$$z_t, u_t, k_t \geq 0 \text{ for } t = 1, \ldots, T$$

Medlock and Soligo (2002) indicate that the income elasticity of passenger vehicle demand is decreasing as the real GDP per capita increases, no matter in the long run or in the short run. For example, with 1988 purchasing power parity dollar, if the real GDP per capita is $500, the short-run elasticity is 0.74 and the long-run elasticity is 3.61; if the real GDP per capita is $20,000, the short-run and the long-run elasticity are 0.02 and 0.09, respectively.

Energy Supply

OPEC

The Organization of the Petroleum Exporting Countries (OPEC) comprises countries that have organized for the purpose of negotiating with oil companies on matters of petroleum production, prices, and future concession rights. Founded on 14 September 1960 at a Baghdad conference, OPEC originally consisted of only five countries – Iran, Iraq, Kuwait, Saudi Arabia and Venezuela – but has since expanded to include several others: Algeria, Indonesia, Libya, Nigeria, Qatar and United Arab Emirates. The members of OPEC, which constitute a cartel, agree on the quantity and the prices of the oil exported. OPEC seeks to regulate oil production, and thereby manage oil prices, primarily by setting quotas for its members. Member countries hold about 75 per cent of the world's oil reserves, and supply 40 per cent of the world's oil. Loury (1990) is an excellent clarification; it studies a dynamic, quantity-setting duopoly game. The author considers a model of competition between two independent firms, A and B, facing indivisibility in production, with given limitations on their cumulative capacities to produce. At date t the flow rates of production of firms A and B are denoted by q_t^a and q_t^b respectively.

The demand side of the market is passively modelled; buyers do not behave strategically. There is an inverse demand function, $P(\cdot)$, which is time invariant and dependent only on the total rate of flow of output of the two firms. Define the discount factor δ^t, a dollar received on date t is worth dollars at date zero. Then their respective payoffs are V_A and V_B where:

$$V_A = \beta \sum_t \delta^t \left[q_t^a p(Q_t)\right]; \text{and} \, V_B = \beta \sum_t \delta^t \left[q_t^b p(Q_t)\right]$$

for β, the lump sum equivalent of the flow of one dollar. It is shown that the ability to precommit can be disadvantageous. Loury (1990) also formalizes the intuition that, when indivisibilities are important, tacit coordination of plans so as to avoid destructive competition is facilitated by establishing a convention of 'taking turns', that is, a self-enforcing norm of mutual, alternate forbearance. Since worldwide oil sales are denominated in US dollars, changes in the value of the dollar against other world currencies affect OPEC's decisions on how much oil to produce. After the introduction of the euro, Iraq unilaterally decided it wanted to be paid for its oil in euros instead of US dollars.

OPEC decisions have a strong influence on international oil prices. A good example is the 1973 energy crisis, in which OPEC refused to ship oil to Western countries that had supported Israel in its conflict with Egypt, the Yom Kippur War. This refusal caused a fourfold increase in oil prices, which lasted five months, starting on 17 October 1973 and ending on 18 March 1974. OPEC nations then agreed, on 7 January 1975, to raise crude oil prices by ten per cent. The high and rising price of oil burdens industrial oil-importing countries in two ways. First, it renders the standard of living lower than otherwise. Second, it affects the economy in ways that are difficult for policymakers to manage: on the one hand, the rising oil price spurs general inflation; on the other hand, it depresses domestic demand and employment. Unlike many other cartels, OPEC has been successful at increasing the price of oil for extended periods. Much of OPEC's success can be attributed to Saudi Arabia's flexibility. It has tolerated cheating on the part of other cartel members, and cut its own production to compensate for other members exceeding their production quotas. This actually gives them good leverage because, with most members at full production, Saudi Arabia is the only member with spare capacity and the ability to increase supply, if needed. The policy has been successful. However, OPEC's ability to raise prices does have some limits. An increase in oil price decreases consumption, and could cause a net decrease in revenue. Furthermore, an extended rise in price could encourage systematic behaviour change, such as alternative energy utilization, or increased conservation. As of August 2004, OPEC has been communicating that its members have little excess pumping capacity, indicating that the cartel is losing influence over crude oil prices.

The six major non-OPEC oil-producing nations are Norway, Russia, Canada, Mexico, the United States and Oman. Russian production increases dominated non- OPEC production growth from 2000 onward and was responsible for most of the non-OPEC increases since the turn of the century. In 2001, a weakening US economy and increases in non-OPEC production put downward pressure on prices.

In response OPEC once again entered into a series of reductions in member quotas, cutting production by 3.5 million barrels per day by 1 September 2001. In the absence of the September 11, 2001 terrorist attack this would have been sufficient to moderate or even reverse the trend.

In the wake of that attack the crude oil price plummeted. Under normal circumstances a drop in price of this magnitude would have resulted in another round of quota reductions, but, given the political climate, OPEC delayed additional cuts until January 2002, when it reduced its quota by 1.5 million barrels per day and was joined by several non-OPEC producers, including Russia, which promised combined daily production cuts of an additional 462,500 barrels. This had the

desired effect, with oil prices moving into the $25 per barrel range by March 2002. By mid-year the non-OPEC members were restoring their production cuts, but prices continued to rise and US inventories reached a 20-year low later in the year. By year's end oversupply was not a problem. Problems in Venezuela led to a strike at Petroleos de Venezuela (PDVSA) causing Venezuelan production to plummet. In the wake of the strike Venezuela was never able to restore capacity to its previous levels. On 19 March 2003, just as some Venezuelan production was beginning to return, military action began in Iraq. Meanwhile, inventories remained low in the United States and other OECD countries. With an improving economy US demand was increasing, and Asian demand for crude oil was growing at a rapid pace. The loss of production capacity in Iraq and Venezuela, combined with increased production to meet growing international demand, led to the erosion of excess oil production capacity. During much of 2004 and 2005 the spare capacity to produce oil has been less than one million barrels per day. A million barrels per day is not enough spare capacity to cover an interruption of supply from almost any OPEC producer. In a world that consumes over 80 million barrels of petroleum products per day, that adds a significant risk premium to crude oil price and is largely responsible for prices in excess of $40 per barrel. For further information, see Energy Information Administration (EIA).

Future Energy Supply

Undoubtedly, depletable resource use cannot dominate forever. Therefore, a future transition from depletable resources, particularly from fossil fuels, is inevitable.

However, which renewable energy sources will dominate future consumption is unclear. And there is great uncertainty about the timing of a shift to renewable energy resources. Although this is a formidable question, Wiser et al. (2004) introduce green pricing programmes, which represent one way whereby consumers can voluntarily support renewable energy. Their analysis yields several interesting results. Programme duration affects customer response. The longer a programme has been operating, the more likely it is that its message has spread and the higher the probability of strong programme success. Initial customer participants in green pricing programmes may not be highly sensitive to cost, and may be willing to purchase higher quantities of renewable energy, which makes the case for utilities focusing on maximizing renewable energy sales, not customer participation rates. Price premiums and minimum monthly costs are not the primary determinants of programme success. Price may become a more important determinant as green pricing programmes expand beyond the early innovator customers. And smaller utilities appear to have a greater likelihood of achieving success.

The prospect of producing clean, sustainable power in substantial quantities from renewable energy sources is arousing renewed interest worldwide. Hydroelectricity is the only renewable energy source today that makes a large contribution to world energy production. Its long-term technical potential is believed to be 9 to 12 times current production, but increasingly environmental concerns block new dams. The large areas affected may have a negative environmental impact. Hydroelectricity dams, like the Aswan Dam, have adverse consequences both upstream and downstream.

Wind power is one of the most cost-competitive renewable sources today. Its long-term technical potential is believed to be five times current global energy consumption. But this requires 12.7 per cent of all land area and the facilities have to be built at certain height. Geothermal power and tidal power are the only renewable sources not dependent on the sun, but are today limited to special locations. Most renewable sources are diffuse and require large land areas and great quantities of construction material for significant energy production. There is some doubt that they can be built rapidly enough to replace fossil fuels. The large and sometimes remote areas may also increase energy loss and cost from distribution. On the other hand, some forms allow small-scale production and may be

placed very close to or directly at consumer households, businesses, and industries. We may forecast the future coexistence of multi-renewable energy sources. Boyle (1996) provides a comprehensive overview of the principal renewable energy sources: solar thermal, biomass, tidal, wave, photovoltaic, hydro, wind and geothermal.

Forecasts of the Energy Markets

According to Energy Information Administration (EIA 2005b), based on its expectations for world energy prices, world energy consumption is projected to increase by 57 per cent from 2002 to 2025. World oil use is expected to grow from 78 million barrels per day in 2002 to 103 million barrels per day in 2015 and 119 million barrels per day in 2025. The projected increment in worldwide oil use would require an increment in world oil production capacity of 42 million barrels per day above 2002 levels.

Members of OPEC are expected to be the major suppliers of the increased production that will be required to meet demand, accounting for 60 per cent of the projected increase in world capacity. In addition, non-OPEC suppliers are expected to add nearly 17 million barrels per day of oil production capacity between 2002 and 2025. Substantial increments in new non-OPEC supply are expected to come from the Caspian Basin, Western Africa, and Central and South America.

Natural gas is projected to be the fastest-growing component of world primary energy consumption. Consumption of natural gas worldwide increases in the forecast by an average of 2.3 per cent annually from 2002 to 2025, compared with projected annual growth rates of 1.9 per cent for oil consumption and 2.0 per cent for coal consumption. From 2002 to 2025, consumption of natural gas is projected to increase by 69 per cent, and its share of total energy consumption is projected to grow from 23 to 25 per cent.

Natural gas is seen as a desirable alternative to electricity generation in many parts of the world, given its relatively efficiency in comparison with other energy sources, as well as the fact that it burns more cleanly than either coal or oil and thus is an attractive alternative for countries pursuing reductions in greenhouse gas emission.

World coal consumption is projected to increase at an average rate of 2.5 per cent per year. From 2015 to 2025, the projected rate of increase in world coal consumption slows to 1.3 per cent annually. Coal is expected to maintain its importance as an energy source in both the electric power and industrial sectors.

Hydroelectricity and other renewable energy sources are expected to maintain their 8 per cent share of total energy use worldwide throughout the projection period. Much of the projected growth in renewable electricity generation is expected to result from the completion of large hydroelectric facilities in emerging economies, particularly in Asia.

Energy Policies

The study of depletable resource economics began with articles by H. Hotelling (1931), which examined economically intertemporal optimal extraction from a perfectly known stock of the resource, with perfectly predictable future prices of the extracted commodity. Sweeney (1977) and Stiglitz (1976) both clarified the Hotelling rule in the presence of monopoly, and Gilbert and Richard (1978) and Salant (1976) extended this to the case of a dominant producer with a competitive fringe and several dominant producers, analogous to the case of OPEC. Pindyck (1982) and Kolstad (1994) extended the model to several imperfectly substitutable exhaustible resources.

Energy security refers to loss of economic welfare that may occur as a result of a change in the price of availability of energy. In the years following the 1973 oil price rise, US energy policy could be characterized as generally suspicious of the market. Supply augmentation was a major strategy pursued by the US government in addressing the ‘energy crisis’. The security dimensions of energy supply have always been viewed as appropriate concerns of the government. One could argue that the Gulf War in the early 1990s was

simply a form of energy policy, protecting Western oil supplies originating in the Middle East. Countries other than the United States (such as Japan and China) have tried to diversify their sources of energy to reduce the risk of disruption. Security was also viewed as threatened by sudden fluctuations in the price of oil, hence the establishment in the United States of the Strategic Petroleum Reserve (SPR): petroleum.

Stocks are maintained by the federal government for use during periods of major supply interruption. The idea is that, if the price of oil were to rise rapidly due to disruption in supply, then the SPR could be called upon to provide supplies, thus reducing the price shock.

Nuclear power was declared dead in the United States because it is too expensive and unacceptably risky. Around the world, nuclear plant ended up achieving less than ten per cent of the new capacity and one per cent of the new orders (all from countries with centrally planned energy systems) forecast in the early 1980. The industry has suffered the greatest collapse of any enterprise in industrial history. Scientists still have not developed reliable ways to handle nuclear wastes and decommissioned plants, which remain dangerously radioactive for far longer than societies last or geological foresight extends.

Strong economic growths across the globe and new global demands for more energy have meant the end of sustained surplus capacity in hydrocarbon fuels and the beginning of capacity limitations. In fact, the world is currently precariously close to utilizing all of its available oil-production capacity, raising the chances of an oil-supply crisis with more substantial consequences than seen since the early 1970. These limits mean that the United States can no longer assume that oil-producing states will provide more oil. Nor is it strategically and politically desirable for the United States to remedy its present tenuous situation by simply increasing its dependence on a few foreign sources. As a result, expanding demand for energy will change US policy towards the Middle East, Russia and China. A recent example is that, in 2005, the state-owned Chinese company CNOOC eventually abandoned its bid for Unocal due to strong political opposition in the United States.

Effects of Energy Demand

Energy and Macroeconomics

In fact, almost every recession since the Second World War in the United States, as well as many other energy-importing nations, has been preceded by a spike in the price of energy (Hamilton 1983; Ferderer 1996; Mork et al. 1994).

The oil price movement affects certain sectors: oil-dependent manufacturing such as paper and packaging, consumer-related sectors such as autos, refiners' margins, the energy-intensive utility sector, and of course exploration companies and the big oil majors themselves.

Energy, Economy and Environment

Many important environment damages stem from the production, conversion, and consumption of energy. The costs of these environmental damages generally are not incorporated into prices for energy commodities and resources; this omission leads to overuse of energy. It has been shown that estimates of damage costs resulting from combustion of fossil fuels, if internalized into the price of the resulting output of electricity, could clearly lead to a number of renewable technologies being financially competitive with generation from coal plants. Environmental impacts currently receiving most attention are associated with the release of greenhouse gases in the atmosphere, primarily carbon dioxide, from the combustion of fossil fuels. During combustion, carbon combines with oxygen to produce carbon dioxide, the primary greenhouse gas. Carbon dioxide accumulates in the atmosphere and is expected to result in significant detrimental impacts on the world's climate, including global warming, rises in the ocean levels, increased intensity of tropical storms, and losses in biodiversity. Concern about this issue is common to energy economics, environmental economics, and ecological economics. Cropper and Oates (1992) suggest measuring benefits and costs with a review of cases where benefit–cost analyses have actually been used in the setting of environmental standards. Owen (2004) suggests that penalizing high pollutant-emitting technologies not only creates incentives

for 'new' technologies but also encourages the adoption of energy-efficiency measures with existing technologies and consequently lower pollutants per unit of output.

World carbon dioxide emissions are expected to increase by 1.9 per cent annually between 2001 and 2025. Much of this increase is expected to occur in developing countries. The United States produces about 25 per cent of global carbon dioxide emissions from burning fossil fuels, primarily because of it has the largest economy in the world and meets 85 per cent of its energy needs through burning fossil fuels. The United States is projected to lower its carbon intensity by 25 per cent from 2001 to 2025. There are numerous proposals aimed at reducing the carbon dioxide emissions, of which the Kyoto Protocol is a well-known and influential one. During 1–11 December 1997, more than 160 nations met in Kyoto, Japan, to negotiate binding limitations on greenhouse gases for the developed nations, pursuant to the objectives of the Framework Convention on Climate Change of 1992. The outcome of the meeting was the Kyoto Protocol, in which the developed nations agreed to limit their greenhouse gas emissions relative to the levels emitted in 1990. The United States agreed to reduce emissions from 1990 levels by seven per cent during the period 2008 to 2012.

Sickles and Jeon (2004) evaluate the role that undesirable outputs of the economy, such as carbon dioxide and other greenhouse gases, play on the frontier production process. This paper also explores implications for growth of total factor productivity in the OECD and Asian economies.

Natural disasters shock the energy market, too. According to the Minerals Management Service (2005), Gulf of Mexico daily oil production was reduced by 89 per cent as a result of Hurricane Katrina in 2005. The MMS also reports that 72 per cent of daily Gulf of Mexico natural gas production was shut in. In 2004, Hurricane Ivan caused lasting damage to the energy infrastructure in the Gulf of Mexico and interrupted oil supplies to the United States. US Secretary of Energy Spencer Abraham agreed to release 1.7 million barrels of oil in the form of a loan from the Strategic Petroleum Reserve.

A Concluding Comment

The world runs on energy, primarily energy generated from coal and petroleum. The current war against terrorism and the tensions in the Middle East have raised new questions about the reliability of America's oil supply from that region. Concerns about global climate change have also focused increased attention on the search for cleaner fuels and energy-generating methods. Russia's determination to become a major petroleum supplier, OPEC's periodic moves to restrict oil production and the rising energy needs in China and other developing countries are all important issues forming the future world energy market.

I would like to thank Robert Thomure, Rice University, for his research assistance.

Energy Price Shocks

Lutz Kilian

Abstract

Oil price shocks have been a recurring phenomenon since the 1970s. This article reviews alternative explanations of oil price shocks. It puts the evolution of the US price of crude oil into historical perspective and compares it with that of the price of coal and natural gas.

Keywords

Oil; Coal; Natural gas; History; Shocks; Price determinants

Energy is necessary to sustain a country's real economic activity and to ensure the physical survival of its population, except under the most favorable climatic conditions. The main sources of energy to this day have been fossil fuels, such as coal, crude oil and natural gas. Electricity in turn is produced mainly from power plants burning coal or natural gas (or, in rare cases, fuel oil), augmented by nuclear power and to a lesser extent by hydroelectric, solar and wind power.

The prices of oil, coal and natural gas thus are of immediate concern to policymakers, firms and consumers. Unexpected changes in the price of energy have the potential to wreak havoc on an economy. Unanticipated increases in energy prices may cause far-reaching disruptions of economic plans, as consumers and firms are forced to economise on the use of energy, to curtail other expenditures to pay for higher energy costs and to

replace energy-inefficient equipment with energy-saving equipment. Such energy price shocks and their effects on the economy are the subject of a large literature in economics.

Much of this literature has focused on the price of crude oil (see, for example, Barsky and Kilian (2002), Kilian (2008a, 2014) and Hamilton (1983, 2003, 2008)). Crude oil stands out among energy commodities because of its importance for the transportation sector. Although crude oil is not consumed directly and is not used as a factor of production outside of the refining industry, oil products such as petrol/ gasoline, diesel, heating oil or jet fuel are highly visible in everyday life. Their prices affect, for example, the cost of commuting to work, the cost of shipping goods, the cost of air travel and in some areas the cost of home heating.

Until the early 1970s, the global market for crude oil looked much different from typical industrial commodity markets, with the USA able to produce most of the oil it consumed and regulating the price of domestically produced crude oil, while other industrialised countries, such as Japan or Germany, were heavily dependent on crude oil imports. This situation changed when even the USA became heavily dependent on oil imports in the early 1970s, following an increase in domestic oil demand. Initially the required additional oil imports came primarily from the Middle East, but later increasingly from oil producers in other regions as well. As global oil trade expanded and national oil market structures were gradually broken up, a global market for crude oil emerged. From 1974 until 2010, the price of crude oil has been determined in this global market place. As a result, adjusting for transportation costs and the inevitable differences in the quality of crude oil produced in different regions of the world, the price of crude has been largely the same worldwide. In recent years, as the production of unconventional crude oil surged in the USA and Canada, the global market for crude oil appears to have fragmented, with US oil prices deviating from world prices because of bottlenecks in transporting crude oil and because of capacity constraints in refining (see Kilian 2015).

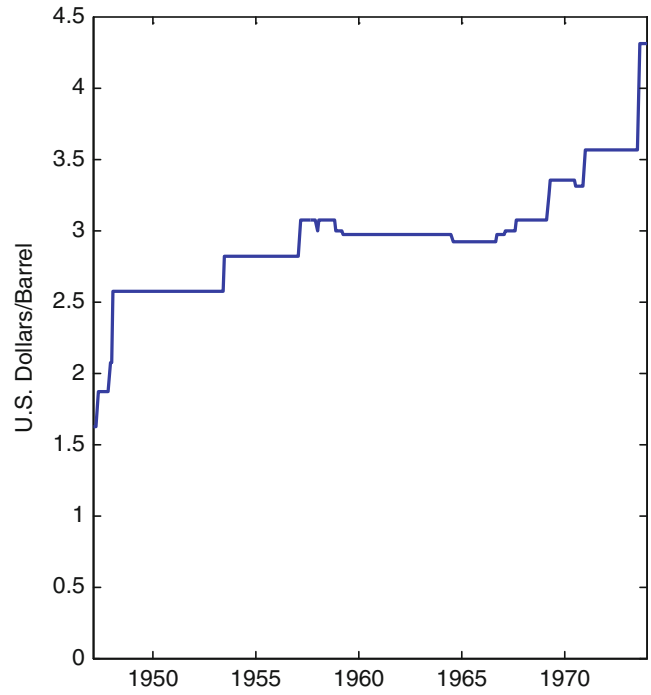
Long before the emergence of a global market for crude oil in the 1970s, there was already a well-developed global market for coal. Well into the 20th century, coal was as important for the US transportation sector as oil is today. It was the primary fuel used in shipping until the 1920s and in railroading until the 1950s. It also served as an important source of home heating until the 1950s. Coal continues to play an important role today in producing electricity and heat as well as in the manufacturing of chemicals and metals.

In producing electricity and in manufacturing coal competes with natural gas. The market for natural gas, in contrast to that of coal or crude oil, has largely remained regional to this day. Natural gas is primarily transported by pipelines. Although natural gas may be cooled down and liquefied, allowing it to be shipped as liquefied natural gas (LNG) to any port in the world, both the cost of LNG shipping and the infrastructure required to load and unload LNG are expensive, which has prevented the integration of regional natural gas markets and the emergence of a global price to date.

Thus, in studying energy prices over longer time periods one inevitably has to take the perspective of one country. This article focuses on the USA because of its long history in producing coal, oil and natural gas and the availability of long continuous price series for these markets. The objective is to document the history of energy price shocks and to examine whether price shocks in oil markets are different from those in other energy markets such as coal, which in the past were as important as crude oil is today.

The Traditional Interpretation of Oil Price Shocks

It is useful to begin with a review of the oil price data in the post-Second World War period. Sometimes oil price shocks are associated with sudden increases in the price of oil. This idea can be traced back to the work of Hamilton (1983) who studied the evolution of the nominal price of West Texas Intermediate (WTI) crude oil in the USA between 1948 and 1972. Figure 1 illustrates that

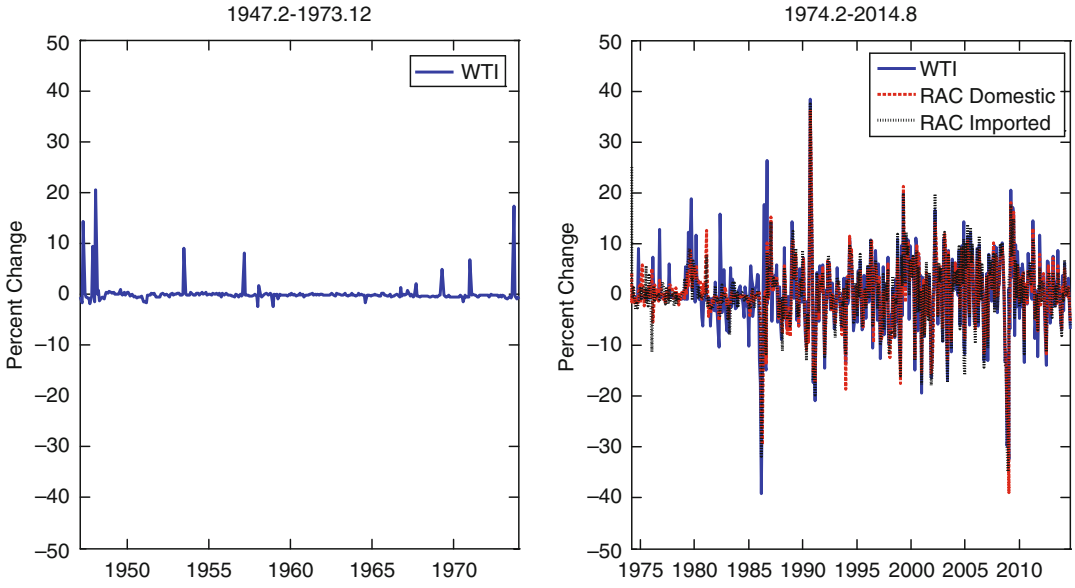


Energy Price Shocks, Fig. 1 Evolution of the monthly WTI price of crude oil during 1947.1–1973.12 (the WTI data are from the US Energy Information Administration (EIA))

this price series differs from most other commodity prices in that it often remains unchanged for extended periods, followed by discrete adjustments. When expressed in growth rates and adjusted for inflation, as shown in the left panel of Fig. 2, this step-function pattern implies unpredictable spikes in the growth rate that represent shocks to the price of oil.

This pattern reflects the fact that the US price of crude oil during this period was regulated by state-level agencies such as the Texas Railroad Commission, as discussed in Hamilton (1983). Under normal circumstances the regulator was able to keep the price of oil unchanged for extended periods. At irregular intervals, however, major oil price adjustments took place. Hamilton documents that these adjustments were associated with oil supply disruptions in the Middle East that were unforeseen by the regulator and that justified ex-post adjustments of the regulated price of oil. These events could be used either to implement long overdue adjustments to the price of oil reflecting domestic inflation and/or unexpectedly high domestic demand for oil, or to accommodate additional demand for US oil from abroad. In short, Hamilton's review of the evidence suggested that the timing of the oil price shocks under the Texas Railroad Commission regime was associated with oil supply shocks in the Middle East driven by political events unrelated to the state of the US economy, allowing us to treat them as exogenous with respect to the US economy.

This regime came to an end in the early 1970s, when demand for oil grew much faster than US oil production and the US economy became heavily dependent on oil imports. Much of the additional oil was imported from the Middle East. The fact that state-level agencies were unable to regulate the price of imported crude oil spelled the end of the Texas Railroad Commission regime, even though the last vestiges of this system survived until the early 1980s. After 1974, the market for crude oil, for all intents and purposes, became a global market with the price of oil being ultimately determined by the forces of demand and supply, much as in other global commodity markets. This structural shift in the crude oil market is reflected in a structural break in the evolution of the growth rate of the real price. Figure 2 shows a



Energy Price Shocks, Fig. 2 Evolution of the growth rate of the monthly real price of oil (the data are from the US EIA and Federal Reserve Economic Data (FRED). RAC denotes the US refiners' acquisition cost)

dramatic increase in the volatility of three alternative measures of the growth rate of the price of oil, but especially of the US refiners' acquisition cost for crude oil imports, which may be viewed as a proxy for the global price of crude oil. Rather than exhibiting occasional spikes, the growth rate of the real price of oil as of 1974 begins to look like that of most other commodity prices.

The Modern Interpretation of Oil Price Shocks

Initially, it was thought that this structural change was inconsequential and that at least the major fluctuations in the real price of crude oil after 1973 could be explained by exogenous oil supply disruptions abroad, much like those in the 1950s and 1960s. Kilian (2008b) demonstrated that this is not the case. Examples of political events in oil-producing countries thought to have triggered oil supply disruptions include the 1973 Yom Kippur War and the subsequent Arab oil embargo, the Iranian Revolution of 1978–79, the invasion of Kuwait in 1990, the Venezuelan unrest of late 2002 and the Iraq War of early 2003, as well as the Libyan Revolution of 2011. The challenge for the traditional view of oil price shocks has been that the predictive power of these supply disruptions for the price of oil is quite modest. Oil supply disruptions explain at most a quarter of the increase of the price of oil in 1973–74, for example, and with the exception of the 1990 spike in the level of oil price have not had a major impact on the evolution of the real price of oil since 1974. The major oil price fluctuations instead appear to be driven by shifts in the demand for oil, as has been shown in a series of studies, including Baumeister and Peersman (2013), Kilian (2009), Kilian and Hicks (2013), and Kilian and Murphy (2012, 2014).

By far the most important determinant of the real price of oil is shifts in the flow demand for oil associated with fluctuations in the global business cycle. Flow demand refers to demand for raw materials to be consumed right away in the process of producing more domestic goods rather than being stored for future use. As China's industrial growth accelerates unexpectedly, for example, the flow demand for industrial raw materials, including crude oil, increases. As the demand curve shifts to the right along the upward-sloping

supply curve, the real price of crude oil (and of other industrial raw materials) increases. Put differently, the real price of oil is endogenous with respect to global macroeconomic conditions. This phenomenon attracted much attention after 2003, but is by no means new. Shifts in the flow demand for oil played a major role during almost all major surges in the real price of oil including the 1973–74 and 1978–80 episodes.

Another potentially important determinant of the real price of oil is shifts in the demand for oil stocks, reflecting forward-looking behaviour by oil market participants. Such demand shocks are also known as speculative demand shocks. They arise, for example, when market participants expect the real price of oil to go up in the future, reflecting expectations of a shortfall of future supply relative to future demand. In this case there is an incentive to buy crude oil now and to store it in anticipation of rising oil prices. The resulting shift in the current demand for oil stocks increases the current real price of oil, as the demand curve shifts to the right along the supply curve.

Such forward-looking behaviour is crucial for understanding oil markets. It has been shown that exogenous political events in the Middle East matter for the real price of oil not so much because of the actual disruptions of the flow of crude oil they cause, but because of the expectations of future supply disruptions that they may create. Likewise, the anticipation of a global economic recovery or economic slowdown will affect expectations of future oil prices, as will any number of other events and developments that are not commonly included in economic models. Even an increase in uncertainty, all else equal, may cause a shift in the demand for oil stocks (see Pindyck 2004; Alquist and Kilian 2010). As Kilian and Murphy (2014) and Kilian and Lee (2014) show, speculative demand shocks driven by expectations of future oil price changes help explain, for example, the surge in the real price of oil in 1979 (following the Iranian Revolution), the collapse of the real price of oil in 1986 (following the collapse of OPEC) and the spike in the real price of oil in 1990 (following the invasion of Kuwait), but they played no important role during the 2003–08 surge in the real price of oil.

Finally, there are a myriad additional idiosyncratic shocks to the demand for oil, ranging from politically motivated changes to the Strategic Petroleum Reserve before elections to shifts in the demand for oil as a result of hurricanes in the Gulf of Mexico shutting down US refineries. These idiosyncratic demand shocks, however, do not appear to be capable of explaining sustained changes in the real price of oil.

Once it is recognised that not all oil price shocks are the same, it becomes immediately clear that one would expect the evolution of the US economy in the wake of an oil price shock to differ depending on the composition of the oil demand and oil supply shocks underlying this price shock. If we ignore this insight, we may find that the statistical relationship between the real price of oil and the US economy appears unstable over time, even when the underlying structural relationship is stable. This point has been illustrated, for example, by Kilian and Park (2009) in the context of US stock markets.

One can still ask how the US economy responds on average to an oil price shock, of course, but there are two important caveats in interpreting the answer. First, these responses cannot be interpreted as the causal effects of the oil price shock, because nothing ensures that the price shock under consideration occurs holding everything else constant. For example, an unexpected increase in the real price of oil driven by increased flow demand would also be associated with increases in the real prices of other industrial raw materials, violating the *ceteris paribus* assumption. Thus the response we observe in the economy is the response to increases in the prices of both oil and industrial raw materials, rather than the price of oil alone.

Second, the average response to an oil price shock can be misleading when it comes to interpreting specific episodes of rising oil prices. For example, traditional models of oil price shocks implied that the US economy should have gone into recession in 2005–06, following the surge in the price of oil that began in 2003. Such a recession obviously never occurred, because the preceding increase in oil prices was caused by an unexpectedly booming global

economy, not by oil supply disruptions or increased speculative demand. Unlike in the traditional view of oil price shocks as being driven entirely by exogenous oil supply disruptions, in the modern view, rising oil prices may very well be compatible with an expanding economy and a rising stock market, at least for some time.

A final point to bear in mind is that the traditional question of how an oil price shock affects the economy becomes inherently ill-posed once we recognise that the state of the economy in turn affects the price of oil. A more useful way of posing this question would be to ask how an exogenous shift in the demand for oil in some part of the world, for example, affects the real price of all commodities including crude oil, the US economy and the economy in rest of the world. Answering the latter question requires a global structural model of the economy and of commodity markets. An example of this type of analysis can be found in Bodenstein et al. (2012). Related work also includes Nakov and Pescatori (2010).

Other Explanations of Oil Price Shocks

Especially near the peak of the real price of oil in 2008, a popular view among some pundits has been that the real price of oil is no longer determined by the laws of demand and supply, but by the actions of financial traders in oil futures markets (sometimes informally referred to as financial speculators). This view reflects several misunderstandings. One is that it is logically impossible for the price of crude oil to be determined by anything else but demand or supply. The only question is what determines the demand for and supply of crude oil. In fact, economic theory suggests that prices in the physical market for crude oil and in the oil futures market are jointly and simultaneously determined by the same underlying shocks rather than changes in one price being caused by exogenous changes in the other. Another misunderstanding is that the actions of financial speculators in the oil futures market are believed to be exogenous with respect to developments in the physical market for oil. Not only is it unclear what exactly a financial speculator is, but the claim of exogenous financial speculation moving oil markets is difficult to sustain in practice. Proponents of this view have not been able to provide convincing empirical evidence in support of the financial speculation hypothesis. For a review of this debate the reader is referred to Fattouh et al. (2013).

Upon closer examination, it becomes clear that the real concern articulated by these pundits is not about a failure of the laws of demand and supply at all, but about the perception that economic fundamentals, as measured by shocks to the flow of oil being produced and shocks to the flow demand for oil, are not capable of explaining the surge in the real price of oil, especially in 2007–08. This is a misperception. Formal empirical models show that economic fundamentals do an excellent job at explaining the surge in the price of oil between 2003 and mid-2008, as well as the collapse and recovery of the real price of oil thereafter (see, for example, Kilian and Murphy (2014) and Kilian and Lee (2014)).

The debate about financial speculation as a driver of oil prices illustrates a tendency among pundits to reduce complicated economic relationships in oil markets to simple formulaic explanations. The notion of nefarious speculators in oil markets is one example of trying to make sense of the evolution of the real price of oil without engaging with economic models. Another example is the tendency to attribute oil price increases to actions of the so-called OPEC cartel. OPEC is the Organization of Petroleum Exporting Countries. It includes oil producers in the Middle East as well as some oil producers in other parts of the world. The presumption is that there is a concerted effort by OPEC oil producers to prop up oil prices either directly or by withholding oil supplies from the market. Until ten years ago, major oil price increases were routinely attributed to the machinations of this alleged cartel rather than to the underlying forces of demand and supply. Only with the rise of the debate about financial speculation does interest among pundits in OPEC seem to have waned.

The evidence in support of the cartel explanation has always been thin (e.g. Smith 2005;

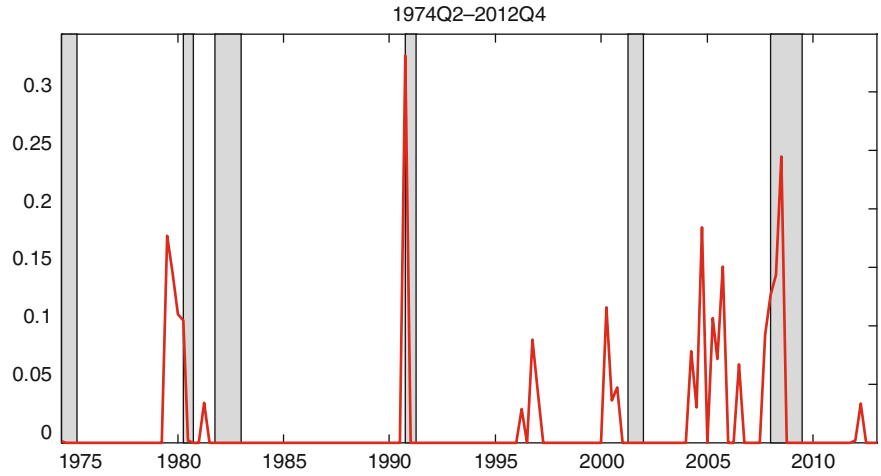
Almoguera et al. 2011). There is no evidence that OPEC caused the 1973–74 or the 1979–80 oil price shock episodes, for example, even if this claim is often repeated in macroeconomic textbooks. OPEC was far from a unified body in the 1970s and incapable of acting as a cartel. Only in the early 1980s did OPEC attempt to curtail its oil production in an effort to prevent oil prices from falling in response to the Volcker recession. As predicted by the economic theory of cartels, most OPEC members cheated on their cartel obligations, however, which prompted Saudi Arabia to take responsibility for reducing oil production on behalf of the rest of OPEC. This approach proved not only ineffective, in that the price of oil continued to fall (albeit at a slower rate), but unsustainable in that falling production in conjunction with falling oil prices resulted in a substantial reduction in Saudi oil revenues. By late 1985, Saudi Arabia was forced to reverse course, and the real price of oil collapsed along with fears of what OPEC might do. There has been no indication of OPEC being able or willing to control the price of crude oil since then. Indeed, it would be hard to explain why Saudi Arabia would have permitted the oil price to fall to $11/barrel in 1998 if it were endowed with the market power sometimes ascribed to it.

How to Measure Oil Price Shocks

So far we have defined an oil price shock informally as a change in the price of oil relative to the price of oil that consumers and firms expected. More formally, oil price shocks can be defined as the unpredictable component of the price of oil. One approach is to measure oil price shocks within the context of an econometric model as movements in the price of oil that cannot be explained based on past data. Such oil price shocks are also known as oil price innovations, and can be decomposed further into mutually uncorrelated oil demand and oil supply shocks with the help of additional identifying assumptions. An alternative approach would be to define oil price shocks based on the market expectation of the price of oil. For example, Baumeister and Kilian (2014) discuss how oil price expectations for a given horizon may be recovered by adjusting the oil futures price by an empirical measure of the risk premium. By comparing the three-month ahead financial market expectations of the oil price to the realisations of the oil price three months later, for example, one can infer a time series of quarterly oil price shocks.

More colloquially, the term ‘oil price shock’ is also used to denote episodes of unusually high (or in some cases unusually low) oil prices. Such episodes typically extend over several years. In fact, most surges in the price of oil do not involve any large changes in the price of oil on a monthly basis. Rather, they arise because for extended periods the price of oil experiences small but persistent increments. Examples are the 1979–80 and 2003–08 oil price surges. Sometimes appearances can be misleading. A case in point is the sudden increase in the price of oil in 1973–74. Kilian (2008b) shows that the real price of oil would have increased much earlier than late 1973, and more gradually, had the price of Middle Eastern oil not been constrained by the Tehran-Tripoli agreement of 1971. The sudden increase in late 1973 occurred when oil producers reneged on these contractual agreements and the oil price reverted to market levels. In fact, overall the real price of metals and non-oil industrial raw materials between 1971.11 and 1974.2 increased by 75% as much as the real price of oil, even in the absence of supply shocks in these markets, suggesting that all these prices were largely driven by the same forces of demand. Hence, historically, the oil price spike of 1990, following the invasion of Kuwait, is the only example of a large and sudden increase in the price of oil since the 1960s. All other oil price shock episodes have involved more gradual increases in the real price of oil.

Finally, yet another notion of oil price shocks has been proposed by Hamilton (1996, 2003). The idea is that an oil price shock occurs only to the extent that the price of oil exceeds the highest price of oil that consumers and firms have experienced in recent memory. More formally, this *net oil price increase* measure of oil price shocks is defined as the censored variable max (0, $pt-p^*$),



Energy Price Shocks, Fig. 3 Three-year net oil price increase in real US refiners' acquisition cost for oil imports with US recession dates imposed as shaded areas (Source: Kilian and Vigfusson (2014). The business cycle dates are from the National Bureau of Economic Research)

where *pt* refers to the current oil price and *p** refers to the maximum oil price over the preceding year (or, more commonly, over the preceding three years). By construction, the net oil price increase is predictable based on its own past. At some point it was believed that this statistical transformation of the price of oil would effectively isolate the component of the price of oil associated with exogenous shocks to the flow supply of oil. It has become readily apparent that this is not the case. An alternative and more common interpretation has been that net oil price increases are the relevant measure of oil price shocks because they explain or at least help predict variation in US real GDP.

