concepts and their generalizations will be discussed in the following sections. It will be illuminating, however, to close this section by demonstrating an interesting connection between the information concepts defined so far and an important definition given by R.A. Fisher (1925):

Let x be a random variable taking values in the space S with the p.d.f. $f(., \boldsymbol{\Theta})$ with respect to a σ-finite measure υ. Assume $f(\cdot, \boldsymbol{\Theta})$ differentiable w.r.t. $\boldsymbol{\Theta}$ and:

$$\frac{\mathrm{d}}{\mathrm{d}\boldsymbol{\Theta}} \int_c f(x, \boldsymbol{\Theta}) \ \mathrm{d}\upsilon = \int_c \frac{\mathrm{d}\ f(x, \boldsymbol{\Theta})}{\mathrm{d}\boldsymbol{\Theta}} \ \mathrm{d}\upsilon$$

for any measurable set $c \in S$. Fisher defined the following measure of information on $\boldsymbol{\Theta}$ contained in x:

$$\phi(\boldsymbol{\Theta}) = E\left(\frac{\mathrm{d} \log f}{\mathrm{d}\boldsymbol{\Theta}}\right)^2 = V\left(\frac{\mathrm{d} \log f}{\mathrm{d}\boldsymbol{\Theta}}\right)$$

where V denotes the variance when $E(\mathrm{d} \log f/\mathrm{d}\boldsymbol{\Theta}) = 0$.

If there is a unique observation (of x) with probability 1 corresponding to *each value of* $\boldsymbol{\Theta}$, then the random variable (i.e. its distribution) has the maximum information. The least information exists if the random variable has the *same distribution* for all $\boldsymbol{\Theta}$. Thus, one might measure the sensitiveness of x with respect to $\boldsymbol{\Theta}$ by the extent to which its distribution changes in response to (infinitesimal) changes in $\boldsymbol{\Theta}$. If $\boldsymbol{\Theta}$ and $\boldsymbol{\Theta}' = \boldsymbol{\Theta} + \delta\boldsymbol{\Theta}$ are two values of $\boldsymbol{\Theta}$, a suitable measure of 'distance' or 'divergence', $D[f(\boldsymbol{\Theta}), f(\boldsymbol{\Theta}')]$, is required. An example of $D[\cdot]$ was given earlier, and many more criteria have been proposed. It may be shown that many such criteria are *increasing* functions of Fisher's information $[\phi(\boldsymbol{\Theta}) \geq 0]$. To give an example, consider the Hellinger distance:

$$\cos^{-1} \int \left[f(x, \Theta) \cdot f(x, \Theta')\right]^{1/2} \ \mathrm{d}\upsilon.$$

Using a Taylor expansion of $f(x, \boldsymbol{\Theta}')$ and neglecting terms of power 3 or more in $\delta\boldsymbol{\Theta}$, we find:

$$\cos^{-1} \int f(\boldsymbol{\Theta}) \left\{1 - \frac{1}{8}\left[\frac{f'(\boldsymbol{\Theta})}{f(\boldsymbol{\Theta})}\right]^2 (\delta\boldsymbol{\Theta})^2\right\} \mathrm{d}\upsilon$$
$$= \cos^{-1}\left[1 - \frac{1}{8}\phi(\boldsymbol{\Theta})(\delta\boldsymbol{\Theta})^2\right]$$

where $\phi(\boldsymbol{\Theta})$ is indeed Fisher's information. Thus, such divergence criteria and $\phi(\boldsymbol{\Theta})$ are equivalent measures of the sensitivity of the random variables (p.d.f., s) with respect to small changes in the parameter values. These observations provide a basis for measuring the distance between competing hypotheses (on $\boldsymbol{\Theta}$) and model selection techniques in econometrics.

Applications in Economics and Econometrics

Measurement of Economic Inequality

Theil (1967) observed that the entropy, $H(y)$, was a remarkably useful measure of 'equality'. If $y = (y_1, \ldots, y_N)$ denotes the non-negative income *shares* of N individuals, the entropy of y, by definition, measures its distance from the rectangular distribution, $y_i = 1/N$, which is the case of complete equality. Thus, the difference between $H(y)$ and its maximum value, $\log N$, may be used as a measure of *inequality*. This measure satisfies the 'three fundamental welfare requirements', namely symmetry (S), Homogeneity (H), and the Pigou–Dalton principle of transfers (PT). In addition, Theil (1967) demonstrated extremely useful *additive decomposability* properties of this measure. In recent axiomatic treatments by Bourguignon (1979), Shorrocks (1980), Cowell and Kuga (1981) and Foster (1983), the following question is posed: what is a suitable measure of inequality among general classes of functional forms which are restricted to satisfy the above three requirements in addition to Theil's decomposability? The last condition identifies Theil's first measure, $\mathrm{T1} = \log N - H(y)$, and a second information measure proposed in Theil (1967). The latter is defined as follows:

$$\mathrm{T2} = -\log N - \frac{1}{N}\sum \log y_i.$$

The choice between these two measures implies preferences that may be formulated by Social Welfare Functions (SWF). From a practical viewpoint, however, the choice between T1 and T2 may also be made on the basis of their decomposability properties. These may be briefly described as follows:

Let there by G exclusive sets (groups) of individuals, $S_1, \ldots, S_G$, with N_g denoting the number of individuals in S_g, $g = 1, \ldots, G$ ($\Sigma N_g = N$). Let y_g be the *share* of S_g in total income. Then we have:

$$\mathrm{T1}(y) = \sum_{g=1}^{G} y_g \log \frac{y_g}{N_g/N} + \sum_{g} y_g \left[\log N_g - H_g(y)\right].$$

Here, $H_g(y)$ denotes the entropy of group g calculated from (y_i/y_g) for all $i \in S_g$. The first term above is the 'between-group' inequality, and the second term is a weighted average of the 'within-group' inequalities (the term in the square brackets). This decomposition is essential in analysing the incidence of inequality amongst the population subgroups (e.g. defined by age, race, region, etc.)

A similar decomposition formula holds for the second measure T2. The major difference is that the 'within-group' inequalities in T2 are weighted by the groups' *population shares* (N_g/N) rather than their income shares (y_g). The decomposition for T2 is somewhat preferable to that for T1 (see Shorrocks 1980) as it permits a less ambiguous discussion of such questions as: what is the contribution of the inequality in the gth group to total inequality? This is partly because y_g are sensitive to redistributions (distributional changes) whereas population shares (N_g/N) are not so by design.

A generalization of the concept of information functions and the entropy has been employed by Toyoda, Cowell and Kuga to define the family of Generalized Entropy (GE) inequality indices. The GE is defined as follows:

$$\mu_\gamma(y) = \frac{1}{N} \sum_i \left[(Ny_i)^{1+\gamma} - 1\right] / \gamma(\gamma + 1)$$

where $\mu_0()$ and $\mu_{-1}()$ are, respectively, the T1 and T2 defined earlier. $\gamma \leq 0$ ensures the convexity of GE members, and for values of $\gamma \ll 0$ the GE is ordinally equivalent to the class of measures proposed earlier by Atkinson (1970) by direct reference to the SWFs. $-\gamma = \upsilon \geq 0$ is referred to as the 'degree of inequality aversion' exhibited by the underlying SWF. The information function underlying the GE indices is $-1/\gamma\left(y_i^{\gamma} - 1\right)$ which includes $-\log y_i$ as a special case. The generalized entropy corresponding to this function is given by:

$$H_\gamma(y) = \sum_i \frac{1}{\gamma(\gamma + 1)} \left[(Ny_i)^{\gamma} - 1\right] \cdot y_i.$$

The GE measures are also decomposable in the manner described above.

Multi-Dimensional Welfare Analysis

The recognition that welfare depends on more than any single attribute (e.g. income) has lead to analyses of welfare functions and inequality in the multi-dimensioned space of several attributes, such as incomes (and its factor components), wealth, quality of life and basic needs indices. Pioneering work that deals directly with individual utilities (as functions of these attributes) and Social Welfare Functions is primarily due to Kolm (1977) and Atkinson and Bourguignon (1982). The measurement approach due to Maasoumi (1986a) poses the same question statistically and, surprisingly, provides a pure measurement (index number) interpretation of the SWF approach with equivalent solutions. The measurement approach seeks a 'summary share' or an index which may be employed to represent the miscellaneous attributes of interest. Information theory is utilized to obtain 'summary share' distributions without explicitly imposing any restrictive structure on preferences and behaviour. Noting that a measure of inequality is a summary statistic for a distribution (much as the moments of a p.d.f.). Maasoumi (1986a) poses the following question: Which summary distribution (index) is the 'closest' to the distribution of the welfare attributes of interest? Given suitable information

criteria for measuring the 'distance' between distributions, one can find a summary (or representative) *share vector* (distribution) that minimizes this distance. Briefly: let y_{if} be the share of the ith individual, $i \in [1, N]$, from the fth attribute, $f \in [1, M]$. There are M distributions, $y_f = (y_{1f}, \ldots, y_{Nf})$, and we seek a distribution, $S = (S_1, \ldots, S_N)$, which is closest to these M distributions as measured by the following generalized information measure of divergence:

$$D(\gamma) = \frac{1}{\gamma(\gamma+1)} \sum_{f=1}^{M} \alpha_f \sum_{i=1}^{N} S_i \left[\left(S_i / y_{if} \right)^{\gamma} - 1 \right]$$

where α_f is the weight given to the fth attribute. Minimizing $D(\gamma)$ with respect to S_i subject to $\Sigma S_i = 1$, we find:

$$S_i \propto \left(\sum_f \delta_f y_{if}^{-\gamma} \right)^{-1/\gamma}, \quad \sum_f \delta_f = 1.$$

This is a functional of the CES variety which includes the Cobb–Douglas ($\gamma = 0$) and the linear ($\gamma = -1$) forms as special cases. The S_i may be regarded as individual utility functions with the optimal distributional characteristics implied from $D(\gamma)$.

Once $S = (S_1, \ldots, S_N)$ is so determined, any of the existing measures of inequality may be used to measure multivariate inequality represented in S. Members of GE have been used for this purpose in Maasoumi (1986a). It may be shown that only two members of GE, Theil's T1 and T2, and some values of γ, provide fully decomposable measures of multi-dimensional inequality. Full decomposition refers to decomposition by population subgroups as well as by the inequality in individual welfare attributes. An interesting alternative method, Principal Components, is seen to be a special case of the above approach. It corresponds to the case $\gamma = -1$, with α_f being the elements of the first characteristic vector of $y'y, y = (y_{if})$ being the distribution matrix. This feature of information theory is not surprising. As S. Kullback and others have noted, one of its great advantages is the generality that it affords in the analysis of statistical issues, with the suggestion of new solutions and useful interpretations of the old.

'Information Efficient' Functional Forms

Economic theory is generally silent on the specific form of functional relationships between variables of interest. Certain restrictions on the general characteristics of such relations are typically available, but ideally one must use the available data to determine the appropriate functional form as well as its parameters. The common practice in econometrics is either to specify flexible functional families, or to test specific functional forms for statistical adequacy (e.g. see Judge et al 1980, ch. 11). The criteria of section "Multi-Dimensional Welfare Analysis" may be used, however, to obtain functions of the data with distributions which most closely resemble the empirical distribution of the observations. For instance, using $D(\gamma)$ from the previous section, let $S_i = f(x_i)$ be the indeterminate functional relationship between the variables $x_i = (x_{1i}, \ldots, x_{ki})$ at each observation point $i = 1, \ldots, T$. The variable set x_i may or may not include the endogenous (dependent) variable in an explicit regression context. Maasoumi (1986b) shows that, in the latter case, the CES functional form is 'ideal' according to $D(\gamma)$, and in the former the usual Box–Cox transformation is obtained. According to $D(\gamma)$, any other functional forms will distort the distributional information in the sample. The value of $D(\gamma)$ for any approximate regression function, less its minimum, is an interesting measure of the informational inefficiency of that regression function.

Tests of Hypotheses and Model Selection

Sample estimates of the measures of divergence $I(1, 2)$, $I(2, 1)$ and $J(1, 2)$ defined above may be used to test hypotheses or to choose the 'best' models. For instance, the minimum value of $I(1, 2)$, denoted by $I(*:2)$ and called 'the minimum discrimination information', is obtained for a given distribution $f_2(x)$ with respect to all $f_1(x)$, such that

$$\int T(x) f_1(x) dx = \boldsymbol{\Theta}$$

where $\boldsymbol{\Theta}$ are constants and $T(x)$ are measureable statistics. For example, $T(x) = x$ and $\boldsymbol{\Theta} = \mu$, restricts the mean of possible distributions $f_1(x)$. General solutions for $f_1(x)$ [denoted $f^*(x)$] and $I(*{:}2)$ are given in Kullback (1959, ch. 3) and elsewhere.