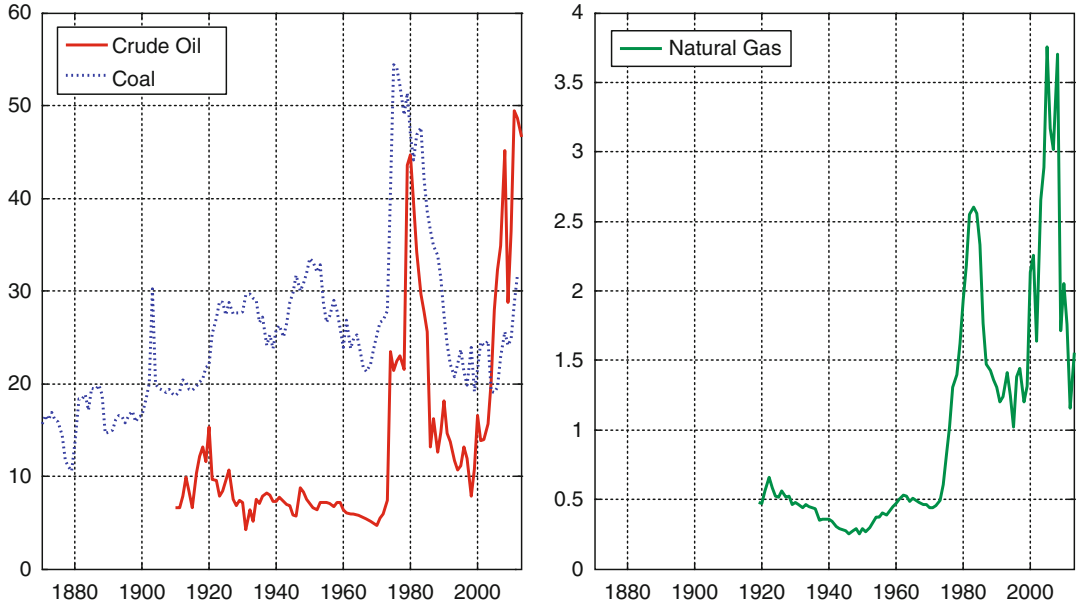
Figure 3 casts doubt on this interpretation. Treating the net oil price increases of 2004–06 as one episode, there have been eight distinct episodes of net oil price increases since 1974, of which only five were followed by recessions. In some cases the net oil price increase occurred well before the recession. A good example is the net oil price increase of 2000. In other cases it occurred immediately before or at the same time as the recession. Examples are 1981 and 1990. In three cases, net oil price increases were not followed by a recession at all. These episodes are 1996 as well as 2004–05 and 2006 (the latter two may be viewed as one episode), and 2011–12. This evidence suggests that there is no mechanical link between net oil price increases and subsequent recessions.

More formally, it can be shown that the evidence that net oil price increases help forecast US real GDP growth is weak at best (Ravazzolo and Rothman 2013; Kilian and Vigfusson 2013). For related discussion of net oil price increase measures and their relationship with more conventional oil price shock measures, see Kilian and Vigfusson (2011a, b).

Putting Oil Price Shocks into Historical Perspective

Crude oil is only one source of primary energy, but it stands out because of its important role in the transportation sector. Historically, coal played much the same role for the transportation sector as oil did starting with the increased adoption of the automobile during the First World War. Steam ships and steam locomotives were as dominant in transportation then as oil is today for trucking, shipping, air transport and railroading. A natural question therefore is whether coal prices were subject to shocks similar to the oil price shocks documented earlier.

This question can only be addressed with annual data, because there are no quarterly or

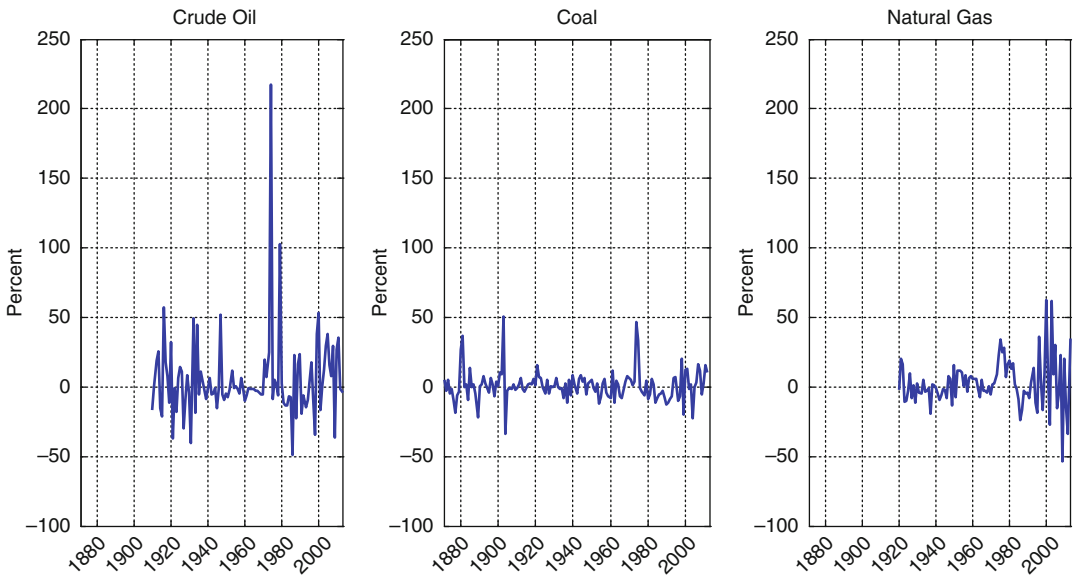


Energy Price Shocks, Fig. 4 Historical evolution of US real energy prices: 1870–2013 (expressed in real US$ per barrel (crude oil), per metric ton (coal) and per MMBtu (natural gas). The coal price refers to anthracite coal. The coal and gas prices are based on Manthy (1978) and EIA sources; the oil price series is from British Petroleum (2014))

monthly oil price series prior to 1947. The left panel of Fig. 4 plots the historical evolution of the real prices of coal and crude oil since 1870. The plot deliberately ignores the oil price data prior to 1910, because, before the adoption of the automobile, crude oil was used primarily to produce kerosene to be used for lighting, heating and cooking. It therefore makes sense to discount the history of oil prices prior to 1910. Figure 4 shows that prior to 1970 the degree of comovement between the prices of oil and coal was quite low. Subsequently, there is increased comovement, but the increase in the real price of coal during the 2000s was not nearly as dramatic as that in the real price of oil.

Because these prices are measured in different units, it is useful to express them in percentage changes. Figure 5 suggests that the Texas Railroad Commission era, which was characterised by unusually low volatility at annual frequency followed by an extreme spike in 1973–74, was a historical aberration. In contrast, the volatility of the real price of oil prior to the Second World War largely resembles that since the 1970s. Even discounting the early 1970s, however, the volatility in the growth rate of the annual price of oil appears to be more than twice as high as the corresponding volatility in the price of coal. This is not to say that there are no sustained increases in the real price of coal – in fact the sustained increases in the level of the real price of coal during the 1920s and 1940s dwarfed those in crude oil – but that the year-on-year changes tended to be smaller. In this sense, there is a clear difference between the crude oil market and the coal market.

It is also instructive to compare the real price of oil with the real wellhead price of natural gas. Although natural gas prices are available as far back as 1919, as shown in the right panel of Fig. 4, it was only with the creation of a nationwide network of natural gas pipelines in the 1950s that natural gas became an important energy resource for the US economy (see Davis and Kilian 2011). Figure 5 shows that the volatility of the growth rate of the real price of natural gas since the late 1950s has been quite similar to that of the real price of oil before and after the Texas



Energy Price Shocks, Fig. 5 Percent growth rates of the real US price of energy: 1871–2013 (all results are obtained from the data underlying Fig. 4)

Railroad Commission interlude. Figure 4 in turn suggests that traditionally US natural gas and crude oil prices have moved in the same direction. There are indications, however, that with the rapid growth in US shale gas production in recent years this traditional pattern no longer holds. Figure 4 shows a dramatic fall in the real price of natural gas after 2008, even as the annual real price of oil recovered after the financial crisis. In contrast, there remains some degree of positive comovement between coal and crude oil prices going back as far as the 1970s.

The observed pattern of positive comovement across coal, oil and natural gas prices between the 1970s and the 2000s reflects in part the fact that industrial consumers of energy often had the ability to use dual technologies that allowed them to switch between natural gas and fuel oil, depending on price and availability. Such substitution tends to be more difficult for residential consumers of energy, however. For example, to this day there are parts of the USA in which heating oil remains the main source of home heating because there are no natural gas pipelines in that region. Likewise, there is essentially no substitution between oil and either coal or natural gas in US power plants, and the process of replacing coal power plants by natural gas power plants is quite slow. Finally, especially in transportation, there is only very limited substitutability between oil and natural gas to date. Even the indirect substitution of coal, natural gas or nuclear power for oil in the form of electric power has not played a large role in US transportation so far.

Thus, much of the observed comovement in real energy prices appears to reflect common shifts in the demand for all forms of primary energy associated with shifts in flow demand. This comovement only breaks down when there are large increases in the supply of an energy commodity, as occurred in the natural gas sector after 2008. In contrast, there is no indication that a similar structural shift is under way in the oil market. At the global level, the quantitative importance of US shale oil remains small compared with the size of the market for crude oil. Thus, the response of the global price of oil to the US shale oil revolution has been muted (see Kilian 2015). In contrast, in the natural gas sector, US gas production must be balanced against domestic demand rather than global demand, with correspondingly larger effects on the price.

An interesting question for future research will be to compare the evolution of energy prices across countries and to disentangle the contributions of various demand and supply shifts to the evolution of these historical energy price series. The latter question has received increasing scrutiny in years, including contributions by Hamilton (2013), van de Ven and Fouquet (2014), and Stürmer (2014). For very long run trends in energy prices such as those of charcoal, coal, town gas and kerosene see Fouquet (2011).

Conclusions

Why do we care about oil price shocks (and by extension other energy price shocks)? One reason is that positive oil price shocks historically have been associated with recessions in oil-importing countries, although the recessionary effects associated with oil price shocks do not appear to be as large and systematic as originally thought.

Of course, not all increases in the real price of oil are bad. Increases in the price of oil may also serve to transmit signals about the increased scarcity of crude oil (see Hamilton 2014). In fact, rising oil prices are a precondition for the development and adoption of alternative energy technologies. In this sense, the concern for policymakers is not so much increases in the real price of oil in general, but rather the fact that rapid increases in the real price of oil tend to put economic stress on the oil-importing economy as the economy adjusts to the increased scarcity of oil.

An even bigger concern is high volatility in the growth rate of the real price of oil, which may prevent the necessary investment in alternative energy technologies or for that matter in additional oil exploration (see Dixit and Pindyck 1994; Kellogg 2014). There has been no shortage of discussions of the need to stabilise oil prices. One response has been the creation of the US Strategic Petroleum Reserve (SPR). It is clear, however, that relative to the magnitude of the global oil market, changes in the SPR are too small to stabilise the real price of oil. Of course, the biggest source of volatility in oil prices in recent years has been the financial crisis. The case can be made that policies preventing such misalignments in the economy may be the most effective approach to reducing the volatility of oil prices and other primary energy prices.

Energy Services

Roger Fouquet

Abstract

Energy consumers are driven by their demand for energy services (such as space and water heating, cooking, transportation, lighting, entertainment and computing). This piece introduces the reader to the concept of energy services, and explains why it is important to analyze energy markets and climate policies from the perspective of energy services. The

paper discusses the theoretical foundations and empirical evidence, particularly related to the rebound effect and the demand in developing economies. The paper concludes that governments should encourage the collection of statistical information about energy services in order to help economists analyse markets and policies through this lens. Most importantly, governments should formulate more integrated policies that focus explicitly on energy services, connecting markets for energy and for energy-using equipment with the development of technologies. Careful and balanced energy service policies are especially important as economies industrialise because they can help reduce economic, political and environmental vulnerability.

What Are 'Energy Services'?

Energy services refer to the services that are generated from consuming energy combined with appliances. For residential consumers, these services include space heating and cooling, water heating, cooking, refrigeration, lighting, computing, entertainment and passenger transport (Reister and Devine 1979, 1981; Goldemberg et al. 1985). For firms, these include high temperature processes, such as iron smelting, low temperature processes, moving of motors and machinery, separation, drying, and compressing air, as well as refrigeration, lighting, space and water heating, and freight transport.

For space heating and cooling, the service is measured in terms of the increase or decrease in temperature compared with the existing temperature (in degrees Centigrade or Farenheit) for a specified surface area. For example, a 100 square metre house is warmed 10°C for two hours – which is the equivalent to warming 2,000 square metres 1°C for one hour. Transport is measured in terms of passenger-kilometres (or –miles), or tonne-kilometres (or ton-miles) for freight. The more efficient the vehicle, then the more passenger-kilometres can be achieved with, say, a litre or gallon of gasoline. The number of vehicle-kilometres in a country, divided by the gasoline consumed in that country, offers an indicator of the average fuel efficiency of vehicles (Frondel et al. 2008; Stapleton et al. 2016). For lighting, the unit of measurement is lumen-hours, which indicates the amount of illumination generated by a light source (Nordhaus 1997). A 100 watt incandescent bulb provides about 1,300 lumens. So, if it is left on for 10 hours, it will have generated 13,000 lumen-hours and used 1,000 watts. The same amount of lighting could have been produced over the same amount of time using a 20 watt CFL bulb, but consuming only 200 watts.

Energy services are closely related to end-use energy consumption and the concept of exergy. End-use energy consumption refers to the energy consumed for individual services. However, focusing on end-use energy consumption or prices does not take account of the efficiency of conversion of the energy into the service. Exergy, on the other hand, does take account of the efficiency and refers to the amount of 'work' produced (Ayres and Warr 2009). The strength of the concept of exergy is that it looks at all energy services in the same unit; however, it does not focus on the nature of the specific output, which risks ignoring important dimensions of the analysis (Sovacool 2011).

The purpose of this piece is to introduce readers to the concept of energy services. The next section explains why energy economists are increasingly analyzing energy service consumption, rather than only energy use. The third section presents the foundations for analyzing the demand and provision of energy services. In the fourth section, empirical evidence of the demand for energy services in the residential and transport sectors is presented, focusing on price elasticities and the size of direct rebound effects. The fifth

section discusses the two-way relationship between energy services and economic development. Due to space constraints, other topics related to energy services are not discussed in detail – including fuel poverty (Boardman 2010), exergy (Ayres and Warr 2009), the impact of smart meters (Römer et al. 2012) and of net-metering (Gillingham et al. 2016a), energy service companies or ESCOs (Weiller and Pollitt 2013), and energy systems planning and operation, such as demand-side management (Strbac 2008). The final section draws conclusions about our knowledge of energy services and its role in improving policy-making.

The Importance of Energy Services

Energy consumption is driven by the demand for energy services. Individuals do not consume electricity for the voltage that speeds down the wires, or put gasoline in their cars for the pleasure of having a full tank. Instead, they consume them because of the lighting the electricity creates or the mobility the gasoline provides.

Consequently, studies of energy demand may strongly benefit from considering the relationship between energy services, technologies and energy consumption (Haas et al. 2008). If the relationship remains constant, it may not be crucial to focus explicitly on energy services. For instance, in the short run, the relationship does stay broadly constant, because the efficiency of the technology (that is, the amount of service generated for a given unit of energy) does not change much and, so, the focus on energy services may not alter the results of the analysis.

However, analyzing energy services is especially important in the long run, as technological change can radically alter energy consumption behaviour. Nordhaus (1997) showed how the price of fuel for lighting fell three-fold and the price of lighting (measured in lumen-hours) fell 75-fold in the last century, thus, traditional methods of measuring the price of lighting using the fuel price were off by a factor of 25. Fouquet (2011) and Muller (2016) showed that this is not an isolated example and that, in general, the trend in the (nominal and real) price of an energy service diverges from the trend in the price of energy for this service in the long run. While the average energy price has not shown a discernible trend in the long run, the price of energy services has tended to fall. The divergence implies that focusing exclusively on energy prices and consumption rather than energy services will generate misleading conclusions about energy consumption behavior. This long run perspective is particularly relevant when thinking about climate change mitigation.

As Fouquet and Pearson (2012) argued, by not focusing on energy services, the analyst is making an implicit assumption about the price elasticity of demand for the energy service. Two 'straw-man' examples can be used to show this. First, the 'efficiency optimist' might suggest that if energy efficiency improves by 10%, energy consumption will fall by 10%. However, since the efficiency has improved by 10%, the consumer can get the same quantity of service with 10% less energy. This implies that the price of the energy service has fallen 10%. For energy consumption to fall by 10%, energy service use must remain unchanged. So, the 'efficiency optimist' implicitly assumes that the price elasticity of demand for energy services is zero. Alternatively, the 'laggard economist' might propose that since the price of energy is unchanged consumption of energy will remain the same. In this case, since the price of this energy service has fallen by 10%, for energy consumption to remain unchanged, energy service use must increase by 10%. So, the implicit assumption here is that the price elasticity of demand for energy services is one. Thus, focusing on energy rather than energy services forces the analyst to make assumptions about consumer behavior and is likely to create misleading estimates of consumer responses to long run energy price and efficiency changes. Ultimately, the size of the price elasticity of demand is an empirical question and needs to be estimated in order to help identify the scale of the 'rebound effect', which will be discussed in the fourth section.

Hunt and Ryan (2015) have made this point explicit, emphasizing the misspecification of models that fail to incorporate energy service

demand and the biased elasticity estimates that result. In their analysis, the income elasticity of demand for energy is underestimated and the price elasticity is overestimated, because of the failure to model energy services and include energy efficiency improvements. However, they explain that the bias depends on the trends in income, real prices and efficiency improvements, implying that it is not possible to generalize the direction of bias (Hunt and Ryan 2015, p. 283).

An additional advantage of focusing on energy services is that the demand for energy services stays relatively stable with the introduction of new energy sources and technologies. Traditional analysis sees energy transitions as disruptive events – with a radically declining demand for, say, biomass fuels and rapidly rising demand for coal – with no continuity. However, they can be seen as competing technologies and sources for producing the same energy service. In this way, long run patterns in energy service consumption can be identified that would be hidden by focusing only on the uptake and decline of energy sources and technologies (Fouquet 2014).

In addition, Smulders and de Nooij (2003) highlight the limitations of a study of economic growth that ignores energy services. They show that, within their model, energy conservation policies, which reduce energy consumption, lower economic growth. However, this assumes that growth in energy use is a key source of the growth in economic output, rather than energy service consumption, which is unlikely to decline following energy conservation policies. Indeed, Toman and Jemelkova (2003) emphasize the importance of energy services in driving economic development. They show that energy services can affect economic development through a number of different channels, and that these effects can change at different levels of economic development, and it is essential to model them explicitly.

Finally, the Nordhaus (1997) piece sought to highlight that the consumer price index (CPI) and the gross domestic product (GDP) are mismeasured if they do not take account of increases in the quality of service provision, which result from technological improvements. Lighting is just one example amongst many in which conversion of a good into a service is underestimated. In fact, Nordhaus (1997, p. 60) suggests that 'estimates of the growth of real consumption services is hampered by significant errors in the measurement of prices and that for almost two-fifths of consumption the price indexes are virtually useless.'

In other words, focusing on energy services rather than energy consumption can greatly improve our understanding of energy consumption behavior, including the rebound effect (see the fourth section), of the relationship between energy markets and economic growth, and even of fundamental measurements of cost-of-living and economic activity. The main reason economists have tended to ignore energy services has been a lack of data on energy efficiency to convert data into services. As Sorrell (2007, p. 25) explains: 'For many energy services, the relevant data is simply unavailable, while for others the data must be either estimated or subject to considerable error.'

The Demand for Energy Services and Its Household Production

Having discussed the importance of focusing on energy services, and before reviewing the empirical evidence, it is valuable to outline briefly the basic theory underlying the demand and provision of energy services. Energy service markets often involve the same agent demanding and providing the service by consuming energy and acquiring related equipment (that is, the physical capital). Here, the focus is on the residential and transport sector, although similar issues apply to energy service markets in industrial and tertiary sectors. One difference is the increasing separation of demand and supply with ESCOs (Energy Service Companies) providing the services, which will be briefly discussed.

The first modelling of the derived demand for energy, combining complementary durable equipment, dates back to Houthakker (1951). Early studies highlighted the fundamental importance of the relationship between energy use and appliances, but were not explicit about the consumer's objectives related to energy services (Berndt and

Wood 1975; Pindyck 1979; Hausman 1979; Khazzoom 1980; Dubin and McFadden 1984; Dubin et al. 1986) – for a review of the early literature on energy demand modelling, see Taylor (1975). Then, a growing literature emphasized the importance of modelling energy end-use or service consumption, starting with Reister and Devine (1979, 1981), Neels (1981), Goldemberg et al. (1985), Quigley (1984), Klein (1988), and Quigley and Rubinfeld (1989), though focusing on the production of services.

However, economists have been slow to explicitly model the demand for energy services, and were eventually stimulated by Nordhaus' (1997) seminal piece on the price of lighting, by Modi et al.'s (2006) emphasis on the provision of energy services in developing economies and by the interest in the rebound effects that hamper efforts to mitigate climate change through energy efficiency improvements. The following outline summarises the demand-side perspective presented in Hunt and Ryan (2015), while incorporating the supply-side approach proposed by Neels (1981) and Quigley (1984), which is also discussed in Frondel et al. (2008).

A consumer or household's objective is to maximize utility – here, the focus is explicitly on taking account of the energy services consumption (ES) generated for meeting this utility:

$$\text{Max } U_t = u(ES_t, X_t), \tag{1}$$

subject to constraints

$$Y_t = P_{ESt} \cdot ES_t + P_{Xt} \cdot X_t \tag{2}$$

where X_t is a composite of goods and services, P_{ESt} and P_{xt} refer to the prices of the energy services and of the composite goods, and Y_t is the consumer's budget, which should be permanent wealth (although it is often proxied by income). Other constraints, for example, relating to the availability of information, technical problems using certain products and the existence of institutional factors which influence the ability to make decisions and to choose goods, might also be included for a more realistic (but more complicated) optimization problem.

Based on the above analysis, but for simplicity assuming only economic constraints, utility depends indirectly on prices and income; the indirect utility function is

$$U'_t = (P_{ESt}, P_{xt}, Y_t). \tag{3}$$

The fact that the indirect utility function represents the consumption of energy services and composite goods as a function of prices and income is particularly valuable for analyzing economic behaviour since neither utility nor preferences can be observed, whereas prices and income can. Thus, for example, the demand function for energy services is

$$ES_t = f(P_{ESt}, P_{xt}, Y_t). \tag{4}$$

By specifying the nature of the optimization problem, principally the constraints faced by consumers, and solving it, we can examine the way optimal choices vary with changing constraints. Tracing out these variations in consumption, the behavioural relationships between consumption and constraints, such as described in the energy service demand function, can be identified. Knowledge of the energy service demand function, for example, can then be used to assess the implications of changing economic activity and policies on fuel consumption. The effects of these changing constraints can be analyzed in the form of the own price elasticity of demand:

$$\varepsilon_{PESt} = (\partial ES_t/ES_t)/(\partial P_{ESt}/P_{ESt}), \tag{5}$$

the income elasticity of demand:

$$\eta_{Yt} = (\partial ES_t/ES_t)/(\partial Y_t/Y_t), \tag{6}$$

and the cross price elasticities:

$$\varepsilon_{Pxt} = (\partial ES_t/ES_t)/(\partial P_{xt}/P_{xt}). \tag{7}$$

This conventional model of consumer behavior outlines the demand for energy services. The supply of energy services is less conventional, however. Rooted in Becker's (1965) theory of the allocation of time, households produce their

own services by combining labour, capital and energy. At a larger scale, firms similarly generally produce their own energy services.

Technological developments over the last two centuries have led to a move away from labour inputs and towards physical capital and energy sources, implying that many energy services, such as heating and lighting, are now provided with virtually no labour requirements. Car driving is the only energy service where substantial labour is required today – and suggests that the diffusion of driver-less cars, and the associated decline in the labour costs (in time), may have a significant impact on the consumption of passenger transport services. With this feature of the modern provision of most energy services, a simplified model of the household production would include only capital (k_t) and energy used (e_t).

The relationship depends on the efficiency of the technology (ϕ_t) – that is, the amount of energy services generated by a specified quantity of energy. As Hunt and Ryan (2015, p. 274) explain: 'three particular characteristics of energy-using equipment are of relevance: much of it is longlived – once installed it may have a useful life that spans decades; much of it is fuel(s)-specific; and its technical characteristics tend to be fixed, requiring a given level of energy use per unit of services produced.' Given that this relationship is often a constant at any point in time, the provision of energy services can be determined by the energy consumption multiplied by the efficiency of the appliance:

$$ES_t = \varphi_{et} \cdot e_t. \tag{8}$$

Frondel et al. (2008) highlight that improvements in energy efficiency may be associated with higher capital costs. Therefore, ideally, the cost of producing energy services should take account of an estimate of these capital costs, as well as any time expenditure and the price of energy. However, a common assumption made is that the price of energy services is determined by the marginal cost of production, which is generally simplified to the price of energy (P_{et}) divided by the technical efficiency of the appliance being used (see Nordhaus 1997):

$$P_{ESt} = P_{et}/\varphi_{et}. \tag{9}$$

Feeding Eqs. 8 and 9 into Eqs. 5 and 6 enable energy economists to estimate the own-price and income elasticity of demand for energy services.

This section presented a simple model of the demand for energy services in which the consumer also produced the service. This implies that the same consumer and producer is actively involved in selecting the production technology and the energy sources. Recently, energy service companies (ESCOs) have begun to take on the responsibility for producing these services. While this can create a principal-agent problem, it is also seen as a way to stimulate energy efficiency improvements and reduce the energy efficiency gap (Gillingham and Palmer 2014). If these companies expand their role beyond the provision to firms, in the future, energy service markets may become more conventional, in the sense of the consumer and producer being different agents - for more on this particular development, see Groscurth et al. (1995), Olerup (1998), and Weiller and Pollitt (2013).

The opposite may be occurring in the market for power. While the final services associated with power (for example some heating, cooling, lighting, entertainment, computing, and so on) are provided by consumers, they have not produced their own power since the early days of electricity generation. However, since the introduction of micro-wind turbines and the drop in the price of solar panels, more households are becoming 'prosumers'. That is, consumers are entering the market for the production of electricity (and, in some cases, selling their surplus, known as 'net-metering'), and blurring the roles (Römer et al. 2012; Gillingham et al. 2016a). In other words, no single model can capture the different characteristics of all energy service consumption and provision. Nevertheless, the model presented above outlines a simple framework for thinking about the market for energy services.

The Direct Rebound Effect and the Price Elasticity of Demand for Energy Services

The main reason energy services have received a great deal of attention in the last decade is due to the debate about rebound effects. They refer to consumer, producer and market responses to energy efficiency improvements (Sorrell and Dimitropoulos 2008; Gillingham 2014). As mentioned before in the second section, they include a direct effect on the consumption of energy services and, thus, energy in response to a higher efficiency improvement and lower energy service price. There are also indirect effects on consumption behaviour related to complements and substitutes of the cheaper energy service (and associated energy source), to a probable increase in purchasing power (after taking account of the expenditure on the new efficient technology) and, therefore, to an increase in the consumption of other goods and services. Finally, macroeconomic rebound effects occur because the reduction in the price of energy services tends to boost the economy, stimulating further energy service and energy consumption. Thus, for instance, a 10% improvement in energy efficiency is unlikely to lead to a 10% saving in energy use. Instead, the sizes of the different and combined rebound effects are empirical questions (see, for instance, Sorrell 2007; Gillingham 2014).

Despite the recent interest, the origins of the debate on the size of the rebound effects began 150 years ago. In 1865, William Stanley Jevons published *The Coal Question*. As a leading political economist of the time, his book sought to shed light on the murky debates surrounding the potential exhaustion of coal resources that were central to Britain's economic supremacy (Madureira 2012). One of his most controversial passages in the book warned that '....it is wholly a confusion of ideas to suppose that the economical use of fuel is equivalent to a diminished consumption. The very contrary is the truth.... Every improvement of the engine when effected will only accelerate anew the consumption of coal...' (1865). The idea that energy efficiency improvements could lead to increases in energy consumption became known as Jevons' Paradox.

Jevons' Paradox (also now known as 'backfire') is effectively an extreme case in which the rebound effects are sufficiently large that the efficiency improvements lead to increases in consumption. There is now a large theoretical literature supporting the existence of rebound effects which either implicitly or explicitly analyze the price elasticity of demand for energy services (Khazzoom 1980; Saunders 1992; Howarth 1997; Turner 2013; Gillingham and Chan 2015). However, empirical studies have tended to estimate much smaller rebound effects than Jevons (1865) anticipated. So, in the recent cases investigated, energy efficiency improvements led to savings in energy consumption, all other things being equal (Greening et al. 2000; Sorrell 2009). Thus, the inconsistency between Jevons' predictions and the recent empirical evidence suggests a paradox to the Jevons' Paradox.

Ultimately, measuring all the different (i.e. the direct, indirect and macroeconomic) rebound effects empirically at the same time is challenging (Gillingham 2014; Gillingham et al. 2016b). "Measuring the rebound effect is not an easy task, as it involves an estimation of the elasticity of the demand for a particular energy service with respect to energy efficiency. Instead of using this original definition, the majority of available studies have estimated the rebound effect using price elasticity, since data on energy efficiency has always been limited. In principle, rational consumers should respond in the same way to a decrease in energy prices as they do to an improvement in energy efficiency. This assumption, however, does not always hold up, as energy efficiency itself may be affected by changes in energy prices" (Sorrell 2007, p. 4).

Nevertheless, the price elasticity of demand for energy services offers a means of estimating the direct rebound effect associated with efficiency improvements. As Hunt and Ryan (2015) explain, a number of early studies tried to include data on energy efficiency, either by using a deterministic or a stochastic trend (Beenstock and Willcocks

1981; Dimitropoulos et al. 2005) or by measuring energy efficiency directly or indirectly (Walker and Wirl 1993; Haas and Schipper 1998; Haas and Biermayr 2000; Fouquet and Pearson 2012; Fouquet 2014; Schleich et al. 2014). Earlier studies used the efficiency indicator as an additional explanatory variable. The more recent studies used these measures of efficiency to produce indicators of the price and consumption of energy services, which were used to estimate the price elasticity of demand for energy services.

Frondel et al. (2008) outline the assumptions made in efforts to estimate this price elasticity and direct rebound effects. Ideally, as explained in the third section, the price elasticity of demand for energy services can be estimated based on variations in the fixed costs of capital (and labour, associated with the capital investment), and the marginal costs of labour and energy services. However, this is rarely done or even possible, and a second-best is to estimate the elasticity based on variations in the marginal cost of energy services – as a number of the later studies above did. These studies ignore the endogeneity of the fixed costs of capital and the marginal cost of the energy services (as often more efficient equipment is more expensive). Finally, traditional studies have used the price elasticity of demand for energy as a proxy for energy services. Frondel et al. (2008) offer a rare study where all three methods were used on the same data, and so provide an opportunity to compare the results. The authors were surprised to find that the price elasticity estimates using the three different methods were similar, but the coefficients on other explanatory variables were substantially different. Thus, their study highlights the ambiguity of using only energy data given that consumer behaviour is driven by energy service demand.

Given the greater availability of data on transport use and energy consumption related to transport services, this service has been studied most extensively and has offered an opportunity to estimate actual price elasticities of energy services and measure the direct rebound effect. For instance, using a panel data set of US states between 1960 and 2004, Small and van der Dender (2007) estimated the long run price elasticity of demand for car transport to be −0.22 in the second half of the twentieth century, falling to −0.06 between 2001 and 2004. This implies that the direct rebound effect associated with a 10% efficiency improvement fell from 2.2 to 0.6%. Focusing on the more expensive and densely populated Great Britain, Stapleton et al. (2016) estimated the direct rebound effects for car transport over a similar time period to have ranged from 0.9 to 3.6%. The similar results for these two studies suggest that the widely different economic, political and behavioural characteristics may not have influenced greatly the sensitivity to changes in the price of car transport. On the other hand, Frondel et al. (2008) found substantially larger direct rebound effects for Germany – averaging 5.8% for a 10% efficiency improvement, which they explain as due to greater potential for substitution between modes of transport.

While some uncertainty about the scale of the direct rebound effect still remains, the growing number of studies are offering a range of values for the price elasticities of demand for various energy services. The first effort to summarise the finding was in Greening et al. (2000), indicating the range to be between 0 to −0.5, with a concentration in the range of −0.1 to −0.3. More recent efforts include Sorrell (2007), Azevedo (2014), Gillingham (2014), and Gillingham et al. (2016b). The latter selected estimates from nine studies based on rigorous identification strategies, and argued that this lowers slightly the range (between −0.05 and −0.40). An early example of a randomized controlled trial (that is, an experiment set up purposefully to identify the causality) associated with energy efficiency improvements found that the price elasticity of demand for clothes washing was −0.06 (Davis 2008). Table 1 presents estimates for a few key energy services based on a general review of the literature. The broad conclusion is that direct rebound effects are an important issue, but they are unlikely to lead to Jevons' Paradox (or 'backfire') for households or personal transport in developed countries – without drawing a conclusion about the combined impact of direct, indirect and macroeconomic rebound effects – see

Chitnis and Sorrell (2015) for an attempt to measure the combined effects.

As discussed earlier, modelling energy service demand is important for explaining past behaviour, forecasting future consumption and anticipating the impact of policies, including efforts to mitigate climate change and potentially begin the transition towards a low carbon energy sources (Pearson 2016). An important issue is the projection of dramatic increases in air conditioning demand and use over the next few decades, because of declining costs of air conditioning and electricity, improving energy efficiency, and rising incomes and temperatures in developing economies, with potential positive feedback loops (Davis and Gertler 2015). Other studies, such as Anandarajah et al. (2009), Anandarajah and Strachan (2010) and Fujimori et al. (2014), also explicitly model energy service demands for their long run scenarios – see Table 2, as an example. These studies show the relevance of the estimates for practical purposes. However, these are generally based on limited reviews of the evidence, and the assumptions made in the model tend to remain constant through time. Indeed, a key issue raised in the literature reviews, such as Azevedo (2014), Gillingham (2014) and Gillingham et al. (2016b), is about the 'external validity' of the studies. That is, it is unclear whether those estimates will be the same if different methods or models are used and in different time periods or contexts. Gillingham et al. (2016b) emphasize the empirical strategy used, and that these studies tend to assume other characteristics related to the energy source and technology remain unchanged and increases in energy efficiency are costless. Azevedo (2014) stresses that most studies are for the residential and transport sectors in developed economies, particularly in the US.

In fact, over decades, price elasticities of demand for energy services appear to have changed considerably as per capita income has increased (Fouquet 2014). Estimates for residential heating, transport and lighting in the United Kingdom indicate that price elasticities peaked (at values of about −1.5) at levels of per capita income of between $(2010) 4,000 and $(2010) 5,000 (see Fig. 1, bottom-half). That is, in Britain in the 1870s and 1880s, a 10% reduction in energy prices or a 10% improvement in energy efficiency (both reducing the price of energy services) increased transport and lighting use by around 15%. This implies that energy efficiency improvements associated with transport and lighting led to rises in energy consumption, as Jevons (1865) had predicted – offering an explanation for the paradox of Jevons' paradox. Furthermore, given that elasticities of demand for energy services change, efforts should be made to incorporate more

Energy Services, Table 1 Estimates of price elasticities of demand for energy services in industrialised economies

Energy service	Range of estimates	Number of studies
Space heating	−0.02 to −0.60	9
Space cooling	0.00 to −0.50	9
Water heating	−0.10 to −0.40	5
Lighting	−0.05 to −0.12	4
Transport (car)	−0.05 to −0.87	20

realistic assumptions, including changes in energy service demand at different phases of economic development (as will be discussed in the next section), in long run scenarios of energy consumption and climate mitigation strategies, as prepared by the IPCC and the IEA.

Energy Services and Economic Development

Energy services have been increasingly linked to the debate about the role of energy access for economic and sustainable development. Energy services are seen as key to stimulating economic growth and development, and to ensuring improving living standards (Modi et al. 2006; AGECC 2010; UNDP 2011).

This then feeds through into greater consumption of energy services. Davis et al. (2014), in a rigorous analysis of Mexican households, find evidence of increased electricity consumption associated with air conditioning following improvements in the efficiency of equipment – in other words, there appear to be very large rebound effects. Sorrell (2007), for instance, argued that the direct rebound effect in developing countries may be larger since the demand for energy services may be far from saturated. In general, the hypothesis is, and the limited evidence suggests, that price and income elasticities of demand for energy services are greater in developing economies.

The main finding from Fouquet (2014) is that, as the United Kingdom's economy developed over the last 200 years, trends in income elasticities followed an inverse U-shape curve (see Fig. 1, top half). For instance, they reached a peak (about 2.3, 3.0 and 4.0 for income elasticities of demand for heating, transport and lighting, respectively) in the nineteenth century (at levels of GDP per capita below $(2010) 6,000). After the peaks, there were,

at first, rapid declines, then more gradual declines. Income elasticities took almost 100 years to reach unity (that is, a 10% increase in income led to a 10% rise in energy service consumption), in the mid-twentieth century, at between $(2010) 9–12,000 per capita. The results also indicate that income elasticities were significantly different from zero at high levels of per capita income in the twenty-first century, implying that current increases in income generate rises in energy service consumption (roughly, around 5% rises for a 10% increase in income). These rises feed through directly into greater energy consumption.

Developing economies may well also experience inverse U-shaped income elasticities, given saturation effects – that is, an additional unit of energy service generates less benefit or utility to the consumer. However, whether they peak and reach unit elasticity at similar levels of per capita GDP as the United Kingdom is unclear. Because today's developing economies have access to cheaper energy services (compared with the United Kingdom at the same level of income), they may experience earlier peaks (Fouquet 2014; van Benthem 2015).

These results offer the beginnings of a stylised fact about the relationship between elasticities of demand and economic development (Fouquet 2008, 2014). Sovacool (2011) describes the process as the 'energy service ladder'. That is, at very low levels of economic development, consumers focus on meeting basic needs, particularly food and cooking. As income grows, shelter and indoor climate become important – such as space and water heating, in temperate climates. As income rises further, these demands start to grow less proportionately than income (for example, income and price elasticities for heating fall). In turn, other demands are met, for instance, mobility, lighting and entertainment (implying rising income and price elasticities for transport and lighting demand). As income increases further, these income and price elasticities start to fall. Thus, pending confirmation from further studies, these general patterns could help to guide forecasts of energy service and, therefore, energy consumption. For example, while the IEA (2014) does incorporate saturation into its models (thus implying declining elasticity through time), they do not take account of the likelihood of peaking elasticities in developing economies.

As mentioned at the beginning of this section, while rising income drives up demand, rising consumption of energy services is likely to stimulate economic and social development – although it is hard to disentangle the direction of causality. This is made even harder by the idea that energy services can affect economic development through a number of different channels, and that these effects can change at different levels of economic development (Toman and Jemelkova 2003). Access to modern sources of energy for heating, cooking and power can bring about substantial health benefits, associated with reducing exposure to indoor air pollution or providing clean water and refrigeration, which can in turn yield improvements in productivity. Equally, they can enable a reallocation of household time (particularly for women) which can stimulate additional livelihood opportunities and improved education. Lighting may allow for greater flexibility in time allocation through the day and evening, as well as better conditions for education. Finally, lower transportation and communication costs may enable greater market size and access. In other words, although it can sometimes be hard to identify in the macroeconomic data, there appears to be a close relationship between electricity access and economic development (Toman and Jemelkova 2003; Modi et al. 2006; AGECC 2010; UNDP 2011).

Fuel poverty in general, and especially in developing economies, has major social consequences. 'Worldwide, approximately 3 billion people rely on traditional biomass for cooking and heating, and about 1.5 billion have no access to electricity. Up to a billion more have access only to unreliable electricity networks. The "energy-poor" suffer the health consequences of inefficient combustion of solid fuels in inadequately ventilated buildings, as well as the economic consequences of insufficient power for productive income-generating activities and for other basic services such as health and education. In particular, women and girls in the developing world are disproportionately affected in this regard' AGECC (2010, p. 7).

However, these health, education and welfare benefits tend to be ignored by policy-makers in developing economies (Reddy et al. 2009). Looking at experiences in Brazil, Bangladesh and South Africa, Winkler et al. (2011) stress that, despite access, affordability limits the ability to meet demands for specific energy services, and that policies addressing affordability appear to have more success in stimulating low energy-intensive services, such as lighting and entertainment, than high-intensive ones, such as cooking and cooling. Reddy (2015) discusses practical ways to make available affordable and reliable energy service to poor and often rural populations. One recommendation is to promote the development of small enterprises to provide relatively basic energy technologies. However, the implementation and scaling-up of the provision of energy supplies to meet service demands will need the close collaboration among numerous different stakeholders including households, local bodies, energy utilities, governments, entrepreneurs, research organisations, non-governmental organisations, community groups, financial institutions, and international agencies. Inevitably, coordination failures are a major barrier to enabling these multiple stakeholders to achieve the objectives in socially desirable ways.

Sovacool (2011) highlights how thinking about energy services emphasizes the role culture and social values play in influencing energy use. Indeed, the challenges of governing the development and expansion of energy markets will differ in each country partly because of the cultural aspects. For instance, an awareness of the value of travelling long distances to eat turkey with relatives in late November in the US or the value placed on well-ironed clothes on Sunday mornings in Uganda inform us about national patterns of energy service demands.

Providing an in-depth study of energy service behavior in Mexico, Cravioto et al. (2014) confirm that services are prioritised differently as incomes rise. Furthermore, they stress that the ability to measure the levels of satisfaction or utility generated may be easier by focusing on energy services. With this in mind, they find high levels of utility associated energy services provided to poor populations. However, they find that there is a relatively rapid declining marginal utility as energy service uses and incomes rise.

Concluding Discussion

This piece has sought to introduce the reader to the concept of energy services. This piece has shown why it is important to take account of energy service demand. Ignoring services, when analyzing energy markets, (especially when looking at the long run, where technical efficiencies of appliances and equipment can change considerably) is likely to lead to mis-estimation of price trends, mis-specfication of models, and biases in estimates.

The debate about the rebound effect, and identifying the actual energy savings resulting from efficiency improvements, has created a major increase in the interest in energy services. These empirical studies have shown that the non-zero price elasticity of demand implies that, after improving technical efficiency, consumers increase their consumption of energy services, but also generally reduce their energy consumption - though not by the same percentage as the efficiency improvements due to generally small, but non-negligible, rebound effects.

One of the historical barriers to using energy services in energy economics was that it 'distanced' the analysis from the influence of energy producers and suppliers. Particularly following the 1970s oil crises, and the growing role of OPEC, energy economics had tended to focus on energy supply and market structures (Fouquet 2013). Since the 1990s, environmental concerns have driven energy economists' research agendas, and issues related to the demand have become more important. This has meant a growing interest in incorporating energy end-use and service consumption.

As mentioned before, another limitation of this approach to understanding energy consumption behaviour (and a barrier to becoming the dominant modelling method) is the lack of data. Information about aggregate production and consumption by broad fuel categories is readily

available. Detailed data on end-use energy consumption, on energy efficiency or on energy services require far more effort and expense for statistical agencies.

A conclusion of this paper is, therefore, that there is a need to coordinate the methodological development for the collection of data on energy end-use and energy services consumption and prices across national statistical agencies, and encourage the collection of this data. Once this data becomes readily available, over time and across countries and regions, energy economists will be able to model and analyze the drivers of energy demand more accurately. This is likely to improve the reliability of future energy consumption and carbon dioxide emission scenarios. Furthermore, this information will enable stakeholders to observe the success of policies aimed at providing cheaper energy services while reducing energy use.

With this in mind, another important recommendation is that governments should be developing policies that seek the decoupling of energy services from energy (Fouquet 2015). They ought to create packages of measures, including targeted energy efficiency investments, that encourage more service consumption (which is welfare-enhancing), and less energy use and carbon emission (which is welfare-reducing). In other words, they need to develop policies that focus explicitly on energy services. For instance, there is a long run trade-off between lower energy prices and higher investment in energy efficiency (Newell et al. 1999; Popp 2002). Here, it is proposed that governments should take account of the trade-offs between energy prices and efficiency investment in the long run and ideally find the optimal trade-off between them. Indeed, energy service policies should go beyond simply looking at balancing energy prices and technical efficiency. They should seek to integrate policies related to the pricing and provision of energy sources with those focusing on promoting energy efficiency improvements, including research, development and demonstration (R,D&D) and considerations about behavioural features to address the energy efficiency gap (Gillingham and Palmer 2014) – and not exclusively through efficiency standards, which have received considerable criticism (Anderson et al. 2011). Finally, the active development of energy service policies should seek a broader and more strategic approach to thermal comfort, mobility, illumination, entertainment and computing.

The need to integrate policies related to energy services is particularly important for developing economies. Indeed, Fouquet (2016) stresses that policies promoting cheap energy (through large energy infrastructure projects and fuel subsidies) tend to discourage energy efficiency investment and lock economies into energy-intensive consumption patterns for decades. In turn, this behaviour leaves these economies vulnerable to energy price shocks, inflation, trade balance deficits, political pressures from energy companies and environmental pollution. Thus, successful long run economic development depends partly on careful and balanced policies related to energy services.

Despite the statistical and institutional barriers, it is hoped that there is sufficient grounds to convince analysts and policy-makers of the value of focusing on energy services in analyzing energy markets and in formulating climate policy. For analysts, their models and data ought to be based on energy services. Policy-makers need to, first, set up the framework for collecting data on energy services, combining information about energy price and consumption with the technical efficiency of equipment, then use models and analysis to determine the appropriate strategies. This may help formulate policies that are more effective at achieving their economic, social and environmental objectives.

Energy Transitions

Peter J. G. Pearson

Abstract

This article explains why past, present and future energy transitions matter and why there is so much current interest in them in both developing and industrialised countries. It explores past transitions, including the first and subsequent industrial revolutions – and shows that although energy transitions have proceeded at various speeds in different places and times, and some of the more recent transitions have been faster, transitions do not usually happen quickly. An examination of lock-in, path dependence and the role of incumbents explains why there can be considerable inertia in energy systems and their technologies and institutions – but also suggests that incumbents may have an important role to play in a low-carbon transition. A brief review of recent studies in the area of sustainability transitions shows how researchers have aimed to understand transitions as interacting, co-evolving socio-technical processes and how studies that were mainly qualitative have now achieved better integration with quantitative analyses. A concluding discussion explores the many challenges involved in the governance and implementation of modern purposeful transitions, particularly low-carbon transitions. In these transitions, private incentives to adopt low-carbon fuels, technologies and practices are currently insufficient to ensure their adoption to the extent that makes sense for society; at the same time, the urgency of addressing greenhouse gas emissions from fossil fuels calls for unprecedentedly rapid change and the use of well-targeted, sustained but flexible policies and instruments.

What are Energy Transitions and Why Do They Matter?

An energy transition is often simply described as a shift from one dominant energy carrier to another. In practice, energy transitions involve changes or

shifts in how, where and by whom energy is produced, converted, supplied and used. These changes lead to new patterns, quantities and qualities of fuels, technologies and uses that interact and co-evolve with wider socioeconomic, demographic, technological and environmental developments and patterns: consequently, energy transitions are now often known as socio-technical transitions.

Energy transitions have included shifts from the dependence of early humans on firewood and human labour, to the growing use of animal labour and more sophisticated processing and uses of biomass fuels (peat, wood, grass, crop residues, charcoal), to wind and water power, coal, oil, gas and electricity. Such transitions have unfolded over decades and even centuries and are ongoing (Fouquet 2010; Smil 1994, 2010). Although the new sources may grow and dominate, the incumbent energy source(s) and technologies often continue to be used for several decades or longer (Fouquet 2008; Kander et al. 2013, Ch. 5).

Energy transitions matter because they have enabled – and been influenced by – increases in economic growth, welfare and population and the exploitation of natural resources. Economic history has shown how they have contributed greatly to human welfare through enabling significant, sustained increases in productivity and economic output and the production of new commodities and services (Kander and Stern 2014; Mokyr 2009). For many developing and emerging nations, transitions that provide affordable access to modern fuels, energy technologies and end-uses to large and growing populations are crucial elements of their development strategies (Barnes et al. 2005; IEA 2014; 2015a, b). Transitions also matter because different transitions and fuel mixes lead to different profiles of resource use and depletion (for renewable and fossil fuels respectively). And because fuels have different chemical properties (e.g. different fossil fuels have different ratios of hydrogen to carbon), and footprints in extraction, capture and use, transitions lead to different spatial and temporal environmental implications in the form of short-or long-lived local, regional and global impacts on air, land and water.

Policy on current transitions includes a focus on moves towards low-carbon fuels and technologies to reduce greenhouse gas emissions, particularly those from fossil fuels, and so address the threat of climate change (IPCC 2014). In most past transitions, however, there were obvious benefits that producers and consumers could gain from switching to the new energy sources and their uses, so such transitions were largely endogenous. Such private benefits are as yet much less evident for low-carbon technologies and practices. Both this gulf between private and social benefits and the widely (although not universally) perceived urgency of addressing climate change (Capstick et al. 2015) mean that a low-carbon transition has to be purposefully guided through public policy, a challenging contrast with most previous transitions (Pearson and Foxon 2012). Moreover, the avoidance of damages from climate change constitutes a global public good, i.e. one that is non-rival (one nation's benefit from avoided emissions and concentrations does not reduce the benefit available to others) and non-excludable (nations cannot be excluded from the benefits of avoided damage, even if they have not contributed towards such avoidance); this implies that it needs to be provided and financed via a form of global governance that is proving hard to construct.

Studies of past energy transitions include: Smil (1994, 2000) at an international scale; a range of international studies in Fouquet and Pearson (2012a); Kander et al. (2013), on five centuries of European experience; Schurr and Netschert (1960) on energy in the USA from 1850s, and more recently O'Connor and Cleveland (2014) on US transitions since 1780; and for the UK, Fouquet and Pearson (1998), Warde (2007) on primary energy transitions since 1760, Fouquet (2008, 2014) on energy services and Arapostathis et al. (2013) on the gas industry. Reviews and commentaries on energy transitions include Araújo (2014), Elzen et al. (2004), Fouquet (2015), Grin et al. (2010), Grubler (2008, 2012), Markard et al. (2012) and Smil (2010).

Transitions occur in the use of forms of primary energy (energy embodied in sources which involve human induced extraction or capture, so

as to make the energy available for trade, use or transformation), such as coal, oil, sunlight and wind. Transitions also occur in secondary energy forms or carriers delivered to the final user, such as gasoline, electricity and hydrogen. They help produce valued energy services, such as heat and comfort, mobility and illumination, with the aid of delivery infrastructures (pipes and wires) and end-use devices, such as light bulbs or passenger cars (Fouquet 2008). These secondary forms of energy are often of higher quality, such that they can be used for a wider and/or more valuable range of economically productive or satisfying activities (Cleveland et al. 2000; Stern 2010; Gentilvaite et al. 2015). They often cost more because of the conversion processes and losses involved (e.g. electricity and gasoline cost more than the fuels used to obtain them). However, users have been willing to pay for them because of their greater value and range of application in particular uses. For example, electricity is more flexible in use and, with efficient electric motors, enabled higher productivity than mechanical power from coal; gaseous and liquid fuels were essential for the internal combustion engine and more efficient, more flexible transport. Consequently they and their associated end-use devices tend to be increasingly demanded when incomes and living standards rise (Fouquet 2008, 2015; Grubler 2008), as recent experience in India, China and elsewhere confirms.

Recent Growth of Interest in the Study of Energy Transitions

Although energy transitions have long been of interest to many disciplines, academic and public policy interest in energy transitions grew steeply from the 1970s, partly in response to the stimuli of higher oil prices and environmental concerns. While economic historians have long studied them, energy transitions were of much less importance to mainstream economics until the past half-century or so of growth in the sub-disciplines of energy and environmental and development economics.

The 1970s saw rising concerns over oil availability and prices, resource depletion and energy-related environmental pollution, especially in the industrialised world, following the 1973–74 and 1979–80 oil price shocks; and in the developing world over 'the other energy crisis' (Eckholm 1975), i.e. worries about shortages of biomass fuels (e.g. wood fuel, charcoal, crop residues and animal dung), postulated impacts of wood fuel collection on deforestation (contested, since deforestation has many other more significant causes, such as land clearance for agriculture) (Anderson 1987) and other forms of environmental degradation, including soil erosion and health impacts from indoor air pollution from unenclosed stoves (Barnes et al. 2005; Fullerton et al. 2008).

From the late 1980s, along with continuing debate about petroleum resource depletion, the volatile geopolitics of oil and gas and ideas of sustainable development, we have seen a tightening policy focus on transitions to low-carbon forms of energy (renewables and nuclear electricity) and behavioural changes towards more efficient and reduced use of energy.

This arose *inter alia* from studies of the global climate impacts of concentrations of greenhouse gases associated with emissions from fossil fuels and other energy-related human activities, including cement production and land use change (IPCC 2014), and growing emphasis on the bringing together of climate policy and energy policy (Pearson and Watson 2012). Recent developments in seismic and drilling technologies, along with hydraulic fracturing ('fracking'), have led to significant exploitation of shale and unconventional gas and oil resources, especially in the USA. This has also brought a new set of environmental implications, both negative and positive, as well as impacts beyond the USA on the relative price and availability of coal and its use in power generation, and in some jurisdictions issues about the public acceptability of fracking (Hammond et al. 2015; Joskow 2015; Rasch and Köhne 2015; Stevens 2013).

Today, there are serious concerns about various ongoing and prospective transitions and their economic, environmental and social implications. These concerns include the challenges of mitigating and adapting to the very long-run impacts of

potential climate change; disquiet over the implications of the very rapid growth in fossil fuel use and associated urban air pollution and greenhouse gas emissions in recently industrialising countries like China and India; and the desire in many developing countries for rapid transitions from traditional biomass to modern fuels. As noted, common to all these areas is that they imply active management and guiding of transitions, which was largely absent from earlier energy transitions, while low-carbon energy transitions require a new form of global energy governance. They also imply largely unprecedented moves away from highly valued energy-dense fossil fuels towards less energy-and power-dense (and in some cases intermittent) forms of renewable energy (such as wind), which bring their own challenges and opportunities (Smil 2010).

Past Transitions: The First and Subsequent Industrial Revolutions

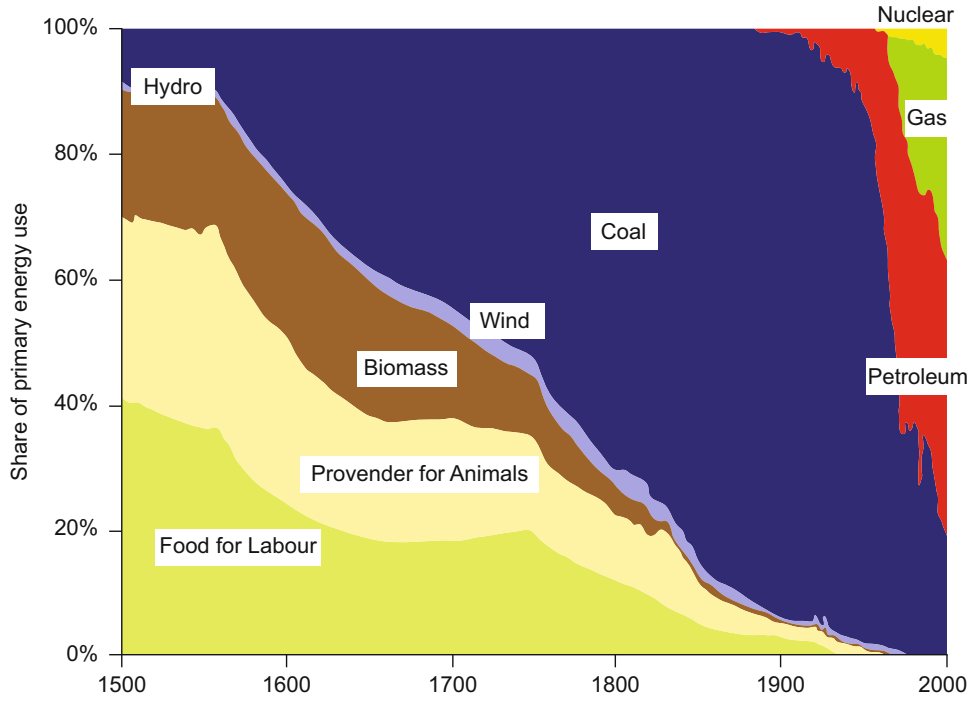
Although the past does not offer a blueprint for the future (Allen 2012), a knowledge of the characteristics, patterns and key relationships involved in past transitions can yield insights, parallels and partial analogues that may be instructive for policy thinking today. Indeed, Grubler (2012) suggests that part of the value of historic transitions work is that it helps develop 'storylines' for future transitions and invites us to question prevailing policy wisdom. It is not surprising, therefore, that part of the attention now paid to past transitions has been stimulated by the current concerns just described.

There has been rising interest in understanding how past transitions unfolded and in collating, recovering and analysing data on them (Fouquet 2008; Kander et al. 2013). Energy transitions have played major roles in industrial revolutions that have transformed economy and society. One of the most studied examples of a long, slow transition is that to coal before and during the first Industrial Revolution in Britain (in which much of the key activity took place in the 18th and 19th centuries). The second Industrial Revolution in the late 19th and early 20th centuries, which saw particularly striking developments in the USA and Germany, was intimately bound up with developments in petroleum, the internal combustion engine and electricity. Today, developments in the use of ICT in the energy system, including in 'smart grids', 'smart controls' and the 'internet of things', sometimes described as part of a third Industrial Revolution, could have major implications for energy use and economic growth and welfare; moreover, energy transitions in the developing world have the potential to transform – or not – the lives and life chances of billions whose living standards are constrained by lack of access to affordable modern fuels and technologies (GEA 2012a).

The long-drawn-out transition from wood and charcoal to coal in Britain before and during the first Industrial Revolution offers valuable insights into the complexities, causes and consequences of energy transitions, even though so much has changed since then. Figure 1 shows how the shares of different energy sources in Britain evolved over 500 years.

Wrigley (1988, 2010) shows how the 16th to 19th century transition from the limited energy flows possible in a constrained 'organic', largely biomass-based energy system to one based on coal helped transform Britain's economy in the Industrial Revolution. In the 'organic' economy – apart from intermittent wind and water power, energy *flows* were limited to what could be captured each year with available technologies and knowledge via photosynthesis. The organic material could feed people and draft animals and their labour and be used to provide heat and other energy services. The growing exploitation of *stocks* of coal, the fossilised, energy-dense accumulation from past photosynthesis, relaxed these constraints: 'To us the evidence points to the impossibility of sustaining high levels of growth or transformation in a world wholly dependent on 'organic' or vegetable sources of energy' (Kander et al. 2013, pp. 14–15).

Innovations, including the steam engine, the substitution of coal and coke for wood and charcoal in metal manufacture, new spinning and weaving technologies and textile mills, along with other socio-economic changes, helped lead

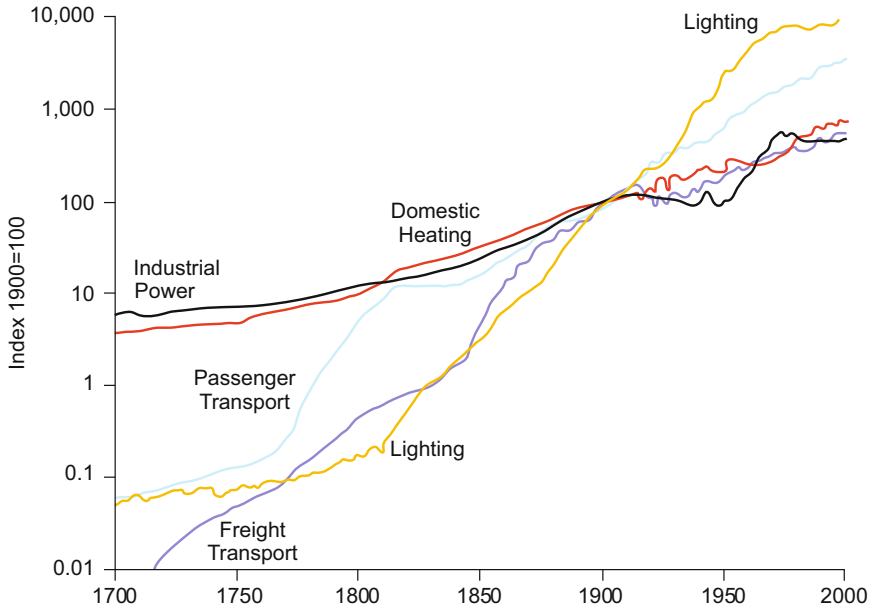


Energy Transitions, Fig. 1 Shares of primary energy consumption in Britain, 1500–2000 (Source: Reproduced from Fig. 5 in Fouquet (2010), with permission from the author and Elsevier. http://www.sciencedirect.com/science/article/pii/S0301421510004921. Original data from Fouquet (2008), with updates.)

and sustain the urbanisation, mechanisation and industrialisation of the Industrial Revolution. They led to striking declines in the cost of direct energy services (Fouquet 2008; Fouquet and Pearson 1998, 2006, 2012b; Pearson and Fouquet 2003) and increases in their consumption (see Fig. 2). They also led to efficiency improvements in manufacturing and other processes that yielded higher productivity and economic growth and better quality products. And they gradually meant much higher standards of living for the general population, as well as producing new problems of land, air and water pollution.

Unlike later transitions outside the UK, much of the transition to coal was pre-industrial; however, by around 1750, on the eve of the main years of the Industrial Revolution, coal already provided half of England's fuel (see Fig. 1). By 1900, 140 years later, almost all of the country's energy came from coal. Allen (2012, p. 17) states that 'Britain's transition to coal was bound up – both as cause and as effect – with the Industrial Revolution. . . High British wages and cheap coal underpinned the Industrial Revolution by creating a demand for technology that substituted capital and energy for labour. In Asia and much of Europe, low wages and dear energy had the opposite effect.'

The high wage/cheap energy price structure came from Britain's foreign trade boom in the 17th and 18th centuries. London's growing demand for fuel for industrial and domestic heating energy, a rising price of wood fuel relative to coal and the development and construction of the coal-burning house also created incentives to shift to coal and the means of doing so. On the supply side, Allen concentrates on the role of increased literacy and numeracy and the connections between the scientific discoveries of the 17th century and technological advances. For steam power he argues that the kind of R&D needed to bring the pan-European science to fruition, 'was more profitable in Britain than elsewhere, which is why the Industrial Revolution was invented in



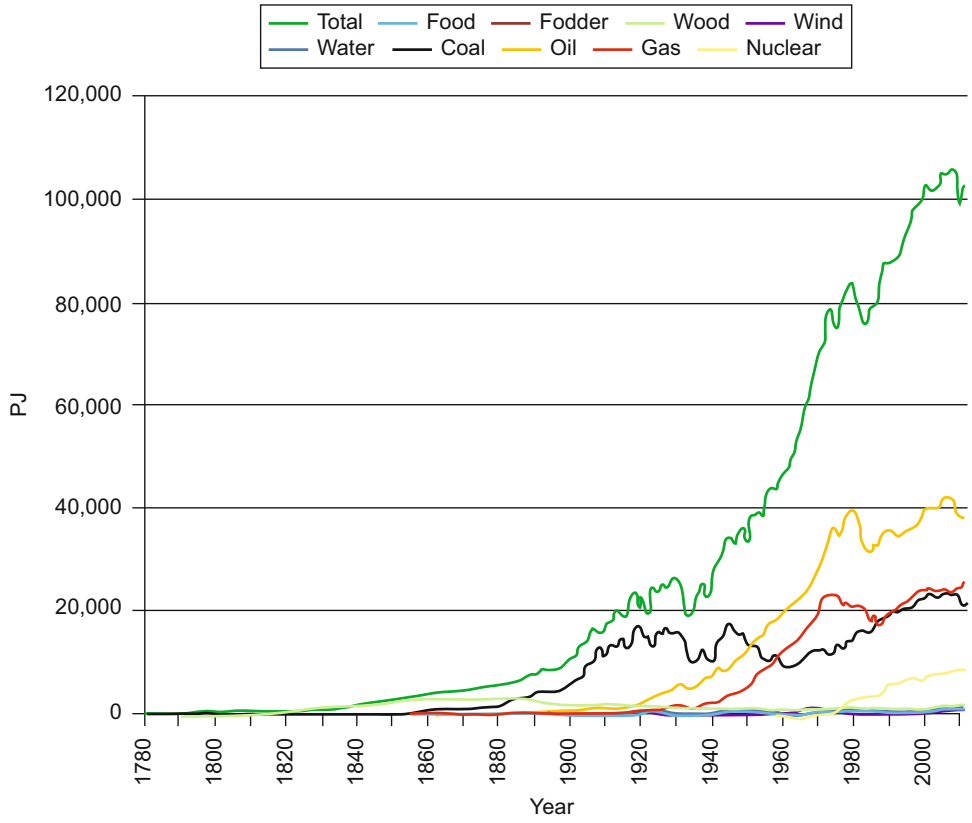
Energy Transitions, Fig. 2 Consumption of energy services in the UK, 1700–2000 (index 1900 = 100) (Source: Fig. 1 in Fouquet (2014). Reproduced with author's permission, under a Creative Commons license. http://creativecommons.org/licenses/by/4.0/.)

Britain.' The 'macro-invention' of the Newcomen engine was followed by a series of 'micro-inventions' that more than decimated the steam engine's coal consumption, to the point where the cost of coal became irrelevant to its commercial application and the steam engine became an 'appropriate technology' for other countries with different relative price structures.

Mokyr places much more emphasis than Allen on the view that the Industrial Revolution grew out of 'the social and intellectual foundations laid by the Enlightenment and the Scientific Revolution' (Mokyr 2009, p. 11). Britain led the Industrial Revolution because it could exploit its favourable human and physical resource endowment 'thanks to the great synergy of the Enlightenment: the combination of the Baconian program in useful knowledge and the recognition that better institutions created better incentives' (Mokyr 2009, 122). What was needed 'was the right combination of useful knowledge generated by scientists, engineers and inventors to be exploited by a supply of skilled craftsmen in an institutional environment that produced the correct incentives for entrepreneurs' (Mokyr 2009, p. 116).

The period between the late 1900s and the early 20th century, sometimes said to run between 1870 and 1914, with some precursor activity from the 1850s (although the boundaries are disputed), 'saw the lusty childhood, if not the birth... of a cluster of innovations that have earned the name of the Second Industrial Revolution' (Landes 1969, p. 235), which variously influenced the economies of the USA and Western Europe (especially Germany), with smaller and later effects in Eastern Europe and some parts of Asia and South America. These inventions and activities included many that were directly to do with energy, including electrical power, motors and lamps, telegraphy, the telephone and radio, the internal combustion engine and vehicles that used it and the growing use of oil and its products, as well as developments in organic chemicals and synthetics, in steel production, in the factory system and mass production and a range of advances in medical knowledge, public and private health and sanitation.

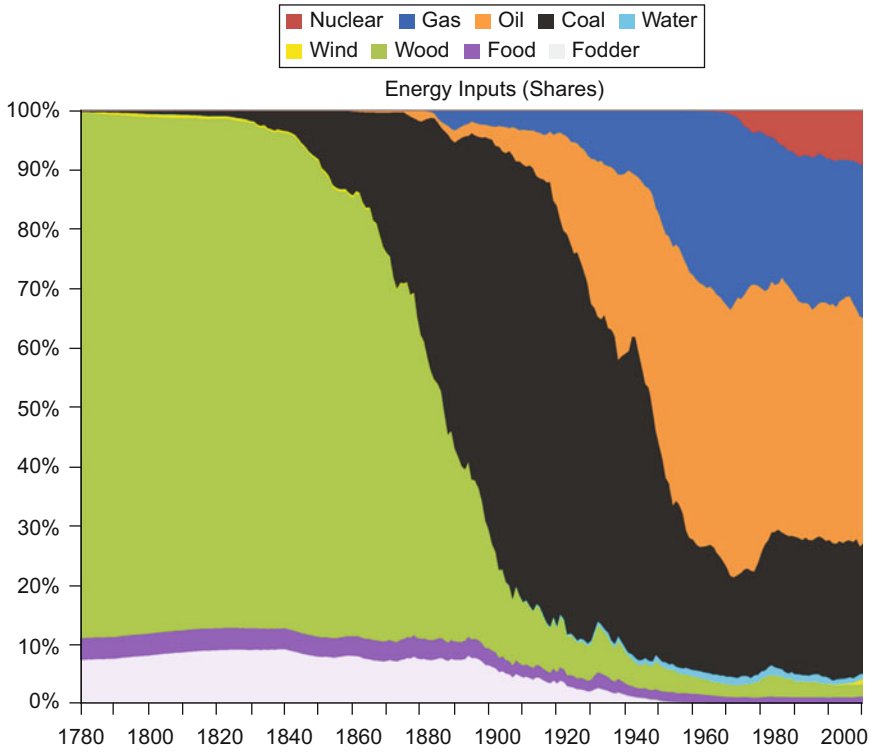
Mokyr (1999) argues that the path-breaking inventions of the second Industrial Revolution were crucial not because they necessarily had a



Energy Transitions, Fig. 3 US energy consumption 1780–2010 (in petajoules) (Source: O'Connor and Cleveland (2014, Fig. 13); reproduced under a Creative Commons license and with the author's permission. http://creativecommons.org/licenses/by/4.0/. See also O'Connor (2014).)

major direct impact on production but because they raised the effectiveness of research and development in microinventive activity and led to a range of further applications. While the first Industrial Revolution had a very limited scientific base, 'the persistence and acceleration of technological progress in the last third of the nineteenth century was due increasingly to the steady accumulation of useful knowledge' from science and the interplay with novel techniques and learning from experience. Along with this, changes in the organisation of production and the growing exploitation of economies of scale and scope, partly through mass production, meant that the second Industrial Revolution saw the rise of the large technological system, as with electrical power (Hughes 1983). Indeed, Gordon (2000, p. 1) argues that 'it was the Second Industrial Revolution, not the first, that created the golden age of productivity growth' that was to follow, with concomitant rises in income, wealth and living standards.

It should not be thought, however, that the pattern and duration of the energy transitions experienced in Britain during and after the Industrial Revolution would be simply replicated in other countries with different economies and resource endowments. For example, O'Connor and Cleveland (2014) undertook a comprehensive study of US energy transitions, through the assembly and use of a database of energy use for 1780–2010 that includes both traditional forms of energy (food, fodder, firewood, wind, water etc.) and the usual commercial forms (fossil fuels, nuclear and renewable electricity etc.). Figure 3 shows the remarkable rise in total energy use of

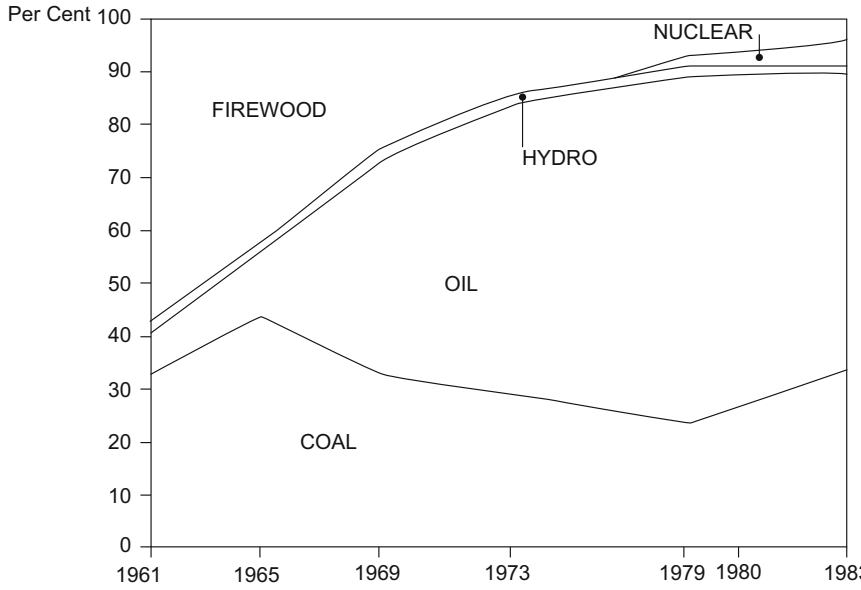


Energy Transitions, Fig. 4 Shares of inputs to US energy consumption, 1780–2010 (Source: O'Connor and Cleveland (2014, Fig. 14); reproduced under a Creative Commons license and with the author's permission. http://creativecommons.org/licenses/by/4.0/. See also O'Connor (2014).)

well over 300 times in 230 years (around 300 PJ (petajoules) in 1780 to 100,000 PJ by 2010). There is particularly rapid growth as the economy expanded in the 20th century, albeit with evidence of the impacts of major events, including the Great Depression, world wars and the oil price shocks of the 1970s.

O'Connor and Cleveland discuss major US transitions, building on the assumption that a reasonable benchmark for the start of a transition is when a new energy source captures 5 % of primary energy use (Smil 2010). Figure 4 shows that, in contrast with the dominance of coal early in the British Industrial Revolution (Fig. 1), as the US developed, wood retained a 50 % share of total energy use even through the mid-1880s. Although coal reached 5 % in the mid-1840s, it only gained a half share in the late 1880s, four decades later (through its use in steam engines, for transport and stationary power, in iron production and electricity generation); its share peaked at about 75 % three decades further on. Oil, first produced there in 1859, did not significantly replace coal until the early 20th century, when demand grew with the spread of the internal combustion engine and new and cheaper supplies of oil could satisfy it. Oil did not exceed coal's share until about 1950, peaking at just under 50 % in the late 1970s, whereas natural gas overtook coal's share by about 1960.

O'Connor and Cleveland also examine the changing energy intensity of the American economy, in terms of its energy/GDP (E/GDP) ratio. It is often thought that energy intensity rises with development, then falls in an inverted-U shape as an economy matures. When traditional energy sources are included, however, the US graph shows an overall declining trend, albeit with a 40-year period from around 1880 to 1920 when it was constant or rose. They ascribe the changing



Energy Transitions, Fig. 5 South Korea: shares in total primary energy supply, 1961–83 (Source: Pearson (1988) and the sources described there.)

slope of the E/GP ratio largely to the influence of three factors: (a) changes in energy quality (which they define as the marginal increase in GDP flowing from the use of one additional heat unit of a fuel), with higher quality fuels substituting for lower quality fuels over time, as in Fig. 3; (b) improvements in the efficiency of energy end-use, from incremental improvements in existing technologies and from the adoption of new technologies (which they illustrate via the example of changes in lighting technologies, but which have arisen in other main energy conversion processes and heat production); and (c) more efficient operational organisation and new manufacturing systems. And, of course, aggregate energy efficiency is influenced over time by the changing sectoral mix of activities with different energy intensities across the sectors of an economy (for a discussion of the reasons for the declining trend in aggregate energy intensity in Europe in the 20th century, see Gentilvaite et al. 2015).

Just as Britain's energy transitions were not replicated in nature or timing by those of the USA, Rubio and Folchi (2012) present evidence on the energy transitions from coal to oil for 20 Latin American countries over the first half of the 20th century. They argue that these small energy consumers had earlier and faster transitions than leading nations. By outlining a whole series of energy transitions, they identify a number of different transition processes. Factors such as domestic energy resources, the size of the internal market for energy services, trade relations and policy decisions were important in determining the nature and speed of the transitions experienced. They suggest that the lessons will be particularly relevant for understanding the way in which non-pioneering countries might adopt low-carbon energy sources and technologies.

The experience of the Republic of Korea (South Korea) since the beginning of the 1960s provides a striking example of more recent and much more rapid and highly directed transitions, illustrated in Fig. 5.

The figure shows that in less than 20 years, Korea transited from nearly 60 % dependence on wood fuel (and serious deforestation problems) to 90 % dependence on modern commercial fuels (Pearson 1988). Total energy supplies grew at an average of more than 8 % per year between 1962 and 1979, at a time when Korea experienced remarkably rapid economic growth and structural

change. In less than two decades, the country was transformed, via an outward-oriented industrialisation strategy, from a poor developing country into a semi-industrial middle income country, even though it was poorly endowed with energy resources or a mineral base for heavy industry (Kim 1983).

The first of three major transitions was from fuel wood to anthracite coal during the first five-year plan (1962–66); the second saw the growing replacement of coal by oil during the second plan (1967–71); and the third saw transition away from heavy dependence on oil towards a wider mix of fuels, after the first oil shock (1973–74), and more strikingly, after the second shock (1979–80). These were highly directed transitions in which, until the second oil shock, the main aim of energy policy was to ensure that energy did not become an obstacle to economic growth, with efforts directed towards supplying cheap and often subsidised energy to critical sectors (electrical power and industry). The increase in world oil prices and import costs and other inflationary pressures after the second shock led the government to re-evaluate the expansionist policies it had pursued until that point (Kim 1983).

Kander et al. (2013), in a major study of energy and economic development in Europe, have recently analysed the unfolding of energy transitions in several countries over five centuries. They do this through exploring first the pre-industrial economies and then the First, Second and Third Industrial Revolutions. In their analysis, they employ the term 'development blocks' 'to describe the series of systems of technology, infrastructure, energy sources and institutions by which economic growth proceeded'. Development blocks are constantly evolving systems centred on a generic technology (Dahmén 1988; Enflo et al. 2008). For instance, they say that it was the combination of coal, steam engine and iron, the raw material from which much of the new technology was made, that characterised and drove the first Industrial Revolution in Britain and then Western Europe. Kander et al. argue that although the process of growth is fairly continuous, it has been 'achieved through fundamentally discontinuous processes involving major structural shifts that take time to achieve' because of a significant lag between early inventions and the widespread adoption of a technology. They argue that transitions to higher quality energy carriers and rising thermal efficiencies in machines have led to improvements in economic energy efficiency, indicated by the ratio of GDP to Energy (GDP/E).

In addition, technological shifts associated with development blocks and industrial revolutions have produced structural shifts (changes in the relative importance of different activities) that have also significantly affected economic energy efficiency, making technologies more affordable, sometimes with concomitant *rebound* or *take-back* effects from increased demand (see Turner (2013) for a review of rebound concepts).

As with most analyses, Kander et al. (2013) emphasise and explore the interplay between energy, economic growth and population. As part of this, they examine the growth in total energy consumption (E) by decomposing it into the effects of three factors, energy intensity (E/GDP) – the inverse of economic energy efficiency, per capita income (GDP/P) and population (P) (these latter comprise the *scale effect*):

$$E = (E/GDP) \times (GDP/P) \times P$$

They show, for example, that for Western Europe between 1820 and 1910, while energy grew on average at the rate of 2.04 % per year, population grew at 0.76 %, income per capita by 1.08 % and energy intensity by 0.19 %.

Later they explore the evolution of carbon emissions (C) and the key factors that have influenced it by decomposing the widely used Kaya Identity (Ogawa 1991) into carbon intensity (C/GDP), energy intensity, per capita income and population, each of which can exert a significant influence:

$$C = (C/E) \times (E/GDP) \times (GDP/P) \times P$$

For other examples of such decompositions, see Pearson and Fouquet (1996, 2006).