$I(*{:}2)$, and the corresponding values for $I(1{:}*)$ and $J(*)$, may be estimated by replacing $\boldsymbol{\Theta}$ (and the other unknown parameters) by their sample estimates ($\widehat{\boldsymbol{\Theta}}$) when $f_2(x)$ is the generalized density of n independent observations. Given a sample 0_n, we denote this estimate by $\widehat{I}(* : \ 2; 0_n)$. This statistic measures the minimum discrimination information between a population with density $f^*(x)$ (with $\Theta = \widehat{\boldsymbol{\Theta}}$ etc.), and the population with the density $f_2(x)$. The justification for its use in tests of hypotheses and model selection is that, the non-negative statistic $\widehat{I}(\cdot)$ is zero when $\widehat{\boldsymbol{\Theta}}$ is equal to $\boldsymbol{\Theta}$ of the population with density $f_2(x)$, becoming larger the worse is the resemblance between the sample and the hypothesized population $f_2(x)$.

To illustrate, consider the linear regression model

$$y = X\beta + U$$

where $U \sim N\ (0,\ \Sigma)$ and $X \sim T \times K$ and of rank K.

Consider two competing hypotheses:

$$H_1 : \beta = \beta(\text{no restriction}), \qquad H_2 : \beta = \beta^2.$$

Then, it may be verified that:

$$J(1,2) = 2I(1,2) = \left(X\beta - X\beta^2\right)' \Sigma^{-1} \left(X\beta - X\beta^2\right)$$
$$= \frac{1}{\sigma^2} \left(X\beta - X\beta^2\right)' \left(X\beta - X\beta^2\right).$$
$$\text{if } \Sigma = \sigma^2 I = \left(\beta - \beta^2\right)' (X'X) \left(\beta - \beta^2\right) / \sigma^2.$$

Replacing the unknown parameters, $\boldsymbol{\Theta} = (\beta, \sigma^2)$, with their respective unbiased OLS estimates, we find:

$$\widehat{J}(H_1; H_2) = \left(\widehat{\beta} - \beta^2\right)' (X'X) \left(\widehat{\beta} - \beta^2\right) / \widehat{\sigma}^2.$$

And if $\beta^2 = 0$:

$$\widehat{J}(H_1, H_2) = \widehat{\beta}' (X'X) \widehat{\beta} / \widehat{\sigma}^2$$

which may be recognized as proportional to Hotelling's T^2 statistic with an F distribution with K and $T - K$ degrees of freedom.

The above example produced a statistic with a known finite sample distribution. In this situation, we are in effect rejecting H_2 if:

$$\text{Prob}\left\{\widehat{I}(* : H_2) - \widehat{I}(*H_1) \geq C | H_2\right\} \leq \alpha$$

where C is chosen to control the size (α) and the power of the test.

More generally, when the exact distributions are not known, asymptotic procedures may be employed. Suppose, for instance, that the competing populations (hypotheses), H, are members of the exponential family [which includes $f^*(x)$]. Let the admissible range of parameter values be denoted by Ω, and the range (value) specified by $H_i \in H$ denoted by ω_i. It may be shown that (see Kullback 1959):

$$\widehat{I}(* : H) = \log \left[\max_{\Omega} f*(x) / \max_{\omega_i} f*(x) \right]$$
$$= -\log \lambda_i$$

where $_i$ is the Neyman–Pearson (likelihood-ratio) statistic. Under certain regularity conditions, the statistic $-2 \log \lambda_i$ is asymptotically distributed as X^2. Also, in the same situation, for two competing hypotheses H_1: $\boldsymbol{\Theta} \in \omega_1$, H_1: $\boldsymbol{\Theta} \in \omega_2$ it may be shown that:

$$\widehat{I}(* : H_2) - \widehat{I}(* : H_1) = -\log \lambda*$$

where $\lambda^* = \max_{\boldsymbol{\Theta} \in \omega 2} f^*(x) / \max_{\boldsymbol{\Theta} \in \omega 1} f^*(x)$. Variants of such statistics are also useful for tests of 'non-nested' hypotheses. For the distribution of $\lambda*$ and its extensions see (e.g.) Chernoff (1954) and Cox (1961). Finally, we note that the above test reduces to $\widehat{I}(* : H_2)$ when H_2: $\boldsymbol{\Theta} \in \omega$ and H_1: $\boldsymbol{\Theta} \in \Omega - \omega$. In such cases $\widehat{I}(* : H_1) = 0$.

Variations to the information criteria described above have been proposed for 'model selection' in econometrics. Akaike (1973) proposed a measure

based on the Kullback–Leibler criterion. We give this criterion (AIC) for the problem of choosing an optimal set of regressors in the standard regression model. As before, let $y = X\beta + U, U \sim N(0, \sigma_u^2 I)$, be the 'comprehensive' model, with $X = [X_1, X_2]$ and $\beta = (\beta'_1, \beta'_2)'$ representing a full rank partition $K_1 + K_2 = K$. Under the null hypothesis $R\beta = [0, I_{k2}]\beta = 0$ ($\beta_2 = 0$), the AIC is as follows:

$$\begin{aligned} \text{AIC} &= -\frac{2}{T}\log l(y, \beta) + 2K_1/T \\ &= \log(y'M_1 y/T) + 2K_1/T \end{aligned}$$

where $l()$ is the likelihood function and $M_1 = I - X(X'_1X_1)X'_1$. One proceeds to choose K_1 (and hence M_1) so as to minimize AIC. The first term decreases with K_1, thus the above criterion incorporates the trade-off between parsimony and 'fit' of a model. If one proceeds as though σ^2 were known in the likelihood function. Amemiya (1976) shows that:

$$\text{AIC}\ \left(\sigma^2\ \text{known}\right) = y'M_1 y/T + \sigma^2(2K_1)/T$$

An estimate of this last criterion may be based on the unbiased OLS estimates of σ^2 with or without the restrictions ($\beta_2 = 0$). The latter estimate is equivalent to the so-called 'Cp criterion', and the former is equivalent to the 'Prediction Criterion' for model selection. For other variations to AIC (e.g. Sawa's BIC criterion) see Judge et al. (1980, Section 11.5).

Conclusions

The above examples do not do justice to a remarkable range of currently available applications of the information criteria in economics and econometric inferences. We hope, however, that they suffice to show: (1) the usefulness of the general approach in encompassing many different and often ad hoc procedures in econometric inference; and (2) how new methods with plausible and intuitive appeal may be derived in order to resolve many hitherto unresolved problems. The full potential for further applications of information theory and its formal discipline in economic and econometric theory is great. The current level of interest in this potential is extremely promising.

Infrastructure and Growth

César Calderón and Luis Servén

Abstract

An adequate supply of infrastructure services has long been considered essential for economic development by both academics and policymakers. This article reviews recent theoretical and empirical literature on the effects of infrastructure development on growth. The theoretical literature has employed a variety of analytical settings regarding the drivers of income growth and the degree to which infrastructure represents a public or a private good. In turn, the empirical literature has tested for the growth effects of infrastructure development using various econometric methodologies on time series and cross-section macro- and microeconomic data. However, the empirical tests face challenging issues of measurement, identification and heterogeneity. Overall, the literature finds positive effects of infrastructure development on income growth. Still, the precise mechanisms through which these effects accrue, and their full impact on welfare, remain relatively unexplored.

Introduction

An adequate supply of infrastructure services has long been considered essential for economic development by both academics and policymakers. The role of transport infrastructure, for instance, in fostering economic prosperity goes back to Adam Smith's *Wealth of Nations*, which listed 'the duty of erecting and maintaining certain public works' among the three core obligations of the sovereign.

Over the last quarter century, research has devoted considerable attention to the contribution of infrastructure development to the growth of productivity and aggregate income. A vast literature has explored a multitude of theoretical scenarios characterising the economic role of productive public services and their financing. In turn, a large empirical literature has examined the evidence on the growth impact of infrastructure development in a variety of cross-section, time-series and panel data settings. As discussed below, however, these empirical assessments are subject to a number of methodological caveats.

Infrastructure and Growth: Theory

Starting with the work of Aschauer (1989), a vast analytical and empirical literature has been concerned with the effects of infrastructure

development on income growth, productivity and welfare. Below is a summary view; more comprehensive accounts can be found in Irmen and Kuehnel (2009) and Romp and De Haan (2007).

Much of the relevant analytical literature examines the growth effects of productive public expenditure rather than just infrastructure. The two concepts are not necessarily equivalent. The government's involvement in productive activities is not limited to infrastructure sectors in many countries. Also, the public sector has traditionally played the leading role in the provision of infrastructure; however, private sector participation is growing in an increasing number of countries.

Following the seminal work of Arrow and Kurz (1970), the output impact of infrastructure has been modelled by including either the stock of infrastructure assets or the flow of infrastructure services as an additional input in the economy's aggregate production function, and further assuming that infrastructure is a gross complement for non-infrastructure inputs – labour and non-infrastructure capital. In this framework, an increase in the volume of infrastructure services raises output not only directly, but also indirectly, by 'crowding-in' other inputs owing to the accompanying rise in their marginal productivity. This indirect effect may take place instantaneously (for variable inputs in elastic supply) or over time (for fixed inputs such as human and non-infrastructure physical capital).

However, the expansion of infrastructure needs to be financed, and this represents a countervailing force: increasing taxation to finance public infrastructure crowds out the use of other inputs, which offsets partly or fully the crowding-in effect via productivity. This was highlighted by Barro (1990) in an endogenous growth framework in which the government's contribution to current output is captured by the flow of productive public expenditure (rather than the stock of public capital) financed through proportional income taxation. The welfare-maximising level of productive expenditure is shown to be the same as that which maximises the economy's growth rate, and it is achieved when the share of productive government expenditure in GDP (and hence the tax rate) equals the elasticity of aggregate output with respect to the same variable – what is often called the '*Barro rule*'. If productive expenditure exceeds this level, the additional distortionary taxation needed to finance it diverts non-infrastructure investment away to the point that income growth is reduced. These results apply in more general settings; for instance, Fisher and Turnovsky (1998) show that, in the Ramsey-type framework of Arrow and Kurz (1970) and with Cobb–Douglas technology, an increase in the stock of public infrastructure raises the private capital stock only if infrastructure spending is below the level defined by the Barro rule. With more general technologies, the elasticity of substitution between infrastructure and other capital also comes into play; see Eden and Kraay (2014).

Many of the theoretical contributions after Barro (1990) use an endogenous growth framework allowing infrastructure to impact the economy's long-run growth rate. However, in many cases (including Aschauer's (1989) pioneering empirical analysis), the focus is on the stock of infrastructure assets rather than the flow of infrastructure-related expenditure. The underlying logic is that, while the flow-based approach offers the important advantage of analytical tractability, the availability of infrastructure services (e.g. road transport) often relates more closely to the stock of infrastructure assets (e.g. the stock of public highways) than to the flow of expenditure on infrastructure-related activities (e.g. annual spending on road construction).

Following this logic, Futagami et al. (1993) extended Barro's (1990) model to include both public and private capital, with the rate of public investment as the government's key decision variable. This framework yields some new results. On the one hand, the economy displays nontrivial transitional dynamics. On the other, the growth-maximising level of public investment (as share of output) is still equal to the elasticity of output with respect to public capital; however, its welfare-maximising level is lower. Intuitively, public investment takes time to become productive, and this delay entails an additional sacrifice of current consumption for future consumption.

I

In reality, infrastructure provision requires both capital and recurrent expenditure – for example to build and maintain roads, respectively. Tsoukis and Miller (2003) and Ghosh and Roy (2004) examine how the above results are affected when the stock of public capital and the flow of non-investment spending are considered simultaneously. Overall, the earlier results stand: the welfare and growth-maximising levels of recurrent expenditure coincide, but they differ in the case of investment expenditure, for which growth maximisation implies public investment in excess of the welfare-maximising level.

Modelling infrastructure just like another input in production is a natural way to capture producers' direct use of electricity or transport services. But infrastructure may also enter the production function as a determinant of aggregate TFP, i.e. an 'unpaid factor' with spillover effects on the productivity of other inputs (Hulten and Schwab 2000). For example, Bougheas et al. (2000) and Agénor (2013) argue that transport and telecommunications services facilitate innovation and technological upgrading by reducing the fixed cost of producing new varieties of intermediate inputs. In a Romer-style framework, this raises output growth.

Aside from its role in the production function, another strand of the literature highlights the role of infrastructure in the accumulation of other inputs. For example, better transport networks may reduce the installation costs of new capital (Turnovsky 1996). Likewise, improved access to electricity may raise educational attainment and reduce the cost of human capital accumulation (Agénor 2011). In these cases, the growth-maximising output share of infrastructure spending is not given just by the elasticity of output with respect to infrastructure capital; one must also account for the output effect accruing through the accumulation of other inputs, and this tends to make the growth-maximising rate of infrastructure provision (as well as its welfare-maximising level) higher than when the latter effect is absent.

Contrary to what much of the literature assumes, few infrastructure services are pure public goods. In particular, congestion tends to make most services rival; think of road transportation, for example. Further, many services – such as power and telecommunications, or even toll roads – are excludable, and thus suitable for financing through user fees (and for private provision); see Ott and Turnovsky (2006) for a discussion of this issue.

The literature has considered two forms of infrastructure congestion. Under absolute congestion, services received by an individual user depend negatively on aggregate usage. Under relative congestion, they depend positively on the individual's usage relative to aggregate usage. Analytical details vary depending on the chosen option as well as the production technology (Barro and Sala-i-Martin 1992; Eicher and Turnovsky 2000). Nevertheless, some basic results from the models without congestion continue to hold. For example, in an endogenous growth setting with infrastructure modelled as a service flow, the welfare-maximising level of public infrastructure spending is still dictated by the Barro rule. If infrastructure is viewed instead as a stock, such a rule leads to excessive accumulation, just like in the absence of congestion (Turnovsky 1997). However, in an exogenous growth setting, the crowding-in effect of infrastructure on non-infrastructure capital tends to be diminished, or even reversed, especially when the financing is done through distortionary taxes (Fisher and Turnovsky 1998).

Another important feature of infrastructure is the presence of network effects, which can lead to strong nonlinearities in its marginal productivity. For example, road construction may have limited effects until the road network is minimally developed, at which point the marginal output contribution of additional roads may rise sharply. Once the entire network has been completed, however, additional road building is likely to have rapidly declining output effects (see Fernald 1999). Under appropriate conditions, these nonlinearities may lead to multiple equilibria, and to an enhanced role of infrastructure development policy: with a poor infrastructure endowment, the marginal productivity of infrastructure is low, and only a low-growth equilibrium may be attainable by the economy. However, a sufficient expansion of infrastructure networks would raise the

productivity of infrastructure and permit reaching the high-growth equilibrium (Agénor 2013).

Empirical Evidence

Few in academic or policy circles would dispute the view that infrastructure development fosters growth, but there is little consensus on the actual size of the effect and the factors that shape it. The empirical literature concerned with this issue took off following Aschauer (1989), who found that the stock of public infrastructure capital is a significant determinant of US aggregate TFP. However, his estimates of the elasticity of output with respect to infrastructure were implausibly large (around 0.40), owing to problems of econometric specification (see Gramlich 1994).

The massive empirical literature that followed focused on the impact of infrastructure on the level and growth rate of aggregate output or productivity, with numerous papers employing a large variety of data and empirical methodologies. Many authors estimated the elasticity of GDP with respect to infrastructure in an aggregate production function setting, using national or subnational data and time-series or panel techniques suitable for dealing with nonstationary variables and spillover effects. Early applications to panel data on US states found much smaller elasticities than those estimated by Aschauer (e.g. Holtz-Eakin 1994; Baltagi and Pinnoi 1995). Drawing from a large number of subsequent empirical studies using aggregate data, primarily from industrial countries, a meta-regression analysis of the elasticity of output with respect to public capital yields an average estimate of around 0.10, although the individual estimates from the underlying studies vary widely, from −1.73 to + 2.04 (Bom and Ligthart 2014).

These studies use monetary measures of public capital, constructed by accumulating investment flows. Alternatively, others employ physical measures of infrastructure assets encompassing multiple infrastructure sectors – sometimes aggregated into a synthetic indicator. Empirical studies using the latter approach on cross-country panel data typically report a significant GDP (or productivity) contribution of infrastructure; see Canning (1999), Calderón and Servén (2003) and Calderón et al. (2014). Regarding individual sectors, Röller and Waverman (2001) find a large output impact of telecommunications infrastructure in industrial countries while Fernald (1999) reports similar results for roads using US industry-level data.

In the Cobb–Douglas framework used by many empirical papers, it is not possible to assess the extent to which the effects of infrastructure reflect its TFPaugmenting role. This is the focus of relatively few studies. Hulten and Schwab (2000) use a growth decomposition approach to examine the contribution of public capital to manufacturing TFP growth across US states. They fail to find significant effects. Hulten et al. (2006) apply a similar approach to data from Indian states, using physical indicators of infrastructure assets in transport and power, and find that infrastructure development accounted for almost half of the observed TFP growth. Duggal et al. (1999) allow for nonlinear production technologies. Using aggregate US data, they find that public infrastructure capital is an important determinant of TFP. Duggal et al. (2007) extend the framework to include also privately supplied IT infrastructure, which contributes to production both as a standard input and as a driver of TFP. Both types of infrastructure are found to have a significant positive effect on productivity.

A related line of research, pioneered by Berndt and Hansson (1991), takes a dual approach and focuses on the estimation of cost and/or profit functions augmented by either infrastructure or public capital stock measures. The empirical finding in most cases is that infrastructure reduces production costs or increases profits – see Demetriades and Mamuneas (2000) on OECD cross-country data, and Cohen and Morrison Paul (2004) on US state data.

A different strand of literature evaluates the long-term growth impact of infrastructure, typically using a reduced-form growth-regression framework relating long-run growth to suitable indicators of infrastructure, public capital or public investment, often in conjunction with standard control variables from the empirical growth literature. Measures of infrastructure and conditioning

variables differ across studies, so they are not easy to compare. However, those papers using monetary measures of public capital stocks or public investment yield mixed results – for example Holtz-Eakin and Schwartz (1995) and Crihfield and Panggabean (1995) find no significant growth effects of infrastructure across US states and metropolitan areas. In turn, Easterly and Rebelo (1993) find that public investment in transport and communications significantly raises growth across countries. Devarajan et al. (1996) find a negative relationship between the share of infrastructure in total public expenditure and economic growth in panel data for developing countries, while Gupta et al. (2005) find the opposite result in a different cross-country panel data set.

In contrast, growth regressions using physical indicators of infrastructure stocks almost invariably find significant growth effects. In many cases, they use the number of telephone lines proxy for infrastructure (e.g. Easterly 2001). In others, they use synthetic indicators capturing physical stocks in multiple infrastructure sectors – transport, power and telecommunications. Sánchez-Robles (1998) and Calderón and Servén (2004, 2010a, b) find that these summary measures are positively and robustly related to per capita GDP growth in panel datasets combining industrial and developing countries. The magnitude of the effects is substantial: a 1% increase in physical infrastructure stocks, given other variables, temporarily raises GDP growth by as much as 1–2 percentage points, although the growth acceleration gradually tapers off as the economy approaches its long-run per capita income.

The literature cited so far takes a country-level perspective. However, there are also studies that examine the effects of infrastructure development for income growth at a more disaggregated level. For example, Rud (2012) investigates the impact of electricity provision on manufacturing output across Indian states. Electricity provision is not exogenously assigned, and to deal with this problem the study takes advantage of the introduction of a new irrigation-intensive agricultural technology, viewed as a natural experiment. Adoption of new varieties of high-yield seeds required, among other things, timely irrigation, for which electric pumps were used. Thus the initial availability of groundwater across states is employed to control for the endogeneity of the expansion of the electricity network. The evidence shows that, on average, a one standard deviation increase in the measure of electrification is associated with a 14% expansion in state manufacturing output.

In turn, Datta (2012) examines the consequences of a major road improvement program in India – the Golden Quadrilateral Program (GQP) – for the performance of firms. The location of each individual firm relative to the upgraded highway provides firm-specific exogenous variation in the degree to which the quality of the roads improved as a result of the GQP. The study finds that firms located on the GQP-improved highways significantly enhanced their inventory management and reduced their input costs by switching suppliers.

The bulk of the empirical literature summarised here focuses on measuring the output (or productivity) gains from infrastructure assets. Less attention has been paid to the cost of acquiring and operating these assets. Yet comparison of (social) marginal costs and benefits is necessary to determine whether infrastructure is under- or over-provided. To some extent, this is implicitly done in the reduced-form growth regressions mentioned earlier, given that their estimates of the impact of infrastructure allow for the adjustment of other production inputs as well as the changes in fiscal parameters required to accommodate infrastructure shocks. However, the issue is ignored in most other studies.

Among the exceptions are Canning and Pedroni (2008), who use a simple empirical model in the spirit of Barro (1990) to compare physical infrastructure stocks with their growth-maximising levels in a panel of countries. Their finding is that infrastructure is under-provided in some countries and over-provided in others, and the verdict shows no clear correlation with countries' per capita income. On average, the level of infrastructure is 'just about right' from the point of view of growth maximisation, so there is no evidence of a generalised infrastructure shortage. Using a similar framework, Kamps (2005) likewise concludes that there is no shortage of public

capital in EU countries. In turn, Eden and Kraay (2014) assess public capital shortages in low-income countries, using a Ramsey-type framework that highlights the degree of substitutability between public and private capital. Their estimate of the marginal return on public capital exceeds the user cost, given by the rate of depreciation plus the world real interest rate (thus implicitly assuming nondistortionary taxation). They conclude that, on average, public capital is under-provided in their sample countries.

Limitations of the Empirical Literature

Three major concerns arise from the empirical literature on the development impact of infrastructure: measurement, identification and heterogeneity. Take *measurement* first. Infrastructure is a multi-dimensional concept, comprising services that range from transport to clean water. However, many studies take a single indicator (most often telephone density) to proxy for 'infrastructure'. Omitting other indicators of infrastructure where they are relevant – e.g. in growth empirics – leads to invalid inferences. However, simultaneous consideration of multiple types of infrastructure assets in econometric estimation will often lead to imprecise estimates. This motivates the use of synthetic infrastructure indices – see Sánchez-Robles (1998) and Calderón and Servén (2004, 2010a, b).

Furthermore, measures of infrastructure based on spending flows – typically, public investment or its accumulation via perpetual inventory into public capital stocks – pose their own problems. Public investment and public capital are likely to be poor proxies for infrastructure accumulation if private participation in infrastructure provision is significant, as has become the case in many countries, or if the public investment is partly allocated to non-infrastructure industrial and commercial activities of the public sector. And even aside from these caveats, the link between observed public capital expenditure and the accumulation of infrastructure assets or the provision of services – which is what really matters for growth and equity – may be weak or nonexistent, owing to inefficiencies in public procurement and outright corruption (Pritchett 2000; Keefer and Knack 2007). Furthermore, investment may not translate into commensurate increases in the supply of infrastructure services because of inefficiencies in the selection and implementation of projects or the absence of high-quality projects in the pipeline (Kilby 2013). These limitations do not apply to physical measures of infrastructure, which may be the reason why studies based on them are more conclusive than those based on monetary measures of infrastructure.

Identification remains a thorny issue. The impact of infrastructure supply on growth that empirical studies aim to estimate may be confounded with increased demand for infrastructure services prompted by rising levels of income (Canning and Pedroni 2008).

There is no easy solution for this problem. In theory, one could base inference on the estimation of a full structural model. However, that approach poses difficult specification choices and challenging data requirements. Esfahani and Ramírez (2003) and Cadot et al. (2006) present two-equation models that jointly describe the aggregate production function and the accumulation of infrastructure. The former paper highlights the role of institutional factors for accumulation decisions in a cross-country setting, while the latter puts emphasis on the political economy of investing in transport routes across French provinces. Both papers find that the contribution of infrastructure services to GDP more than exceeds the cost of providing them. Interestingly, Cadot et al. (2006) find that the estimated elasticity of output with respect to infrastructure (around 0.08–0.09) remains invariant regardless of whether one accounts for the likely endogeneity.