Although coal and steam power are widely acknowledged to be key elements in the first

Industrial Revolution, it has not proved easy to demonstrate formally their rapid impact on output and productivity growth (Crafts 2004). It should be noted, however, that in a broader European context Kander et al. (2013, p. 368; also Appendix A) argue strongly that 'energy is more important to economic growth than generally believed among economists'. They suggest that such economists' focus on overall efficiency gains may miss the 'capital deepening' effect (linked to the growing use of machinery stimulated by cheap energy) that in their view has played an essential part in raising labour productivity (see also Kander and Stern 2014). They also argue that scepticism about energy's role in explaining economic growth is partly a reflection of economic growth models set up with low-or zero-cost shares for energy.

Energy Transitions and Time

As we have seen, economic historians have argued that the coming together of the elements that made up the transition from wood to coal in the UK not only had deep historical roots but also took a considerable time to develop. Pearson and Foxon (2012) note how evolutionary economists, drawing on some earlier economic ideas of Kondratiev and Schumpeter, identified five 'long waves' of economic development. In these waves, while the application of innovative technologies and processes, such as the steam engine, electrification and mass production, drove growth, the full societal benefits were only realised when wider institutions and practices had time to adapt to them. It is argued that structural crises of adjustment tend to arise in the face of the widespread introduction of radical new technologies because suitable new institutions and industrial structures have to be established to accommodate them (Freeman and Perez 1988; Freeman and Louça 2001).

Grubler (2012), considers the speed at which transitions have taken place. He notes that at the global level, characteristic 'change over times' (Marchetti and Nakicenovic 1979) in primary energy range from 80 years for the growth of oil/gas/electricity replacing steam power to 130 years for the growth of steam power displacing pre-industrial renewable sources. He also observes that while European late adopters of new technologies achieved faster transitions through profiting from learning externalities that reduced the costs of later adoption, early adopters faced the challenge of sunk costs associated with human, technological and infrastructural capital.

Wilson (2012) has also explored how and why energy supply and end-use technologies take time to mature. He studied processes of scaling-up, formative phases and learning in the historical diffusion of energy technologies from the early 1900s. He used logistic growth functions to help establish the time from initial commercialisation to market saturation. He concluded that: (1) increases in unit size come after an often prolonged experimentation with many smaller-scale units; and (2) that the peak growth phase of an industry can lag these increases in unit size by up to 20 years. Correspondingly, for a low-carbon transition, he suggested that it may be risky to use low-carbon technology policies that push for big jumps in unit size before a 'formative phase' of experimentation with smaller-scale units.

Fouquet (2010) examined past energy transitions and their drivers in the UK between 1500 and 1920, by end-use energy service (for heat, power, light and transport) and sector, to help find common features relevant for future transitions. He gives greater weight to post-Industrial Revolution transitions and reminds us of the dangers of aggregation: partly from a lack of detailed data, many historical studies have tended to analyse broad transitions within an economy. However, as he shows, a 'single' energy transition (say, from wood fuel to coal) may be composed of several different transitions, some running in parallel and others at very different times.

Fouquet identified the opportunities to produce cheaper and/or better energy services as the main economic drivers in the 14 cases he examined (and in most cases he also identified catalysts for faster adoption). The new services began in niche markets or market segments. Here, despite their often initial higher costs, users might be willing to pay for their extra service attributes (e.g. greater ease, cleanliness or flexibility in use, or faster

speed of transport). These new energy sources and energy-using technologies could be subsequently refined (e.g. leading to lower fuel costs or enhanced energy conversion efficiencies) until they could compete successfully across the market with the incumbent service provider (e.g. the switch from horse to rail transport or from gas to electric light). This process of refinement, performance or quality improvement and cost reduction meant that on average the whole innovation chain took more than 100 years and the diffusion phase nearly 50 years. Fouquet also suggests that, based on past experiences, a complete transition to a low-carbon economy could be very slow. This, he concludes, suggests that 'early action and favourable conditions may be warranted to steer any transition to a low-carbon economy'.

The studies reported in Fouquet (2008) found remarkable increases over time in the efficiency of converting energy flows into energy service flows, which were particularly striking in the case of lighting. Indeed, Grubler (2012) states that past energy transitions were essentially driven by technological and associated institutional and organisational transformations in energy end-use: 'transitions in energy services, in which new technological combinations enabled entirely new, or vastly improved traditional services, at greater energy efficiency and ever falling costs in a virtual, self-re-enforcing positive feedback loop drove associated transitions in energy supply systems'. While accepting that energy demand and supply systems co-evolve, and that there have been transformative changes in supply systems and technologies, he asserts that in the absence of energy service demand changes, we would not have seen the kinds of radical energy supply changes that have emerged so impressively from studies of the past. This implies the particular importance for policy of acting on the end-use and demand side, as well as the supply side. For example, it is clear that a successful low-carbon transition requires the decarbonisation of both heating and transport systems, which currently often depend on liquid and gaseous fossil fuels, with many consumers deeply attached to their current cars and heating systems; moreover, many current policy strategies are predicated on significant behavioural changes by energy consumers on an unprecedented scale.

Numerous studies suggest that although energy transitions have proceeded at different speeds in different places and times, and some of the more recent transitions have been faster, transitions do not usually happen quickly (Sovacool 2016). When they do, they seem likely to have built on a foundation of precursor activities in areas including infrastructure, institutions, technology, niche experimentation and an openness to change. For example, although the headline events of the UK's transition from town gas (produced from coal) to natural gas from the North Sea took 10 years between 1967 and 1977, the seeds were sown in the 1940s as the newly nationalised industry accepted the need to respond to the challenge of rising costs and growing competition from coal, oil and electricity. It not only experimented with alternative technologies and feed stocks but also made major institutional and organisational changes that enabled it to respond rapidly to the discovery of natural gas in the North Sea and to decide to strand its hundreds of town gas-producing assets (Arapostathis et al. 2013).

Lock-in, Path Dependence and the Role of Incumbents

In energy transitions, the penetration of innovative new fuels and technologies depends on their ability to compete with and displace the incumbent fuels, technologies and their industries. This in turn is influenced by the strategies and reactions of those incumbents. Long-term technological systems change can be path-dependent, in that a system's future evolution depends on the past sequence of events that led to its current state, i.e. its 'evolution is governed by its own history' (David 2007). So a system state may be locked in because of particular historical experiences, creating barriers to moving to an alternative state, although the conditions leading to that lock-in may no longer obtain (David 2001; Foxon 2007).

Arthur (1994) showed that increasing returns relating to scale, learning, adaptation and network

effects can lead to technological lock-in, while North (1990) and Pierson (2000) suggested that increasing returns can also apply to institutions, including market or regulatory frameworks – such that rule systems become hard to alter, enabling incumbents to protect their interests (see also Foxon 2011). These processes have important implications for future low carbon transitions. Thus Unruh (2000, 2002) and Unruh and Carrillo-Hermosilla (2006) suggest that co-evolutionary processes and mutually reinforcing positive feedbacks have led to the lock-in of current fossil fuel energy systems, i.e. carbon lock-in, and hence to systemic barriers to investment in low-carbon technology systems that can retard low-carbon transitions.

Nevertheless, it has also been argued that if increasing returns to new alternatives can be set off, this may lead to virtuous cycles of rapid change. Thus Garud and Karnøe (2001) have suggested there can also be 'path-creation' by incumbents: entrepreneurs may choose to depart from the structures they have jointly created. Incumbents may also, of course, sometimes increase their competitiveness. The sailing ship effect or last gasp effect of obsolescent technologies (Rosenberg 1976) is postulated to occur where competition from new technologies stimulates improvements in incumbent technologies/firms (but see Mendonça 2013). Analyses of energy industries threatened by technological discontinuities have, for example, offered insights into how the UK gaslight industry eventually responded to the threat from newly introduced incandescent electric light (Arapostathis et al. 2013) and why incumbent automotive technologies might show a sudden performance leap (Furr and Snow 2014); and, on the other hand, how current analyses may overestimate new entrants' ability to disrupt incumbent firms and underestimate incumbents' capacities to see the potential of new technologies and to integrate them with existing capabilities (Bergek et al. 2013). Given the urgency of climate change and the time taken for new entrants to scale up their activities, growing attention is now being paid to the potential of encouraging large relatively high carbon incumbents' positive engagement with low-carbon transitions, as well as to limiting their ability to constrain them.

Sustainability Transitions Studies

The growing interest in sustainable energy futures (e.g. GEA 2012a,b) is reflected in recent theoretical and empirical work in areas ranging from innovation to low-carbon transition pathways and policies to achieve them. We briefly explore an approach, often called 'sustainability transitions', that has attracted recent academic and policy attention. In sustainability transition studies, researchers explore potential societal transformations in production and consumption that combine economic and social development with reduced pressures on the environment.

In their review, on which this section draws, Markard et al. (2012) explain how this new field of studies has grown, as those in the policy arena and social scientists have paid growing attention to how to promote and govern a low-carbon transition to sustainability. In transition studies, sectors like energy are viewed as socio-technical systems that comprise interacting networks of actors (people, firms etc.), broadly defined institutions, material artefacts and knowledge. Thus an energy transition might unfold over several decades, and involve many actors and lead to new products, services, user practices, business models and organisations, as well as changes in technological and institutional structures and impacts well beyond the energy sector. Sustainability transitions are, therefore, complex, long drawn-out processes, involving governance and guidance (Smith et al. 2005), through which systems shift towards more sustainable modes of production, consumption and living.

The idea of the socio-technical regime brings ideas from evolutionary economics together with insights from the history and sociology of technology. It emphasises how scientific knowledge, engineering practices and processes are socially embedded. The regime tends to persist unless destabilised, leading to the emergence of a new regime. Much of the interest in this area is in regime changes, transitions, and the factors that

might result in such destabilisations (e.g. Kemp et al. 1998). For example, Turnheim and Geels (2013), explored the factors that led to the decline and ultimate demise of the UK's coal mining industry from its late 19th century dominance of the world coal market.

Researchers in sustainability transitions have carried out numerous empirical studies of historical energy transitions. These studies drew on the notion of the multi-level perspective (MLP), an approach built on the researches of Kemp, Rip and Schot (Kemp et al. 2001; Rip and Kemp 1998). The MLP posited that transitions could arise from dynamic interactions between the three interconnected levels of niche, regime and landscape. Pressures on the regime from the landscape, such as higher world oil prices or concern over climate change, might help prise open windows of opportunity for innovations in niches (i.e. 'protected spaces' in which innovations can develop and that might be managed strategically); some innovations might then break through, leading perhaps to fundamental regime shifts (Geels 2002, 2005; Raven et al. 2015). Different interactions could then lead to several different types of transition pathway, including pathways to future energy systems (Geels and Schot 2007). This approach has been used to help develop forward-looking analyses of the challenge of developing low-carbon energy transition trajectories, as in Hammond and Pearson (2013) and Trutnevyte et al. (2014), which describe studies of pathways to the UK's legislated target of 80 % reductions in greenhouse gas emissions by 2050.

Notions of transition management brought transition research together with insights from the areas of complex systems theory and governance. From these ideas came procedures to try to guide ongoing transitions toward greater sustainability (Kemp and Loorbach 2006). The guiding principles for transition management were derived from thinking about existing sectors as complex, adaptive systems and understanding management as a reflexive and evolutionary governance process (Voss et al. 2009). Transition management has been attempted in the Netherlands but has proved challenging, while questions have been raised about the political feasibility of trying to 'manage' national level transitions through such processes.

Energy Innovation Systems approaches have constituted another key approach in transition studies. Truffer et al. (2012), review the energy-related areas of the emerging socio-technical innovation systems literature, which has aimed to address the interacting social and technical aspects of innovation processes. This literature ranges across four innovation system areas: those of national (NIS), regional (RIS), sectoral (SIS) and technological (TIS) innovation systems.

The NIS developed in the late 1980s, partly as a riposte to what was seen by its proponents as the failure of neo-classical economics to explain the major economic challenges of that period: 'The core assumption was that nationally specific institutional arrangements between science, policy and industry explained differences in innovation success among different countries (especially the technology leaders US, Germany and Japan)' (Truffer et al. 2012, p. 4). The other three innovation systems approaches started from a criticism of the original NIS for limiting systems within their national boundaries and ignoring wider influences and interactions, such as the role of multinational companies. However, of these areas, Truffer et al. argue that the TIS tradition has been much the most productive in the energy field (see also Markard et al. 2015). TIS has its roots in the seminal paper of Carlsson and Stankiewicz (1991), which drew on Dahmén's work on development blocks (Dahmén 1988; Enflo et al. 2008), mentioned earlier.

Studies have gone from looking at selected energy innovations in particular countries, often focusing on the functions of the innovation system necessary for it to operate well (Hekkert et al. 2007), to inter-country comparisons and to some regional and global analyses of technological innovation systems. Much of the focus is on Europe, but with growing attention to emerging economies. The work includes an analytical framework of an 'energy technology innovation system' that claims to produce innovation policy guidelines that 'diverge substantially from policies implied by partial perspectives on innovation' (Gallagher et al. 2012). Despite the

progress in energy innovation systems research, Truffer et al. (2012) rightly suggest that there is room for further integration of the four systems approaches, and for further conceptual and empirical developments, including in the analysis of longer term energy transitions and their dynamics.

While much of the research on energy transition pathways has been historical and qualitative, belated but increasing attention is being given to the development of forward-looking quantitative approaches (Li et al. 2015) and with their consistent integration with qualitative analyses (Trutnevyte et al. 2014; Turnheim et al. 2015). Such developments are essential if these approaches are to provide more effective insights into guidance and policy for low-carbon transitions.

Energy Transition Pathways, Scenarios and Policies

While most past energy transitions were not purposefully guided along particular trajectories or pathways, modern transitions are different. Thus, developing and emerging countries and their citizens seek rapid economic growth, poverty reduction and higher living standards through wider access to modern fuels and energy-using technologies (IEA 2014; 2015a, b). For many, except in niche applications, the most direct and cheapest route has been via the exploitation of fossil fuels and fossil-generated electricity, often – as in China and India – through particularly rapid growth in the use of carbon-intensive coal and oil (IEA 2015a, c; National Bureau of Statistics of China 2015; Central Statistics Office 2015). At the same time, as well as growing recognition of the need to tackle carbon emissions (e.g. Liu et al. 2013; Reddy 2014), there has been growing governmental concern and public disquiet over energy-related pollution, particularly over the cumulative health impacts of air pollution in cities.

At the global level, the perceived urgency of addressing climate change was reflected in the 2015 Paris Agreement under the auspices of the United Nations Framework Convention on Climate Change (IPCC 2014; UNFCCC 2015). Although the developing world has strong incentives to avoid the damaging impacts of climate change, to which many will struggle to adapt, there is tension between the urgency of development now and the mitigation of greenhouse gases (GHGs), evident in the demands for financial transfers and technology transfer from the richer countries. Few in the developing world need extra incentives to adopt new fuels and technologies, and might be pleased to leapfrog to the most modern technologies if they could access and afford them. But, as noted earlier, the private benefits of adopting currently more expensive low-carbon technologies and practices are much less than the societal benefits of doing so. This, along with the fact that many low-carbon technologies do not, as yet, possess evidently superior bundles of performance characteristics to the fuels that they replace, means that policymakers face an unprecedented challenge (Pearson and Foxon 2012).

The desire for directed transitions to modern and/or low-carbon energy has led to a proliferation of energy transition scenarios and pathways. Although many earlier low-carbon transition scenarios provided technological detail, they tended to over-rely on exogenous emission constraints and high-level trends, without paying sufficient attention to how policy, technology and behaviour might interact and how scenario trajectories and end-points might be achieved (Hughes and Strachan 2010). Recently, however, growing attention has been paid to scenario or pathway construction that, in line with some of the thinking in the sustainability transition studies area, acknowledges this interaction, incorporates the roles of different system actors and, rather than focusing on their notional endpoints, explores the means whereby the trajectories of transition pathways might be realised (e.g. GEA 2012a; Foxon 2013; Hammond and Pearson 2013; ETI 2015; RTP Engine Room 2015). Nevertheless, much remains to be done to make low-carbon scenarios and pathways contribute more effectively to our understanding of the challenges and dynamics of the transition and how to address them.

Any transition from fossil fuels poses significant challenges for electricity generation (widely

dependent on coal, natural gas and oil), for all forms of transport (widely dependent on petroleum-based fuels and natural gas), and for process heat and domestic and commercial heating, ventilation and cooling (HVAC) (widely dependent on coal, gas, oil and fossil-generated electricity). To respond to these challenges will require significantly more (low-carbon) electrified provision of transport, heat and HVAC, with corresponding implications for infrastructure investment and management, such as electric vehicle charging and hydrogen refuelling stations for fuel cell vehicles.

The decarbonisation of electricity, for example, raises technical, social, behavioural and financial issues. On the supply side, incorporating very large proportions of renewable energy brings issues of power density (the rate of flow of energy per unit of land area) (Smil 2010) and intermittent generation (e.g. from the variability of wind and sunlight). The latter requires compensating backup and/or storage capacity, while low utilisation of some of this capacity might undermine its efficiency and economic viability. Although any electrical system must balance supply and demand, greater use of renewables may place new short-run (e.g. hourly) and longer run (e.g. seasonal) challenges. These can be eased by better forms of storage and by managed demand side responses across the whole system to enhance the efficiency of generation, transmission and distribution network capacity and manage its operational and economic performance (Aunedi et al. 2013; Pudjianto et al. 2014).

While nuclear electricity is widely proposed as a potentially valuable element in a low-carbon portfolio, its technologies tend to be relatively capital-intensive (like many renewables), to be slow to construct and not infrequently to meet with public distrust about operational safety, waste disposal or proliferation risks. Consequently, in many countries it remains too risky for private investors, in the absence of the sustained comfort of long-term financial support from the state (Joskow and Parsons 2012). Its economic prospects may depend on the development of more modular, flexible, rapidly constructible, publicly acceptable designs and waste disposal strategies. Some countries, such as China, are proceeding with significant nuclear electricity programmes. In others, including Germany, however, nuclear power has met with considerable political opposition, exacerbated by concerns raised by the 2011 Fukushima Daiichi events.

Increasing interest has developed in various forms of decentralised or distributed electricity generation (and other forms of energy). As well as the technical challenges of interfacing them with larger transmission and distribution systems, they will also require regulatory, financial and business model innovation, which is likely to involve selling energy services, such as illumination and comfort (RTP Engine Room 2015). Existing electricity (and other energy) utilities face the challenge of adapting their business models, which have been predicated on the expansion of demand via large-scale, centralised technologies, and have often been associated with limited consumer satisfaction and trust (Richter 2013). Recent electricity utility reorganisations, such as those of the German-based companies E. ON in 2014 and RWE in 2015, indicate attempts to respond to some of these issues and opportunities (as well to as the 2011 government decision to phase out and close Germany's nuclear power plants by 2022).

Not least because of recent rapid and projected growth in coal-based generation in China (IEA 2015c) and India (IEA 2015a), emphasis has been placed on the development of systems of carbon capture and sequestration (CCS), e.g. in depleted petroleum reservoirs or salt caverns, at either pre-or post-combustion stages. Moreover, some low-carbon scenarios depend for their ultimate effectiveness on combinations of sustainable biomass with CCS that could yield negative carbon emissions. CCS faces issues that are technical, economic (imposition of a cost penalty), financial and social (in terms of public acceptability) (Hammond and Spargo 2014; Watson 2012). Similarly, ideas of geoengineering and climate manipulation, from solar radiation management to carbon dioxide removal, to offset the greenhouse effect or limit GHG concentrations, also raise analogous and perhaps more challenging

issues, as well as those of the international governance and stability of such a global undertaking (Bellamy and Lezaun 2015).

On the demand side, many scenarios or pathways incorporate significant restraint of the growth of energy demand. Such restraint comes partly from elements of behavioural change and acceptance of new 'smarter' technologies, ranging from monitoring and control of the use of domestic devices, like dishwashers, washing machines and refrigerators, to possible management and uses of the storage and discharge capacities of automotive batteries. A growing body of research suggests that while there is real interest in such developments, the modification of energy-using social practices is far from straightforward and will require much better understanding of different groups' knowledge, beliefs and habits if it is to occur. Long-run scenarios also tend to include significant and challenging modifications to and investment in the design, regulation and energy efficiency of the built environment, from dwellings to neighbourhoods and cities, including the retrofitting of existing structures (Dixon et al. 2014).

There has been some concern about possible rebound effects, i.e. whether, as energy services such as lighting, thermal comfort or transport become more efficiently delivered and hence cheaper, a significant amount of the efficiency is taken back in the form of increased consumption and energy use (Turner 2013). In this area, there are likely to be significant differences between situations of latent demand in rapidly growing emerging or developing countries, in which consumer demands may be highly responsive to increases in income and wealth and falling energy service prices, and mature economies where responsiveness may be expected to be much less (Fouquet 2015).

The Stern Review of the Economics of Climate Change (Stern 2007) argued that the innovation and deployment of low-carbon technologies requires at least three types of government policy measure: (1) a carbon price, through a carbon tax or tradable permit scheme; (2) direct support for research, development and demonstration (RD&D) and early stage commercialisation of low carbon technologies; and (3) measures to remove or address institutional and non-market barriers to the uptake of energy-efficient and low-carbon options.

In orthodox economic terms, these three measures address three types of 'market failure' that justify government intervention. The carbon price is there to 'internalise' the negative externality of climate change from CO_2. The innovation supports are there to harness the positive externalities or spillovers available from RD&D, including addressing the 'valley of death' between a technology's demonstration and the commercialisation phases. Following Kenneth Arrow, it is argued that the private market will underinvest in invention and research because such activities are risky, because social value exceeds private value and because of increasing returns in the use and scaling up of innovations. The institutional and non-market barriers are those that can delay or inhibit the commercialisation and growth of innovations; this also connects with ideas of path dependence and lock-in, mentioned earlier. Alternatively, and drawing on ideas from the innovation literature, it has also been argued that broader ideas of 'systems failures' should be seen as complements to or superior substitutes for the market failure approach (Bleda and del Rio 2013; Foxon 2015). This approach includes proposals that addressing large-scale societal challenges, including climate change, requires a long-term visionary and mission-oriented approach in which public investment should play a significant part (Mazzucato and Penna 2015).

There is continuing debate about the relative merits of carbon taxes (setting a 'price' to achieve a quantity reduction) and marketable permits (setting a quantity that achieves a price) as one of the routes to controlling the climate externality. And it is clear that there are significant practical challenges with both instruments, e.g. the problem of setting politically acceptable tax levels and the governance issues of agreeing and running a permit system across multiple jurisdictions and sectors (as in the EU tradable permits scheme). Moreover, distributional issues arise, since expenditures on energy normally form a larger proportion of lower than of higher incomes and there can

be serious concerns over levels of 'fuel poverty'. These issues can be addressed by the use of other policy instruments, such as income supports, provided that such instruments are available and workable.

Governments may provide financial and regulatory support for appropriate levels of low-carbon RD&D, via policy instruments such as renewable energy certificates (or 'green certificates'), feed-in tariffs (FiTs) and auctions for electricity generating capacity. This raises the question of how such supports should be paid for. They are sometimes paid for via energy consumers' bills, as in the UK. However, Newbery (2015) argues that the general principles of public finance imply that societal public goods like climate change mitigation should be financed from general taxation of the population at large. Several jurisdictions have recently shown greater interest in electricity generating capacity auctions, because a well-designed bidding process may reduce the cost of such supports. Moreover, if a support instrument is set up without appropriate exit strategies to phase it out when costs fall – because of learning, economies of scale or other sources of cost reduction – it may either prove hard to change or sudden changes may disrupt investor confidence.

Similarly, there are arguments for providing public funds for investment in low-carbon infrastructure, as now happens in countries like Germany, since the state may be able raise finance at lower cost than the private sector (Newbery 2015). Private sector investors may insist on risk premiums that reflect the perceived risks of new technologies, whose prospects depend on uncertain future state commitments to climate change targets and their associated carbon price trajectories. More broadly, a key challenge for the low-carbon transition is for the state, and ultimately the global community, to give sufficiently credible, consistent longer term commitments and to help create the policy structures and instruments to achieve them, while also retaining a necessary flexibility in the face of changing conditions.

Successful transitions to new fuels and technologies depend, as suggested earlier, not only on the cost and performance of low-carbon technologies, but also on what is happening to incumbent technologies, infrastructures and institutions. Fossil fuel incumbents use a variety of strategies to protect their interests (and in some cases even embrace the new technologies). Their position may be, however, considerably bolstered by the effective inverse of a carbon tax, namely a subsidy. Thus many countries maintain very large subsidies to fossil fuels and infrastructure investments, distorting relative prices and creating significant barriers to low-carbon fuels and developments. Estimates of such subsidies vary widely but are big. According to the International Energy Agency's (IEA) estimates, worldwide fossil fuel subsidies, measured as the gap between end-user prices and reference prices, totalled $490 billion in 2014; this is almost four times the size of subsidies to help deploy renewable energy technologies in the power sector of $112 billion, plus $23 billion for biofuels (IEA 2015a). Coady et al. (2015) offer a tentative but strikingly larger estimate, on the basis of post-tax subsidies, i.e. the subsidy that arises when consumer prices are below supply costs plus a tax to reflect environmental damage, including non-climate damage, and a tax applied to consumption goods to raise revenues; they estimate that in 2013 these subsidies amounted to $4.9 trillion (6.5 % of global GDP) and were continuing to rise.

The International Energy Agency (IEA) suggest in a 2015 *World Energy Outlook Special Report* (IEA 2015b) that several targeted policy actions might be done at zero net economic cost, leading to a peak in energy-related GHG emissions by 2020: increasing energy efficiency in the industry, buildings and transport sectors; progressively reducing the use of the least-efficient coal-fired power plants and forbidding their construction; raising investment in renewable energy technologies in the power sector from $270 billion in 2014 to $400 billion in 2030; phasing out remaining fossil fuel subsidies to end-users by 2030; and reducing methane emissions in oil and gas production (since methane is a potent GHG). Nevertheless, the achievement of such policies would require significant political will and public acceptance.

Since energy and climate policies and instruments are administered by regional, national and

local governments, governance matters. This is not only in terms of the efficiency and transparency of the processes of government and their implementation, but also in terms of the balance of policy objectives and the means whereby they are achieved. For example, for many countries policy has three overarching broad objectives, sometimes called the 'Energy Policy Trilemma'. They are: climate and environment; energy security; and affordability and cost. The balance of these objectives and the trade-offs between them tend to shift through both internal and external influences, as for example when energy security became a key objective in oil-importing countries after the oil price shocks of the 1970s. Such shifts can be a challenge for a stable policy trajectory towards a targeted energy transition.

Policy implementation can be variously in the hands of the state, the market and civil society, depending on the dominant governance framing or 'logic' of the time (Foxon 2013; Johnson et al. 2016). Frequently it involves a hybrid mix of two or even all three of these. In the UK, for instance, the dominant logic of the 1980s/1990s/early 2000s was that of the private market, reflecting the neoliberal ideology of Margaret Thatcher's governments and its influence on later administrations. After the Climate Change Act of 2008 committed successive UK governments to 80 % reductions in GHGs by 2050 from a 1990 base, and partly because of difficulties in meeting both climate change and energy security objectives purely via the private sector, the UK has moved towards a more hybrid market/state form of governance, along with growing interest in decentralised energy and greater involvement of civil society (Pearson and Watson 2012; Emamian 2014). While the preferred mix of logics varies by country and political system, it is clear that governments and citizens have had cause to reflect on how best to promote, govern and guide an unprecedented low-carbon transition.

Energy-GDP Relationship

David I. Stern

Abstract

Energy use and GDP are positively correlated, although energy intensity has declined over time and is usually lower in richer countries. Numerous factors affect the energy intensity of economies, and energy efficiency is obviously one of the most important. However, the rebound effect might limit the possibilities for energy efficiency improvements to reduce energy intensity. Natural science suggests that energy is crucial to economic production but mainstream economic growth theory largely ignores the role of energy. Ecological economists and some economic historians argue that increasing energy supply has been a principal driver of growth. It is possible that historically energy scarcity imposed constraints on growth, but with the increased availability of modern energy sources energy's importance as a driver of growth has declined. Empirical research on whether energy causes growth or vice versa is inconclusive, but meta-analysis finds that the role of energy prices is central to understanding the relationship.

Introduction

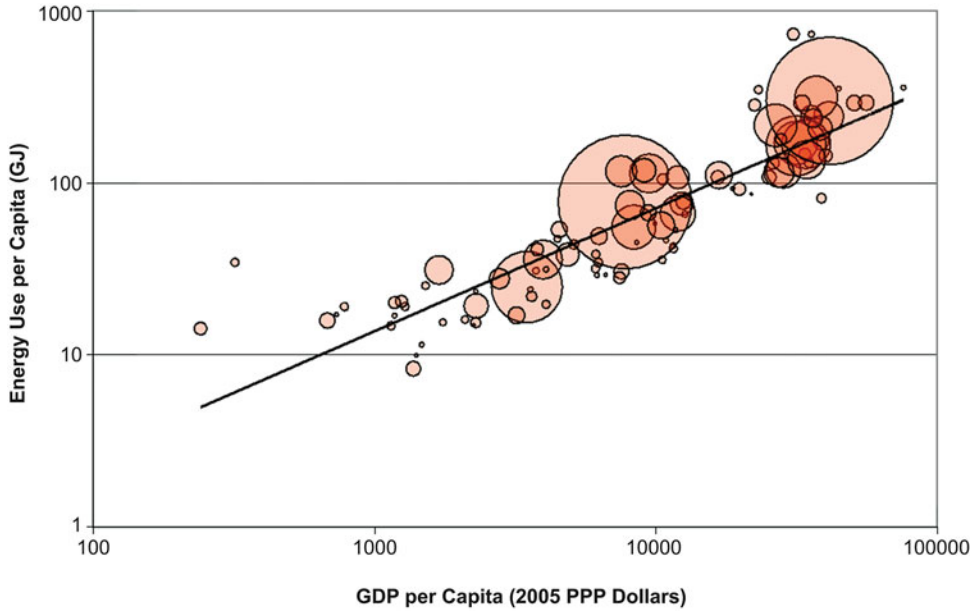
Figure 1 shows that energy use per capita increases with GDP per capita, so that richer countries typically use more energy per person than poorer countries. In fact, this relationship has been very stable over the last several decades, and the graph for 1971 looks very similar except that most countries were poorer and therefore used less energy. Van Benthem (2015) finds similarly that energy intensity – energy used per dollar of GDP – in today's middle-income countries is similar to that in today's developed countries when they were at the same income level.

The slope of the graph is a bit less than 1, so that a 1% increase in income per capita is associated with only a 0.7% increase in energy use per capita (Csereklyei et al. 2016). This means that energy intensity is on average lower in higher income countries, but that this relationship is not so strong (Fig. 2).

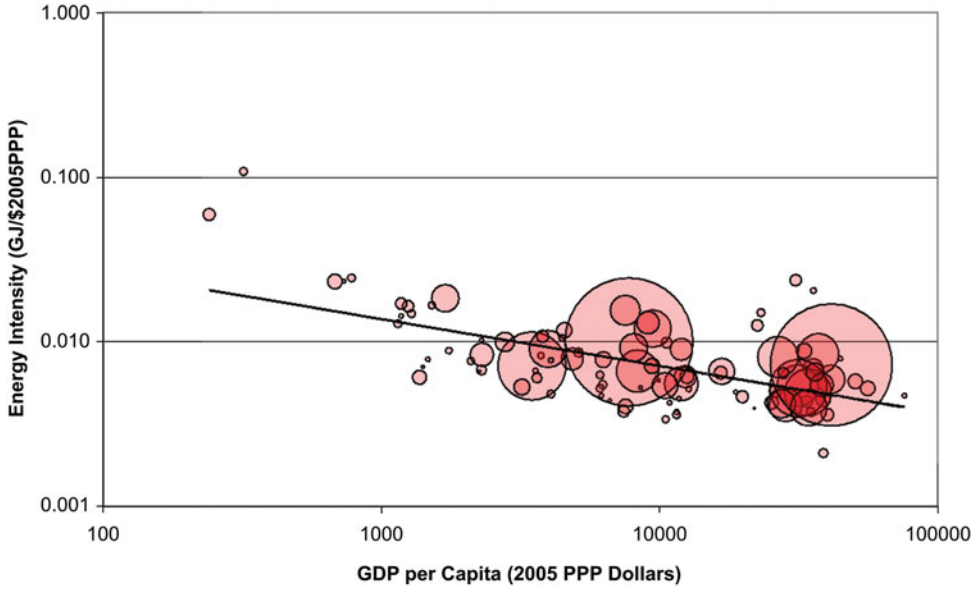
Globally, total energy use has increased over time and energy intensity has decreased (Fig. 3). This is mostly due to countries decreasing in energy intensity as they get richer, as the cross-sectional relationship in Fig. 2 has been fairly stable over time. Energy intensity has, however, become more similar over countries over time, so that countries that were more energy intensive in the 1970s reduced their energy intensity by more than less energy-intensive countries on the whole and the least energy-intensive countries often increased in energy intensity. This convergence relationship is shown in Fig. 4.

Though data are limited to fewer and fewer countries as we go back further in time, these relationships also appear to hold over the last two centuries – energy use has increased, energy intensity has declined globally and countries have converged in energy intensity (Csereklyei et al. 2016).

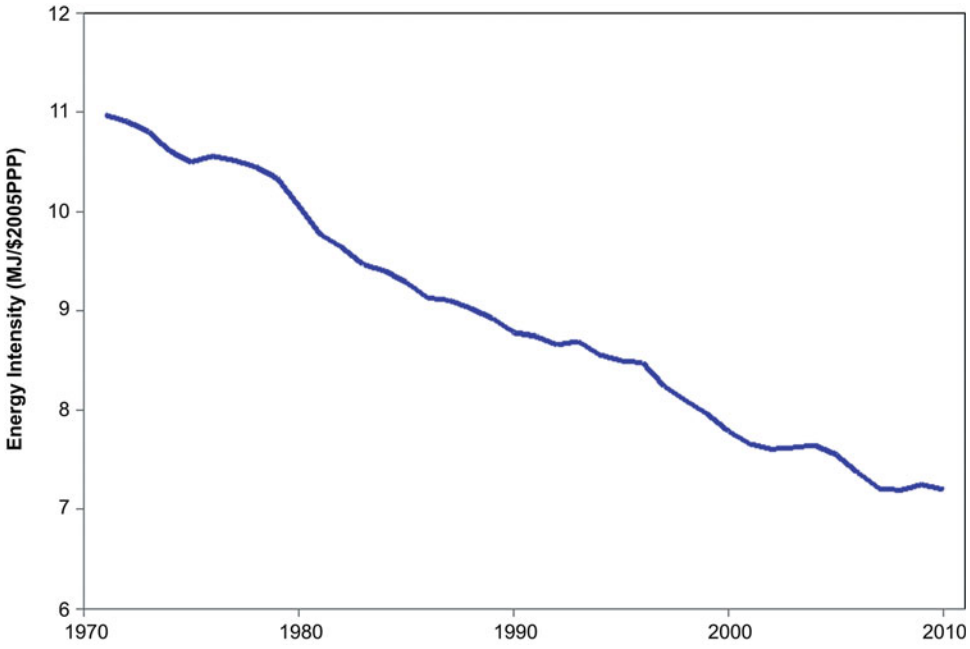
Of course, although energy intensity has declined, per capita energy use has increased over time, and when we also take population growth into account total energy use has risen strongly, though at a slower pace than total world economic output. Between 1971 and 2010 total world energy use increased by about 140% and GDP by 270%. Population increased by 80%.



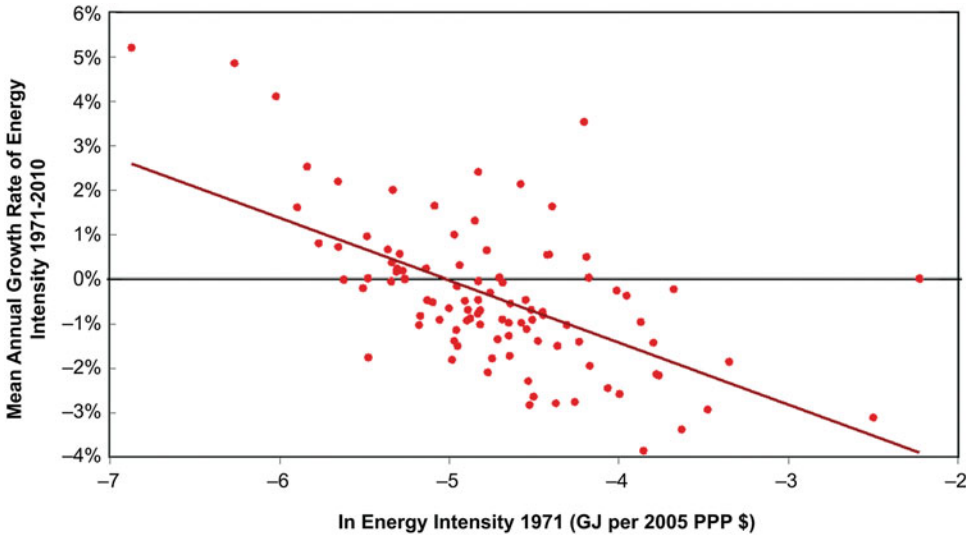
Energy-GDP Relationship, Fig. 1 Energy consumption per capita by GDP per capita 2010. Bubbles are proportional to total energy use. The two largest circles are the USA at upper right and China in the middle (Sources: International Energy Agency and Penn World Table 7.1)



Energy-GDP Relationship, Fig. 2 Energy intensity by GDP per capita 2010. Bubbles are proportional to total energy use. The two largest circles are the USA at lower right and China in the middle (Sources: International Energy Agency and Penn World Table 7.1)



Energy-GDP Relationship, Fig. 3 Global energy intensity (Sources: International Energy Agency and Penn World Table 7.1)



Energy-GDP Relationship, Fig. 4 Convergence of energy intensity (Sources: International Energy Agency and Penn World Table 7.1)

This article next examines the factors that might lead to lower energy intensity with higher GDP and convergence in energy intensity, as seen in Figs. 2, 3, and 4. Then it reviews the literature on the theoretical relationship between energy and economic growth. Third, it reviews estimates of the elasticity of energy use with respect to GDP. The penultimate section looks at the empirical evidence on the question of whether changes in energy use cause changes in

GDP or vice versa. Concluding remarks point to the main gaps in our knowledge.

Factors Affecting the Linkage Between Energy and GDP

Introduction

We saw above that energy intensity is lower in richer countries and has declined globally over time. What are the reasons for this change in the ratio of energy to GDP? We can use a production frontier approach to examine the factors that could weaken or strengthen the linkage between energy use and economic activity over time. A general production frontier, assuming separability between inputs and outputs, is given by:

$$(Q_1,\ldots,Q_m)' = f\left(A_{X1}X_1,\ldots,A_{Xn}X_n,A_{E1}E_1,\ldots,A_{Ep}E_p\right) \tag{1}$$

where the Q_i are various outputs, such as manufactured goods and services, the X_j are various non-energy inputs, such as capital and labour, the E_k are different energy inputs, such as coal and oil, and the A_{Xj} and A_{Ek} are indices of the state of factor-augmenting technology. The relationship between energy and an aggregate of output such as GDP is then affected by:

- substitution between energy and other inputs,
- technological change,
- shifts in the composition of the energy input, and
- shifts in the composition of output.

We discuss each of these below. Also, shifts in the mix of the other inputs – for example to a more capital-intensive economy from a more labour-intensive economy – could affect the relationship between energy and output, but this issue has not been much discussed in the literature and so will not be pursued further here. An important factor offsetting the effects of technological change is the rebound effect, so we discuss this separately. Because all of these factors affect energy intensity, energy intensity is a poor proxy for energy efficiency, which is usually defined more narrowly (Ang 2006; Stern 2012b).