Another option recently used by Calderón et al. (2014) in a panel time-series setting is to establish the existence of a single long-run relation between infrastructure, aggregate output and other production inputs, which can then be interpreted as the economy's aggregate production function. If infrastructure and the other productive inputs do not react systematically to temporary deviations from the long-run relation, its parameters can be estimated by conventional single-equation methods (even if the parameters

I

characterising the short-run dynamics cannot). Formal exogeneity tests confirm that this is the case, and the estimation places the long-run elasticity of output with respect to a synthetic index of infrastructure in the range 0.08–0.10.

A third alternative is to use an instrumental variable approach, ideally featuring external instruments for infrastructure. In this vein, Calderón and Servén (2003, 2004) employ demographic variables as instruments, alone or in combination with internal instruments, in a GMM panel framework. Röller and Waverman (2001) follow a similar approach.

Lastly, *heterogeneity* is also a major concern. The contribution of infrastructure to income growth may vary across countries and over time for multiple reasons – starting with the heterogeneous quality of infrastructure assets and services themselves. However, few studies take into account the quality dimension, in large part due to data limitations. Hulten (1996) finds that differences in the effective use of infrastructure resources explain one-quarter of the growth differential between Africa and East Asia, and more than 40% of the growth differential between lowand high-growth countries. Rioja (2003) likewise finds that poor infrastructure quality imposes large output and welfare costs across Latin American countries. Calderón and Servén (2004, 2010a, b) and Seneviratne and Sun (2013) find significant growth effects of a synthetic indicator of infrastructure quality in an empirical framework including also the quantity of infrastructure.

Aside from asset quality, variation across space and time in the effects of infrastructure could arise from many other sources, such as network effects that create nonlinearities in the output contribution of infrastructure and institutional factors that constrain the efficient use of infrastructure assets. However, assessments of heterogeneity are not abundant in the empirical literature. As an exception, Calderón et al. (2014) test for parameter heterogeneity in a large cross-country sample, using an infrastructure-augmented production function framework. Their tests consider heterogeneity across countries both of unrestricted form – affecting the parameters of infrastructure or any other input – as well as heterogeneity in the effects of infrastructure related to specific country features. These include the level of per capita GDP, the extent of infrastructure development and the size of population – to capture network and congestion effects, respectively. All these tests fail to reject homogeneity. The implication is that, other things equal, the percentage increase in real GDP (or its growth rate) that results from a given percentage increase in the availability of infrastructure does not vary much across countries. In the paper's setting, this means that the marginal productivity of infrastructure is higher, other things being equal, where the (relative) stock of infrastructure is lower.

Final Remarks

In spite of the above caveats, the balance of empirical research does reveal a positive contribution of infrastructure development to aggregate income. In itself, this just confirms that the marginal productivity of infrastructure capital is positive. But there has been also some convergence in quantitative estimates of its magnitude, to levels generally much lower than those found in the earlier macro literature. Still, the precise mechanisms at work remain understudied – including, for example, the role of infrastructure quality, the extent of crowding-in effects and the significance of the TFP channel of transmission. Furthermore, in contrast with the effort devoted to quantify the output impact of infrastructure, research has paid much less attention to the costs of infrastructure development. As a consequence, there are few empirical results regarding the extent to which different infrastructure services may be over- or under-provided across countries or regions. In this context, one key ingredient in need of more attention is the fragile link between infrastructure expenditures and the accumulation of infrastructure assets or the provision of services, and especially how such a link is shaped by institutional and political economy factors.

Infrastructure and Inequality

César Calderón and Luis Servén

Abstract

An adequate supply of infrastructure services has long been considered essential for economic development by both academics and policymakers. This article reviews recent theoretical and empirical literature on the effects of infrastructure development on income distribution. The theoretical literature has employed a variety of analytical settings regarding the dynamics of income distribution, the extent of market distortions – notably in capital markets – and the externalities surrounding infrastructure services. In turn, the empirical literature has tested for the distributive effects of infrastructure development using multiple approaches, from cross-country aggregate data to micro-level studies of specific infrastructure interventions. However, these empirical tests face challenging issues of measurement, identification and heterogeneity. Overall, the empirical evidence suggests that infrastructure development may have a positive effect on distributive equity. Still, little is known about the likely magnitude of such an effect and the precise mechanisms through which it may accrue.

Introduction

Infrastructure has long been regarded as an essential ingredient for economic development. Over the last quarter century, a large body of analytical and empirical research has examined the contribution of infrastructure development to the growth of productivity and aggregate income (see the article on '▶ Infrastructure and Growth'). More recently, however, there has been growing recognition that, in addition to its impact on average productivity and income, infrastructure can also affect income inequality, and this issue has attracted increasing attention from theoretical and empirical research.

Conceptually, there are good reasons why infrastructure development could have a differential positive effect on the incomes of the poor, over and above its effect on aggregate income. Infrastructure facilitates the poor's access to productive opportunities – for example, by helping connect lower-income segments of the population to markets for their inputs and outputs, so that their incomes may rise more than the average, as may the value of their assets (land or human capital). Infrastructure can also help improve health and education outcomes for the poor, thus enhancing their human capital. More broadly, access to and use of infrastructure services – telecommunications, electricity, roads, safe water and sanitation – play a key role in the integration of individuals and households into social and economic life (World Bank 2003).

The theoretical literature on the linkages between infrastructure and inequality is not as vast as that on infrastructure and growth. It has examined the distributional effects of infrastructure development under various assumptions about income distribution dynamics, economic distortions – notably in capital markets – and infrastructure-driven externalities. Empirical research has likewise employed a variety of approaches, from cross-country and time-series regressions using macroeconomic data, to micro-level studies of the effects of specific infrastructure interventions on the incomes of the poor, especially in rural areas. However, as discussed below, these empirical assessments are not free of methodological caveats.

Theory

Attempts to model the relationship between public investment and inequality are grounded in the literature on wealth distribution dynamics in the presence of capital market imperfections – see Banerjee and Newman (1993), Galor and Zeira (1993) and Piketty (1997). In these models, wealth redistribution towards the poor or the middle class can improve productive efficiency (Aghion and Bolton 1992, 1997). Enhanced availability of productive services – such as education, health and infrastructure – to the general population may not only improve efficiency, but also help reduce inequality. In this vein, Ferreira (1995) builds a model with private–public capital complementarity in an environment with capital market imperfections. The government participates in the production of certain goods and services in which it has a comparative advantage (e.g. infrastructure, education and health), and only higher-income individuals can afford to purchase private alternatives to public services. In this context, expanding public infrastructure services reduces the inequality of opportunity among entrepreneurs, increases the return on investment and raises entrepreneurial activity among the less-favoured segments of society.

Building on this framework, more recent contributions model the joint dynamics of public investment, growth and inequality in a general equilibrium setting with heterogeneous agents that differ in their initial endowments of private capital. In these models, a pure public good or service (e.g. infrastructure) interacts with private capital in the production of other goods.

Getachew (2010) presents a two-sector growth model with capital market imperfections in which public capital not only contributes to the production of goods, but also promotes the accumulation of private (human) capital. Like in earlier models, income inequality hinders growth. Increased provision of productive public services not only raises aggregate growth, but can also influence the distribution of income (and thereby exert a further indirect impact on growth) if the services accrue heterogeneously across individual households. Specifically, greater provision of public infrastructure benefits the poor more than proportionally because of their lesser access to private substitutes.

Chatterjee and Turnovsky (2012) likewise examine the dual role of public capital as growth engine and determinant of inequality. In their setting, public capital affects both productivity and labour–leisure choices. Greater public investment raises factor incomes through the productivity channel, while also affecting relative factor returns and the distribution of income and welfare through the labour–leisure choice. However, the mode of financing public investment matters for factor income shares and income inequality. Numerical simulation of the model shows that any distributional gains may be only temporary if public investment is financed through non-distortionary taxes. On the other hand, income distribution improves in both the short and long run when public investment is financed by levies on capital.

Another dimension of income inequality that may be affected by public infrastructure development is the skill premium. It is examined by Pi and Zhou (2012) using a static multi-sectoral model with skilled and unskilled labour, in which public infrastructure is an input in the production of the different goods. A greater supply of public infrastructure raises the marginal productivity of both skilled and unskilled labour – and hence their respective remuneration. The effect on the skill premium depends on factor intensities: if the sector using unskilled labour is relatively more intensive in public infrastructure services, there will be an outflow of capital from the skilled to the unskilled sector. Hence the wage rate of skilled labour will decline and that of unskilled labour will increase. This reduces skilled–unskilled wage inequality. Of course, the effect is the opposite if the sector using skilled labour is more intensive in the use of the publicly provided infrastructure input.

The literature has devoted particular attention to the distributive impact of opening up infrastructure provision to private sector initiative. The impact may accrue through changes in employment, in the composition of public spending, and in the access and affordability of infrastructure services for the poor (Estache et al. 2000). Employment effects are particularly controversial, as former public enterprises acquired by private providers often become profitable by downsizing (Estache et al. 2002). In turn, the distributive impact of downsizing depends on the proportion of lower-income workers in the infrastructure labour force, and on the monetary compensation to laid-off workers. In addition, if the investment by newly reformed providers of infrastructure promotes growth and new jobs, downsizing in the public infrastructure sector may be offset by job creation in other sectors (Benitez et al. 2003).

Aside from employment effects, private sector participation in infrastructure also affects public revenues and expenditures. Subsidies to the provision of infrastructure services may be eliminated, and revenues from privatisation may be generated. What happens with inequality depends also on what is done with the increased fiscal resources. If they are devoted to improving the efficiency and coverage of public (infrastructure and/or non-infrastructure) service provision, income inequality may decline (Estache et al. 2000).

Finally, infrastructure reform may lead to price and/or supply responses that reduce the access and affordability of services for the poor. For example, removing subsidies may lead to higher post-reform prices, and new private providers may charge higher connection fees than government-owned providers or be reluctant to reach poorer areas (Estache et al. 2002). As a result, infrastructure services may become unaffordable to lower-income groups. The likelihood of this outcome depends on the overall design of the reforms. In practice, however, there are numerous episodes in

which access by the poor improved after reforms involving private participation.

Empirical Evidence

The empirical literature on infrastructure and inequality broadly follows two main strands. One is concerned with the effects of infrastructure stocks and/or service flows on standard inequality indicators. It includes the majority of the studies using macroeconomic data. The other examines the effects of specific infrastructure interventions, usually focusing on the income of poor households or backward geographic areas.

A few studies have directly examined the inequality impact of infrastructure at the aggregate level, by regressing Gini coefficients and similar inequality measures on indicators of infrastructure development in a cross-country panel data setting. Among them, López (2004) proxies infrastructure development by fixed telephone density, while Calderón and Chong (2004) consider the quantity and quality of different infrastructure sectors (telecommunications, energy, roads and railways), both separately and jointly, using a qualitative summary indicator in the spirit of Hulten (1996). In turn, Calderón and Servén (2004, 2010a, b) employ synthetic indices of infrastructure quantity and quality combining multiple infrastructure sectors, built through a principal components procedure. These papers find that, *ceteris paribus*, income inequality is negatively related to their respective measures of infrastructure development. In a similar setting, Seneviratne and Sun (2013) reach the same result for ASEAN countries, but they also find that public investment does not bear any significant relation to inequality. This suggests that public investment data offer a poor proxy for infrastructure development.

The literature also advances the testable hypothesis that increased access to infrastructure services should help raise the income and the value of the assets of the poor. However, the availability of information on access to infrastructure services varies dramatically across countries and infrastructure sectors. For telecommunications, water and sanitation, existing data provide fairly good coverage across countries and over time. For power and transport availability is sparse, especially in the time dimension. Subject to these constraints, Calderón and Servén (2010b) find a negative correlation across countries between measures of access to multiple infrastructure services and standard indicators of inequality – although it is not obvious to what extent this result may reflect a causal relation.

At the microeconomic level, another strand of literature examines the poverty effects of infrastructure interventions using matching techniques that combine samples of beneficiaries with samples drawn from regular household surveys (taken as control group). These studies usually evaluate the impact on income of a particular intervention affecting a given group of households or a specific geographic area.

Some studies of this type find that physical infrastructure in roads and communications facilitates spatial access and information flows, raising labour mobility, boosting rural non-farm economies and reducing the incidence of poverty in some geographic areas (Jalan and Ravallion 2003; Zhu and Luo 2006; Reardon et al. 2007). They also show that public infrastructure provides a boost for local community and market development. For instance, rehabilitating rural roads in Bangladesh raised non-agricultural wage employment in targeted households and fostered markets that have become increasingly diversified across sectors – with the largest impact on households in the second-lowest quartile of the income distribution being the most mobile in changing activity from agriculture to non-farm work (Khandker and Koolwal 2007, 2010). This type of intervention has also proved successful in Vietnam by increasing workers' wages and developing local markets in poor communities (Mu and van de Walle 2007).

Granting access to new and improved roads in rural areas has also expanded the set of opportunities in non-agricultural activities in Peru (Escobal and Ponce 2008) and in non-farm activities among women in Georgia (Lokshin and Yemtsov 2005). There is also evidence from large emerging markets such as China and India. For example, public

investment in rural roads and electrification has contributed to rapid growth in agricultural production across Chinese regions. However, the impact on poverty and inequality was boosted when infrastructure expansion was accompanied by public investment in education, science and technology (Fan and Zhang 2004; Zhang and Fan 2004). On the other hand, an expansion of regional infrastructure facilities (e.g. power and roads) in certain regions and districts of India was found to have improved average living standards and lowered the share of people living below the poverty line, even when infrastructure investment was accompanied by divestitures in education and health (Majumder 2012).

Recent literature examines the impact of electrification programs on rural areas in developing countries. Dinkelman (2011) evaluates the effect of the massive roll-out of the electricity grid in rural South Africa on employment – and, most notably, female employment. This roll-out, started in 1995, targeted low-capacity household use in rural areas rather than industrial users. The study employs the land gradients of the communities to adjust for the endogenous location of projects. The main finding is that electrification leads to rising female employment on both the extensive and the intensive margins. For instance, women work nearly 9 hours more per week in districts that experienced an average increase in electrification. This occurs as households with access to electricity replace wood burning at home with electricity for cooking and lighting, which frees up female time from home to market work. It also provides new opportunities to produce home-based goods and services for the market, through either self-employment or micro-enterprises.

One particular intervention found to have significant distributional effects is the construction of large irrigation dams. Duflo and Pande (2007) find that the benefits of building a dam on irrigated areas, in terms of agricultural production and rural poverty, accrue to the districts located downstream from the dam – as opposed to those districts were the dam is built. Furthermore, downstream districts can use the dam as insurance against rainfall shocks while agricultural production in districts where the dam is built is more vulnerable. In sum, rural poverty falls in districts located downstream, but this decline is smaller in magnitude than the increase in districts where the dam was built.

Other empirical studies shed light on the theoretical claim that improved access to infrastructure services can raise the income of the poor through its impact on human capital – specifically, education and health outcomes. Better transportation systems and safer roads help raise school attendance (Brenneman and Kerf 2002), while improved access to electricity allows more time for study and the use of computers (Leipziger et al. 2003). Cross-country research shows that enhanced access and use of basic infrastructure services reduces rates of child and maternal mortality. Likewise, Jalan and Ravallion (2003) find that the prevalence and duration of diarrhoea in children under five in rural India is lower among households with piped water, although the impact on the poor is amplified if public investment in water and sanitation is accompanied by other interventions in education and incomepoverty reduction. Analogous benefits resulted in Argentina when privatisation expanded access to water and sanitation by the poor – child mortality fell by 8% (Galiani et al. 2005).

Recent evidence shows that the benefits to the poor of improved access to water may go beyond the conventional health effects. Better access reduces time devoted to water collection, thereby freeing up time for additional leisure or production. It reduces important sources of stress and tension within the household and/or community. Moreover, it provides women greater mobility and the opportunity to socialise and improve their well-being. Overall, welfare gains may result even in the absence of income or health gains; see Devoto et al. (2011) for evidence from the city of Tangiers.

Finally, evidence from Latin America shows that privatisation of infrastructure sectors often benefited the poorest groups by granting them access to services. For instance, Chisari et al. (1999) and Navajas (2000) find that the privatisation of infrastructure services in Argentina hurt the middle class relatively more than the rest of the income groups through the elimination of existing subsidies. However, it benefited the

poor by improving their access to services. Estache et al. (2000) show that the less-favoured segments of the population in Latin America had very limited (or no) access to many utility services, and thus did not benefit from their expansion prior to the privatisation. However, the extent of the benefits from privatisation reaped by the poorest differed across sectors. In many countries, the rapid expansion of mobile telephone networks led to increased access to a wide array of service suppliers. The power sector, on the other hand, moved at a slower pace post-privatisation, and reforms often failed to provide low-cost solutions to remote households in rural areas (Foster et al. 2001). More broadly, an encompassing review of Latin America's experience offers several examples of improved access to infrastructure post-privatisation (World Bank 2003). For instance, improved access to electricity, water and telephones for poorer groups lifted their incomes in Guatemala. The expansion of infrastructure services to rural areas in El Salvador reduced the time required to reach markets, which created significant gains for poorer groups. Lastly, improving road quality had an important impact on non-agricultural income for the rural population in Peru, most notably arising from wage employment.

Limitations of the Empirical Literature

Empirical assessments of the distributional effects of infrastructure development face methodological challenges concerning measurement, identification and heterogeneity similar to those that affect studies of the growth impact of infrastructure. Since these are described at length under 'Infrastructure and growth', the discussion below highlights only the particular forms that these methodological issues take when assessing the distributive consequences of infrastructure development.

Regarding *measurement*, perhaps the key obstacle is the lack of systematic information on access to, and affordability of, infrastructure services for different percentiles of the income distribution, whether over time or across countries. This makes it very hard to reach robust conclusions regarding the consequences of infrastructure development for the equality of opportunities and incomes across households. Researchers have resorted to aggregate data on access – that is, without a breakdown across income percentiles – under the implicit assumption that changes in access at the margin affect primarily the poorer segments of the population, but this may not always be the case. More fundamentally, even aggregate access figures are available for only a limited number of countries, in most cases without any geographic disaggregation, and only for recent years.

Identification remains a challenging problem. While infrastructure may help reduce inequality, at the same time inequality may hamper the provision of infrastructure services to the poor. The reason is that more unequal societies devote fewer resources to the provision of public goods, including infrastructure (Alesina et al. 1999). Cross-country (or cross-region) studies that fail to account for this and similar forms of simultaneity are likely to overstate the effects of infrastructure development on equity. More broadly, unobserved factors affecting both distributional outcomes and infrastructure accumulation may likewise lead to biases.

Recent microeconomic studies of the impact of specific infrastructure interventions have used randomised control trials (RCTs) to establish causality. This approach enables researchers to assess whether any changes observed in the target population are due to the public infrastructure program, exogenous factors, or unmeasured individual effects. RCTs isolate the impact of interventions by randomly assigning individuals to treatment and control groups. In this vein, several studies have examined the impact of improved water and sanitation on health outcomes (Capuno et al. 2011; Andrés et al. 2014). A limitation of this approach, however, is that the findings may depend on the specific context and time frame in which the experiment is conducted, so evidence of a successful policy intervention might not be relevant to other cities, regions or countries.

Lastly, *heterogeneity* is also a relevant issue. The effects of infrastructure on inequality may vary across locations and over time for multiple

reasons. One is the heterogeneous quality of infrastructure assets and services themselves, difficult to account for due to data limitations. Attempts to bring infrastructure quality into the analysis, along with quantity, include Calderón and Servén (2004) and Seneviratne and Sun (2013). However, variation in the measured effects of infrastructure development could arise from many other sources. This is a particular relevant concern given the major role that studies of particular infrastructure interventions play in this empirical literature, because their findings may reflect a host of unmeasured (or hard-to-replicate) factors specific to the intervention under consideration.

Final Remarks

Overall, available empirical research offers some suggestive evidence that infrastructure development has equity-enhancing effects. The analytical literature has proposed a number of specific mechanisms through which such effects might accrue, but evidence on their actual relevance is, in most cases, still incomplete. Data limitations are largely responsible for this. Infrastructure development should affect poorer households primarily by improving their access to affordable services. However, the limited information available on access and affordability for households at different percentiles of the income distribution represents a major obstacle to progress in establishing unambiguously the consequences of infrastructure development for inequality and, therefore, its overall contribution to poverty reduction.

JEL Classifications

B31

Ingram's whole professional career was spent at Trinity College, Dublin, of which he became a Fellow in 1846. He subsequently held a remarkable variety of offices there – Professor of Oratory

(1852) and English Literature (1855), Regius Professor of Greek (1866), Librarian (1879) and Vice-Provost (1898) – but was never a professional teacher of political economy.

Nevertheless, Ingram played a notable part in the debates of the 1870s on the future of political economy and became one of the leading advocates in English of the use of the historical method in that science. Ingram's views were initially stated in his presidential address to Section F of the British Association in 1878. Here he attacked the 'vicious abstraction' and attachment to the deductive method of the classical economists, blaming this for the low repute into which political economy had fallen. He advocated the replacement of the deductive by the historical method and that 'the study of the economic phenomena of societyn... be systematically combined with that of other aspects of social existence'. In adopting this approach Ingram was influenced partly by his contemporary T.E. Cliffe Leslie (1826–1882) but chiefly by the positivist philosophy of Auguste Comte, of whom he was an active and lifelong disciple. Of his later economic writings, the best known was, and still is, his *History of Political Economy,* which was for a long time the fullest account in English of the work of the historical school in Germany, France and Belgium. All Ingram's economic work displayed the holistic and normative outlook which he derived from Comte, but did not go far towards fulfilling the programme of historical and comparative studies to which his earlier critique of classical economics pointed.

Inheritance

Jack Goody

Inheritance, in the strict sense, is the transmission of relatively exclusive rights at death. Such transmission is part of the wider process of the *devolution* of rights between or within the generations (eventually always between), and particularly between persons regarded as holders and heirs. Devolution continues throughout an individual's life, involving him both as giver and as receiver, and entailing transfers *inter vivos*, between the living for education, marriage, housepurchase, etc. as well as the residuum at death. The connection between inheritance and earlier transfers is given explicit recognition in some customary systems of endowment of sons and daughters where what has already been received is deducted from the final share of the parental estate (as in the revision clause of the Paris–Orleans region from the 16th century). In the same way the trend in European and American tax laws, epitomized in the British Capital Transfer Tax, is to treat as a whole the transfers of property from an estate (in the case of an estate tax) or to one individual or donee (in the case of an inheritance tax).

In a society where production is based upon the household and where rights (whether of ownership, tenancy or use) are vested in the domestic group, then the central importance of the devolution of such rights is clear. This is the case in most sectors of pre-industrial economies, but especially in agriculture and crafts. Where individuals have no such rights in the basic means of production, being employed as wage-labourers or as salaried employees, then the productive system is involved in interpersonal transfers only through

share ownership, the transmission of managerial functions having been 'bureaucratized'; the handing over of such functions takes place at retirement rather than death and involves succession to 'office' rather than inheritance to property.

Thus in industrial societies of whatever political complexion, inheritance is of less significance for individuals and for society (except as windfall income in the first instance and windfall revenue in the second) than in earlier times when, except for the landless, it involved the transfer of rights in the means of livelihood. Even in industrial societies, the state may make special provision for family farms or firms to ensure continuity of the working group.

A radical instance of such a law was enacted in Germany by the National Socialists in 1933, providing for undivided inheritance and forbidding partition by will, the sale of the land or its encumbrance with a mortgage. The law was repealed after World War II, but in Germany as in France and other European countries, the transmission of farm property within the family is protected with the primary aim of ensuring continuity and providing an incentive to work and improve the farm for the next generation.

The Argument About the Inheritance of Wealth

Two divergent views on inheritance are current. On an ideological level, 'socialist' societies, parties and individuals regard inheritance as a way of transmitting inequalities and are therefore in favour of its restriction by taxation or even expropriation. Those espousing 'capitalist' theories look upon the right to transmit acquired wealth to one's offspring as part of the incentive necessary for accumulation, saving and investment. The extreme 'socialist' position is not simply a matter of recent theories of society. At the end of the 18th century the Abbé Raynal declared that at an individual's death, any land he possessed should become a free good. The theme has played a subdominant role in Christian thought over a long period. In 5th-century Gaul, the priest Salvian maintained that since all property came from God, at death it should be returned to his representatives on earth, the Church, for distribution to the poor as well as for its own purposes. Such assumptions left no room for inheritance, so the argument for the social uses of wealth depends not only on the negative case for reducing inequalities but on the positive one for assisting charities. Both positions involve an 'individualistic' view of property, 'freedom' to testate on the one hand and the reduction of the share or relatives (especially of collateral kin) on the other.