The theoretical rationale for considering energy as a factor of production is discussed later in this article. Of course, if energy is an input to production, then there is also a derived demand function for energy and the level of output or income is one of the factors that determine demand. Estimates of the income elasticity of energy are also discussed below.

Substitutability of Energy and Capital

Koetse et al. (2008) conduct a meta-analysis of the (Morishima) elasticity of substitution (MES) between capital and energy for an increase in the price of energy. Their base case finds that the MES between energy and capital is 0.216, so that capital and energy are poor substitutes. The MES estimated using panel and cross-section data are greater: 0.592 and 0.848, respectively. It is likely that these larger values reflect long-run elasticities and the lower values short-run elasticities (Stern 2012a). Relatively little research has looked at whether capital–energy substitution has driven part of the decline in energy intensity. Stern (2012b) found that capital deepening reduced energy intensity by 7% globally from 1971 to 2007. On the other hand, Wang (2011) found that capital accumulation was the main driver of reduced energy intensity in China.

Energy Efficiency and Technological Change

There are several ways of measuring changes in energy efficiency that take into account the shifts in other factors, such as the quantities of other inputs. The distance function approach measures the change in energy efficiency as the change in the minimum energy requirement to produce a given level of output holding all other inputs constant. Equation (2) compares the minimum energy requirements given the technologies in two different periods but the same levels of inputs and outputs:

$$B_t = \frac{E_0(\mathbf{y}_0,\mathbf{x}_0)}{E_t(\mathbf{y}_0,\mathbf{x}_0)} \tag{2}$$

where $\mathbf{y}$ is the vector of outputs and $\mathbf{x}$ the vector of non-energy inputs with subscripts indicating the

periods and $E_i(\ )$ is a function indicating the minimum energy required in period i in order to achieve the given outputs given the level of inputs. The functions in Equation (2) can be estimated econometrically (e.g. Stern 2012b) or non-parametrically.

A second approach is to use an index of energy augmenting technical change. Based on equation (1), the index of energy augmenting technical change can be constructed as:

$$A_E = \sum_{i=1}^{p} S_i A_{Ei} \tag{3}$$

where S_i are the shares of each type of energy in the total cost of energy. Change over time in this index can be computed using an index method such as Divisia aggregation. The actual energy augmentation indices need to be estimated econometrically.

Bottom up, engineering-based measurements of energy efficiency represent a third approach. For example, Ayres et al. (2003) and Warr et al. (2010) estimate the useful work performed per joule of energy by various fuels and uses of energy. With some exceptions, the general trend over the 20th century in the USA, UK, Japan and Austria has been to greater energy efficiency measured in this way. Over shorter periods energy efficiency has declined in some countries, as it has in the long term for some fuels, especially food and feed.

Estimates of the trends in energy efficiency are mixed (Stern 2011). The direction of change has not been constant and varies across different sectors of the economy. Judson et al. (1999) show that technical innovations tend to introduce more energy-using appliances to households and energy-saving techniques to industry. Stern (2012b) finds that energy efficiency improved from 1971 to 2007 in most developed economies, the former communist countries (including China) and in India. But there was no improvement or a reduction in energy efficiency in many developing economies. Globally, such technological change resulted in a 40% reduction in energy use over the period than would otherwise have been the case and so was the most important driver of reduced energy intensity.

When there is endogenous technological change, changes in prices may induce technological changes. Newell et al. (1999) provide some information on the degree to which energy price increases induce improvements in the energy efficiency of consumer products. For room air conditioners they found that only about one quarter of the gain in energy efficiency since 1973 was induced by higher energy prices. Another quarter was found to be due to raised government standards and labelling. For gas water heaters the induced improvements were close to one half of the total, although much less cost-reducing technical change occurred. Using US data, Popp (2002) similarly finds that increased energy prices have a significant though quantitatively small effect on the rate of patenting in the energy sector. Dechezleprêtre et al. (2011) broaden the analysis to cover patents from 84 national and international patent offices covering various climate mitigation technologies, including renewable energy and energy efficiency technologies. They find that until 1990 patenting in these fields closely followed oil prices. After 1990 patenting increased steadily, although oil prices remained stagnant until 2003. They argue that the increase in patenting since 1990 was driven by environmental policies as they occurred, especially in countries that ratified the Kyoto Treaty.

New energy-using technologies initially diffuse slowly due to high costs of production that are typically lowered radically by a fairly predictable process of learning by doing (Grübler et al. 1999). Diffusion tends to follow a logistic curve, with the speed of diffusion depending, among other things, on how well the innovation fits into the existing infrastructure. Energy-saving innovations such as LED light bulbs would be expected to diffuse rapidly once their price becomes competitive, while more radical innovations that require new support infrastructures diffuse much more slowly due to 'network effects'.

Research also investigates the factors that affect the adoption of energy efficiency policies or energy efficiency technology (Matisoff 2008;

Fredriksson et al. 2004; Gillingham et al. 2009; Linares and Labandeira 2010; Wei et al. 2009; Stern 2012b). Differences in the adoption of energy efficiency technologies across countries and states, over time and among individuals might be optimal due to differences in endowments, preferences or the state of technology. But the rate of adoption may also be inefficient due to market failures and behavioural factors. Market failures include environmental externalities, information problems, liquidity constraints in capital markets, failures of innovation markets and principal–agent problems, such as between landlords and tenants (Gillingham et al. 2009; Linares and Labandeira 2010). Fredriksson et al. (2004) find that the greater the corruptibility of policymakers the less stringent is energy policy, and that the greater lobby group coordination costs are the more stringent energy policy is. Matisoff (2008) finds that the most significant variable affecting the adoption of energy efficiency programs across US states is citizen ideology. A broad band of states from Florida to Idaho had not adopted any policies.

The Rebound Effect

Energy-saving innovations reduce the cost of providing energy services, such as heating, lighting and industrial power. This reduction in cost encourages consumers and firms to use more of the service. As a result, energy consumption usually does not decline by as much as the increase in energy efficiency implies. This difference between the improvement in energy efficiency and the reduction in energy consumption is known as the rebound effect. Rebound effects can be defined for energy-saving innovations in consumption and production. In both cases, the increase in energy use due to increased use of the energy service where an efficiency improvement has happened is called the direct rebound effect. For consumer use of energy, the estimated rebound effects are usually small: in the range of 10–30% (Greening et al. 2000; Sorrell et al. 2009). Roy (2000) argues that because high-quality energy use is still small in households in India, demand is very elastic, and thus rebound effects in the household sector in India and other developing countries can be expected to be larger than in developed economies. Fouquet (2014) confirms how the price elasticity of demand for energy services declines and how the direct rebound effect decreased as Britain developed.

In the case of energy efficiency improvements in industry, the rebound effect at the firm level could be large as the firm could greatly increase its sales as a result of reduced costs. However, under perfect competition for an industry supplying domestic demand it is much harder for the industry as a whole to expand output, so the direct rebound effect would be more limited. Rebound effects are likely to be larger for export industries that have more opportunity to expand production (Grepperud and Rasmussen 2004; Allan et al. 2007; Linares and Labandeira 2010).

As a result of the reduction in the cost of the energy service, consumers will demand less of substitute goods and more of complementary goods. These include other energy services. Firms will make similar changes in their demands for inputs. There will also be additional repercussions throughout the economy. Non-energy goods whose demand has increased require energy in their production. The fall in energy demand may lower the price of energy (Gillingham et al. 2013; Borenstein 2015), increasing energy use again, and the efficiency improvement is a contribution to an increase in total factor productivity, which tends to increase capital accumulation and economic growth, which again results in greater energy usage (Saunders 1992). These additional effects are called indirect rebound effects, though the latter two may be treated separately as 'macro-level rebound effects' (e.g. Howarth 1997). Direct and indirect rebound effects together sum to the economy-wide rebound effect.

Estimates of the economy-wide rebound effect are few in number (e.g. Turner 2009; Barker et al. 2009; Turner and Hanley 2011) and vary widely (Stern 2011; Saunders 2013; Turner 2013). At the economy-wide level, 'backfire', where energy use increases as a result of an efficiency improvement, or even 'super-conservation', where the rebound is negative, are both theoretically possible

(Saunders 2008; Turner 2009). It is usually assumed that the indirect rebound is positive and that the economy-wide rebound will be larger in the long run than in the short run (Saunders 2008). Turner (2013) argues, instead, that because the energy used to produce a dollar's worth of energy is higher than the embodied energy in most other goods, the effect of consumers shifting spending to goods other than energy will mean that the indirect rebound could be negative and the economy-wide rebound may also be negative in the long run. Borenstein (2015) presents further arguments for negative rebounds.

All evidence on the size of the economy-wide rebound effect to date depends on theory-driven models, which have limited empirical validation. Turner (2009) finds that, depending on the assumed values of the parameters in a simulation model, the rebound effect for the UK can range from negative to more than 100%. Barker et al. (2009) provide the only estimate of the global rebound effect, estimating the rebound from a set of IEA recommended energy efficiency policies at 50%.

However, these are rebounds in energy use rather than energy intensity. As the economy-wide rebound effect is largely due to an increase in output, the rebound effect probably has small effects on energy intensity.

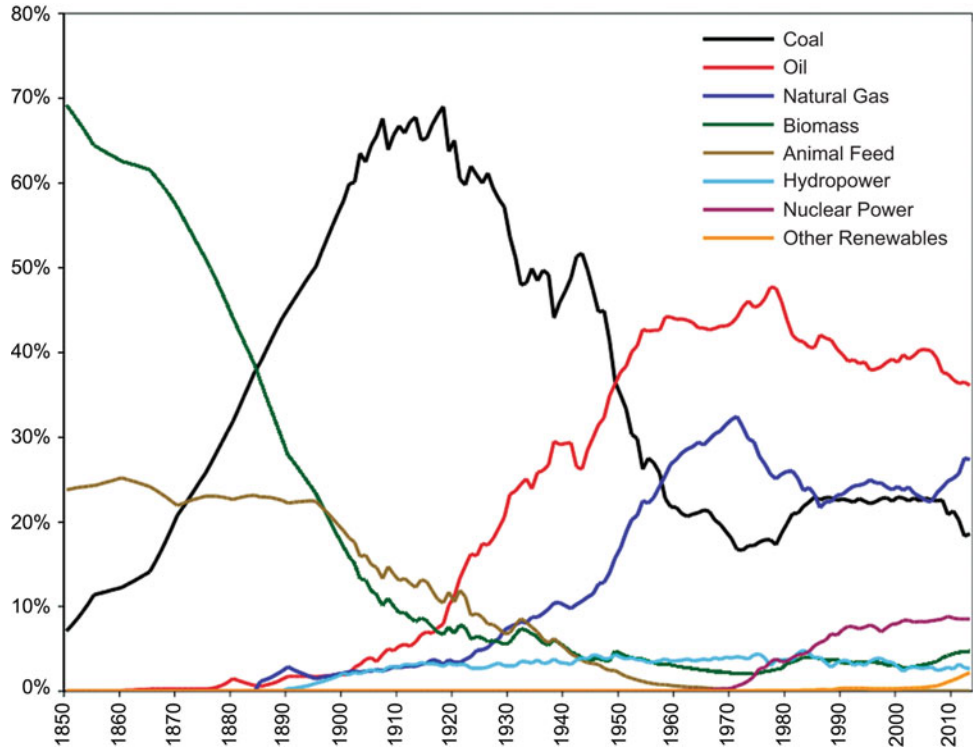
Energy Quality and Shifts in Mix of Energy Inputs

In the course of economic development, countries' fuel mix tends to evolve as the mix of energy sources used shifts to higher quality fuels (Burke 2013). Energy quality is the relative economic usefulness per heat equivalent unit of different fuels and electricity. Fuels have a number of physical attributes that affect their relative qualities, including energy density (heat units per mass unit); power density (rate of heat units produced per unit or per unit time); ease of distribution; the need for a transfer medium; controllability (the ability to direct the position, direction and intensity of energy use); amenability to storage; safety; and environmental impacts (Berndt 1978; Schurr 1982; Cleveland et al. 2000; Stern 2010). Some fuels, in particular electricity, require innovations to allow their use that must be embodied in capital equipment, which can transform the workplace entirely and change work processes, thus contributing to productivity gains (Schurr and Netschert 1960; Toman and Jemelkova 2003; Enflo et al. 2009).

In the least developed economies, as in today's developed economies before the Industrial Revolution, the use of biomass and muscle power dominates. The evolution of the energy mix over the course of economic development and over history in the technologically leading countries depends on each country's endowments of fossil energy and potential for renewables, such as hydroelectricity, but some regularities apply. The share of electricity in total energy use tends to rise. Low-income countries tend to generate electricity from hydropower and oil, while high-income countries have more diverse power sources, including nuclear power. Direct use of coal tends to rise and then fall over time and with income. Natural gas use has increased significantly in recent decades, mostly in more developed economies. Finally, electricity generated from solar and wind power is only now beginning to take off in more developed economies. Figure 5 illustrates this pattern for the USA.

Surprisingly, relatively few studies evaluate the role of the change in energy mix on energy intensity. Schurr and Netschert (1960) were among the first to recognise the economic importance of energy quality in understanding trends in energy and output. Noting that the composition of energy use has changed significantly over time, Schurr and Netschert argued that the general shift to higher quality fuels reduces the amount of energy required to produce a dollar's worth of GDP. Berndt (1990) also noted the key role played by the shifting composition of energy use towards higher quality energy inputs.

Cleveland et al. (1984) and Kaufmann (1992, 2004) presented analyses that explain much of the decline in the US energy/GDP ratio in terms of structural shifts in the economy and shifts from lower to higher quality fuels. Kaufmann (2004) found that shifting away from coal use and, in particular, shifting towards the use of oil reduced



Energy-GDP Relationship, Fig. 5 Composition of US primary energy input 1850–2013 (Source: US Energy Information Administration)

energy intensity in the USA. This shift away from coal more than explained the decline energy intensity over the entire 1929–99 time period. Other studies find, however, a much larger role for technological change than for changes in the composition of energy in the reductions in energy intensity seen around the world. For example, Ma and Stern (2008) find that interfuel substitution had negligible effects on the decline in energy intensity in China between 1994 and 2003. Technological change reduced energy intensity by more than the actual reduction in energy intensity due to the intensity increasing effects of structural change. Stern (2012b) finds that between 1971 and 2007, changes in fuel mix within individual countries increased world energy use by 4%, while global energy intensity declined by 40%. Shifts in the distribution of economic activity towards countries with lower quality energy mixes, such as China and India, contributed further to increasing energy intensity globally.

Shifts in the Composition of Output

Output mix also typically changes over the course of economic development. In the earlier phases of development there is a shift away from agriculture towards heavy industry, while in the later stages of development there is a shift from the more resource-intensive extractive and heavy industrial sectors towards services and lighter manufacturing. Different industries have different energy intensities. It is often argued that this will result in an increase in energy used per unit of output in the early stages of economic development and a reduction in energy used per unit output in the later stages of economic development (Stern 2004).

However, there is reason to believe that the energy-saving effects of structural changes are overstated (Henriques and Kander 2010). When the indirect energy use embodied in manufactured products and services is taken into account, the service and household sectors are more energy-

intensive than they first appear. Service industries still need large energy and resource inputs. The service being sold may be intangible, but the office towers, shopping malls, warehouses, rental apartment complexes etc. where the activity is conducted are very tangible and energy is used in their construction, operation and maintenance. Furthermore, consumers use large amounts of energy and resources in commuting to work, going shopping etc.

Furthermore, on a global scale there may be limits to the extent to which developing countries can replicate the structural shift that has occurred in the developed economies, to the degree that this is due to outsourcing manufacturing overseas rather than simply from an expansion in service activities. However, the evidence shows that trade does not result in reductions in energy use and pollution in developed countries through the offshoring of pollution-intensive industries (Levinson 2010; Aguayo and Gallagher 2005; Kander and Lindmark 2006). Additionally, if the service sector does require substantial material support, it is not clear whether the developed world can continue to shift in the direction of a growing service share of GDP indefinitely. In fact, as manufacturing prices have fallen relative to the prices of services, even the relative decline of manufacturing in developed countries is exaggerated when the relative sizes of the sectors are computed in current prices (Kander 2005).

Kander (2002) and Stern (2012b) find a relatively small role for structural change in reducing energy intensity in Sweden (1800–2000) and the world (1971–2007), respectively. But, using a much finer disaggregation of industries, Sue Wing (2008) finds that structural change explained most of the decline in energy intensity in the USA (1958–2000), especially before 1980.

The Theory of Energy in Economic Production and Growth

Energy as a Factor of Production

Physical laws describe the operating constraints of economic systems (Boulding 1966; Ayres and Kneese 1969). Conservation of mass means that, to obtain a given production output, greater or equal quantities of materials must be used as inputs, and the production process results in residuals or waste (Ayres 1969). Additionally, production requires energy to carry out work to convert materials into desired products and to transport raw materials, goods and people. The second law of thermodynamics (the entropy law) implies that energy cannot be reused and there are limits to how much energy efficiency can be improved. As a result, energy is always an essential factor of production (Stern 1997) and continuous supplies of energy are needed to maintain existing levels of economic activity as well as to grow and develop the economy. Before being used in the production of goods and services, energy and matter must be captured from the environment, and energy must be invested in order to extract useful energy (Hall et al. 1986).

The Mainstream Theory of Growth

Despite these facts, the core mainstream economic growth models disregard energy or other resources. Aghion and Howitt's (2008) textbook on economic growth does discuss growth and the environment, but only in a chapter near the end of the book. Acemoglu's (2009) textbook does not cover the topic at all. There has been some analysis of the potential for resources to constrain growth in the journal literature, but it has mostly been contained within the sub-field of environmental and resource economics, and the main focus has been on the implications of non-renewable resources for economic growth.

Solow (1974) introduced non-renewable resources – which could represent fossil or nuclear fuels – into neoclassical growth models and showed that sustainability – or the ability of a nation to support a constant level of economic production indefinitely – is achievable under certain institutional and technical conditions. Assuming that there is no population growth or technological progress, Solow shows that technology must allow the use of natural resources and manufactured capital – machines and buildings – to be sufficiently responsive to changes in prices. As the price of natural resources relative to that of capital rises, capital is substituted for resources in

production. In Solow's (1974) model the elasticity of substitution is 1, as implied by the Cobb–Douglas production function. This means that resources are essential, but that a constant level of production could be maintained even with infinitesimally small resource inputs. An elasticity of substitution greater than unity means that resources are not essential and so achieving sustainability is much easier. These are all conditions concerning the technology available to society. But the institutional framework – for example, whether an economy is a free market economy or whether it follows a particular planning rule – is just as important. From an institutional perspective, sustainability can be achieved only if the welfare of future generations is given equal weight to that of the present generation. This implies that the discount rate used to aggregate costs and benefits over time must be zero.

If instead the economy is a free market economy with perfect competition, but has the same technology as Solow's (1974) model, the resources are exhausted and consumption and social welfare eventually fall to zero (Stiglitz 1974a). Dasgupta and Heal (1979) showed that with any constant discount rate the efficient growth path also leads to eventual depletion of the natural resource endowment and the collapse of the economy. Hartwick (1977, 1995) has shown that, if sustainability is technologically feasible, a constant level of consumption can be achieved by investing the rents from exhaustible resources in other forms of capital, which in turn can substitute for exhausted resources. It is difficult to apply this rule in practice, as the rents and capital must be valued at prices that are compatible with sustainability (Asheim 1994; Asheim et al. 2003; Pezzey 2004). Such prices are unknowable given that we have poor understanding of the costs of current environmental damage and resource depletion or of the future development of technology.

In addition to the substitution of capital for resources, technological change might permit continued growth or at least constant consumption in the face of a finite resource base. Stiglitz (1974b) showed that, when the elasticity of substitution between capital and resources is 1, exogenous technical progress will allow consumption to grow over time if the rate of technological change divided by the discount rate is greater than the output elasticity of resources. Technological change might enable sustainability, even with an elasticity of substitution of less than 1.

Once again, technical feasibility does not guarantee sustainability. Depending on preferences for current versus future consumption, technological change might instead result in faster depletion of the resource (Smulders 2005).

The Ecological Economics Approach

A prominent tradition in ecological economics, known as the biophysical economics approach (Hall et al. 1986), is based on thermodynamics (Georgescu-Roegen 1971; Costanza 1980; Cleveland et al. 1984; Hall et al. 1986, 2003; Ayres and Warr 2005, 2009; Murphy and Hall 2010). Ecological economists usually argue that substitution between capital and resources can only play a limited role in mitigating the scarcity of resources (Stern 1997). Furthermore, some ecological economists downplay the role of technological change in productivity growth, arguing that growth is a result of either increased energy use or innovations allowing the more productive use of energy (Hall et al. 1986, 2003; Cleveland et al. 1984; Ayres and Warr 2009). Therefore, in this view, increased energy use is the main or only cause of economic growth.

In this approach, value is derived from the action of energy that is directed by capital and labour. Energy flows into the economy from fossil fuels and the Sun.

In some biophysical economic models, geological constraints fix the rate of energy extraction so that the flow rather than the stock can be considered as the primary input to production (Gever et al. 1986). Capital and labour are considered as intermediate inputs that are created and maintained by the primary input of energy and flows of matter. The level of the flows is computed in terms of the embodied energy use associated with them. Prices of goods should then ideally be determined by their embodied energy cost (Hannon 1973) – a normative energy theory of

value – or are seen as actually being correlated with energy cost (Costanza 1980) – a positive energy theory of value (Common 1995). This theory – like the Marxian paradigm – must then explain how labour, capital etc. end up receiving part of the surplus (Kaufmann 1987; Burkett 2003; Hornborg 2014).

However, because the quality of resources and the level of technology do affect the amount of energy needed to produce goods and services, it is difficult to argue for a model where energy is the sole factor of production (Stern 1999). For example, the quality of resources such as oil reservoirs is critical in determining the energy required to extract and process fuels. As an oil reservoir is depleted, the energy needed to extract oil increases. On the positive side, improved geophysical knowledge and techniques can increase the extent to which oil can be extracted for a given energy cost. Odum's energy approach (Brown and Herendeen 1996) and the framework developed by Costanza (1980) address the resource quality issue by including the solar and geological energy embodied in natural resource inputs in indicators of total embodied energy. An alternative approach is to measure material and energy inputs on the common basis of their exergy (Ayres et al. 1998; Ukidwe and Bakshi 2007).

However, both approaches seem too reductionist. For example, other services provided by nature, such as nutrient recycling, the provision of clean air and water, pollination and the climate system, that make economic production – and life itself – possible should also then be accounted for. Models that allow a number of different factors of production while complying with the physical laws of the conservation of mass and thermodynamics to varying degrees were developed by Georgescu-Roegen (1971), Perrings (1987), and O'Connor (1993) among others. The ecological economics approach does not have to reduce to an energy-only model of the economy.

A key concept in biophysical economics is energy return on investment (EROI), which is the ratio of useful energy produced by an energy supply system to the amount of energy invested in extracting that energy. Lower quality energy resources have lower EROIs. Biophysical economists argue that the more energy that is required to extract energy, the less energy is available for other uses and the poorer an economy will be. In this view, the increase in EROI allowed by the switch from biomass to fossil fuels enabled the Industrial Revolution and the period of modern economic growth that followed it (Hall et al. 1986).

Thus, declining EROI would threaten not just growth but overall economic output and, therefore, sustainability. Murphy and Hall (2010) document EROI for many energy sources, arguing that it is declining over time despite the extensive innovation in the industry. Wind and direct solar energy have more favourable EROIs than biomass fuels, but worse than most fossil fuels. However, unlike fossil fuels, the EROI of these energy sources tends to improve over time due to innovation (Kubiszewski et al. 2010). Declining EROI could be mitigated by substituting other inputs for energy or by improving the efficiency with which energy is used. However, biophysical economists argue that both these processes have limits.

Substitution can occur *within* a category of similar production inputs – for example between different fuels – and *between* different categories of inputs – for example between energy and machines. There is also a distinction to be made between substitution at the micro level – for example within a single engineering process or at a single firm – and at the macro level – in the economy as a whole.

As shown in Fig. 5 for the USA, the long-run pattern of energy use in industrial economies has been dominated by substitutions from wood and animal power to coal, oil, natural gas and primary electricity (Grübler et al. 2012). Meta-analysis of existing studies of interfuel substitution suggests that the long-run substitution possibilities at the level of the industrial sector as a whole are good. But there seems to be less substitutability at the macro-economic level (Stern 2012a).

Ecological economists emphasise the importance of limits to inter-category substitution – in particular, the substitution of manufactured capital for resources including energy (Costanza and Daly 1992). Thermodynamic limits on substitution can be approximated by a production function with an elasticity of substitution significantly below one (Stern 1997). As discussed above, a

meta-analysis of the existing empirical literature finds that the elasticity of substitution between capital and energy is less than 1 but much greater than 0 (Koetse et al. 2008).

In addition to this micro-economic limit to substitution, there may also be macroeconomic limits to substitution. The construction, operation and maintenance of tools, machines and factories require a flow of materials and energy. Similarly, the humans that direct manufactured capital consume energy and materials. Thus, producing more of the 'substitute' for energy – manufactured capital – requires more of the thing that it is supposed to substitute for. This again limits potential substitutability (Cleveland et al. 1984).

The mainstream economic argument that technological change can overcome limited substitutability would be more convincing if technological change were really something different from substitution. Changes in technology occur when new techniques are developed. However, these new techniques represent the substitution of knowledge for other factors of production. The knowledge is embodied in improved capital goods and more skilled workers and managers. But there are still thermodynamic restrictions on the extent to which energy and material flows can be reduced in this way. Although knowledge is non-rival in use, it must be used in conjunction with the other inputs, such as energy, and the productivity of knowledge is limited by the available quantities of those inputs.

Synthesis: Unified Model of Energy and Growth

As a first step to integrating the ecological economic and mainstream approaches and explaining historical economic growth, Stern and Kander (2012) add an energy input that has low substitutability with capital and labour to Solow's (1956) growth model. As discussed above, low substitutability between capital and energy is one of the key assumptions of ecological economists. Using 200 years of Swedish data Stern and Kander estimate that the elasticity of substitution between energy and the other two inputs is 0.65. This figure is similar to the other estimates of the elasticity also discussed in the previous section. Stern and Kander ignore the issue of whether the energy resource is non-renewable, as depletion of fossil fuels does not seem to have been a very important factor in constraining economic growth to date.

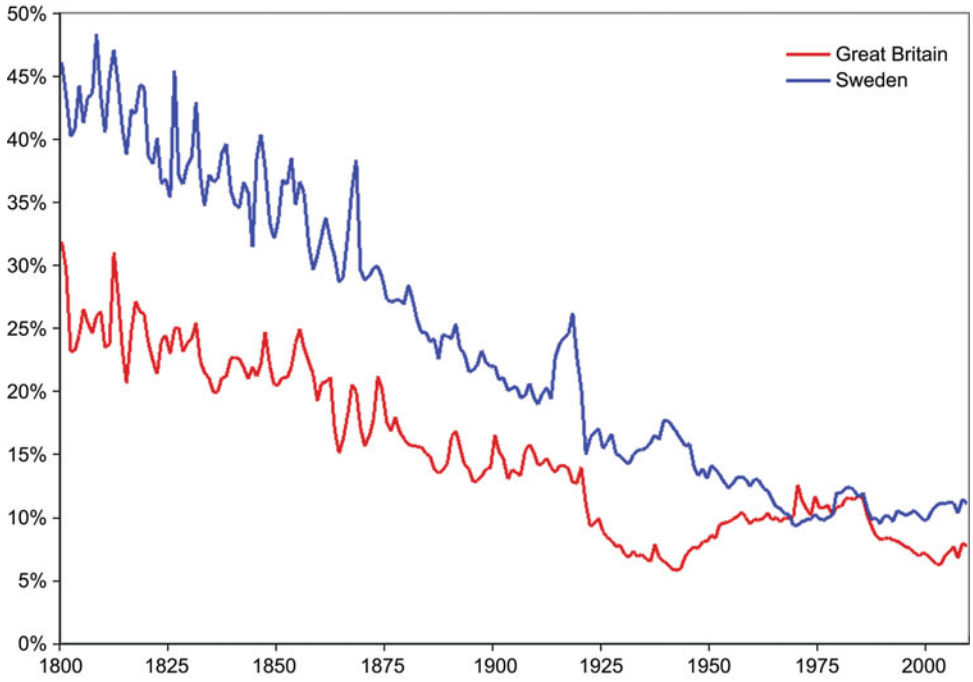
Assuming that the elasticity of substitution between energy and capital is less than 1 allows the share of energy in production costs to fall over time. When the elasticity of substitution is unity, cost shares must be constant in the long run. The cost share of energy has fallen in the long run in both Britain and Sweden, countries for which we have data from 1800 till the present (Fig. 6). An elasticity of substitution of less than unity also allows us to distinguish between labour-augmenting innovations and energy-augmenting innovations, which again is not possible using a Cobb–Douglas production function.

The production function is given by:

$$Y = \left[(1-\gamma)\left(A_L^{\beta}L^{\beta}K^{1-\beta}\right)^{\phi} + \gamma(A_E E)^{\phi}\right]^{\frac{1}{\phi}} \quad (4)$$

Equation (4) embeds a Cobb–Douglas function of capital, K, and labour, L, $L^{\beta}K^{1-\beta}$, in a constant elasticity of substitution production function of this combined input and energy, E, to produce gross output, Y. $\phi = (\sigma - 1)/\sigma$, where σ is the elasticity of substitution between energy and the capital–labour aggregate. A_L and A_E are the augmentation indices of labour and energy, which can be interpreted as reflecting both changes in technology that augment the effective supply of the factor in question and changes in the quality of the respective factors. $A_E E$ and $A_L L$ are called effective energy and effective labour, respectively.

In Solow's (1956) model, as long as there is technological change the economy can grow. In Stern and Kander's model, depending on the availability of energy and the nature of technological change, energy can be either a constraint on growth or an enabler of growth. When effective energy, $A_E E$, is very abundant, the model behaves very similarly to Solow's original model and energy neither constrains nor drives growth. The more energy there is, the less important energy appears to be. But when effective energy is relatively scarce,



Energy-GDP Relationship, Fig. 6 Share of energy in total production costs: Britain and Sweden 1800–2009 (Source: Gentvilaite et al. (2015))

the level of output depends on the level of energy supply and the level of energy-augmenting technology. Labour-augmenting technological change alone no longer results in economic growth.

Before the Industrial Revolution most energy was in the form of wood and animal and human muscle power – wind- and water-power contributed relatively little energy (Kander et al. 2014). The supply of this renewable energy was constrained by the availability of land, so energy was scarce (Wrigley 2010). Therefore, as the data show (Maddison 2001), until the Industrial Revolution, output per capita was generally low and economic growth was not sustained. Stern and Kander (2012) find that increases in energy use and energy-augmenting technological change were the main contributors to economic growth in the 19th and early 20th centuries, but in the second half of the 20th century labour-augmenting technological change became the main driver of growth in income per capita, as it is in the Solow growth model.

The Elasticity of Energy with Respect to GDP

How much does energy use increase with economic growth? Various studies have estimated by how much energy use tends to be higher as income increases without controlling for other factors, while other studies attempt to estimate the macro-level elasticity of demand for energy, controlling for energy prices and changes in technology. I summarise some recent econometric results. As mentioned in the introduction, Csereklyei et al. (2016) find that there has been a remarkably stable relationship between energy and GDP over the last four decades in a sample of 99 countries. The elasticity, which does not control for energy prices or technological change, is 0.7. Similarly, using panel data for middle-income countries, including today's developed countries in earlier decades, Van Benthem (2015) finds an elasticity of 0.9 or 0.97 controlling for energy prices and time effects. He finds lower elasticities for higher and lower income

bands. Similarly, Fouquet (2014) finds that energy income elasticities first rose and then fell over the course of economic development in Britain. Using a cointegration approach, Joyeux and Ripple (2011) estimate that the long-run income elasticity is 1.08 for OECD countries and 0.853 for 19 developing countries between 1973 and 2007. These estimates do not control for energy prices or time effects. Thus energy is a normal good and most estimates of the elasticity are between 0.5 and unity. However, there does not seem to be a consensus on whether the income elasticity declines or not with increasing income.

Testing for Causality Between Energy and GDP

Two methods for testing for causality among time series variables are Granger causality tests and cointegration analysis (Granger 1969; Engle and Granger 1987). Hendry and Juselius (2000) discuss the application of these methods to energy economics, where they have been applied extensively to test for causality and cointegration between energy, GDP and other variables from the late 1970s on (Kraft and Kraft 1978; Ozturk 2010). There are now hundreds of journal articles on this topic (Bruns et al. 2014).

Early studies relied on Granger causality tests on unrestricted vector autoregressions (VARs) in levels of the variables, while more recent studies use cointegration methods. A vector autoregression model consists of one regression equation for each variable of interest in a system. Each variable is regressed on lagged values of itself and all other variables in the system. If the coefficients of the lagged values of variable X in the equation for dependent variable Y are jointly statistically significant, then X is said to Granger cause Y. Cointegration analysis tests whether variables that have stochastic trends – their trend is a random walk – share a common trend. If so, then at least one variable must Granger cause the other.

Early studies also used bivariate models of energy and output, while more recent research tends to employ multivariate models. Ignoring other relevant variables can generate spurious causality findings. The most common additional variables used are capital and labour or energy prices. A third way to differentiate among models is whether energy is measured in standard heat units or whether a method is used to account for differences in quality among fuels.

The results of early studies that tested for Granger causality using a bivariate model were generally inconclusive (Stern 1993). Stern tested for Granger causality in the USA in a multivariate setting using a vector autoregression (VAR) model of GDP, capital and labour inputs, and a Divisia index of quality-adjusted energy use in place of the usual heat equivalent of energy use. When both the multivariate approach and quality-adjusted energy index were employed, energy use was found to Granger cause GDP.

Yu and Jin (1992) conducted the first cointegration study of the energy–GDP relationship using the bivariate approach. Stern (2000) estimated a dynamic cointegration model for GDP, quality weighted energy, labour and capital. The analysis showed that there is a cointegrating relation between the four variables and, depending on the version of the model used, found that energy Granger causes GDP or that there is mutual causation between energy and GDP. Some subsequent research appeared to confirm these findings using other measures of energy quality (Warr and Ayres 2010) or data for other countries (Oh and Lee 2004; Ghali and El-Sakka 2004) and panels of many countries (Lee and Chang 2008; Lee et al. 2008).

Bruns et al. (2014) carry out a meta-analysis of 75 single-country Granger causality and cointegration studies comprising more than 500 tests of causality in each direction. They find that most seemingly statistically significant results in the literature are probably the result of statistical biases that occur in models that use short time series of data – 'overfitting bias' – or the result of the selection for publication of statistically significant results – 'publication bias'. The most robust findings in the literature are that growth causes energy use when energy prices are controlled for in the underlying studies. Using a panel cointegration model of GDP, energy use and energy prices for 26 OECD countries (1978–2005), Costantini and Martini (2010) also

find that in the long run GDP growth drives energy use and energy prices, though in the short run energy prices cause GDP and energy use, and energy use and GDP are mutually causative.

However, Bruns et al. (2014) find that studies that control for capital do not find a genuine effect of energy on growth or vice versa. But they had too small a number of studies that used quality-adjusted energy to test whether there was a genuine relationship between energy and growth when this measure of energy use was employed. So their findings do not necessarily contradict the previous research by Stern and others reviewed above.

Gaps in Knowledge

As this article has shown, the relationship between energy and GDP is one where there is remarkably little consensus, and large gaps in knowledge remain. The field of energy economics has expanded rapidly in the last decade, but much research is repetitive and adds little to existing knowledge (Smyth and Narayan 2015). In particular, there is a very large literature using reduced form time series models to test for causality and cointegration between energy and output. But this literature is completely inconclusive, with equal numbers of studies finding causation in each direction (Bruns et al. 2014). Research in this area needs to be more closely based on testing potential mechanisms which link energy and output. However, researchers are only starting to build theoretical models of the role of energy in the economic growth process.

There is also a lack of consensus in research on the drivers of changes in energy intensity. In particular, energy intensity has risen in many developing countries. The reasons for this are little researched. There is also a lack of consensus on the size of the economy-wide rebound effect. Existing estimates are all derived from simulation models and range from negative rebound to backfire, where energy efficiency improvements actually increase rather than reduce energy use. Therefore there is little guidance on the potential for energy efficiency policies to actually conserve energy.

Research is also hampered by inadequate data. With the exception of traditional biomass, energy use data are normally of good quality. But data on prices is much more fragmentary. Most economic research is based on understanding the linkages between prices and quantities. So this is an important area where international comparable datasets could be very useful.

Enforcement

Kevin Roberts

Enforcement, with its usual connotations of agents being compelled to behave in ways that are at variance with how they would like to act, seems a long way removed from the conventional neoclassical approach of laissez-faire inherent in a decentralized economic system. If an enforcement mechanism is viewed as a method by which rule-breaking may be discouraged then laissez-faire attempts to be a set of rules that are self-enforceable so that no formal enforcement mechanism is required (see Stigler 1970 for a useful discussion of enforcement). But it is clear that decentralizability is not, in itself, enough. For instance, the fact that tax evasion is kept in check only by legal pressure shows how the addition of a tax system to a decentralized competitive structure may destroy self-enforceability. The possibility of gain by the exercise of monopoly power shows how the rule of price-taking behaviour is not immune to the problems of enforcement.

Except when self-enforceability holds, so that agents wish to follow the given set of rules – the rules are incentive compatible – an enforcement mechanism will be necessary to prevent rule-breaking. A formal enforcement mechanism has two components. First, there must be a method of monitoring agents so that it is possible to observe, perhaps imperfectly, rule-breaking. Second, there must exist a sanction or punishment which can be imposed on rule-breakers. If perfect observability is costless and there is no limit to the disutility that a punishment can impose then there is no difficulty in enforcing a rule and, importantly, the enforcement procedure never needs to be exercised. Thus, the existence of an enforcement procedure alters the incentives to obey rules and can be used as a component of the incentive structure within an economic system. It is clear that this is in part the role of a legal system.

To examine enforcement procedures in greater detail, first consider the monitoring mechanism. If monitoring is impossible then agents will abide with a rule only if it is self-enforceable. If monitoring is costly then there may be a decision to be taken with regard to the best monitoring mechanism. Two dimensions of choice seem natural. First, there is the quality of the monitoring mechanism. After monitoring, an inference will be made with regard to whether a rule has been broken. The better the quality of the monitoring mechanism, the more accurate will be this inference. Accuracy will involve both a low probability of inferring rule-breaking when it has not occurred and a low probability of inferring rule-compliance when rule-breaking has occurred.

The second component of the monitoring mechanism is the intensity with which it is applied. The same agent may be monitored several times to improve the accuracy of the test; agents may be monitored on a random basis so that any one agent will be monitored with a probability of less than unity. The overall mechanism is likely to be more effective if agents must decide upon their behaviour with regard to rule-compliance before they know the intensity with which they will be monitored.

A high punishment level will deter rule-breaking more than a low punishment level. To see what an optimal enforcement mechanism may look like, consider a planner who wishes to deter rule-breaking (which, for instance, imposes significant negative externalities on other agents). Assume that the planner wishes to maximize the expected utility of agents whilst deterring rule-breaking – rule-breaking is assumed to be privately optimal. If a is the accuracy of the test used then let $p(a)$ be the probability of a rule-breaking inference if rule-breaking has not occurred. Similarly, let $q(a)$ be the probability of such an inference if rule-breaking has occurred.

Thus, $p(a) < q(a)$, $p(a)$ is falling in a and $q(a)$ is rising in a. Let U be the utility that an agent gets from rule-compliance before the introduction of an enforcement mechanism and V be the utility that would result from rule-breaking. Then if m is the probability of being monitored and f is the punishment cost then, taking the

simplest specification of linear utility, the expected utility of an agent who complies with the rule is given by

$$U - mp(a)f - am \tag{1}$$

where am is taken to be the cost of operating the enforcement mechanism, the money being raised through taxation, say. The punishment f is assumed to be a deadweight loss rather than a monetary fine which could be used to finance the monitoring mechanism. An agent compares (1) with the expected utility from rule-breaking:

$$V - mq(a)f - am \tag{2}$$

so that rule-breaking can be deterred if

$$mf[q(a) - p(a)] \geq V - U. \tag{3}$$

If the planner wishes to maximize (1) subject to (3) then the first point to notice is that (1) can always be increased while still satisfying (3) if mf is held constant but m is reduced. Thus, it is desirable to increase the punishment whilst reducing the rate of monitoring and it is optimal to punish as severely as possible (this argument is credited to Becker 1968). Once the worst punishment is chosen, the optimal monitoring mechanism satisfies

$$\frac{fp' + 1}{fp + a} = \frac{q' - p'}{q - p} \tag{4}$$

which gives rise to the comparative statics results that would be expected. If f can be chosen without limit (punishment can reduce utility to minus infinity) then m will be set arbitrarily small and, keeping mf fixed, (1) can be increased by increasing a if $p'(a)$ is strictly negative. If perfect accuracy is attainable ($p(a) = 0$ for some a) then the expected utility of the agent will be U – the first-best is achievable – and the enforcement mechanism will take the form of an infinitesimally small amount of monitoring using a very accurate procedure and infinitely large punishments being imposed on rule-breakers. This strong result depends upon the strong assumptions that have been imposed on the model. However, Nalebuff and Scharfstein (1985) obtain a similar result in a richer setting than that of the above model. For a model where finite levels of punishment are optimal because of the risk aversion of agents, see Polinsky and Shavell (1979).

The structure outlined above has the property that the enforcement mechanism is operated by a planner. One reason for assuming this is that it is unnecessary to consider the planner's incentives to operate the mechanism. In some situations, it is necessary for a group of agents to operate an enforcement mechanism that will be imposed upon themselves. The classic example of this is the operation of a cartel (Stigler 1964). A major problem introduced by not having an external agency is that costs may be imposed on firms if they choose to punish a firm that breaks the cartel's rules. An example of this is when a firm is punished by all firms entering into a price-cutting war. To provide an incentive to punish, it may be necessary to have a mechanism to enforce the operation of the original enforcement mechanism, and so on. For an insightful analysis of this problem, see Abreu (1986). Considerations of this sort show the potential richness of the structure of enforcement mechanisms in general.

Engel Curve

Arthur Lewbel and H. S. Houthakker

Abstract

An Engel curve describes how a consumer's purchases of a good like food varies as the consumer's total resources such as income or total expenditures vary. Engel curves may also depend on demographic variables and other consumer characteristics. A good's Engel curve determines its income elasticity, and hence whether the good is an inferior, normal, or luxury good. Empirical Engel curves are close to linear for some goods, and highly nonlinear for others. Engel curves are used for equivalence scale calculations and related welfare comparisons, and determine properties of demand systems such as aggregability and rank.

An Engel curve is the function describing how a consumer's expenditures on some good or service relate to the consumer's total resources, with prices fixed, so $q_i = g_i(y, z)$, where q_i is the quantity consumed of good i, y is income, wealth, or total expenditures on goods and services, and z is a vector of other characteristics of the consumer, such as age and household composition. Usually y is taken to be total expenditures, to separate the problem of allocating total consumption to various goods from the decision of how much to save or dissave out of current income. Engel curves are frequently expressed in the budget share form $w_i = h_i[\log(y), z]$ where w_i is the fraction of y that is spent buying good i. The goods are typically aggregate commodities such as total food, clothing or transportation, consumed over some weeks or months, rather than discrete purchases. Engel curves can be defined as Marshallian demand functions, with the prices of all goods fixed.

The term 'Engel curve' is also used to describe the empirical dependence of q_i on y, z in a population of consumers sampled in one time and place. This empirical or statistical Engel curve coincides with the above theoretical Engel curve definition if the law of one price holds (all sampled consumers paying the same prices for all goods), and if all consumers have the same preferences after conditioning on z and possibly on some well-behaved error terms. Since these conditions rarely hold, it is important in practice to distinguish between these two definitions.

Using data from Belgian surveys of working class families, Ernst Engel (1857, 1895) studied how households' expenditures on food vary with income. He found that food expenditures are an increasing function of income and of family size, but that food budget shares decrease with income. This relationship of food consumption to income, known as Engel's law, has since been found to hold in most economies and time periods, often with the function h_i for food i close to linear in $\log(y)$.

Engel curves can be used to calculate a good's income elasticity, which is roughly the percentage change in q_i that results from a one per cent change in y, or formally $\partial \log g_i(y, z)/\partial \log(y)$. Goods with income elasticities below zero, between zero and 1, and above 1 are called inferior goods, necessities and luxuries respectively, so by these definitions what Engel found is that food is a necessity. Elasticities can themselves vary with income, so a good that is a necessity for the rich can be a luxury for the poor.

Some empirical studies followed Engel (1895), such as Ogburn (1919), but Allen and Bowley (1935) firmly connected their work to utility theory. They estimated linear Engel curves $q_i = a_i + b_i y$ on data-sets from a range of countries, and found that the resulting errors in these models were sometimes quite large, which they interpreted as indicating considerable

heterogeneity in tastes across consumers. Working (1943) proposed the linear budget share specification $w_i = a_i + b_i \log(y)$, which is known as the Working–Leser model, since Leser (1963) found this functional form to fit better than some alternatives. However, Leser obtained still better fits with what would now be called a rank-three model, namely, $w_i = a_i + b_i \log(y) + c_i y^{-1}$, and in a similar, earlier, comparative statistical analysis Prais and Houthakker (1955) found $q_i = a_i + b_i \log(y)$ to fit best. More recent work documents sometimes considerable nonlinearity in Engel curves. Motivated by this nonlinearity, one of the earlier empirical applications of nonparametric regression methods in econometrics was kernel estimation of Engel curves. Examples include Bierens and Pott-Buter (1990), Lewbel (1991), and Härdle and Jerison (1991). More recent studies that control for complications like measurement error and other covariates Z, including Hausman et al. (1995) and Banks et al. (1997), find Engel curves for some goods are close to Working–Leser, while others display considerable curvature, including quadratics or S shapes. Even Allen and Bowley (1935, p. 123) noted 'there is a good fit, allowance being made for observation and sampling errors,. . ., to a linear expenditure relation and occasionally to a parabolic relation'.

Other variables z also help explain cross-section variation in demand. Commonly used covariates include the number, ages and gender of family members, location measures, race and ethnicity, seasonal effects, and labour market status. Variables indicating ownership of a home, a car or other large durables can also have considerable explanatory power, though these are themselves consumption decisions.

Engel's original work showed the relevance of family size, and later studies confirm that larger families typically have larger budget shares of necessities than smaller families at the same income level. Adult equivalence scales model the dependence of utility functions on family size, and use this dependence to compare welfare across households, assuming that a large family with a high income is as well off as a smaller family with a lower income if both families have demands that are similar in some way, such as equal food budget shares or equal expenditures on adult goods such as alcohol. The ratio of total expenditures needed to equate food budget shares across households are known as Engel equivalence scales, while the ratio that equates expenditures on adult goods are called Rothbarth scales (Rothbarth 1943).

Shape invariance assumes that budget share Engel curves for one type of consumer, such as a household with children, is a linear transformation of the budget-share Engel curves for other types of consumers, such as households without children. Shape invariance is necessary for constructing what are known as exact or independent of base equivalence scales, and has been found to at least approximately hold in some data-sets. See Lewbel (1989), Blackorby and Donaldson (1991), Gozalo (1997), Pendakur (1999), and Blundell et al. (2003).

The level of aggregation across goods affects Engel curve estimates. Demand for a narrowly defined good like apples varies erratically across consumers and over time, while Engel curves based on broad aggregates like food are affected by variation in the mix of goods purchased. The aggregate necessity food could include inferior goods like cabbage and luxuries like caviar, which may have very different Engel curve shapes.

Other empirical Engel curve complications include unobserved variations in the quality of goods purchased, and violations of the law of one price. When price or quality variation is unobserved, their effects may correlate with, and so be erroneously attributed to, y or z. Examples of such correlations could include the wealthy systematically favouring higher quality goods, and the poor facing higher prices than other consumers because they cannot afford to travel to discount stores.

Assume a consumer (household) h determines demands q_{hi} facing prices p_i for each good i by maximizing a well-behaved utility function over goods (which could depend on z_h), subject to a budget constraint $\sum_i p_i q_{hi} \leq y_h$. This yields Marshallian demand functions $q_{hi} = G_{hi}(P, y_h, z_h)$, with Engel curves given by these functions with the price vector p fixed. Utility functions that yield Engel curves of the form $q_{hi} = b_i(z) y_h$ are called homothetic, and $q_{hi} = a_i(z) + b_i(z) y_h$ are quasihomothetic. Many theoretical results

regarding two-stage budgeting and aggregation across goods require homotheticity or quasi-homotheticity, most notably Gorman (1953).

The shape of Engel curves plays an important role in the determination of macroeconomic demand relationships. For example, if we ignore z for now, suppose individual consumers h each have Engel curves of the quasihomothetic form $q_{hi} = a_{hi} + b_i y_h$. Then, letting Q_i and Y be aggregate per capita quantities and total expenditures in the population, we get $Q_i = A_i + b_i Y$ by averaging q_{hi} across consumers h. This is a representative consumer model, in the sense that the distribution of y affects aggregate demand Q_i only through its mean $E(y) = Y$. Gorman (1953) showed that only linear Engel curves have this property, though linear Engel curve aggregation dates back at least to Antonelli (1886). Gorman's linearity requirement, which does not usually hold empirically, can be relaxed given restrictions on the distribution of y; for example, Lewbel (1991) shows that $E(y \log y)/Y - \log(Y)$ is very close to constant in US data, and if it is constant then Working–Leser household Engel curves yield Working–Leser aggregate, representative consumer demands.

Exactly aggregable demands are defined by $q_i = \sum_{j=1}^{J} A_{ji}(p) c_j(y, z)$, and so have Engel curves $q_i = \sum_{j=1}^{J} a_{ji} c_j(y, z)$that are linear in the functions $cj(y, z)$. These models have the property that aggregate demands Q_i depend only on the means of $c_j(y, z)$. Utility theory imposes constraints on the functional forms of $c_j(y, z)$. Properties of exactly aggregable demands and associated Engel curves are derived in Muellbauer (1975), Jorgenson et al. (1982), and Lewbel (1990), but primarily by Gorman (1981), who proved the surprising result that utility maximization forces the matrix of Engel curve coefficients a_{ji} to have rank three or less.

Lewbel (1991) extends Gorman's rank idea to arbitrary demands, not just those in the exactly aggregable class, by defining the rank of a demand system as the dimension of the space spanned by its Engel curves. Engel curve rank can be nonparametrically tested, and has implications for utility function separability, welfare comparisons, and for aggregation across goods and across consumers. Many empirical studies find demands have rank three.

One area of current research concerns the observable implications of collective models, that is, households that determine expenditures based on bargaining among members. For example, the Engel curves of such households could violate Gorman's rank theorem, even if each member had exactly aggregable preferences. Another topic attracting current attention is the role of errors in demand models, particularly their interpretation as unobserved preference heterogeneity, random utility model parameters. This matters in part because another of Allen and Bowley's (1935) findings remains true today, namely, Engel curve and demand function models still fail to explain most of the observed variation in individual consumption behaviour.

Born in Dresden, Engel was a German statistician best known for the discovery of the Engel curve and of Engel's Law. In his early years he was associated with the French sociologist Frédéric Le Play, whose interest in the family led him to conduct household surveys. The expenditure data collected in these surveys convinced Engel that there was a relation between a household's income and the allocation of its expenditures between food and other items. This was one of the first functional relations ever established quantitatively in economics. Furthermore, he observed that households with higher incomes tended to spend more on food than poorer households, but that the share of food expenditures in the total budget tended to vary inversely with income. From this empirical regularity he went on to infer that in the course of economic development agriculture would decline relative to other sectors of the economy (Engel, 1857). From 1860 to 1882 Engel was director of the Prussian statistical bureau in Berlin, in which capacity he did much to expand and strengthen official statistics. His resignation resulted from his opposition to Bismarck's protectionist policies. In his own research he dealt particularly with the value of human life (Engel, 1877), which he approached from the cost side. He also investigated the influence of price on demand. His influence on official statistics extended well beyond Germany, and in 1885 he was among the founders of the

International Statistical Institute. He died in Radebeul in 1896.

Engel's law states that food is not a luxury. This is one of the earliest empirical regularities in economics and also one of the most robust. The widespread finding is that regressions of food expenditures, quantities or budget shares on income or total expenditure and other variables such as prices, demographics and regional dummies uniformly imply that the income elasticity of food is less than 1 (and greater than zero). For example, time series from individual countries, cross-sections within countries and cross-country analyses all find the same qualitative empirical finding.

This correlation seems to have been highlighted for a number of reasons. First, food is an important component of household budgets everywhere so that it is intrinsically of interest. Second, the finding suggests that over the long run countries experiencing significant growth will find that agriculture provides an increasingly unimportant part of national income. This argues against balanced growth in long- run development. Third, we do not observe such a consistent pattern for any other wide commodity grouping such as clothing or durables. Finally, the fact that the food budget share is a decreasing function of the material standard of living (if other factors are held constant) suggested at one time that it can be used as an indicator of the latter. In particular, iso-prop ('same proportion') methods have been used to compute adult equivalence scales by finding the level of income that would equate the food budget share across different demographic groups. The conditions under which the iso-prop method is valid are very strong – essentially, extra people in the household have to make the household behave as though it is poorer and should not cause any change in the structure of demands above this – and such methods have fallen out of favour (see Deaton and Muellbauer 1986, for discussion and references).

Despite the venerability of the literature on Engel's law, the inferences that can be drawn from it are limited. For example, the cross-section finding is consistent with all households having a decreasing relationship so that increasing the income of a household will lead to a decrease in the food budget share. On the other hand, the correlation might be completely spurious if it is due to poorer households having a higher 'taste' for food. In this case the apparent dependence is simply due to heterogeneity in tastes, which is correlated with income. The fact that studies using aggregate time series-data find different elasticities from those found in cross-section data from the same country and time period suggests that the empirical finding is a combination of both causes. The paucity of panel data with full expenditure information makes any inference hazardous. Thus Engel's law remains what it has always been: a very robust but unsurprising partial correlation with many alternative interpretations.

Born in Barmen, the eldest son of a textile manufacturer in Westphalia, Engels was trained for a merchant's profession. From school onwards, however, he developed radical literary ambitions which eventually brought him into contact with the Young Hegelian circle in Berlin in 1841. In 1842, Engels left for England to work in his father's Manchester firm. Already converted by Moses Hess to a belief in 'communism' and the imminence of an English social revolution, he used his two-year stay to study the conditions which would bring it about. From this visit came two works which were to make an important contribution to the formation of Marxian socialism: *Outlines of a Critique of Political Economy* (generally called the *Umrisse)* published in 1844, and *The Condition of the Working Class in England,* published in Leipzig in 1845.

Returning home via Paris in 1844, Engels had his first serious meeting with Marx. Their lifelong collaboration dated from this point with an agreement to produce a joint work (*The Holy Family*), setting out their positions against other tendencies within Young Hegelianism. This was followed by a second unfinished joint enterprise *(The German Ideology,* 1845–6), where their materialist conception of history was expounded systematically for the first time.

Between 1845 and 1848, Engels was engaged in political work among German communist groups in Paris and Brussels. In the 1848 revolution itself, he took a full part, first as a collaborator of Marx on the *Neue Rheinische Zeitung* and subsequently in the last phase of armed resistance to counter-revolution in the summer of 1849.

In 1850, Engels returned once more to Manchester to work for his father's firm and remained there until he retired in 1870. During this period, in addition to numerous journalistic contributions, including attempts to publicize Marx's *Critique of Political Economy* (1859) and *Capital,* volume 1 (1867, second edition 1873), he first developed his interest in the relationship between historical materialism and the natural sciences. These writings were posthumously published as *The Dialectics of Nature* (1925). In 1870 Engels moved to London.

As Marx's health declined, Engels took over most of his political work in the last years of the First International (1864–72) and took increasing responsibility for corresponding with the newly founded German Social Democratic Party and other infant socialist parties. Engels's most important work during this period was his polemic against the positivist German socialist, Eugen Dühring. The *Anti-Dühring* (1877) was the first comprehensive exposition of a Marxian socialism in the realms of philosophy, history and political economy. The success of this work, and in particular of extracts from it like *Socialism, Utopian and Scientific,* represented the decisive turning point in the international diffusion of Marxism and shaped its understanding as a theory in the period before 1914.

In his last years after Marx's death in 1883, Engels devoted most of his time to the editing and

publishing of the remaining volumes of *Capital* from Marx's manuscripts. volume 2 appeared in 1885, volume 3 in 1894, a year before his death. Engels had also hoped to prepare the final volume dealing with the history of political economy. But the difficulty of deciphering Marx's handwriting, his own failing eyesight and the formidable editorial problems encountered in constructing Volumes 2 and 3, induced him to hand over this task to Karl Kautsky, who subsequently published it under the title *Theories of Surplus Value.*

Engels's work was of importance, both in the construction and interpretation of Marxian economic theory and in the laying down of important guidelines in the subsequent development of Marxist economic policy.

In the realm of theory, his contribution is of particular significance in three respects.

First, and of real importance in the formation of a distinctively Marxian stance towards political economy was Engels's *Outlines of a Critique of Political Economy* (the *Umrisse),* published in 1844. In 1859 in his own *Critique of Political Economy,* Marx acknowledged this sketch as 'brilliant', and its impact is discernible in Marx's 1844 writings. The *Umrisse* represented the first systematic confrontation between the 'communist' strand of Young Hegelianism and political economy. The communist aspiration was expressed in Feuerbachian language, while the mode of analysis was Hegelian. But, as has recently been demonstrated (Claeys 1984), the content of Engels's critique was first and foremost a product of his early stay in Manchester. For, apart from some indebtedness to Proudhon's *What is Property?* (1841), the main source of Engels's essay was John Watts, *The Facts and Fictions of Political Economy* (1842), a resumé of the Owenite case against the propositions of political economy. At this stage, Engels's own acquaintance with the work of political economists seems to have been mainly at second-hand.

The *Umrisse* was an attempt to demonstrate that all the categories of political economy presupposed competition which in turn presupposed private property. He began with an analysis of value, which juxtaposed a 'subjective' conception of value as utility ascribed to Say with an 'objective' conception as cost of production attributed to Ricardo and McCulloch. Reconciling these two definitions in Hegelian fashion, Engels defined value as the relation of production costs to utility. This was the equitable basis of exchange, but one impossible to implement on the basis of competition which was responsive to market demand rather than social need. (Engels still adhered to this definition of value 30 years later in the *Anti-Dühring.* Discussing the disappearance of the 'law of value' with the end of commodity production, he wrote:

> As long ago as 1844, I stated that the above mentioned balancing of useful effects and expenditure of labour would be all that would be left, in a communist society, of the concept of value as it appears in politicaleconomy . . . The scientific justification for this statement, however,. . . was only made possible by Marx's *Capital.* (Engels 1877, pp. 367–8)

This shows how much greater continuity of thought there was between the young and the old Engels than is normally imagined.)

He next analysed rent, counterposing a Ricardian notion of differential productivity to one attributed to Smith and T.P. Thompson based upon competition. Interestingly, in this analysis Engels differed both from Watts and Proudhon, in denying the radical form of the labour theory – the right to the whole product of labour – both by citing the case of the need to support children and in querying the possibility of calculating the share of labour in the product.

Finally, after an attack on the Malthusian population theory, which closely followed Alison and Watts, Engels attacked competition itself, both because it provided no mechanism of reconciling general and individual interest, and because it was argued to be self-contradictory. Competition based on self-interest bred monopoly. Competition as an immanent law of private property led to polarization and the centralization of property. Thus private property under competition is self-consuming.

What particularly impressed Marx was the argument that all the categories of political economy were tied to the assumption of competition based on private property. This, for him,

represented an important advance over Proudhon whose notion of equal wage would lead to a society conceived as 'abstract capitalist' and whose conception of labour right presupposed private property. Proudhon had not seen that labour was the essence of private property. His critique was of 'political economy from the standpoint of political economy'. He had not 'considered the further creations of private property, e.g. wages, trade, value, price, money etc. as forms of private property in themselves' (Engels and Marx 1844b). The *Umrisse* suggested a new means of underpinning the Marxian ambition to transcend the categorical world of political economy and private property altogether. Moreover, by representing competition as a law which would produce its opposite, monopoly, the elimination of private property and revolution, Engels preceded Marx in positing the 'free trade system' as a process moving towards self-destruction through the operation of laws immanent within it.

These conclusions were amplified in Engels's other major work of this period, *The Condition of the Working Class in England.* Here, the law of competition by engendering 'the industrial revolution' had created a revolutionary new force, the working class. The single thread underlying the development of the working class movement had been the attempt to overcome competition. Such an analysis prefigured the famous statement in the *Communist Manifesto* that the capitalists were begetting their own gravediggers (Stedman Jones 1977).

Between the mid-1840s and the mid-1870s, Engels played no discernible part in the elaboration of *Capital* beyond supplying Marx with practical business information. His vital contributions to the prehistory of the theory were forgotten and it was only in his better-known role as interpreter and publicist of Marx's work that his writings received widespread attention. During the Second International period, these writings attained almost canonical status, but in the 20th century they generally provided a polemical target for all those attempting to re-theorize Marx in the light of the publication of his early writings.

In the realm of political economy more narrowly conceived, Engels helped to set up the 'transformation' debate by his dramatization of Marx's switch from value to production price in his introductions to Volumes 2 and 3 of *Capital.* Engels's own contribution to this debate in his last published article in *Neue Zeit* in 1895 (now published as 'Supplement and Addendum' to volume 3 of *Capital)* was to argue that the shift from value to production price was not merely a logical development entailed by the enlargement of the scope of investigation to include circulation and the 'process of capitalist production as a whole', but also reflected a real historical transition from the stage of simple commodity production to that of capitalism proper. 'The Marxian law of value has a universal economic validity for an era lasting from the beginning of the exchange that transforms products into commodities down to the fifteenth century of our epoch' (Marx 1894, p. 1037).

Leaving aside the empirical question whether during the pre-capitalist era commodities were exchanged in accordance with the amount of labour embodied in them, commentators as diverse as Bernstein and Rubin have objected that this makes no sense in terms of Marx's theory, since during this epoch there existed 'no mechanism of the general equalisation of different individual labour expenditures in separate economic units on the market' and that consequently it was not appropriate to speak of 'abstract and socially necessary labour which is the basis of the theory of value' (Rubin 1928, p. 254). They have further objected, appealing to Marx's 1857 'Introduction to the Critique of Political Economy', that there is no necessary connection between the logical and historical sequence of concepts, and that the order of appearance of concepts in *Capital* is determined simply by the logical place they occupy in an exposition of the theory of the capitalist mode of production.

Engels could certainly claim explicit textual support from volume 3 for his historical interpretation of value ('It is also quite apposite to view the value of commodities not only as theoretically prior to the prices of production, but also as historically prior to them. This applies to those conditions in which the means of production belong to the worker. . .'; Marx 1894, p. 277). It should also be stressed that there was nothing new in

Engels's representation of the character of Marx's theory. Back in 1859, in a review of Marx's *Critique of Political Economy,* Engels stated, 'Marx was, and is, the only one who could undertake the work of extracting from the Hegelian Logic the kernel which comprised Hegel's real discoveries . . . and to construct the dialectical method divested of its idealistic trappings'; and in characterizing that method as a form of identity between logical and historical progression, he continued, 'the chain of thought must begin with the same thing that this history begins with, and its further course will be nothing but the mirror image of the historical course in abstract and theoretically consistent form . . . ' (Engels 1859). It is implausible to suppose that Marx at this time should have sanctioned a fundamental distortion of his method and it is suggestive that he himself, describing his relationship to Hegel, should have endorsed the metaphor of discovering 'the rational kernel in the mystical shell' in his 1873 Postface to the second edition of *Capital,* volume 1 (Marx 1873, p. 103). Perhaps the real difficulty lies not in Engels but in Marx himself. It may be, as Louis Althusser has claimed, that Marx did not find a suitable language in which to characterize the distinctiveness of his approach, or it may be more simply that Marx remained ambivalent about how to characterize the theory. In any event, it is not difficult to establish disjunctions between the way he proceeds and the descriptions he gives of his procedures. Engels stuck fairly closely to Marx's descriptions of his procedures and can hardly be reproached for taking Marx at his word.

The problem of Engels's role as an interpreter of Marx's theory debouches onto a third and potentially yet more contentious aspect of Engels's legacy, his role as editor of *Capital,* Volumes 2 and 3. Engels's work was not confined to the transcription of Marx's illegible handwriting. He had to make active editorial choices. The published versions of these volumes contain over 1300 pages, but the original manuscripts amount to almost twice as many. For volume 2, for instance, Marx had composed eight versions of his treatment of the process of circulation, from which Engels made a collation. In the absence of an independent transcription and publication of the manuscripts, from which Engels worked, it is impossible to assess whether the emphasis and meaning of the published volumes differ in any significant way from the original. What seems clear, is that in his cautious desire to reproduce as much of the original material as possible, Engels produced a much bulkier and more repetitive version than Marx originally intended. Marx, it seems, always hoped that *Capital* should consist of two volumes and a further volume on the history of political economy (Rubel 1968; Levine 1984). From a detailed comparison of volume 2, Part 1, with the original manuscripts, it appears that Engels also occasionally committed inaccuracies in the citation of the manuscripts he had used (Levine 1984). Much more doubtful, given all we know of Engels's caution as an editor, is the further suggestion that Engels's editing procedures may have shifted the meaning of the text in ways that lent support to a 'collapse theory' of capitalism *(Zusammenbruchstheorie)* (Levine 1984). Apart from the smallness of the sample and Engels's own reservations about such a theory, the fact is that proponents of such a position already had sufficient ammunition from *Capital*, volume 1. Moreover, it simply begs the question whether Marx's attitude to the collapse of capitalism was any more or less apocalyptic than that of Engels.

This discussion by no means exhausts Engels's importance in the history of economic theory or policy. A fuller treatment would have to discuss his analysis of the 'peasant question' which included the important prescription that collectivization must be by example rather than force, his definition of political economy in the *Anti-Dühring,* his interpolations in *Capital,* volume 3, on banks, the stock exchange and cartels which set the agenda for the early 20th-century discussion of finance capital, his various writings on the relationship between the state and economic forces and his later surveys of English developments since 1844 which prepared the way for later Marxist theories of labour aristocracy. These are only some of the more salient examples.

Finally, at a time when it seems that the technical debate on value seems to have reached a moment of exhaustion, it is perhaps worth going

back to Engels if only to remind us of the anti-economic purpose underlying Marx's attempt to construct a theory of value in the first place.

Engle, Robert F. (Born 1942)

Tim Bollerslev

Abstract

Robert Engle has published widely on topics ranging from urban economics to band spectrum regression, electricity demand, state-space modelling, testing, exogeneity, seasonality, option pricing, and market microstructure finance. Most notable, however, are his seminal contributions on cointegration and Auto-Regressive Conditional Heteroskedasticity (ARCH), which have revolutionized the field of time series econometrics and the practice of empirical macroeconomics and asset pricing finance, respectively. The research field of financial econometrics and corresponding developments in practical risk management and measurement also derive largely from the insights afforded by the ARCH class of models and Engle's many other research contributions since the 1980s.

Robert F. Engle was born in Syracuse, upstate New York, on 10 November 1942. Shortly thereafter his family moved to Philadelphia, and Engle graduated from high school there in 1960. He majored in physics as an undergraduate at Williams College, and went on to enrol as a Ph.D. student in physics at Cornell University. However, after one year he decided to switch to the Ph.D. programme in economics, where he wrote his thesis on temporal aggregation and the relationship between macroeconomic models estimated at different frequencies, under the direction of T.C. Liu. After graduating from Cornell in 1969, Engle was hired as an assistant professor at MIT. He moved on to University College at San Diego (UCSD) in 1975, where he was promoted to full professor in 1977 and a Chancellors' Associates Chair in 1993. He also chaired the UCSD Economics Department from 1990 to 1994. In 2000 his growing interest in financial markets prompted him to accept the Michael Armellino Professorship in Finance at the Stern School of Business at New York University, and he now lives on Manhattan with his wife of many years, Marianne, for most of the year. Together they have two grown children.

Engle has written and published extensively on a wide array of topics, ranging from urban economics to band spectrum regression, electricity demand, state-space modelling, testing, exogeneity, seasonality, option pricing, and market microstructure finance. However, he is particularly well-known for his contributions to time series econometrics and his path-breaking work on cointegration and AutoRegressive Conditional Heteroskedasticity (ARCH). The 2003 Bank of Sweden Prize in Economic Sciences in Memory of Alfred Nobel was explicitly awarded to Engle for 'methods of analyzing economic time series with time-varying volatility (ARCH)', a prize he shared with Clive W. J. Granger for his seminal contributions to the theory of cointegration. It is hardly an exaggeration to say that since the 1980s the concepts of cointegration and ARCH have completely revolutionized the field of time series econometrics and the practice of empirical macroeconomics and asset pricing finance, respectively. The blossoming new research field of financial econometrics and corresponding developments in practical risk management and measurement may also in large part be attributed to the insights afforded by the ARCH class of models and some of Engle's many other pioneering research contributions.

Encouraged by his senior colleagues Franklin M. Fisher, Robert Solow and Jerome Rothenberg, much of Engle's work as an assistant professor at MIT was in the area of urban economics. In fact, Engle was hired by UCSD as an urban economist, and he continued to teach, and occasionally publish in, urban economics almost up until he left San Diego in 2000. It was Clive Granger, whom Engle had first met at the 1970 World Congress of the Econometric Society in Cambridge, who persuaded Engle to move to the West Coast. Granger had himself just accepted a permanent position at UCSD in 1974 and, only a few years after Engle's arrival in 1975, Halbert White also joined the department. The ensuing two decades may rightfully be referred to as the golden age of modern time series econometrics, and UCSD, along with Yale, home of the group led by Peter Phillips, was *the* place to be. The list of visitors to the UCSD Economics Department over this period reads like a who's who in time series econometrics. Engle's hospitality and generosity with his time, as well as the many successful conferences he organized in San Diego, played a crucial role in fostering this nexus. The group was further strengthened by the arrival of James Hamilton, Graham Elliott and Allan Timmermann as additional faculty members in the early 1990s, and the Engle–Granger UCSD econometrics tradition continues to this day. Many of Engle's former Ph.D. students from that period have also gone on to successful academic careers, continuing the UCSD legacy.

Albert Einstein's famous maxim 'Everything should be made as simple as possible, but not simpler' succinctly characterizes Engle's approach to econometric modelling. Consider his early research on band spectrum regression. The static OLS regression approach routinely employed throughout economics implicitly

assumes that the identical linear relationship holds across all frequencies. Yet in many situations this is obviously a gross oversimplification. For instance, the relation between interest rates and housing starts arguably differs between the short run and the long run. Similarly, the Phillips-curve trade-off between unemployment and inflation may be primarily a business cycle phenomenon. Rather than building a fully fledged complicated dynamic model for analysing these types of temporal dependencies, the band spectrum regression approach offers a simple way of estimating separate regression coefficients, and therefore different relationships, for different frequencies. The idea of estimating different short-run and long-run regressions may also be seen as a precursor to Engle's later work on cointegration and error correction models.

The original idea of cointegration came from Granger. Nonetheless, it was the seminal joint paper by Engle and Granger (1987a) that devised the first empirical test for cointegration and formally established the link between cointegration and the error-correction type models popularized by Denis Sargan and David Hendry at the LSE during the 1960s and 1970s. More specifically, suppose that the two univariate time series yt and x_t are both non-stationary, or I(1), so that their first differences, $\Delta y_t \equiv y_t - y_{t-1}$ and $\Delta x_t \equiv x_t - x_{t-1}$, are stationary, or I(0). Most nominal macroeconomic and financial time series may be characterized in this way. Any linear combination of the two series, say $z_t = y_t - \beta x_t$, will then generally also be non-stationary. However, it is possible that z_t may actually be stationary, or I(0), in which case y_t and x_t are said to be cointegrated, with cointegrating vector $(1, -\beta)$. Indeed, many of the 'classical ratios' in macroeconomics and finance (such as consumption/income and dividends/prices) are naturally thought of as cointegrating relationships when expressed in logs. Engle and Granger showed that in this situation a satisfactory vector autoregression for the stationary bivariate process of first differences, $\{\Delta y_t, \Delta x_t\}$, must necessarily include the z_t 'error-correction' term in at least one of the two equations, the so-called Granger Representation Theorem. Intuitively, while both y_t and x_t are stochastically trending, they trend together, so that in the long run they do not stray too far apart. The inclusion of the stationary z_t term as an additional explanatory variable ensures this condition. On the other hand, if the two variables are not cointegrated z_t will be non-stationary, resulting in an unbalanced regression. Hence, empirically the null hypothesis of no cointegration may be assessed on the basis of the popular Engle–Granger cointegration test for a unit root in z_t or, if β is not known, a least-squares estimate thereof. The cointegration concept has had a profound impact on practical macroeconomic time series modelling in government and private institutions around the world. The academic literature also abounds with hundreds, if not thousands, of papers expanding upon the basic testing and modelling approach first developed by Engle and Granger. Engle's subsequent work on common features may also be seen as a natural extension of the cointegration concept.

Another more technical theme brought to the fore by Engle's research entails the powerful use of one-step-ahead prediction error decompositions and conditional Gaussian likelihoods. For instance, the beauty of his influential work on testing, including the simple-to-implement Lagrange Multiplier (LM) chi-square type test statistics constructed by multiplying the number of time series observations with the R^2 from an auxiliary regression of either unity on the vector of scores evaluated under the null hypothesis, or, alternatively, a regression of the squared residuals on the derivatives of the conditional mean, hinges directly on recursively expressing the likelihood function in terms of conditional one-step-ahead densities. Engle's pioneering contributions on dynamic factor models and Kalman filtering are similarly based on the powerful idea of representing the likelihood function in terms of successive conditional densities. Most important, however, the seminal ARCH class of models is also formulated directly in terms of one-step-ahead conditional expectations and densities.

The ARCH model (aptly named so by David Hendry) was conceived during Engle's sabbatical

visit to the LSE in 1979. Engle's interest in modelling variance dynamics was spurred by the assertion in Milton Friedman's 1976 Nobel Lecture on a trade-off between unemployment and inflationary uncertainty rather than a trade-off between unemployment and the level of inflation as stipulated by the conventional Phillips curve. The actual formulation of the first ARCH model was also influenced by Granger's ongoing work on bilinear models. At the time Granger had noted that in a non-Gaussian setting white noise series need not necessarily be unpredictable, and, in particular, when the squared residuals from otherwise well-specified linear models were regressed on their own lagged squared values, the regression coefficients often turned out to be highly significant. Engle realized that this was not actually a test for bilinearity but rather the optimal LM test for some other nonlinear model. Putting this together, Engle brought forth the ARCH model.

The particular ARCH(p) model first analysed and estimated by Engle (1982) may be succinctly expressed as

$$y_t = m_t + \varepsilon_t, \quad \varepsilon_t | \mathrm{I}_{t-1} \sim \mathrm{N}(0, \ h_t), \quad \text{and} \quad h_t = \alpha_0 + \alpha_1 \varepsilon_{t-1}^2 + \ldots + \alpha_p \varepsilon_{t-p}^2,$$

where I_{t-1} refers to the set of information available at time $t-1$, m_t denotes the conditional mean of the y_t time series, and all of the $\alpha_0, \ldots, \alpha_p$ parameters are restricted to be non-negative. The first equation for the conditional mean is, of course, completely standard (in his original application to UK consumer prices Engle used an error correction model for the mean). However, the key difference – Engle's brilliant new insight – comes from recognizing that even though the residuals, ε_t, must be serially uncorrelated, their conditional variance, and therefore the conditional variance of y_t, need not be constant but may in fact be predictable. Moreover, by explicit parameterizing h_t as a function of the past squared residuals and by assuming conditional normality, the joint density for all of the observations, say y_t, $t = 1, 2, \ldots, T$, may easily be evaluated through a prediction error decomposition type argument, and the log likelihood function maximized with respect to all of the model parameters, in turn resulting in a time series of positively serially correlated conditional variance estimates, $\hat{h}_t$, $t = 1, 2, \ldots, T$ (that is, estimates of inflationary uncertainty in Engle's original application).

While Engle's initial work and empirical applications of the ARCH model were rooted in macroeconomics, the model has shone most brightly in the area of finance. Since Mandelbrot's work in the early 1960s on the behaviour of speculative prices, it had been recognized that, even though most returns are approximately serially uncorrelated (at least over shorter daily or weekly horizons), 'large changes tend to be followed by large changes – of either sign – and small changes tend to be followed by small changes' (Mandelbrot 1963). However, the empirical finance literature up until the mid-1980s had largely ignored this fact, focusing instead on best characterizing the unconditional return distributions. Meanwhile, Engle soon realized that the ARCH model was ideally suited to this type of data: little, or no, serial correlation in the mean, but strong serial correlation in the second moments. Moreover, the ability to directly quantify the risk through a parametric model for the conditional variance, or more generally the conditional covariance matrix, for the returns strikes directly at the heart of the risk-return trade-off central to asset pricing finance. Consequently, Engle quickly shifted the focus of his research agenda to finance. Over the next 20 years, along with his many students and other collaborators, he developed numerous refinements to the basic ARCH model described above designed to account better for specific features of the data and/or questions of economic import: richer ARMA-type representations for the variance, including unit-root and long-memory type dependencies, models in which the variance directly influences the conditional mean, asymmetries or leverage effects in the variance, alternative parametric and non-parametric conditional distributions in place of the normal, multivariate factor models and cointegration in variance, to mention but a few. The corresponding long list of new

acronyms is also legendary: ARCH-M, GARCH, IGARCH, EGARCH, TARCH, GJR-GARCH, NARCH, QARCH, STARCH, VGARCH, SWARCH, FIGARCH – the list goes on. Empirical applications of these models have in turn resulted in many important new insights into the pricing and hedging of financial instruments and functioning of financial markets, and it is no exaggeration to say that the day-to-day risk management and monitoring in financial institutions have been completely altered by the advent of the ARCH class of models.

Not one to rest on his laurels, Engle continues to push forward the research frontier in financial econometrics. Most recently he has worked extensively on new methods for analysing ultra high-frequency, or tick-by-tick, financial data. In particular, whereas most procedures in time series econometrics, including most of Engle's own earlier work, are explicitly designed for modelling discretely sampled equidistant observations, high-frequency financial data are typically not observed at fixed time intervals. Engle's recent Autoregressive Conditional Duration (ACD) model, which derives many of its statistical properties from the ARCH class of models, provides a particularly convenient way of accommodating this feature by explicitly modelling the times between observations as a serially correlated process. His Dynamic Conditional Correlation (DCC) model, which allows for the estimation of large-scale dynamic covariance matrices, represents another recent noteworthy advance. In keeping with his trademark, this latest research represents the perfect blend between sophisticated yet simple-to-implement econometric techniques explicitly designed for answering genuinely interesting economic questions. Like most of his research since the 1970s, his latest work has already found widespread use both inside and outside academia, and spurred a number of ongoing new developments by other researchers in the field.