At an implicit level, we find a similar spread of ideas in simpler societies. In Africa a distinction is often made between self-acquired property, over which an individual may have a measure of freedom of disposal, and inherited property, especially land, which has come down from his forefathers. In the second case alienation is impossible because an individual is only a temporary custodian, having an obligation (as in some earlier European Laws) to hand the property down in the same line from whence it came. If it had been inherited in the agnatic line, then only agnatic relatives could benefit. In other words the property was 'corporate', or at least 'ancestral'. This notion of an heirloom runs quite contrary to the idea firstly that an individual's wealth should be confiscated in the wider interest either of the government or one of the 'great organizations'; and secondly that he should have completely free disposition over all he has accumulated. Clearly the case for inheritance is more tenable in traditional societies like those in Africa where differences in wealth were small, so that the case for redistribution (motivated either by a positive notion of distributive 'justice' or a negative resentment of inequality) was hardly relevant and where the 'poor' were the responsibility of their kin group. It becomes less tenable with the greater differentiation of capital and income, especially where individuals no longer own the means of production because they are working either for an industrial corporation or for a socialized enterprise, and where it is unnecessary, and often thought undesirable from the bureaucratic standpoint, to attach the next generation to the parental enterprise.

The stress on either the 'socialist' or 'capitalist' pole obviously has some relation to the nature of the ideology and to the organization of productive

enterprise. But it is also true that domestic accumulation and extra-domestic redistribution are aspects of all contemporary social systems. In 1926 the Soviet Union reversed its early position which limited inheritance to small amounts passed on to close relatives or to the surviving spouse, providing there were in need. Later property could be left to anyone and its inheritance, listed as one of the rights of citizens in the constitution of 1936, was seen as a useful incentive to productivity. On the other hand every major 'capitalist' country levies some kind of tax at death, the proceeds of which are destined for the public purse rather than for private enjoyment.

Theories of income distribution often start by assuming normal distribution. This assumption is not adequate for all groups because of the inheritance of property at the death of the parents or other kin. But the main reason lies in the differential interest and capacity of parents to 'invest in' and encourage the abilities of their children. Such encouragement is a kind of transfer *inter vivos*, though it is part of the very process of socialization itself, one in which material gifts may play a major part in helping to provide both shelter in the form of house or apartment and more especially training or capital to generate income.

The ability to transfer privilege from one generation to another is, in the end, intrinsic to family life and to the reproduction process itself with its particularistic interests. Many utopian communities and ideologically based communes attempt to equalize opportunity through early 'schooling' or joint upbringing as well as wealth sharing; in the extreme case parenthood has only a physiological function, upbringing being left to the group. In the extreme case the contradictions become apparent in the longer-term development of communities like the Israeli *kibbutz* where family ties, and hence intra-familial differences, begin to manifest themselves, in limited but significant ways, after the initial period of open recruitment.

Taxation

Whatever their ideological position, all modern societies place a progressive tax on inherited property, a tax that socialist countries see as a means of equalizing advantage, just as attempts are made to counter other benefits derived from family through a national system of education. However, many earlier and some modern taxes were primarily visualized as methods of raising income for the ruler rather than equalizing income among the citizens.

From either standpoint death provides the best moment to raise money, since future beneficiaries are unlikely to offer many objections if they have not yet taken possession. Moreover the property of the deceased often had to be listed, especially under the notarial systems of Europe, as part of the process of handing over: consequently the basis for an assessment already existed. Such forms of taxation have a long history, appearing in Rome as the *vicessima hereditatum*, the twentieth penny of inheritance. In feudal Europe the heriot, payable at the transfer of an estate, accrued to the lord; but already in 1694 a central death tax was introduced in England, taking its modern form in 1779–80. Taxes on inherited wealth thus long preceded taxes on income.

Ways of avoiding tax also had a long history. Under English law, trusts and life-estates could be set up in order to skip a generation in the transfer of property. Discretionary trusts were not available in continental Europe. But other avoidance measures included the handing over of property *inter vivos*, a long-established tradition (even extending to the farm itself), although such a practice now runs up against taxes on gifts or capital transfers: a modern alternative, that of changing one's country of residence, is more difficult to control, except by controlling the total outflow of capital from the country.

Today these possibilities remain relatively little used, and yet the revenue role of death taxes is not great. No taxes, remarks Shoup (1968, p. 559), have had a better reputation to less effect. This is partly because of avoidance and high rates of exemption, but mainly because individuals divest themselves of property to their children or use it for support in their old age, which is especially easy when personal property relates to consumption rather than to production. However, in the USA where charitable gifts are exempt, private foundations reap important benefits, while in the UK

major contributions to national collections of art, buildings or land result directly from such taxes.

The History of Inheritance

The system of inheritance, involving the transmission of relatively exclusive rights over material objects, clearly varies with the mode of production. In hunting and gathering societies, rights of this kind are minimal; much of a man's property may be destroyed at his death, each individual fashioning himself or acquiring from others the tools he requires for his own use. The destruction is an aspect of the close identification of a person with the property he has created or used that is characteristic of such societies.

In simple agricultural economies, rights in land become elaborated, although with shifting cultivation access is more important than ownership. Access to the basic means of production is likely to be achieved through membership of a kin group (by descent or affiliation) rather than through an inheritance transaction. But other types of property, livestock, houses and exchange items, are transmitted in the course of long funeral ceremonies.

Where animal or other forms of non-human energy can be harnessed in the process of production, land becomes a scarcer resource, more differentiated in its distribution, with a greater complexity of rights, 'ownership' tending to be the prerogative of the dominant groups, and tenancy (or even labouring) the prerogative of others. In the case of tenancy it is landlords that tend to make the rules for the transfer of property, insisting for example on indivision (keeping the holdings intact) or on redistribution (keeping the holdings equal). The system of inheritance itself is influenced by the existence of stratified access to land, each group attempting to employ strategies of heirship to maintain or improve their position. The situation with regard to stratified access to livestock for pastoral peoples is different in certain important respects (the herd is more easily divided, increased and consumed) but tends to produce broadly similar strategies as are found in plough agriculture.

In industrial societies the situation is radically different because the vast majority of the population labour for wages rather than owning rights in the means of production. As we have seen, inheritance consequently plays a very different and more peripheral role.

Everywhere inheritance is basically a kinship transaction. While other persons may be involved, the core relationships are close 'familial' ones. In the simpler societies eligible kin are rarely, if ever, lacking since virtually all relationships are between kin. In complex ones, the definition of eligibility tends to be narrower, friendship supplements kinship, the percentage of unmarried tends to be higher and in any case other institutions, the 'great organizations' of church, state, as well as the charitable foundations, make their own demands; nevertheless the 'family' continues to dominate the process of the transfer of wealth between generations.

In kinship terms one can transmit laterally to spouses or siblings, or lineally to children or to siblings' children: the choice is one of priority since all ultimately has to go to the next generation. Downwards transmission for men can be to the sister's child (uterine inheritance) or to own children (agnatic inheritance). In simple hoe agricultural societies inheritance between spouses is rare, transmission tending to be homoparental, that is, male to male, female to female. Such is the case in much of Africa where economic differentiation is relatively small and access to land available to all or most free individuals. Historically, these forms of inheritance were usually associated with the presence of unilineal descent groups (clans or lineages) in which property is transmitted between its members of the same sex.

Patrilineal and matrilineal clans with agnatic and uterine systems of inheritance are found in all types of pre-industrial society but matrilineality is more frequent with tropical hoe agriculture (in which women often do much of the farming, continuing their role as food gatherers in hunting societies) while patrilineality predominates when agriculture is combined with the herding of large livestock (whether or not these are used for plough traction).

The alternative form of inheritance, dominant in one form or other since the advent of plough agriculture, is diverging, or bisexual, that is, with children inheriting from both parents, and parents transferring wealth to daughters as well as to sons, but not necessarily at death. One form of early transfer is the direct dowry whereby daughters are 'endowed' when they depart at marriage. While the man-to-man (homoparental) transmission of Africa excludes inheritance by spouses, diverging devolution in Eurasia tends to exclude uterine inheritance by sister's children, concentrating on passing property, after the surviving spouse has been taken care of, directly to one's own 'natural' children, and even encouraging the adoption of outside heirs before allowing property to go to collaterals. The elementary family takes precedence.

Differences in stratification associated with advanced agriculture work in favour of the identification of conjugal statuses. Transmission in such societies is usually bisexual. At marriage some kind of conjugal fund (or identity of interest) is established and the property is transmitted, though not in equal proportions, to the children of both sexes, with certain types tending to be sex-linked; for example, land may be passed down to males alone where it is associated with male status among the nobility, as under the law of the Salian Franks. Since handing down occurs not only at death but on earlier occasions, especially at marriage, questions concerning the equality of 'inheritance' have to be looked at in terms of the total process of devolving property between holder and heir throughout their lifetime. For example, a woman may receive less at death because she has received a larger dowry at the time of her marriage, even as the promise of dower to maintain her as a widow.

The different treatment of siblings depending on birth order takes the form of primogeniture, ultimogeniture, or partition, known to earlier English law as Borough French, Borough English and gavelkind respectively. Rarely if ever does one find the transmission of the entire conjugal estate to a single sibling but rather the preferential treatment of one at the expense of the others. Such a preference may be tied to particular obligations, as when the inheriting child is expected to stay with the parents in their old age. In other cases the preference for one child (unigeniture) is related to the desire to keep the family estate intact, either because it will only support one family (among the poor) or because it is tied in with status consideration (among the rich). The first situation applied to pre-Revolutionary China where the poor tended to live in stem households (containing one member of each generation) while the richer lived in larger, extended ones. The poor either had less children *in toto* or the additional offspring migrated elsewhere or worked locally as landless labourers. The second situation was found in parts of 'feudal' Europe where title and position were linked to estate and income; just as one child succeeded to the title or office, so he had to inherit the bulk of the estate to which it was attached. Younger sons sought their fortunes elsewhere in the great organizations of the church or the army, to which they had access as a consequence of the political power assured by the parental estate.

Devolution, Retirement and Interpersonal Conflict

Until the end of the 19th century (and still today in some areas of rural Europe), propertied classes endowed their daughters at marriage (and sometimes on entering a convent, on becoming 'a bride of Christ') with part of the 'portion' they would otherwise have inherited at the death of the parents. In some farming communities the parents would hand over the farm to their son or daughter on the occasion of their marriage, reserving for themselves certain rights to bed and board which were sometimes embodied in specific retirement contracts. One of the penalties of such an early handing over of property is that parents are placed in a King Lear situation, overly dependent upon the succeeding generation and running the danger of neglect (or 'ingratitude'). On the other hand to hang on till the end to property that is critical to status or survival leads to the opposite kind of tension characterizing the Prince Hal situation, where the son attempted to grasp his father's

crown while he was still alive. These problems are of less significance in wage-earning societies where individuals are more dependent on income than on capital, and it is into training children for future employment that parents invest their time and wealth, rather than devolving property at marriage or even at death. While the state provides a minimum level of support, wealth may be invested in a pension or retained by the elderly for their support, possibly disappearing with their death in the form of annuity. Little conflict arises between holder and heir, who rarely continue to reside together (except in the case of spouses); inheritance tends to come late and to be seen as a 'windfall'. Its distribution may still give rise to conflicts within the group of potential beneficiaries, while even the prospect of a windfall produces enough underlying tension to fill the pages of many a piece of detective fiction (and 19th-century classics like *Middlemarch*), although significantly the plots are frequently located in the past when greater weight attached to rentier income.

Rights Transferred

The rights transferred from the dead to the living are largely those in material property, houses, land, money, heirlooms, but they may also include rights to receive rent, interest, dividends from shares. In earlier societies they included rights to the services of other humans (of serfs and slaves), even to women as wives and to men as husbands, as in the Jewish practice of leviratic inheritance, taking on the widow of a childless brother with a view to breeding offspring to his name. Any semblance of the inheritance of widows was rigidly excluded from the law of England at the time of the Reformation since it was on grounds of the invalidity of such marriages that Henry VIII set aside his first wife (Catherine of Aragon, the widow of his dead brother, Arthur) in his search for a successor and an heir. Inheritance may also involve other types of right, those of a non-corporeal kind, right to songs and stories (copyright), rights to armorial bearings, titles, etc., although here we touch upon the field of succession to social position, to office, to nobility or to similar benefits.

Inheritance is not only concerned with rights; duties too are involved; debts have to be paid from the estate; the acceptance of an inheritance may involve a change of name, of residence and even, especially in societies that resolve disputes by means of feud, of the specific obligation to settle a score.

A broad distinction is made in Anglo-American law between real and personal property, roughly between land a chattels, between movables and immovables. A similar distinction is found in many other cultures and is related to the special position of land within the general category of property, since it acts both as a factor in production and as a locus for all social activity. Hence different rules and practices are applied to these two categories; in England after the Norman conquest it was the royal courts that dealt with real, and ecclesiastical courts with personal property, the former emphasizing indivision, the latter allowing more testamentary freedom and alienation. Land was subject to different rules until 1926 and its transfer is still hedged about with formalities that mark it off from all other forms of property. For a hierarchy of rights is always involved; these may refer to usufruct, tenancy, mortgage, metayage, and a host of arrangements (including sovereignty itself) to which other property is not subject and some of which need to be acknowledged in the deed of transfer itself.

Testate and Intestate

There are two types of inheritance in literate cultures, testate and intestate. The former involves making (writing) a will or testament, the latter describes what happens when there is no such statement. In nonliterate societies inheritance is automatically intestate, and 'custom' lays down how property should be distributed. There is little 'freedom' to alienate goods from the recognized heirs so that even gifts *inter vivos* have to be monitored.

The written will or testament introduces a measure of certainty in situations, reducing possible

conflict or indeterminacy; where this is available, nuncupative (that is, oral) wills are considered valid only under exceptional circumstances. But in early times one of the main functions of the testament was to certify that any alienation from customary heirs was according to the wishes of the deceased. In other words its very existence assumed a degree of 'freedom', by which is meant freedom of choice for the holder, limiting the right of 'society' to say who should be the recipient. It is not surprising that the will with its corresponding freedom of testation was encouraged by the early Christian Church as a way of acquiring property to be put to divine purposes. And in more recent times it has been a central instrument for the transfer of wealth to charitable foundations. Without its intervention, inheritance goes to the family.

Testamentary inheritance occurs by means of the written will, although initially the latter term applied only to real property (land), the testament to personal property. Literacy is thus essential either on the part of the testator or on the part of the notary, lawyer or priest who draws up the will. The fact that the document has to be proven in court means that professionals tend to be employed for the purpose. Hence the whole industry of literate legal specialists involved in writing the will, in helping it to come into effect and in administering the estate, the last being currently the most profitable part of the enterprise in anticipation of which other charges may be scaled down. It is these specialists who help to ensure that the formalities are observed, not only in the words but in the witnesses, and that the will is not invalidated for other reasons. All of which tends to take the mechanics of transfer out of the hands of kin, and places the process firmly under the charge of those who engage in it for their livelihood and who tend to create their own specialist language, codes and organization.

Testamentary Freedom

In oral societies, little scope existed for alienation from the heirs who were regarded as the proper recipients. On the other hand testamentary freedom has disinheritance as its corollary. The problem of exclusion became acute in the early days of Christendom since some religious advisors encouraged the old to leave all to the Church and nothing to their kin. The Church itself, and later 'hell fire' and 'charity-begins-at-home' statutes, legislated against such forms of disinheritance and indeed most contemporary systems reserve a 'legitimate' part for the spouse and the children. In this way testamentary freedom is limited by law so that close kin benefit from a portion of the estate, although not to the same extent as under intestacy. This limitation holds even in ancient Roman and modern Anglo-American law where freedom to disinherit was greater than in the civil law regimes of the continent. In England, the obligation to leave a minimum share of personal property to close kin disappeared in the course of the 17th and 18th centuries, while in 1833 the widow lost her right to a dower. In Scotland, on the other hand, rights such as the bairn's part continued. Indeed in wealthier families in England these rights were always maintained by entails, by the strict family settlement of the 18th century and by earlier devices which prevented the splitting of the estate, while parallel practices deriving from late Roman law existed on the continent. Such arrangements were the subject of objections by some because they kept land from the market and made it impossible to raise a mortgage to effect improvements. In Europe the system collapsed with the French Revolution, following which the Napoleonic Code tried to ensure partition. But in England it persisted until the Settled Land Act of 1882. More recently Family Provision Acts have restored some of the protection given to the surviving spouse and to the children, and in the Soviet Union to anyone previously dependent upon the deceased.

In fact, the beneficiaries of inheritance under a will do not turn out to be greatly different from 'intestate' inheritance, not only because of legal restrictions but because the contents of written wills follow the general sentiments of donors. Indeed because of its flexibility the pattern of

testamentary inheritance may be closer to the moral climate of opinion, as in the preference it gives to the 'spouse-all' provisions of modern Anglo-American law, whereas division with the children obtains in the more conservative case of intestacy. The legal formalism connected with literacy 'tends to generalize rules that have originated in connection with special situations into applications beyond their initial scope' (Rheinstein 1974, p. 590). At the same time the written rule tends to preserve past situations so that intestacy laws have 'frequently looked obsolete, confused, or arbitrary'.

Inheritance Under Current Anglo-American Law

Intestate rules in Anglo-American law usually split the property between the surviving spouse and the children. When people make wills, on the other hand, they use the testamentary freedom to leave all to the spouse, usually the wife as she is often younger and lives longer than the husband. In general it is women as widows that benefit most from inheritance. Only after the widow's death does the property drop a generation. The one exception is in the case of a remarriage where specific provision is often made in advance for the children of 'the first bed' in whose welfare the surviving spouse may have less interest.

Even here, despite the potential difference between the outcome of testate and intestate inheritance, the results are very similar since children normally hand over the portion to which they are legally entitled to their parent so that he or she can continue to lead an independent life. When the next generation eventually inherits, the property is usually split equally between children regardless of sex. However, there is one major exception to equality of partition. When one of the siblings has looked after the parents in their old age, testamentary 'freedom' or intestate adjustment is used to allocate that person a preferential share. This was one of the roles of preferential primogeniture or ultimogeniture in early English law, the last-born son being known in some parts as the *astrier*, the one who remains by the hearth. Otherwise equality is the norm both in law and in practice. Whatever discrimination operates against women in other sections of the society, little is now manifest in testamentary matters, either as spouses or as daughters (however, the 'poor' widow who did not produce a dowry can be helped from the estate, both in Justinian's law and in modern Lousiana). A wife tends to regard an inheritance as her personal peculium, a nest-egg. Given the relatively late age that most people receive legacies, these may make little difference to the lifestyles of the recipients, who sometimes use them as gifts *inter vivos* to assist their own children rather than themselves.

Inheritance and Bequests

Kathleen McGarry

Abstract

The importance of bequests, their role in capital accumulation, and the motivation behind these transfers has long been the subject of debate among economists. Various models of intergenerational transfers yield different predictions about the responsiveness of bequests to changes in incomes of the donors and recipients and thus to the impact public policy. Yet, despite the intuitive appeal of these models, none has proved to be consistent with empirical patterns. This article discusses the alternative theories of transfer behaviour, examines the empirical work testing their predictions, and discusses the role of estate and gift taxes in affecting bequest behaviour.

Fascination with inheritances and bequests began long before economists formalized models of transfer behaviour. Literature and history are rife with examples of the role of inheritances (for example, Shakespeare's *King Lear*). Societies have laws governing bequest behaviour and governments have long employed bequest, gift and/or inheritance taxes (jointly termed 'transfer taxes') as a means of raising revenue. Economists, in turn, have examined the motivation behind bequests and their importance in driving economic behaviours. These transfers have been theorized to play a central role in the accumulation of wealth, the degree of inequality present in a society, and the interactions among generations. This article touches briefly upon several economic dimensions of inheritances and bequests.

Although the focus in here is on inheritances, the distinction between bequests, made at the time of death, and *inter vivos* transfers, made during life, is somewhat arbitrary. Intended bequests may be made prior to death as a means of reducing estate or inheritance taxes, avoiding other legal requirements pertaining to the settling of an estate (such as probate), or alleviating liquidity constraints and smoothing the consumption of an intended heir. Conversely, resources transferred during life could well have been saved and transferred at death in the form of a bequest. Indeed, much of the literature attempting to assess the importance of bequests in contributing to the capital stock has included the magnitude of *inter vivos* transfers along with bequests in any calculations. Similarly, economic models of the motivation for bequests are generally applicable to *inter vivos* transfers as well. Finally, in many cases, transfer taxes apply to both *inter vivos* transfers and bequests.

In this discussion I focus primarily on bequests but, where appropriate, I draw on the research examining *inter vivos* transfers as well. I use the generic term 'transfers' to refer to either bequests or *inter vivos* transfers. Also, for ease of exposition I occasionally refer to donors as parents and recipients as children. Obviously, bequests are frequently made to non-child heirs, but the use of this terminology makes the discussion less abstract and also accurately reflects the situation for the majority of bequests.

Much of the literature examining bequests has sought to assess the relative importance of inherited wealth and life-cycle savings as components of the existing wealth stock. Estimates of the

relative importance of bequests have varied widely. Numerous researchers have put the fraction of wealth due to transfers at 15–20 per cent (see Modigliani 1988, for a discussion), but some studies argue that the figure is much higher, concluding that transfers account for a large share of wealth holdings (for example, Kotlikoff and Summers 1981). Although the existing estimates bracket an extremely large range, even the lower figures indicate that these transfers are an important economic phenomenon and crucial to understanding patterns of savings and life-cycle behaviour. Furthermore, inheritances and *inter vivos* transfers can potentially have substantial impacts on the well-being of the recipient, his economic behaviour, and on broader measures of the distribution of income and measures of inequality.

Intentional Versus Accidental Bequests

The importance of bequests and their impact on macroeconomic measures such as saving rates and individual well-being depends to a great extent on the motivation driving the transfer. One school of thought argues that bequests are accidental, the result of an uncertain length of life. Individuals save to finance consumption during their retirement years and whatever wealth remains when they die is bequeathed to their heirs (Davies 1981). Because they do not know how many years of consumption they must finance and do not want to exhaust their resources prior to death, individuals will typically die with some amount of wealth. Hurd (1987) tests the data for consistency with an accidental-bequest motive. He argues that, if bequests were intentional, one would find that individuals who had a strong bequest motive would dissave at a slower rate than those with a weak bequest motive. As a proxy for the strength of a bequest motive, Hurd uses the presence of children. He finds no difference in rates of spend-down of assets for those with and those without children, and thus concludes that there is no operative bequest motive: observed bequests are the result of an uncertain date of death.

The uncertainty in this accidental-bequest scenario need not arise solely from uncertainty about the length of life, but could stem from a variety of sources: an individual might conserve assets to guard against expenses arising from a negative health shock, the need for long-term care, or uncertainty about returns on investment.

Additional corroborating evidence for the notion of accidental bequest comes from the failure of many individuals to specify a particular distribution of their estates. Although laws in the United States, as in much of the world, allow an individual to distribute his estate in any way he wishes through the use of a will, the use of wills to divide resources is far from universal. An individual who dies without a will is said to have died intestate. In these cases the assets of the deceased are distributed according to the laws specific to the area in which she resided. In the United States, laws differ by state but earmark a large fraction of the estate for a surviving spouse, followed by children, grandchildren and parents, with shares equally divided within kinship category. Although the reliance on succession laws to distribute assets suggests that the individual may not have thought about bequests and therefore does not have a bequest motive, it can also be argued that, if the succession laws mirror (or come close to) the distribution that the deceased would have chosen herself, a reasonable person might forgo the trouble and expense of writing a will and allow the state to divide her assets. Because wills, when they do exist, typically divide estates equally among children, as do succession laws, the failure to execute a will may indeed reflect a satisfaction with the default distribution.

The chief criticism of the notion of accidental bequests is that an individual who is concerned about uncertain future expenses could instead purchase insurance protecting against these expenditures. Insurance against outliving one's assets is available in the form of annuities which guarantee a stream of income for life and eliminate the possibility of dying with unspent wealth; instruments such as health insurance and long-term care insurance can protect against other types of unplanned expenditures. The accidental-bequest

motive thus requires that these insurance markets function imperfectly.