In addition to the much-deserved recognition bestowed on him by the Nobel Prize Committee, Engle is a long-standing fellow of the Econometric Society, of the American Statistical Association, and of the American Academy of Arts and Sciences. He is also an excellent speaker, and he has a long list of invited talks and keynote addresses to his name, including the prestigious A. W. Philips and Fisher-Schultz lectures sponsored by the Econometric Society. (For a more in-depth discussion of Engle's work along with some personal reflections, see Diebold 2003, 2004.)

In conclusion, it is simply impossible to imagine what the field of time series econometrics, let alone the new field of financial econometrics, would have looked like today had it not been for Engle's seminal contributions, both direct and indirect, through the substantial subsequent research programmes his work has helped stimulate. But Engle isn't merely one of the greatest econometricians of his time. He has a wide range of other interests and talents. For example, he is an outstanding ice skater, having competed at the US national level, finishing second in the 1996 and 1999 ice dancing championship competition.

English School of Political Economy

A. M. C. Waterman

Abstract

The 'English School' of political economy describes the tradition of economic thought that began with Malthus, and included Henry Thornton, Chalmers, James Mill, Torrens, West, Ricardo, and Thomas Tooke in the first generation; Whately, Senior, McCulloch and J.S. Mill in the second; and the Fawcetts, Cairnes, Jevons, Bagehot, Foxwell, Sidgwick, J.N. Keynes and Nicholson in the third. J.-B. Say was an honorary member. Karl Marx identified his own work with that school. Its most important production was J.S. Mill's *Principles of Political Economy,* which continued to be used as a textbook until the mid-20th century.

The 'English School' of political economy comprises all major British economists of the 19th century, together with J.-B. Say and perhaps Karl Marx.

'Important changes have taken place in the meaning of the term "political economy," as used by leading writers, since it was first employed', wrote Henry Sidgwick in Palgrave's original *Dictionary of Political Economy* (Palgrave 1899, pp. 128–9). As first used by Mayerne-Turquet and Montchrétien, *'œconomie*

politique' signified an attempt to extend the art of estate management to the entire kingdom of Louis XIII and his successors (Waterman 2004, p. 225). This usage, generalized to mean a 'system' of policy designed to 'increase the riches and power' of a country (Smith 1776, I.xi.n.1; II.5.31; IV.1.3) remained current until the end of the 18th century and was so employed by Steuart.

Adam Smith disliked the usage because of its implicit mercantilism. He recognized it, but proposed a better definition. 'What is properly called Political Œconomy' is 'a branch of the science of a statesman or legislator': namely *'an inquiry',* which is in principle disinterested and open-ended, into *'the nature and causes of the wealth of nations'* (Smith 1776, IV. intro; IV.ix.38; emphasis added). The prestige that *Wealth of Nations* quickly acquired, amplified by Dugald Stewart's widely influential Edinburgh lectures in the new science, redefined 'political economy' as a 'part of the science of human society' (Palgrave 1899, p. 129; cf. Winch 1983, who appears to disagree with this interpretation) and created a circle of younger thinkers committed both to criticizing and refining Smith's ideas and to propagating them among the governing classes. Though the *Edinburgh Review*, founded in 1802, was at first the principal means of propagation, most of the prime movers soon migrated to London, which from the second or third decade of the 19th century became the home of what was soon called the 'English School'.

It is important to recognize that to describe the small community of anglophone political economists in the 1820s and after as a 'school' is to imply neither a quasi- apostolic succession of doctrine in some leading university nor a closed shop of experts defined by their adherence to any orthodoxy. It is rather the fact, as T.S. Eliot observed of all such intellectual circles in general, that 'they are driven to each other's company by their common dissimilarity from everybody else, and by the fact that they find each other the most profitable people to disagree with' (Kojecky 1971, p. 244). Members of the English School, like all subsequent economists, were notorious for their disagreements, both with Adam Smith and with each other. But they did not find it profitable to disagree with hostile critics of their enterprise, such as the Lake Poets (from whom they were all indeed markedly 'dissimilar'), because the latter chose not to acquire the viewpoint and vocabulary of the new, political-economy conversation, but resorted rather to the idioms of a very different conversation: that of Romantic aesthetics and non-utilitarian ethics.

In attending to the conversation of the English School it is necessary first to establish its identity, secondly to consider its members and its literature, and thirdly to distinguish its chief analytical features, especially as these differ both from the economic thought that preceded it and from economics of the present day. Finally, since the boundary between the political economy of the English School and what is generally thought of as 'modern' economics is vague and permeable, some attention should be paid to continuity and 'revolution', if any.

Identity of the English School of Political Economy

Writing of 'the English School of Political Economy' in the original Palgrave dictionary, James Bonar (Palgrave 1894, p. 730) observed that 'The English writers on political economy before Adam Smith do not at any time present the marks of a "school" properly so called.' What Bonar called 'Modern Economics' – meaning 'political economy' in the new, Smithian sense – he then divided into four periods headed respectively: Adam Smith, Malthus and Ricardo, John Stuart Mill, and W.S. Jevons; with all other authors subsumed under these canonical names.

Adam Smith was not an Englishman and he died before Malthus and Ricardo had begun to write. Though the *Edinburgh Review* (Anon 1837, p. 73) referred to the English School as 'the school of which Adam Smith was the founder', this is Caledonian hyperbole. Smith founded no 'school'. His most influential disciple, Dugald Stewart, was the intermediary between Smith and those the *Edinburgh Review* more accurately described later in the article as the 'followers of Dr Smith' practising 'Political Economy, using

the word in the sense of Ricardo and Malthus' (Anon 1837, pp. 77, 79). Subject to this important qualification, Bonar's chronology is helpful. Roughly speaking the English School lasted for about three generations. The first generation, from 1798 to the 1830s is that of which Malthus, Henry Thornton, Chalmers, James Mill, Torrens, West, Ricardo, and Thomas Tooke are now the best remembered. A second generation, whose members were active in some cases before 1830, but who flourished for the most part until the 1860s or even later, included Whately, Senior, McCulloch and J.S. Mill. Political economy of the English School never really died out. It changed, very gradually and almost imperceptibly, into the international, professionalized 'economics' of the mid-20th century. Yet a third and last generation can be detected – and was in fact detected in the 1890s – which included W.T. Thornton, the Fawcetts, Cairnes, Jevons, Bagehot, Foxwell, Sidgwick, J.N. Keynes and Nicholson. The positions of Marshall, Edgeworth and Wicksteed are problematic and will be considered below.

The English School was recognized by its difference from 'the foreign school' (Anon 1837, p. 77) which included Sismondi, Cherbuliez and Villeneuve, but not J.-B. Say who from the first was deemed an honorary Englishman. The English writers distinguished 'the art of government' from the 'science' of political economy. With respect to the former, the latter is 'only one of many subservient sciences; which involves the consideration only of motives, of which the desire for wealth is only one among many, and aims at objects to which the possession of wealth is only a subordinate means' (Senior 1836, pp. 129–30). The foreign writers rejected this minimalist construal, labelled it 'chrematistics' or 'chrysology', and continued to maintain that political economy embraces both the art and the science of government.

The incipient distinction between 'art' and 'science' seemed to imply that any practitioner of the latter must abstain – qua political economist – from political judgements. His analytical conclusions, being strictly positive and abstracted from ethical considerations, 'do not authorize him in adding a single syllable of advice'. His business is 'neither to recommend nor to dissuade, but to state general principles which it is fatal to neglect' (Senior 1836). McCulloch for one strongly disagreed with Senior on this point: the general principles, he thought, had already been completely enounced by Ricardo. What remained was 'to exhibit some of their more important applications' (McCulloch 1843, p. vi). Though Senior's view of the scope of political economy was tidied up and assimilated by the end of the 19th century (J.N. Keynes 1891), all members of the 'school' were agreed at the outset on at least one most important 'application'. The 'great principles of free exchange and natural distribution' that Smith had developed from 'the philosophers of the Continent' (that is, Quesnay, Turgot and so on) showed it to be economically unprofitable 'for the legislature to intermeddle' with trade and income distribution (Anon 1837, pp. 80, 78). Though Cairnes later averred that 'political economy has nothing to do with laisser faire', Sidgwick thought this 'too daring a paradox'.

> There can be no doubt that the interest of Adam Smith's book for ordinary readers is largely due to the decisiveness with which he offers to statesmen the kind of practical counsels which, according to Senior and Cairnes, he ought carefully to have abstained from giving. (Palgrave 1899, pp. 130–1)

Rightly or wrongly, the political economy of the English School was associated in the popular mind with free trade and attacks on corporate privilege, and was denounced for these disturbing ideas by a wide variety of hostile critics.

Both the methodological tendencies of the new science and its 'more important applications' owed much to Dugald Stewart: the former to his influential *Philosophy of the Human Mind* (1792, 1814, 1827) the latter to his annual public lectures at the University of Edinburgh, beginning in the winter of 1800/1.

Though preferring a broader definition of 'political economy' than that of either Smith or his English followers, and emphasizing the historical character of economic knowledge, Stewart argued in *Human Mind* that the hypothetical and a priori reasoning so characteristic of what he called the 'new science' – and which became

one of the hallmarks of the English School – was perfectly legitimate, and compatible with the testing of theories against experience (Fontana 1985, pp. 99–102; Waterman 2004, ch. 8).

Stewart's Edinburgh lectures were crucial in what a recent author has aptly called 'the process of Anglicisation of Scottish thought after 1790' (Fontana 1985, p. 9). Not only were they attended by Jeffrey, Horner, Brougham, Chalmers and the newly arrived Englishman, Sydney Smith, all of whom were influential in propagating political economy; Pryme (1823, p. vii) records that they 'attracted so much attention that several members of our own university [namely, Cambridge] went from the South of England to pass the Winter at Edinburgh, for the purpose of attending them': one of these seems to have been John Bird Sumner (Waterman 1991a, pp. 159–60). According to a later account, 'a wave of young Englishmen . . . went North in lieu of the grand tour made impossible by the renewal of war' (Checkland 1951, p. 43). Though the lectures were diffuse and circumspect, their underlying message was that contained in an early paper that Adam Smith had entrusted to Stewart before his death:

> Little else is required to carry a state to the highest degree of opulence from the lowest barbarism, but peace, easy taxes and a tolerable administration of justice; all the rest being brought about by the natural course of things (Smith 1755). (Winch 1996, p. 90)

Leading members of Stewart's circle – Jeffrey, Horner, Brougham, and Sydney Smith – founded the *Edinburgh Review* to urge this message upon the Holland House Whigs from whom they hoped to receive patronage. First Smith, then Jeffrey, served as editor until 1829, when replaced by McVey Napier. By that date its contributors on political economy had included all the leading members of the English School save Ricardo (who declined out of modesty, and who died in 1823): Malthus, James Mill, Chalmers, Torrens and McCulloch (Fontana 1985, p. 8).

Of these authors, all save Chalmers were members of the Political Economy Club, a London dining club founded in 1821 which, in addition to Malthus, Mill and Torrens, included from the outset Ricardo, George Warde Norman and Thomas Tooke. J.-B. Say was elected as an Honorary Foreign Member in 1822, the only such member until 1919. McCulloch was elected in 1829, shortly after his migration from Scotland; Senior (in 1823), Pryme (1828) and Whately (1831) were elected as Honorary Members by virtue of their professorships in political economy. Cairnes (1862), Cliffe Leslie (1862), Fawcett (1862), Jevons (1873), Foxwell (1882), Marshall (1886), Nicholson (1888) and Edgeworth (1891) were all subsequently elected under this rule. Among those political economists now remembered as influential authors of the English School, only Henry Thornton, Sir Edward West, Archbishop J. B. Sumner, Thomas Chalmers, Poulett Scrope, and Richard Jones were never members of the Club: Thornton because he died in 1815, West because he went to India, Chalmers because he stayed in Scotland, and Sumner because he announced in 1818 – to Ricardo's regret – that he intended to give up political economy for the study of theology (Waterman 1991a, p. 157). Scrope and Jones were on the outer edge of the 'School'.

It has been suggested that the English School was a 'scientific community' of which the Political Economy Club was a 'vital hub' (O'Brien 2004, pp. 12–13). There is merit in this suggestion, but it should be recognized that the original purpose of the club, though including the 'mutual instruction' of members, was chiefly propagandist: 'the diffusion amongst others of the just principles of Political Economy' and

> to watch carefully the proceedings of the Press, and to ascertain if any doctrines hostile to sound views on Political Economy have been propagated . . . to refute such erroneous doctrines, and counteract their influence . . . and to limit the influence of hurtful publications. (Political Economy Club 1921, p. 375)

Many members were Whig or liberal statesmen who knew a 'hurtful publication' when they saw one: 52 of the 115 elected between 1821 and 1870 sat in either the upper or lower House of Parliament; and included Lord Althorp, the Marquis of Landsdown (a descendent of Sir William Petty), Earl Grey and W. E. Gladstone. Fetter (1980) has

documented the activities of 'the economists in Parliament'.

Almost from the first there was a desire by the Club to recognize and foster the academic study of political economy. Though there had been high-level economic analysis at British universities before the end of the 18th century, it was but a small ingredient of 'moral and political philosophy' (for example, see Waterman 1995) and never known as 'political economy'. But in the decade of the 1820s chairs in political economy were established in Oxford, London and Cambridge and their incumbents immediately co-opted (Checkland 1951).

We may therefore identify the English School roughly speaking as that subset of Political Economy Club members in the 19th century who published and disputed with each other on the subject, together with half a dozen or so other major authors who at some time or other were part of their conversation. Despite its name, several leading members were Scotch immigrants, and it included one Frenchman. Though Karl Marx lived in London from 1848 and thoroughly digested the literature of anglophone political economy over the next two decades, he was not known or recognized by the Club. But in the 'Afterword' to the second German edition of *Capital* (Marx 1873, vol. 1, p. 26) he explicitly identified his own work, in method at least, with that of the English School.

Literature of the English School

Literature of the English School begins with Malthus's first *Essay on Population* (1798). For as an unintended consequence of his Whiggish polemic against Godwin's (1793) romantic anarchism, Malthus analysed the effect of population growth under land scarcity to show what was later called 'diminishing returns' (Stigler 1952). Though diminishing returns in agriculture had been identified by Steuart (1767) and Turgot (1768), and had actually been used by Anderson (1777) to adumbrate the 'Ricardian' theory of rent, the concept was not integrated into 18th-century economic thought. Notwithstanding Samuelson's influential interpretation, land scarcity plays little or no analytical part in *Wealth of Nations* (Samuelson 1978; cf. Hollander 1998; Waterman 1999). When Malthus (1815a), West (1815), Torrens (1815) and Ricardo (1815) worked out the implications of Malthus (1798) they believed that they were correcting Smith and saying something new and important (McCulloch 1845, p. 68). Diminishing returns immediately became part of the hard core of the so-called classical political economy of the English School.

Ricardo made diminishing returns in agriculture the cornerstone of his *Principles* (1817), combined it with 'Malthusian' population theory, Smith's account of accumulation and growth, and an ad hoc '93 % Labor Theory of Value' (Stigler 1958) to produce a complete account of value, distribution and growth in a two- sector market economy. The labour theory of value (LTV) was also the key concept in Ricardo's rigorous and elegant analysis of comparative advantage in international trade. Looking back 30 years later, McCulloch (1845, p. 16) called the LTV 'the fundamental theorem of the science of value'. An authoritative and exhaustive account of Ricardo's contribution – which it treats, à la McCulloch, as virtually identical with 'classical economics' – appeared in the first edition of *The New Palgrave Dictionary of Economics* (Blaug 1987).

In addition to the above works, the 'English' literature that already existed by the time the Political Economy Club was founded in 1821 included Malthus's (1800) *High Price of Provisions,* which formally specified a demand function of price and inaugurated the supply-and-demand value theory that eventually 'won out' over the Ricardo–Marx LTV (Smith 1956; Schumpeter 1954, p. 48) which it generalizes, Thornton's (1802) *Paper Currency,* which analysed the macroeconomic relations between monetary and real variables in a manner reinvented by Wicksell a century later, and numerous pamphlets by many authors on monetary questions provoked by the Parliamentary Bullion Committee of 1810. It was this controversy that brought Malthus and Ricardo together, and which seems to have been a catalyst for the nascent

'scientific community'. The pre-1821 literature also includes J.-B. Say's (1803) *Traité d'économie politique*; Lauderdale and Maitland (1804) *Inquiry,* dismissed by McCulloch (1845, p. 15) as without value; Chalmers's (1808) strikingly original but completely neglected *Nature and Stability of National Resources* (see Waterman 1991b); Malthus's (1815b) heretical pamphlet, 'Restricting the Importation of Foreign Corn', which led to his excommunication by the *Edinburgh Review* (Fontana 1985, p. 75); J. B. Sumner's (1816) *Records of the Creation* that Ricardo (1951–73, vol. 7, pp. 247–8) deemed a 'clever book' and which McCulloch (1845, p. 261 described as 'an excellent work'; the fifth edition of Malthus's Essay on Population (1817) substantially modified as a result of Sumner's arguments; Mrs Marcet's (1817) influential work of popularization, *Conversations on Political Economy;* and Copleston's (1819a, b) two brilliant and penetrating *Letters to Peel* that grasped more clearly than Malthus himself the connection between population and poverty, and between the latter and inflation of the currency – and which Ricardo so admired that he made a detailed paragraph-by-paragraph summary (Waterman 1991a, pp. 186–95; Hollander 1932, p. 135–45). Finally, shortly before or just after the first meeting of the Club there appeared important monographs by three of the founding fathers: Malthus's (1820) *Principles,* which quarrelled with Ricardo over value theory and put forward a heterodox macroeconomics of 'general gluts' that Keynes was later to find so appealing, James Mill's (1821) *Elements of Political Economy,* and Torrens's (1821) long undervalued *Essay on the Production of Wealth.*

It is apparent that during the first two decades of the 19th century, and for a further ten years or more, Malthus was at the centre of the political-economy conversation of the English School. This fact has been obscured by the excessive attention paid to Ricardo by those eager to praise or blame him for present-day economics, and by textbook authors wanting a handle on which to hang a student- friendly chapter on 'classical economics'. A long process of reappraisal, beginning with J. M. Keynes's (1972, vol. 10) biographical essay of 1933, has gradually restored the true picture (Waterman 1998). Donald Winch's (1996) *Riches and Poverty* is the latest and most authoritative intellectual history of political economy, covering the period 1750–1834. Nearly half his book is concerned with Malthus. Ricardo, 'treated largely as a foil to Malthus' (Winch 1996, p. 15) gets a few scattered references. Samuel Hollander's (1997) magisterial *Economics of Thomas Robert Malthus* shows that the analytical differences between Malthus and Ricardo have been exaggerated, and that the former was a theoretician of the same order, and of at least as much historical importance as the latter.

Malthus was central because the first *Essay* began a century-long transformation of 'political economy' (the science of wealth) into 'economics' (the science of scarcity). The theological implications of this, totally ignored by most historians, are a vital part of the intellectual context of the English School. Economic thought of the 18th century was believed by all to be wholly compatible with Christianity. But the seeming inevitability of 'misery' or 'vice' produced by human fecundity and resource scarcity challenges the goodness of God; and the political economy of Malthus and Ricardo was therefore condemned as 'hostile to religion'. For most of the 19th century, England was both officially and actually a Christian society. In such a society it is part of the duty of a scientist – essential if his work is to receive serious attention – to reconcile his findings with Christian theology. Malthus attempted this in 1798 and failed. His failure stimulated an important branch of the literature of the English School now known as 'Christian Political Economy' (Waterman 1991a). Works by William Paley (1802), by Malthus himself (1803, 1817), and by J. B. Sumner (1816) who eventually became Archbishop of Canterbury, demonstrated that the new science could be co-opted as theodicy; and even better, be used to demonstrate the benevolent 'design' of the Creator. The approval that Ricardo and McCulloch evinced for Sumner's 'clever book' had less to do with their own religious convictions than with their relief that political economy had been convincingly defended against the damaging charge of irreligion.

Quite different circumstances in the 1820s revived the need to defend political economy against religion, and created a new need: to defend religion against political economy. Jeremy Bentham, James Mill and other Benthamites, who were later called the 'Philosophic Radicals', founded the *Westminster Review* in 1824 to propagate a 'radical' reformism as against the Whiggish reformism of the *Edinburgh.* Anticlerical and at times anti-religious, the radicals hijacked political economy to mount a strictly utilitarian attack on the Establishment in Church and State. Animated by James Mill's puritanical hatred of the Arts, the *Westminster* compounded the injury by gratuitous attacks on the Lake Poets and other romantic authors. Influential Tories at the two universities (then exclusively Anglican) were alarmed, and opposition was made to the teaching of, and the establishment of chairs in, political economy. In this crisis, both political economy and Christian theology were authenticated and insulated against mutual encroachment by two Oxford men, Richard Whately, a former pupil and friend of Copleston, and Nassau Senior, Whately's former pupil and friend (Waterman 1991a, pp. 196–215).

Whately engineered the election of Senior as first Drummond Professor of Political Economy in 1826, and accepted the chair himself when it fell vacant in 1830. His seminal Introductory Lectures (1831) argued for an epistemological demarcation between 'religious and 'scientific' knowledge; and explained how, like all scientific knowledge, political economy depends upon both a priori deduction and the possibility of falsification. Whately thus established the methodological tradition of the English School that runs through Senior, J.S. Mill, J.N. Keynes and Lionel Robbins. Pietro Corsi (1987) has shown that Whately's philosophical apparatus was based on Dugald Stewart's *Philosophy of the Human Mind,* transmitted to Oxford through the friendship between Stewart and Copleston created by the migration from Edinburgh to Oxford in 1799 of J.W. Ward, 1st Earl of Dudley.

Whately's decisive intervention healed a potentially disastrous schism in the young 'scientific community' between Benthamite radicals and Malthusian Whigs. Elections to the Political Economy Club in the 1820s and 1830s included both Whigs and radicals and even the liberal Tory, Lord Althorp. When McVey Napier edited the 1824 *Supplement to the Encyclopaedia Britannica* he commissioned articles on political economy from Malthus and Sumner on the one hand, and from Mill and McCulloch on the other. (Ricardo's contribution, on the Funding System, was posthumous.) The Royal Commission on the Poor Laws (1832) which included Sumner, then Bishop of Chester, united all in the common cause once again. Malthus was the most important witness. The report, which led to the Poor Law Amendment Act (1834), was jointly written by the Benthamite Chadwick and the Whatelian Senior, and was based on Copleston's (1819b, p. 28) crucial distinction between 'propagation' and 'preservation' of human life.

One of the most interesting, certainly the most revealing, contributions to literature of the English School is McCulloch's compendious *Literature of Political Economy* (1845) which appeared about halfway through the life of the 'school'. The usual English and Scotch authors from Mun and Petty are listed, and many of their works praised or censured in light of McCulloch's doctrinal preconceptions. Malthus is predictably belittled. All the leading French authors of the 18th and early 19th centuries appear save Boisguilbert and Cournot. Condillac's pathbreaking *Le Commerce et le gouvernement* (1776) is dismissed with a patronizing comment of J.-B. Say (McCulloch 1845, p. 63; cf. Eltis and Eltis 1997, pp. 30–4). Considerable respect is paid to Italian authors (McCulloch 1845, pp. 28–31, 86), but the Spanish are written off as intellectually impotent until Napoleon's invasion (1845, pp. 31–2, 326). McCulloch seems never to have heard of Thünen, and no other German author is mentioned. Omissions of anglophone authors are equally telling. Whewell's pioneering mathematical economics is ignored, presumably for the same reason as the omission of Cournot and Thünen. Dugald Stewart is cited merely as a biographer of Adam Smith and Robertson (1845, pp. 8, 104, 162). McCulloch seems not have read or understood either Chalmers (1808) or Copleston

(1818), nor to have grasped the analytical significance of Malthus (1800). Everything is viewed through the powerful but slightly distorting lenses of Adam Smith and Ricardo.

Three years later there appeared the single most important production of the School: J.S. Mill's *Principles of Political Economy* (1848), perceptively reviewed by Bagehot (1848) among many others. Mill's *Principles* is the definitive statement of the English School of political economy. It went through seven editions in the author's lifetime; the 1909 scholarly edition by Ashley was based on the seventh (1871), and may be taken as the terminus ad quem of the English School. For though Mill continued to be the principal textbook in political economy until the 1930s at many universities throughout the English-speaking world, Anglophone economic literature of the 20th century gradually became less insular (Palgrave 1894, p. 735) and was formed in the cautiously new idiom of Marshall and Pigou, with at least some peripheral awareness of Jevons and Edgeworth, Walras and Pareto, Weiser and Böhm-Bawerk, Cassel and Wicksell, J.B. Clark and Fisher.

Though Mill dominated, there were many other significant contributions to the literature in the last third of the 19th century. Henry Fawcett's *Manual of Political Economy* (1863) encapsulated Mill's *Principles* for faint-hearted undergraduates; his wife's even more elementary *Political Economy for Beginners* (1870) went through ten editions over the next 41 years. W.T. Thornton's *On Labour* (1869) introduced the concept of multiple equilibria, as Mill (1869, p. 637) admitted. Cairnes's *Leading Principles* first appeared in 1874, Cliffe Leslie's *Essays* in 1879, Bagehot's posthumous *Economic Studies* in 1880, and Henry Sidgwick's *Political Economy* in 1883. Sidgwick's importance in the incipient 'Cambridge' mutation of the English School has lately been documented (Backhouse 2006). J.N Keynes's classic *Scope and Method* first appeared in 1891. Perhaps the last major production of the English School was J. Shield Nicholson's three-volume *Principles of Political Economy* (1893–1901), a basically Millian exposition with the occasional bow to Marshall, used as a textbook in many parts of the British Empire in the early 20th century. Nicholson's appears to be the last widely read work of political economy to consider explicitly the relation between that science and Christian theology (1893–1901, vol. 3, ch. 20).

Stanley Jevons (1871, p. 275) went out of his way to challenge 'the noxious influence of authority' in the English School, above that of Mill. Though elected to the Political Economy Club as a professor in 1873 and as an Ordinary Member in 1882 (the year of his death), he was therefore handled with caution by his fellow-economists – including the powerfully influential Marshall. Whilst crediting him with the intellectual defeat of Ricardian and Marxian value theory, Bonar (Palgrave 1894, p. 735) thought that 'the ideas of Jevons have had greater power since his death than during his life'. Jevons and his two most creative English followers, Edgeworth and Wicksteed, were 'often spoken of as a school by itself, the mathematical school' (Palgrave 1894). The original Palgrave article on 'Recent Developments of Political Economy' (Palgrave 1894, p. 148) alludes to Jevons's *State in Relation to Labour* (1882) but ignores his *Theory of Political Economy* (1871).

Literature of the English School was augmented and popularized by *The Economist* newspaper, founded in 1843 and edited by Walter Bagehot from 1860 to 1877, which, like the Political Economy Club, sought to relate economic analysis to public policy in the spirit of Adam Smith. That literature may be said to have culminated in the three-volume *Dictionary of Political Economy* (1894–1899) edited by R.H. Inglis Palgrave.

Some Analytical Features of the English School

Political economists of the English School inherited much of their economic analysis from their 18th-century predecessors, especially Cantillon, Hume, Quesnay, Smith and Turgot. However, some features of their analysis were as 'novel' as any idea ever is in the social sciences.

And despite loose talk about a 'marginal revolution', much of their analysis, both what they inherited and what they originated, has become part of the stock-in-trade of present-day economics. The standard account by D.P. O'Brien (2004) should be supplemented by S.J. Peart's and D. Levy's (2003) review of the period 1830–1870, which considers catallactics, methodological egalitarianism and the new ideological alliance – a mutation of the old Whig-Liberal orthodoxy – between political economists and reformist Evangelicals in the Church of England.

The central conception of 18th-century economic thought was that of a surplus of production in one period over and above what is necessary (as inputs into production) to sustain that level of production in the next. The agricultural sector is an obvious source of the surplus since land normally produces more than the (food) cost of necessary labour and capital inputs. But Smith generalized the concept to include all produced goods capable of use as inputs. Masters incur production costs in advance, hence control the entire output at the end of the process. Some of this they consume either directly, or in the employment of unproductive labour. The remainder is used to feed and equip productive labour. This unconsumed portion of output is the (circulating) capital stock of a master, firm or community, the growth, stationarity or decay of which depends on a psychological propensity of masters: the extent of their 'frugality' or parsimony (Eltis 2000, pp. 75–100). These ideas, and the necessarily dynamic analytical framework they imply, were taken for granted by most the English School despite its seeming incompatibility with such other conceptions as comparative advantage in trade (Blaug 1987, vol. 1, pp. 439–42). Other characteristically 18th-century ideas accepted by 'the followers of Dr Smith' included that of a labour supply perfectly elastic in the (Malthusian) long period at a socially determined zero-population-growth real wage; enough factor mobility to produce uniform rates of wages and profit throughout the economy; a negative relation between the real wage and the rate of profit; a positive relation between the general price level and the stock of money, and the Cantillon–Hume price-specie- flow mechanism of international monetary adjustment which follows from that relation. Most accepted Smith's account of natural prices that correspond, more or less, to Marshall's long-period equilibrium prices, but O'Brien (2004, ch. 4) has shown in detail how much variation there was in this matter. Perhaps the most important 18th-century idea, certainly that which gave the English School its ideological momentum, was Boisguilbert's vision – derived from the Jansenist theology of Pierre Nicole and Jean Domat – of a self-regulating market economy driven by 'self-love' and producing some kind of social optimum at competitive equilibrium (Faccarello 1999). This powerful conception was transmitted by Mandeville, Cantillon and Quesnay and canonized by Smith in *Wealth of Nations*.

As we have seen, the English School made at least one sharp analytical break with 18th-century thought. The explicit incorporation of diminishing returns (though as yet in agricultural production only) created a fundamentally different view of the economic universe. Though all recognized increasing returns to scale (IRS) resulting from the division of labour, IRS plays a small or negligible part in the implicit growth models of Malthus and his successors (Eltis 2000). The salient feature of the new growth theory was rather a tendency for the rate of profit to fall: either because of rising costs in agriculture as in Malthus and Ricardo, or because of increasing capital intensity in manufactures as in Marx. In the former case, falling real factor payments retarded the growth of capital and labour, leading to a stationary state in the absence of technical progress. Samuelson (1978) has shown that the variable factor in agriculture was conceived as a single 'labor-cum-capital' unit, and though all 'classical' economists recognized the possibility of factor substitution especially in manufacturing, the capital–labour ratio was generally taken as a parameter. The same was true of technique. Improvements were seen to occur from time to time, and their effect upon wages, profits and employment analysed. Malthus, and perhaps some others, recognized that technical progress could become endogenous (Eltis 2000, pp. 150 ff.) and few if any of the English School

regarded it, as some do today, as 'manna from Heaven'. Two other new, or somewhat new, analytical features of the English School deserve note. The first is the LTV theory of comparative advantage, later improved by Mill's analysis of reciprocal demand. The second is Say's Law of Markets, which in its strong form (Say's identity) implies the neutrality of money (Blaug 1996, pp. 143–60). Whether Samuel Hollander (for example, 1987, pp. 6–7) is correct in maintaining that Ricardo and his contemporaries and successors, including Marx, recognized 'a fundamentally important core of general-equilibrium economics accounting for resource allocation in terms of the rationing function of relative prices' is still a matter of debate (Blaug 1987, vol. 1, pp. 442–3).

It is evident that most of these analytical characteristics, both those inherited from the 18th century and those that were new, have been transmitted to present-day economic thought. The obvious exception is the concept of a surplus with its concomitant distinction between 'productive' and 'unproductive' labour; though in the spirit of Feyerabend's (1988) methodological anarchism this venerable doctrine has lately been brought back to useful life (Bacon and Eltis 1976). For the most part however, present-day economists prefer to rely on a putatively constant-returns-to- scale (CRS) general equilibrium model that abstracts from time, and in which each factor-owner is paid the value of his factor's marginal product. The surplus is therefore regarded as a museum piece and left to heterodox Marxists and Sraffians (Walsh and Gram 1980; cf. Blaug 1987, vol. 1, pp. 440–2). It is important to recognize, however, that the eventual disappearance of the surplus in a neoclassical theory of distribution was brought about by an ever wider application of the marginal analysis originally applied by Steuart, Turgot, and Anderson, and then by Malthus, Ricardo and their contemporaries to agricultural production costs alone (Blaug 1987, vol. 1, p. 441). Authors of the next generation such as Longfield and Lloyd began the analysis of marginal utility (O'Brien 2004, pp. 119–22). Replacement of the dynamic surplus macroeconomics by a static general-equilibrium microeconomics dependent on universal CRS created perhaps the most significant analytical difference between political economists of the English School and the new professionalized economists of the early 20th century: an almost complete lack of interest among the latter in macroeconomics and growth theory. Not until Keynes's rediscovery of Malthus (Kates 1994) and Harrod's (1939) critique of Keynesian 'equilibrium' did these return to the theoretical agenda. As for Adam Smith's IRS, quietly forgotten by most of the English School – save Marshall – for most of the time and ignored by their successors, its reintroduction by Sraffa (1926) and Young (1928) has remained a thorn in the flesh for general equilibrium theorists.

Revolution and Continuity

Present-day 'economics' looks quite different from 'political economy' of the English School. Yet despite Samuelson's remarks about Marshall in *Foundations* (1947, pp. 6, 142, 311–12) and despite his focus on Walrasian general equilibrium in that work, the microeconomic part of his immensely influential *Economics* (1948) is unmistakeably Marshallian, at any rate as mediated by Chamberlin (1933) and Joan Robinson (1933). And though Marshall had digested Thünen and Cournot, knew the work of Menger and the Austrian School, and admitted that 'there are few writers of modern times who have approached as near to the brilliant originality of Ricardo as Jevons has done' (Marshall 1920, p. 673), yet he 'consistently discounted the "Jevonian revolution"' (Schumpeter 1954, p. 826) and used all his influence, which was great, to insist that in science, as in the world it contemplates, *Natura non facit saltum.* There are few references to Jevons in his famous *Principles,* and in the most extended of these (Appendix I) Marshall went out of his way to counter the former's 'antagonism to Ricardo and Mill' and to defend their value theory against his intemperate exaggerations' (Marshall 1920, pp. 673–6; see also O'Brien 1994, vol. 2, pp. 325–61).

Upon the evidence of Palgrave's original dictionary it appears that by the last decade of the

19th century the effect of Marshall's efforts had been to co-opt Jevons and his 'marginalist' followers into the mainstream of English political economy with a minimum of fuss, and with a minimum of attention to the continental marginalists. Jevons's 'final utility' became 'marginal utility' in Marshall's *Principles* (1920, pp. 78–85), and there was used with deceptive innocence (see Blaug 1996, p. 322–37) to generate a market demand function of price. Though Edgeworth himself contributed 17 articles to the dictionary, including 'Cournot', 'Curves' and 'Demand Curve' in volume 1, 'Mathematical Methods' in volume 2 and 'Pareto', 'Pareto's Law', 'Supply Curve' and 'Utility' in volume 3, his own work was ignored in the general surveys of 'Political Economy' and 'The English School' and his name omitted from the index of volume 1, along with those of Menger and J.B. Clark. Walras received three short references in that volume. Not until volume 3 (1899, pp. 652–5) was his work recognized, and then only for its use of marginal utility. There is no awareness of general equilibrium in that article, and the term appears nowhere else in the original *Dictionary.*

It would appear from the foregoing that if there really was any such thing as a marginal revolution in Anglophone political economy, it began as early as 1767 with Steuart's *Political Œconomy* and still had some way to go by the time volume 3 of the Palgrave dictionary appeared in 1899. Thünen's (1826) generalization of diminishing returns to all factors of production remained unnoticed by any save Marshall. Though Wicksteed (1894) and Flux (1894) reinvented this wheel, Wicksteed's (Palgrave 1899, pp. 140–2) own contribution to the Palgrave article on 'Political Economy' only hints at what later became known as the neoclassical theory of distribution. In 1895 Edgeworth rejected Barone's submission to the *Economic Journal* showing that product exhaustion is implied by Walras's (1894) cost-minimization equations. A companion article to Wicksteed's baldly states that 'the law of DIMINISHING RETURNS points to an increase in the cost of agricultural produce accompanying increase of population' (Palgrave 1899, p. 140). For that author at any rate, nothing had changed since Malthus.

In summary, it would appear that the English School was alive and well in the first decade of the 20th century. Elections to the Political Economy Club included Pigou (in 1906) and J.M. Keynes (1912), along with the Bishop of Stepney (1904), the Rt Hon. Herbert Samuel MP, the Viscount Ridley (1907) and John Buchan (1909). Mill's *Principles* was still perhaps the most widely used textbook. Questions on Adam Smith still appeared in university examinations in political economy (for example, at Edinburgh, 21 November 1898, 17 March 1899). Mathematics was still an unwelcome eccentricity. Jevons (1871, p. vii) had asserted that economics 'must be a mathematical science in matter if not in language'. Marshall (for example, 1890, p. ix) threw all his influence against this doctrine and locked up his own sophisticated mathematics in well-guarded appendices (Keynes 1972, pp. 182–8). Despite his dependence upon mathematical reasoning and his prominence in the emerging profession of economics, Edgeworth's deference for Marshall deterred him from challenging a Cambridge, anti-mathematical orthodoxy that persisted until the 1950s.

Edgeworth was unusual, too, in his ability and willingness to read foreign authors and to recognize their contributions (Keynes 1972, pp. 263–5). In general, the insularity of the English School persisted until well into the 20th century. When Harrod was about to begin his studies in economics, Keynes advised him not to waste his time on the Continent 'where they knew nothing at all of economics' (Harrod 1952, pp. 317–19). The 'market socialists' of the 1930s, none of whom was English, were the first to specify the complete set of marginal conditions required for a welfare optimum in general competitive equilibrium. J.R. Hicks (1939, p. 6) believed himself to be the first English author to 'free the Lausanne School from the reproach of sterility brought against it by the Marshallians'.

It might have been expected that political economists in the United States, at any rate, would have identified with the English School. In the early 19th century authors such as Wayland

(1837) had assimilated Malthus and Ricardo, and as late as 1888 Amasa Walker regarded Jevons and Marshall as 'an extension of the English School' (Goodwin 1972, p. 562). But throughout much of the century protectionist sentiment in the USA was at variance with the ideology of free trade promoted by the English School. And towards the end of that century there was 'an estrangement from British scholarly life' created by a 'growing attachment to German thought' (Goodwin 1972, p. 563). The American Economic Association was originally formed to promote the Liberal-Protestant 'social gospel', very different in spirit and substance from the aristocratic Whiggery of the Political Economy Club.

Enlightenment, Scottish

John Robertson

Abstract

The Scottish contribution to the Europe-wide intellectual movement of Enlightenment in the 18th century was unusually rich, covering moral philosophy, history, and political economy. It was not the simple product of the Union with England in 1707; more important were the gradual opening up of intellectual life and reform of the country's intellectual institutions, notably the universities, and economic growth, rapid by the last quarter of the century. The Scots set the investigation of economic phenomena in a broad framework; led by David Hume and Adam Smith, they were particularly interested in the comparative development prospects of rich and poor nations.

Between 1740 and 1790 Scotland provided one of the most distinguished branches of the European Enlightenment. David Hume and Adam Smith were the pre-eminent figures in this burst of intellectual activity; and around them clustered a galaxy of major thinkers, including Francis Hutcheson, Lord Kames, Adam Ferguson, William Robertson, Thomas Reid, Sir James Steuart and John Millar. The interests of individual thinkers ranged from metaphysics to the natural sciences; but the distinctive achievements of the Scottish Enlightenment as a whole lay in those fields associated with the enquiry into 'the progress of society' – history, moral and political philosophy and, not least, political economy.