Indeed, the potential for annuities to eliminate the possibility of an accidental bequest has been used to test for a bequest motive. If all wealth is annuitized, one has nothing to leave as a bequest. If complete annuitization is not optimal and a bequest is desired, an individual can convert a portion of his annuity income into a bequest by purchasing a life-insurance policy. Thus, life insurance can be used to offset the effects of an annuity. 'Over-annuitization' may not be uncommon; the prevalence of mandatory old age pensions (either public or private) suggests that many workers may retain a substantial portion of their retirement resources in annuities, perhaps more than they would choose. Bernheim (1991) examines the relationship between annuitization, in the form of US Social Security benefits, and the holdings of life insurance and private pensions. He finds that, conditional on lifetime resources, those with a greater Social Security benefits hold more life insurance and somewhat smaller private pensions. This result suggests that these tools are used to de-annuitize wealth and support the notion of an operative bequest motive. Indeed, the extensive life-insurance holdings observed in the population provide prima facie evidence that individuals are sufficiently concerned about the well-being of their heirs that they are willing to reduce own consumption.

Another argument against the accidental-bequest motive comes from the growing literature on *inter vivos* transfers. The large number of *inter vivos* transfers observed in the data are unquestionably intended and suggest that bequests might likewise be intentional.

Motivation for Bequests

If individuals intentionally leave bequests, the next question is: why? What motivates an individual to forgo consumption in order to leave assets to his heirs? Several behavioural models have been offered to address this question, but the results of empirical tests remain inconclusive.

Perhaps the most obvious explanation for the existence of bequests is that donors are altruistic; they care about the well-being of their heirs. The standard specification of the altruism model (Barro 1974; Becker 1974) includes the heir's utility as an argument in the utility function of the donor. Formally, the utility of the donor (say, parent), U_p, is written as

$$U_p = U\left(C_p, U_k(C_k)\right)$$

where C_k is the consumption of the heir (say, child). (Note that this formalization is based on very specific assumptions and thus has implications that may differ from what one might more generally regard as altruistic behaviour in other contexts; Pollak 2003.) Consumption for p and k depend on the resources of each party prior to the bequest and on the size of the bequest. In this specific formulation the donor will make transfers until the marginal utilities are equalized across arguments of the utility function. Because the marginal utility of consumption is assumed to be decreasing, bequests will increase with the income of the donor but decline with increases in the income of the (potential) recipient. If there is more than one child, the parent will endeavour to equalize the marginal utility of consumption across children. Again, because marginal utility is decreasing in consumption, less well-off children will receive larger bequests. Thus, within a family, bequests will be compensatory and will serve to mitigate inequality.

Alternatively, transfers may be part of an exchange regime wherein the donor reimburses the recipient for specific services or behaviours. A parent compensating a child for providing home health care or simply for paying attention to the parent (Bernheim et al. 1985) would be an example of possible exchange-related transfers. In this case the donor's utility function has as its arguments her own consumption and the goods or services 'purchased' from the child. Formally,

$$U_p = U\left(C_p, S_k\right)$$

where S_k is a measure of services provided to the donor. The price of the services depends on the

price of the recipient's time, with services purchased from high-income individuals being more costly than those purchased from low-income individuals. As the price of the good or service increases, the quantity purchased declines. In this case, then, the parent will be less likely to purchases services from a high-income child and the *probability* of a transfer will decline with the income of the child. However, conditional on purchasing services, the relationship between the transfer and the income of the recipient is indeterminate: the total amount of the transfer, price multiplied by quantity, can either rise or fall with the income of the heir, depending on the relevant elasticities.

Several other models have been discussed in the literature but have received less attention. A 'paternalistic' model argues that parents care not just about the utility of their children but about their actual consumption bundles. In this case a parent might bequeath money to a child through a trust specifying that it be used for certain purposes, such as schooling, or available only at certain ages when the parent believes the child's preferences will more closely mirror her own.

A 'warm glow' model posits that donors receive utility from the act of giving itself and not from the impact the gift has on the utility of the recipient (Becker 1974; Behrman et al. 1982; Andreoni 1989). Such a model might be relevant in the decision to make charitable gifts, wherein the donor is unlikely to observe the increase in utility accruing to the beneficiary as a result of the donation, yet she derives satisfaction from making the gift.

A good deal of research has attempted to discern which of the models best represents observed behaviour. The models are typically written in a static one-period framework and in such a case testing the altruism model is straightforward. Simple tests of the relationship between the probability and amount of the transfer on the one hand and the income of the potential recipient on the other should reveal a negative relationship: that is, transfers should be compensatory. However, there is a stricter test of the altruism model based on the magnitude of the response to variations in the incomes of the donor and the recipient. Specifically, the model requires that, conditional on transfers being made, an increase of one dollar in the income of the donor, accompanied by a decrease of one dollar in the income of the recipient, must be met by an increase of one dollar in the amount of the transfer (Cox 1987). This test imposes a strict 'adding up' constraint on the estimated coefficients on the donor's and the recipient's income variables in a regression equation for the amount of a transfer (conditional on a positive amount). In contrast to this strict test of the altruism model, nearly any relationship between income and transfers is possible in an exchange regime. This ambiguity makes it difficult to discredit the exchange model. Not only can the relationship between the income of the recipient and the amount of the transfer go in either direction, but the components of the exchange need not be made coincidently, making it difficult to observe both sides of the transaction in data.

Observed Patterns

Although *inter vivos* transfers and bequests appear to be substitutes to some extent, the two forms of giving exhibit strikingly different patterns. *Inter vivos* transfers have nearly uniformly been found to be compensatory, with more going to the less well-off children. This negative relationship between the income of the recipient and the probability and amount of a transfer is consistent with the altruism model, but is also consistent with an exchange regime wherein the donor purchases more services from lower-income heirs. Where the strict test for altruism based on the relationship of the income derivatives (that is, the magnitude of the responsiveness of transfers to changes in the incomes of the donor and recipient) has been applied, however, it has failed decisively, with estimated responsiveness closer to zero than to the value of 1 predicted by the model (Altonji et al. 1997).

Perhaps the seminal article testing for the existence of an exchange motive is Bernheim et al. (1985). In that paper the authors hypothesize that parents hold bequeathable wealth and use the

possibility of disinheritance to elicit desired behaviour from their children. The study finds a positive correlation between parental bequeathable wealth and the amount of attention children pay to their parents. Recent work has questioned the empirical results (Perozek 1998) but the notion of a parent reimbursing a child for the provision of care or other behaviour has some appeal as does the idea of an altruistic parent using bequests to compensate a less well-off child.

Although economists often shy away from directly questioning individuals about their motives, one method of attempting to discern the motivation behind the division of bequests is to ask parents about their intentions. The National Longitudinal Surveys (NLS) included such questions, explicitly asking those respondents who reported that their wills provided for unequal division of their estates why they were allocating their assets in such a way. Light and McGarry (2003) examine this question and find that motives based on altruistic concerns and those based on some sort of exchange were of nearly equal importance.

Despite the predictions of the altruism and exchange models and the compensatory transfers observed for *inter vivos* giving, examinations of both actual bequests and existing wills find that equal division among children is the norm. Some of the first work in this arena found evidence that bequests were compensatory (Tomes 1981), but other work appeared to contradict this conclusion – for example, Menchik, (1980). More recent studies have found overwhelming evidence that estates are typically equally divided. Wilhelm (1996) uses a sample of US estate tax returns and finds that two-thirds of decedents with two or more children divided their estate exactly equally among the children and three-quarters used a division in which inheritances differed by no more than two per cent from the within-family average. Although Wilhelm's study is necessarily limited to decedents whose estates filed a tax return and who were therefore in the upper tail of the wealth distribution, similar results have been found for the general population. McGarry (1999) examines reports about existing wills for those who are still living and finds that more than 80 per cent of respondents report that their will divides their estate 'approximately equally' among their children.

This equal division is difficult to reconcile with either the altruism or the exchange model, both of which predict a correlation between the income of the recipient and the magnitude of the bequest. This empirical regularity has thus led several authors to propose alternative models of behaviour. Wilhelm (1996) and Bernheim and Severinov (2003) posit that unequal division is costly to parents in that they foresee that such a division could lead to unhappiness on the part of the children/intended heirs. If the difference between the utility obtained through an equal division and that obtained through an unequal allocation is greater than the utility cost (in terms of unhappy heirs) of unequal division, the parent will simply divide her estate equally among her children. McGarry (1999) provides an alternative model wherein the parent's uncertainty about the future incomes of her children lead her to resort to equal division, except in cases where large differences in the future incomes of children are expected.

Transfer Taxes

Bequest and inheritance taxes have an extremely long history, dating back thousands of years, and can arouse strong feelings. Historically these taxes have been imposed as a revenue-raising mechanism, often in times of war and as a means of diluting the concentration of wealth (see Johnson and Eller 2001, for a discussion of the history of estate taxes). In the United States the modern estate tax was implemented in 1916 to help finance the war effort (Joulfaian 1998). Although the fraction of estates owing a tax has varied over time, it has typically been small, hovering around two per cent. The future of the estate tax in the United States is uncertain. Under current law the tax is being gradually phased out, to be completely eliminated in 2010 but reinstated in 2011.

The form transfer taxes take varies across countries. In the United States taxes are levied on bequests and gifts, with the tax rate applied, broadly speaking, to the total value of the transfer regardless of how it is divided, although various aspects of the tax code lead to important differences in the cost of the two types of transfers (Jolfaian 1998). Transfers to spouses and charitable organizations are exempt from tax. Not all governments have used the same approach as that employed in the United States. Many countries instead have enacted inheritance taxes wherein the tax owed depends on the amount received by an individual heir and often on the legal relationship between the decedent and the heir. These different tax bases, and the particular rules governing the evaluation of the transfers, produce varying incentives for the distribution of estates and gifts. However, the specific behavioural responses also depend on the motivation behind transfers. Although uncertainty exists about this motivation and thus about some of the predicted effects, numerous studies have shown that transfers (both *inter vivos* transfers and bequests) are responsive to tax rates (for example, Bernheim et al. 2004; Joulfaian 2005), and there exist sizable segments of the financial and legal industries devoted to estate planning (that is, reducing estate and gift tax liabilities; see Cooper 1979, for a fascinating look into methods for tax avoidance).

Despite these findings, and the public sentiment against the tax, several empirical studies have shown that some of the simplest tax avoidance schemes often go unexploited. For instance, in the United States *inter vivos* gifts of less than a given amount in any specific year are exempt from gift tax and can thus be used to 'spend down' a potentially taxable estate. Despite this opportunity, at least half of those whose estates appear likely to incur estate tax do not make such transfers (Poterba 1998). Numerous hypotheses have been proposed to explain the failure to make 'early bequests', including the fear that the resources will be needed at some future date, the utility obtained from holding wealth, or the mistrust of children and their ability to manage the funds. None of these explanations appears sufficient to explain this behaviour fully.

Charitable Giving

Bequests are made not just to individuals but often to charitable institutions. In the United States the tax-exempt status granted to charitable bequests reduces the price of donations to these sorts of organization relative to the price of giving to other non-spousal heirs. Numerous studies have found that the lower tax price substantially increases charitable donations. A recent study by the United States Congressional Budget Office estimates that total charitable bequests would decline by 6 to 12 per cent in the absence of the estate tax, an amount similar to the range of estimates produced by various studies over the years (U.S. Congressional Budget Office 2004).

Behaviour of Heirs

Much of the research assessing the importance of bequests in affecting economic behaviours has focused on the behaviour of the donor, the motivation for the transfer, the response to estate and gift taxes, and the effect of desired bequests on savings behaviour. Less frequently examined is the economic response of the heirs.

From the point of view of the heir, inheritances increase financial resources and would therefore be expected to increase the consumption of normal goods, including leisure. The potential reduction in the labour supply of heirs is often cited as a motivation for a transfer tax (for example, Carnegie 1962). Despite the theoretical implications, the several studies examining this issue have found relatively small negative effects on earnings of workers (for example, Joulfaian and Wilhelm 1994). The small responses are not surprising in that the distribution of bequests is extremely skewed, so that for most heirs the amounts received are small relative to their lifetime incomes. Furthermore, as recent work in labour economics has

demonstrated, it may be difficult to adjust hours of work on the margin. Indeed, evidence of a negative labour market effect is somewhat larger with respect to whether one participates in the labour force at all (Holtz-Eakin et al. 1993), suggesting that the length of the working life may be a dimension along which adjustments are more easily made.

Finally, if bequests are fully anticipated, their effect on desired hours of work ought to have been already incorporated into behaviour, and there should be no discernible response at the time the heir receives the inheritance. Thus, only unanticipated bequests or bequests received by previously liquidity-constrained heirs would be expected to spark a change in behaviour. As evidence of the potential importance of liquidity constraints, Holtz-Eakin et al. (1993) find that inheritances can spur entrepreneurial activity.

Conclusion