'Enlightenment' and 'Scottish Enlightenment' were usages unknown in the 18th century: the term 'Scottish Enlightenment' was first coined in the early 20th century, and began to be generally used by historians in the 1960s. (*Lumières* and *Aufklärung* were in 18th-century use, but not to denote a European Enlightenment as a whole.) As a historian's construction, however, the term 'Scottish Enlightenment' is supported by the consciousness of those named above that they shared common intellectual interests (which did not preclude disagreement between them) and a common standing as men of letters in 18th-century Scottish society. This awareness of belonging to a broad intellectual movement extended to the continent of Europe: led by Hume, the Scottish thinkers cultivated connections with Paris, the Enlightenment's acknowledged metropolitan centre. But the Scottish Enlightenment is perhaps best understood when it is compared with the Enlightenment in Italy or in Germany. The concern with economic improvement and its moral and political conditions and consequences was as urgent, for instance, in the distant Kingdom of Naples as in Scotland; and political economy was equally absorbing to the Neapolitan philosophers Antonio Genovesi and Ferdinando Galiani.

At the same time, the experience of Scotland in the 18th century was distinctive in a number of respects, which offered a particular stimulus to Scottish thinkers. First of all, there was the actual achievement of economic growth. The late 17th-century Scottish economy supported an uneasy balance between population and food supply; bad harvests, which occurred in a sequence in the 1690s, could cause severe shortages and even localized famine. Overseas trade was likewise vulnerable. Nevertheless the elites, both landed and urban, were committed to economic development, and showed a marked propensity to invest. Agriculture gradually became commercialized, and landowners joined merchants to invest in manufactures, and, most spectacularly, in the 'Darien venture', intended to establish a Scottish trading colony in Panama. The failure of the latter persuaded many of the elite that economic development could only come through closer union with England. In the event, the economic fruits of the Union were disappointingly slow in coming; but by the third quarter of the 18th century it was clear to contemporaries that agriculture, trade and manufactures were all on an upward curve. The thinkers of the Scottish Enlightenment thus enjoyed an unusually direct acquaintance with the phenomena of economic development.

Scotland's political position was also unusual. Many of Europe's monarchies sought to bring their constituent kingdoms into closer union over the 18th century, for economic as well as administrative reasons. But none did so as successfully as the British monarchy. The Union of 1707 with England was in no simple or direct sense the cause of Scotland's economic growth (or of its Enlightenment). But it secured a common framework of law and a common market, and it also established that the Scottish Presbyterian and the English Anglican Churches should coexist in peace. These gains were important to the great majority of the Scottish elites, and it was never in their

interest to back the Jacobite challenge to the Hanoverian monarchy.

Culturally and intellectually, the position of Scotland looked unpropitious before 1700. There were pockets of interest in the new science, Newton having a group of Scottish adherents; but the latest developments in French philosophy were shunned for their Epicurean, materialist and sceptical tendencies. After the Revolution of 1688, however, change gradually got under way in the institutions most important for intellectual life, making possible the infiltration of new ideas. The fierce, covenanting Presbyterianism of the 17th century was dissipated, as the 'Moderate' group of clergy rose to power in the Kirk. The universities of Edinburgh, Glasgow, Aberdeen and St Andrews were reformed, allowing professorial specialization; and around the universities there developed a vigorous informal culture of voluntary clubs, most famous of which was the Select Society of Edinburgh, founded by David Hume and his friends in 1754. Together these changes secured for Scottish thinkers unprecedented intellectual freedom and social support; and they provided an object lesson in the importance of the moral and cultural as well as the material dimensions of progress.

The intellectual interests which distinguished the Scottish Enlightenment had two more specific sources. One was the explicit preoccupation with the conditions and means of economic development which was fostered by the debate which preceded the Union of 1707. The preoccupation was by no means unique to the Scots, but the contributions of John Law (the future author of the French Mississippi Scheme) and others ensured a high quality of discussion. The other, two decades later, was the initiative taken by two very different philosophers, Francis Hutcheson and David Hume, to transform the agenda by which philosophy was taught and discussed in Scotland. Drawing on the moral philosophy of Shaftesbury and the natural jurisprudence of Pufendorf, Hutcheson taught his Glasgow students, who included Adam Smith, a moderate, benevolent, providential Stoicism. More disturbingly, Hume drew on the scepticism of Pierre Bayle and the Epicurean morals of Bernard Mandeville to offer in his *Treatise of Human Nature* (1739–40) and his two later *Enquiries* (1748; 1751) an account of justice and morals which had no need of divine support. Most of those now associated with the Scottish Enlightenment found Hutcheson's philosophy more congenial; but it was Hume's challenge which galvanized them. It was Hume, moreover, who turned their attention back to economic matters. Recognizing that philosophy alone would never make the Scots into virtuous atheists, Hume decided instead to educate them in political economy, the subject of the leading essays in his *Political Discourses* of 1752.

For Hume as for all the Scottish thinkers, political economy was not a science apart. It belonged within a wider enquiry into the 'progress of society'. There were three principal dimensions to this enquiry: the historical, the moral and the political.

The historical theory of the Scottish Enlightenment developed a line of argument from later 17th-century natural jurisprudence, a tradition made familiar to the Scots by its incorporation in the moral philosophy curriculum of the reformed universities. Discarding the older jurisprudential thesis of the contractual foundations of society and government, the Scots focused on the new insights of Pufendorf and Locke into the origin and development of property. According to Pufendorf, there had never been an original state of common ownership of land and goods; from the first, property was the result of individual appropriation. As increasing numbers made goods scarce, individual property became the norm, and systems of justice and government were established to secure it. What the Scots added to this argument was a scheme of specific stages of social development, the hunting, the pastoral, the agricultural and the commercial. At each of the four stages the extent of property ownership was related to the society's means of subsistence, and these shaped the nature and sophistication of the society's government. Different versions of the theory were offered by Adam Ferguson in his *Essay on the History of Civil Society* (1767) and by John Millar in his *Origin of the Distinction of Ranks* (1770), and it underlay both Lord Kames's investigations into

legal history and William Robertson's historical narratives. The locus classicus of the theory, however, was Adam Smith's Lectures on Jurisprudence, delivered to his students in Glasgow in the early 1760s.

As Smith's exposition makes particularly clear, the stages theory of social development provided the historical premises for political economy. An explicitly conjectural theory – a model of society's 'natural' progress – it provided a framework for a comparably theoretical treatment of economic development as 'the natural progress of opulence'. By positing the systematic interrelation of economic activity, property and government, with consequences which could be neither foreseen nor controlled by individuals, the theory also underlined the limits of effective government action. 'Reason of state', the standby of rulers and their advisers for over two centuries, still had the capacity to distort and obstruct the economic activity of subjects and those with whom they would trade; but the Scots' historical perspective showed it to be a doctrine inadequate to the complexity of a modern commercial economy.

The moral thought of the Scottish Enlightenment was closely related to the historical, sharing a common origin in 17th-century natural jurisprudence. Here the inspiration was the jurisprudential thinkers' increasingly sophisticated treatment of needs. These, it was recognized, could no longer be thought of primarily in relation to subsistence; with the progress of society, needs must be understood to cover a much wider range of scarce goods, luxuries as well as necessities. The potential of this insight was seen by every Scottish moral philosopher, but again it was Smith who exploited it to the full, in the *Theory of Moral Sentiments* (1759). Beyond the most basic necessities, Smith acknowledged, men's needs were always relative, a matter of status and emulation, of bettering one's individual condition. But it was precisely the vain desires of the rich and the envy of others which served, by 'an invisible hand', to stimulate men's industry and hence to increase the stock of goods available for all ranks.

Such an argument, however, had to overcome two of the most deeply entrenched convictions of European moral thought: the Aristotelian view that the distribution of goods was a matter for justice, and the classical or civic humanist view that luxury led to corruption and the loss of moral virtue. The Scots answered the first more confidently (but perhaps less satisfactorily) than the second. Following Grotius, Hobbes and Pufendorf, they defined justice in exclusively corrective terms, setting aside questions of distribution. On the issue of corruption, they were divided. Hume, who ridiculed fears of luxury, was the most confident; Ferguson, who defiantly reasserted the ancient ideal of virtue, was the most pessimistic. Smith was closer to Hume in preferring propriety to virtue, at least for the great majority; but he showed that he shared Ferguson's doubts when he added, at the end of his life, that the disposition to admire the rich and the great did tend to corrupt moral sentiments. At a fundamental level, however, there was general agreement. As a consequence of the progress of society, the multiplication of needs was not only irreversible; it was the essential characteristic of a 'cultivated' or 'civilized' as distinct from a 'barbarian' society. And civilization, however morally ambiguous, was preferable to barbarism. With consensus on this, the moral premises of political economy were secure.

The definition of justice in simple corrective terms provided the starting-point for the political dimension of the Scottish enquiry. The priority of any government, the Scots believed, must be the security of life and property, ensuring every individual liberty under the law. This, as Smith put it, was freedom 'in our present sense of the word'; and there was a general confidence that it was tolerably secure under the governments of modern Europe, including the absolute monarchies. In principle, individual liberty was a condition of a fully commercial society: its provision, therefore, was the institutional premise of political economy.

Few of the Scots took their analysis beyond this relatively simple, if vital, point; the theory of the modern commercial state was not a Scottish achievement. Both Hume and Smith were more concerned to limit the opportunities for enlarging government at the expense of 'productive' society, by confining the former to the minimum necessary provision of justice, defence and public works.

But they also recognized that the proliferation of interests in a commercial society would require more sophisticated institutional mechanisms to ensure their adequate representation within the political system. Smith's analysis in Book IV of the *Wealth of Nations* of the growing alienation of the colonial elites in North America from parliamentary authority was an object lesson in the need for such representation – and a strong hint that it was incompatible with maintaining an extended empire.

A large part of the originality of the Scottish Enlightenment's conception of political economy lay in this exploration of the historical, moral and institutional framework of economic activity. But of course the Scots also engaged directly in economic analysis; and one such work of analysis, Adam Smith's *Wealth of Nations* (1776), would so outshine all others that it came to be regarded as having established political economy as a science in its own right.

The Scots' attention focused on growth in a context of international rivalry. In contemporary terms, Hont has shown, the issue was the means by which poor countries (of which Scotland might be regarded as one) could best hope to catch up on rich countries (such as England certainly was). What is striking is the hard- headedness with which Hume and Smith tackled the issue. Responding to French economists – Hume to Jean-François Melon, Smith to the Physiocrats – who argued that agriculturally endowed countries should follow a different path from purely commercial nations, the Scots insisted that one analysis applied to all. Protection for agricultural economies and their manufactures, a policy supported by the former Jacobite exile Sir James Steuart in his *Principles of Political Economy* (1767), was futile and damaging. But theirs was no naive optimism in the equalizing powers of commerce. The ideal of *doux commerce*, by which trade would be the agent of global peace and prosperity, was as much of a panacea as the belief that commercial success would be self-cancelling, because the advantage of low labour costs would always pass on to others. Instead, Hume and Smith suggested that rich countries could expect to maintain their advantage over poorer ones, whether by flexible specialization and product innovation (Hume) or by constantly increasing industrial productivity through the division of labour (Smith). What distinguished commercial superiority from military conquest was that it was achieved 'without malice'; poor countries would also develop if they followed the same route, even if they might never catch up on the rich.

Brilliant as Hume's economic essays were, it was Adam Smith's *Wealth of Nations* (1776) which set the standard of Enlightenment political economy. To be systematic and comprehensive had earlier been the ambition, at least, of Quesnay's *Tableau Economique* (1758–9), Genovesi's *Lezioni di Commercio* (1765) and Steuart's *Principles;* but the *Wealth of Nations* eclipsed them all. Its success, moreover, was such as to suggest that political economy had an identity all of its own. Smith himself did not admit such an implication, continuing to insist that political economy was but 'a branch of the science of a statesman or legislator': his own engagement with both jurisprudence and moral philosophy left him disinclined to drop the wider intellectual framework in which political economy had been conceived. But a work at once as extensive and as self-contained as the *Wealth of Nations* made it at least plausible to suppose that what it presented was a distinct, autonomous science of political economy.

Smith's death in 1790 coincided with the end of the Scottish Enlightenment. In Scotland as throughout Europe, the French Revolution transformed the conditions and assumptions of intellectual life, while political economy had to come to terms with the increasingly obvious impact of machinery. Within Scotland Dugald Stewart set himself to adapt the Enlightenment conception of political economy to these new circumstances; but while he had French admirers, his expansive, didactic approach had few followers in Britain. Another Scot, Thomas Chalmers, took the lead alongside Malthus in attaching political economy to newly urgent theological concerns, while Ricardo and his followers simply took a narrower view of the subject. Even so, it would be a mistake to see 19th-century classical political economy as

a new departure. As the philosophical analysis of Hegel (who learnt much from Steuart) and the radical critiques of Marx and the early socialists pointed out, the historical, moral and institutional premises on which political economy rested were still those elucidated by the Scots.

Enterprise Zones

Leslie E. Papke

Abstract

Enterprise zones are geographically targeted economic development incentives used in the United States by individual states since the early 1980s and the federal government since 1993. Research on state zone programmes that accounts for the endogeneity of zone designation finds little improvement in the employment and incomes of zone residents, but some evidence that firms respond to tax incentives for capital. In contrast, the federal empowerment zone programme combines tax incentives with local initiatives and access to large federal grants. Recent research on round one of the federal programme finds mixed evidence on zone resident employment.

Enterprise zone programmes are geographically targeted tax, expenditure, and regulatory inducements used by US state and local governments since the early 1980s and by the federal government since 1993. While they differ in their specifics, all the programmes provide development incentives, including tax preferences to capital and/or labour, in an attempt to induce private investment location or expansion to depressed areas and to enhance employment opportunities for zone residents. Most enterprise zones are designated in urban areas, but there are some rural zones. Typically, state and local zone programmes provide larger tax credits for business investment than for employment incentives. Investment

incentives include the exemption of business-related purchases from state sales and use taxes, investment tax credits and corporate income or unemployment tax rebates. Labour subsidies include employer tax credits for all new hires or zone-resident new hires, employee income tax credits and job-training tax credits. Some programmes assist firms financially with investment funds or industrial development bonds.

Enterprise zones have been criticized as ineffective and inefficient in stimulating new economic activity. This criticism is part of a long-standing debate on the effects of intersite tax differentials on the location of capital investment. It is argued that if tax-induced investment represents only relocation from another state, then tax competition is a zero-sum game for the country as a whole. In addition, the preferential treatment of certain types of investment or employment within enterprise zones may induce decisions that would not be economically sound in the absence of the tax incentives. Often, however, redistribution of economic activity within a state may be a desirable goal. If investment is relocated from local labour markets with low unemployment to local labour markets with higher unemployment, the incentives may generate efficiency gains for the economy as underutilized resources are tapped (Bartik 1991). Efficiency gains may also result if reductions in unemployment produce positive externalities, such as reductions in social unrest.

A partial equilibrium model predicts that a labour subsidy or an equal-cost subsidy to both zone capital and zone resident labour will raise zone wages. A capital subsidy alone may actually reduce zone wages – yet many of the subsidies are for capital investment in the zone (Gravelle 1992; Papke 1994).

Empirical evaluations of zone programmes typically measure the amount of investment undertaken after the designation, for example, or the increase in the number of firms in the zone, and the change in zone employment. Two key methodological issues in empirical evaluations are (*a*) to separate the effects of zone designation from jobs and investments arising from other factors – for example, general upswings in the economy; (*b*) to account for the depressed economic characteristics that led to the initial zone designation. If zone sites are better randomly selected, the effect of the programme can be measured by comparing the performance of the experimental and control groups. But zone designation in the 43 state and local programmes in the United States depends on comparative unemployment rates, population levels and trends, poverty status, median incomes, and percentage of welfare recipients, so the data are non-experimental. This sample selection problem can be addressed with a variety of econometric techniques.

Econometric analysis of a zone's success faces a practical difficulty in that conventional economic data are not available by zone. In most states, zones do not coincide with census tracts or taxing jurisdictions. As a result, zone areas cannot be pinpointed in standard data collections. Zip code level data is available from the Census, but outcome measures are ten years apart.

Econometric evaluations of the Indiana and New Jersey programmes find mixed effects on investment and employment. Indiana zones are estimated to have greater inventory growth and fewer unemployment claims than they would have in the absence of the zone designation (from 1983 to 2006, an inventory tax credit was the most lucrative incentive). However, in the 1980s, inventory investment came at the cost of a drop in the value of depreciable property (Papke 1994). Moreover, despite the reduction in unemployment rates in the zones, a comparison of incomes from the 1980 and 1990 Censuses suggests that zone residents are not appreciably better off after the first decade of the Indiana zone programme (Papke 1993) and there is no discernable increase in capital investment or land values (Papke 2001). Similar econometric analysis of the New Jersey enterprise zone programme finds no positive effects on either business investment or employment (Boarnet and Bogart 1996). Multi-state econometric analyses that combine data from many states – thereby assuming zone programmes have similar effects in every state – typically find no positive zone effects on business activity or employment (Bondonio 2003; Bondonio and Engberg 2000). Peters and Fisher (2002) survey state evaluations.

Cost-per-job estimates from zone programmes are rare. The literature also lacks a discussion of the distribution of the cost of the zone programme between state and local governments. For example, local governments may bear the brunt of the cost of a state enterprise zone programme if tax incentives are provided against local taxes without state reimbursement.

Congress established the Empowerment Zone and Enterprise Community (EZ/EC) programme in 1993 and the Renewal Community (RC) programme in 2000 to provide assistance to the nation's distressed communities. By 2007, there had been three rounds of EZs, two rounds of ECs, and one round of RCs leading to a total of 40 empowerment zones (30 urban and 10 rural), 95 enterprise communities (65 urban, 30 rural) and 40 renewal communities.

Empowerment zone incentives include a 20 per cent employer wage credit for the first 15,000 dollars of wages for zone residents who work in the zone, additional expensing of equipment investments of qualified zone businesses, and expanded tax exempt financing for certain zone facilities. Each zone is eligible for 100 million dollars in Social Services Block Grant funds. Selected areas needed to demonstrate pervasive poverty, unemployment and general distress, and applicants had to outline a plan of action that included local business and community interests. The residence- based approach of the income tax credit differs significantly from another federal programme designed to increase employment of the disadvantaged. The Targeted Jobs Tax Credit provides firms with a similar-sized subsidy for wages paid to targeted individuals – primarily welfare recipients and poor youth. Providing a subsidy based on individual characteristics may create a stigma that actually reduces the probability of being hired. Residence-based eligibility may eliminate this problem and encourage individuals who become employed to continue to live in the zone.

Features of the programmes have changed over time. Round I and II EZs and ECs received different combinations of grant funding and tax benefits. By round III, EZs and the RCs received mainly tax benefits. The GAO (1991, 2004, 2006) reports that Round I and II EZs and ECs are continuing to access their grant funds and Internal Revenue Service (IRS) data show that businesses are claiming some tax benefits (Brashares 2000). However, the IRS does not collect data on other tax benefits and cannot always identify the communities in which they were used. The lack of tax benefit data limits evaluation of the programmes.

Evaluation of the federal programme is also confounded by its hybrid structure. The federal EZ/EC programme is based on the idea that effective community revitalization results when the strategy is tailored to the local site. The diverse nature of the Round I EZ/ECs – each may differ in terms of objective, size of targeted area, type of designation, governance structure, projects used, grant money, and strategies for implementation – has made it difficult to generate general conclusions about even the early stages of Round I implementation (GAO 2004, 2006). Further, the tax incentives changed over the three rounds of the federal programme. Third, no easy method of data collection was included in the tax forms so even usage is hard to measure.

Using Census data, Hanson (2007) finds no effect of the first round zone programme on local employment or poverty rates in the targeted areas, but instead finds capitalization into property values. Busso and Kline (2006) find modest improvements in labour market conditions, but sizable increases in owner-occupied housing values and rents along with small changes in the demographic composition of neighbourhoods. Taken together, these two papers suggest that improvements for residents have been limited at best, but that property owners have benefited from the federal programme.

Entitlements

Hillel Steiner

In the strong sense, an entitlement is something owed by one set of persons to another. The thing owed is either a performance of a certain kind, such as a dental extraction, or a forbearance from interfering from some aspect of the title-holder's activity or enjoyment, such as not trespassing on someone's land. Strong entitlements imply the presence of a right in the person entitled and a corresponding or *correlative* obligation in the person owing the performance or forbearance. Typically, the person entitled is further vested with ancillary powers to waive the obligation or, alternatively, to initiate proceedings for its enforcement. A secondary (and contested) instance of a strong entitlement arises with respect to the position of a third-party beneficiary of a right-obligation relation between two other parties, such as the beneficiary of an insurance policy. Third parties usually lack powers of waiver and enforcement, for it is not strictly to them that fulfilment of the obligation is owed.

A weaker form of entitlement may be said to pertain to those of a person's activities which, while not specifically protected by obligations in others not to interfere, are nevertheless indirectly and extensively protected by their other forbearance obligations. Thus, while persons may be under no obligation specifically to allow someone to use a pay telephone, they probably do have forbearance obligations with respect to assault, theft, property damage, etc., the joint effect of which is to afford some high (but incomplete) degree of protection to someone using a pay telephone. However, such an entitlement amounts to less than the full protection afforded by a right inasmuch as it does not, for example, avail against anyone who may already be using that telephone.

Beyond strong and weak entitlements, one may also possess many largely unprotected liberties. These consist in those activities from which one has no obligation to refrain but with which,

equally, no direct or extensive indirect claims to non-interference. So, broadly speaking, persons' strong entitlements may be construed as conjunctively constituting their spheres of ownership, while their weak entitlements and their unprotected liberties constitute the fields of activity within which they exercise the powers and privileges of ownership. Normally, it is persons' strong entitlements that are of primary normative concern, with weak entitlements and unprotected liberties being determined residually.

Entitlements may be either legal or moral. Sets of legal entitlements tend to reflect the multifarious demands of various customs, moral principles, judicial decisions and state policy. A set of moral entitlements, on the other hand, is commonly derived from some basic principle embedded in a moral code. The nature of this derivation varies with the type of code involved. In many single-value codes (such as utilitarianism), entitlements are instrumental in character: whether and what sort of an obligation is owed, by one person to another, depends upon the relative magnitude of the contribution that fulfilment of that obligation would make to realizing that value. Changing causal conditions of maximization warrant alterations in the content and distribution of entitlements. Codes containing a plurality of independent values characteristically generate entitlements from a principle of justice. The set of entitlements thus derived possesses intrinsic and not merely instrumental value, though its normative status depends upon the ranking of justice in relation to the code's other values. In such codes, the chief distinction between moral obligations that (like kindness) are not correlative to any entitlement and those of justice that are, lies in the fact that only the latter are waivable and permissibly enforceable.

Much of the philosophical treatment of entitlements is located in discussions of rival theories of justice. These theories differ according to the various norms they propose for determining who owes what to whom. Endorsing the classical formal conditions of justice – 'rendering to each what is due to him' and 'treating like cases alike' – they diverge widely in their interpretations of what is due to a person and what count as like cases. Procedural and substantive criteria that have been offered for determining individuals' entitlements include: relative need, productivity, equal freedom, equal utility, personal moral worth, interpersonal neutrality, personal inviolability, initial contract and so forth. As is immediately obvious, the nature and distribution of the entitlements mandated by each of these criteria are by no means self-evident, and their identification thus requires supplementary postulates that are variously drawn from psychological theories, from theories of moral and rational choice, and from conceptual analyses of the criteria themselves. It is also true that not all of these criteria are mutually exclusive: given a plausible set of premises, some can be derived from others.

There are other dimensions, apart from their distributive norms, in which theories of just entitlements differ. Some of these differences are logically implied by the nature of the norms themselves, while others are independent of them. One such dimension is the kinds of object to be distributed in conformity with a proposed criterion. Proffered items include all utility-producing goods, means of production, natural resources, the rents of superior skills or talents, and even human body parts. What one may do with the things to which one has strong entitlements – what weak entitlements and unprotected liberties one possesses – is largely a function of the sorts of thing to which others are strongly entitled. The intricate structure of permissibility, jointly formed by the rights one has against others and the rights others have against oneself, constitutes the fields of activity within which each person exercises those rights. It thereby also determines the respective spheres of market, state and charitable activities.

A third differentiating dimension is the range of subjects to be counted as having entitlements. Generally accepting the membership of all adult human beings in the class of title-holders, theories differ over whether their distributive norms extend to minors, members of other societies, deceased persons (in respect of bequest), persons conceived but not yet born (in respect of abortion), persons not yet conceived (in respect of capital accumulation and environmental

conservation) and non-human animals. Again, the nature and interpretation of a theory's distributive criterion often work to delimit its class of title-holders.

In the light of this multiplicity of differentiating dimensions, the classification – let alone assessment – of theories is no simple task. One, but by no means the only, important respect in which many of them can be compared is in terms of the scope they allow for unconstrained individual choice. Thus theories might be ranged along a spectrum from those that prescribe only an initial set of entitlements (permitting persons thereafter to dispose of these as they choose), to those that require constant enforceable adjustment of the content and distribution of entitlements to conform to certain norms. However, even this way of arraying competing theories is somewhat underspecified, inasmuch as it fails to capture the varied ramifications of the restrictions implied by different initial entitlements.

Hence it is an open question as to where on this spectrum one would locate theories that (via a unanimity requirement) construe each person's initial entitlement as a veto on a social or constitutional contract. Such an entitlement may in turn be derived from some interpretation of equal freedom, personal inviolability or interpersonal neutrality. Or it may itself be taken as an intuitively acceptable foundational postulate for deriving a more complex set of entitlements. Whether an initial contract theory is permissive or restrictive of wide individual choice depends upon its account of the terms of that contract. The derivation of these terms usually proceeds from some conception of human nature – of human knowledge and motivation – along with some meta-ethical theory about the nature of moral reasoning. Contractual terms generated by these premises may extend only to the design of political institutions, thereby leaving the determination of individuals' substantive entitlements to the legislative process. Alternatively, such contracts may stipulate a set of basic individual rights that are immune to legislative encroachment. In either case, the resultant scope for individual choice remains underdetermined. In the first case it depends upon the extent of legislation, while in the second it depends upon the size and nature of the stipulated set of rights. Laws and constitutional rights imply both restrictions on each person's conduct but also, *ipso facto*, restrictions on the extent of permissible interference with others' conduct.

Dispensing with the initial contract device and hypothetical unanimous agreement, some theories derive a set of entitlements directly (non-procedurally) from a substantive foundational value. Among such theories, one type assigns entitlements according to the differential incidence of some stipulated variable in the population of title-holders. Need and productivity are particularly prominent variables in this field, often acquiring their normative import from the values of welfare equalization and maximization. Clearly, applications of these distributive criteria respectively presuppose accounts of essential human requirements and of economic value. Although, for such theories, any shift in the incidence of the stipulated variable occasions a corresponding adjustment of entitlements, the issue of whether this adjustment must be imposed or occurs spontaneously partly turns on the model of interactive behaviour employed. In general, models indicating spontaneous adjustment generate that conclusion by ascribing dominance to altruistic (need) or income-maximizing (productivity) behaviour. To the extent that these ascription's are empirically unrealistic, such theories mandate enforceable restrictions on the scope for individual choice.

Another type of directly derived (non-contract-based) entitlement set is drawn from foundational values like equal freedom, personal inviolability or interpersonal neutrality, which, by definition, are of uniform non-differential incidence in the population of title-holders. Varying interpretations of these concepts tend nonetheless to converge on the Kantian injunction that persons must be treated as ends in themselves and, more specifically, that no person's ends may be systematically subordinated to those of another. Here the theoretical task is to design a set of entitlements that is independent of any particular conception of 'the good' – independent of particular preferences and (other) moral values – and that is such as to ensure that the consequences of persons' actions,

whether harmful or beneficial, are not imposed on others. A typical, though by no means invariable, structural feature of such an entitlement set is its extensive use of a threefold classification of things in the world as selves, raw natural resources and objects which are combinations of these. While title-holders are each vested with ownership of themselves (their bodies and labour), such theories often contain some sort of egalitarian constraint on individual entitlements to raw natural resources. The precise form of this constraint determines the nature of the encumbrances that may be imposed on the ownership of objects in the third category. But since these encumbrances exhaust the restrictions on what persons may do with what they own, such theories are presumed to allow considerable scope for individual choice.

It is hardly worth remarking that many theories of entitlement combine aspects of the three types outlined above. The assessment of competing theories – a complex task, as stated previously – commonly consists in testing for internal coherence and in appraising the interpretations placed on core concepts in the theory. Thus, if it is supposed that the moral principle underpinning a set of entitlements is that of justice, and that justice is analytically linked to the concept of rights, there is room for dispute as to whether the first (initial contract) and second (needs, productivity) types of theory are properly viewed as theories of entitlement. A distinctive normative feature of rights is that they are held non-contingently to confer an element of individuated discretion on their owners. It is unclear whether possession of a veto in a collective-choice procedure amounts to a sufficiently individuated sphere of discretion. On the other hand, the entitlements generated by considerations of need or productivity, while sufficiently individuated, appear to lack any necessarily discretionary character. A difficulty besetting the first and third types of theory arises with regard to the notion of initial entitlements. Specifically, it seems clear that the identification of each person's initial entitlement – either in a collective-choice procedure or under an egalitarian constraint on natural resource ownership – cannot be interpreted as an historically 'one-off' determination, in the face of an undecidable number and size of partially concurrent future generations. These are among the more salient problems commanding attention in current work on theories of entitlement.

Entitlements are rights granted by contract, law or practice. Under the assumption of pure self-interest, modelling games with entitlements is fairly straightforward; however, work in behavioural economics has consistently demonstrated the existence of other-regarding preferences, with strong effects of perceptions of what is fair. In the laboratory, behaviour is affected not only by the entitlement per se but also by the procedure by which entitlements come about. One form of laboratory entitlement is a more advantageous position in an economic game, where the advantage arises from a larger endowment, favourable exchange rules or greater decision-making authority. A second type of entitlement is a guaranteed payoff or a payoff floor. Experimental results show that the means by which entitlements are acquired is one cue that influences the nature of other-regarding behaviour. This is important both for understanding behaviour and the design of experiments.

In early experimental work on entitlements, Hoffman and Spitzer (1985) demonstrate that both the existence of an entitlement and its source determine economic outcomes. They study bilateral bargaining problems where one of the two subjects, called the 'controller', has unilateral authority to decide the outcome of a negotiation game in the event of disagreement. Authority is assigned based on either the outcome of a coin flip or the result of a simple test of a skill that is irrelevant to the experimental task. They find that controllers are most willing to exploit their power when they are assigned their role based on the skill test and are told that they 'earned' the right to be the controller – that is, that they have moral authority. These results are consistent with Burrows and Loomes (1994).

The subjects' behaviour illustrates Rawls's (1971) notion of 'desert', which requires that people deserve the conditions underlying their actions as well as the fruits of their actions. Thus subjects divided an endowment equally when the controller was chosen according to the flip of a coin and had low moral authority. On the other hand, both earning the right to be controller and higher moral authority triggered changes in observed allocations, so that outcomes favoured the controller. Entitlements that were earned or that involved 'morally unequal' agents were sufficient to trigger unequal outcomes. Equity theory developed by social psychologists is similar in spirit to this theory of justice.

Ideas of procedural fairness also affect perceptions of government entitlements. Fong (2001) looks at poll data on perceptions of poverty and opportunity, and finds that beliefs about others' effort, luck and opportunity play the largest role in determining support for government entitlement programmes. In particular these beliefs outweigh concerns about tax costs in supporting these programmes. These results are consistent with the experimental results discussed above, where low payoffs are acceptable if one displays low effort. If one's situation is determined by poor luck, however, one will give up some of one's earnings to increase the earnings of others.

A number of experimental studies on income redistribution examine Rawls's claim that individuals prefer an income redistribution rule that maximizes the position of the poorest member of society (Frohlich and Oppenheimer 1990). Studies where subjects must choose a principle of distributive justice and a tax system in addition to participating in a production task find that people choose rules that maximize the productivity of society while maintaining a minimum floor for the worst off members. Subjects generate greater output in experiments where they are able to determine the entitlements for the worst off individual in their group, again demonstrating that the source of entitlements matters.

These results show that researchers need to pay attention to how entitlements are determined. This is a complication for theories of behavioural economics or psychological games. People do not have a pure taste for fair allocations; they are more self-interested, altruistic or fair according to circumstances that depend on how advantage arises. This behaviour is closely related to

reciprocity, but that is often modelled as 'if you are nice to me I'll be nice to you' (Bowles and Gintis 2001). In contrast, this collection of results can be interpreted as, 'I will respect your entitlement if you deserve it'.

A preference for procedural factors also complicates experimental design, since subjects behave in a more self-interested manner when entitlements are earned than when they are randomly assigned. Researchers must be careful to consider how subjects will interpret the rules by which advantages are assigned or they may risk introducing nuisance variables. Future work might deliberately award entitlements in a manner that subjects view as unjust to see whether that produces yet another pattern of behaviour.

Entrepreneur

Mark Casson

There are several theories of the entrepreneur, but very few mathematical models which formally analyse entrepreneurial behaviour within a closed economic system. Indeed, it is often argued that by its very nature entrepreneurial behaviour cannot be predicted using deterministic models. Entrepreneurship, it is claimed, is essentially a spontaneous and evolutionary phenomenon.

The term 'entrepreneur' seems to have been introduced into economic theory by Cantillon (1755), but the entrepreneur was first accorded prominence by Say (1803). It was variously translated into English as 'merchant', 'adventurer' or 'employer', though the precise meaning is the undertaker of a project. John Stuart Mill (1848) popularized the term in England, though by the turn of the century it had almost disappeared from the theoretical literature (though see Marshall 1890).

The 'disappearance' of the entrepreneur is associated with the rise of the neoclassical school of economics. The entrepreneur fills the gap labelled 'fixed factor' in the neoclassical theory of the firm. Entrepreneurial ability is analogous to a fixed factor endowment because it sets a limit to the efficient size of the firm. The static and passive role of the entrepreneur in the neoclassical theory reflects the theory's emphasis on perfect information – which trivializes management and decision-making – and on perfect markets – which do all the coordination that is necessary and leave nothing for the entrepreneur (cf. Baumol 1968).

According to Schumpeter (1934), the entrepreneur is the prime mover in economic development, and his function is to innovate, or 'carry out new combinations'. Five types of innovation are distinguished: the introduction of a new good (or an improvement in the quality of an existing good), the introduction of a new method of production, the opening of a new market – in particular an export market in new territory – the

'conquest of a new source of supply of raw materials or half-manufactured goods' and the creation of a new type of industrial organization – in particular the formation of a trust or some other type of monopoly. Schumpeter is also very clear about what the entrepreneur is *not*: he is not an inventor, but someone who decides to allocate resources to the exploitation of an invention; nor is he a risk-bearer: risk-bearing is the function of the capitalist who lends funds to the entrepreneur. Essentially, therefore, Schumpeter's entrepreneur has a managerial, or decision-making role.

This view receives qualified support from Hayek (1937) and Kirzner (1973), who emphasize the role of the entrepreneur in acquiring and using information. The entrepreneur's alertness to profit-opportunities, and his readiness to exploit them through arbitrage-type operations, makes him the key element in the 'market process'. Hayek and Kirzner regard the entrepreneur as responding to change – as reflected in the information he receives – whilst Schumpeter emphasized the role of the entrepreneur as a source of change. These two views are not incompatible though: a change effected by one entrepreneur may cause spill-over effects which alter the environment of other entrepreneurs. Hayek and Kirzner do not insist on the novelty of entrepreneurial activity, however, and it is certainly true that a correct decision is not always a decision to innovate; premature innovation may be commercially disastrous. Schumpeter begs the question of whether someone who is the first to evaluate an innovation, but decides (correctly) not to innovate, qualifies as an entrepreneur.

Leibenstein (1968) regards the entrepreneur as someone who achieves success by avoiding the inefficiencies to which other people – or the organization to which they belong – are prone. The main virtue of Leibenstein's approach is that it emphasizes that, in the real world, success is exceptional and failure is the norm.

Knight (1921) insists that decision-making involves uncertainty. Each business situation is unique, and the relative frequencies of past events cannot be used to evaluate the probabilities of future outcomes. According to Knight, measurable risks can be diversified – or 'laid off' – through insurance markets, but uncertainties cannot. Those who take decisions in highly uncertain environments must bear the full consequences of those decisions themselves. These people are entrepreneurs: they are the owners of businesses and not the salaried managers that make day-to-day decisions.

It is not clear, at first sight, whether there is any common thread which runs through these various theories of the entrepreneur. Casson (1982) attempts to identify a shared element by introducing the concept entrepreneurial judgement. The entrepreneur is defined as someone who specializes in taking judgemental decisions about the allocation of scarce resources. The essence of a judgemental decision is that there is no decision rule that can be applied that is both obviously correct and involves using only freely available information. Suppose, for example, that a decision rule, is used; then there must be some initial judgement that the chosen rule, and not some other rule, is the appropriate one. No rule can ever be fully self-justifying: there is no definitive model which demonstrates that one rule is always superior to another. Ultimately, the justification for a rule must be some property of the environment, which in many cases cannot be observed.

It is evident that this concept of judgemental decision-making rejects the 'naive neoclassical' view that all decision-making merely involves marginalist calculations based upon public information supplied by the price system. It recognizes that not only is information costly, but that the costs of acquiring information are different for different people. Furthermore, because their access to information differs, different people will make different decisions in the same situation. The essence of judgemental decision-making is that the outcome depends upon *who* makes the decision.

When judgements differ, confident individuals can back their own judgement by taking up speculative positions against other people who hold a conventional view. The confident individuals 'bet' against others by acquiring assets that they believe other people have under-valued, disposing of assets that they believe other people have over-valued, undertaking projects that other people do

not consider profitable, and so on. Using this approach, the arbitraging activity described by Hayek and Kirzner, and the innovative activity described by Schumpeter, are seen to be special cases of the general concept of entrepreneurial speculation based upon self-confident judgement.

In a market economy, individuals who lack confidence in their judgement can delegate decisions to entrepreneurs. The individual entrusts his wealth to an entrepreneur, who allocates this wealth in accordance with his own judgement. In practice, the individual will often diversify his risks by using a 'portfolio' of different entrepreneurs. The delegation of decision-making can be effected in various ways. An individual may supply capital at fixed interest to an entrepreneur who is self-employed or is the owner-manager of a firm. He may own an equity stake in a firm where the entrepreneur acts partly as a salaried employee; or he may deposit his funds in a bank whose managers advance loans to firms and self-employed entrepreneurs.

To overcome the principal-agent problems involved in the delegation of decisions, it is normally necessary for the supplier of finance not only to have confidence in the entrepreneur's judgement, but also to trust the entrepreneur to exercise this judgement in pursuit of maximum profit. Unless the entrepreneur has an established reputation, he has a strategic problem in obtaining the confidence of others. Because of the differences in judgement mentioned earlier, the entrepreneur will normally be more optimistic about a project than are his potential financial backers. His backers will therefore perceive higher risks, and set a higher cost of capital than the entrepreneur believes is warranted. If, however, he persuades his backers to share his optimism, then they may preempt his project, since they already have the finance to proceed with it and he does not.

This leads directly to the question of trust. Just as the financiers must trust the entrepreneur to use his funds in their interests, so the entrepreneur must trust his financial backers not to preempt his project for themselves. Part of the problem can be solved by using an 'honest broker' such as a bank, which vets entrepreneurial projects on behalf of investors but ties its own hands by not entering into entrepreneurial projects on its own account. In countries where the banking system is underdeveloped, the extended family often fulfils a similar function of 'honest broking' between the older generation who are potential investors and the younger generation who are potential entrepreneurs. Another method of building trust is to supply finance in a sequence of small instalments so that both parties have an incentive to behave honourably in order not to put future relations between them at risk.

Much of the information required for decision-making is not merely costly to obtain, but is not available by direct observation at all. Another way of saying this is that decisions are governed not only by objective information but also by subjective beliefs. An individual's beliefs originate with his culture and his religion as well as with his direct experience of life. Some cultures appear to give greater encouragement to entrepreneurship than others. A culture which stresses individuality rather than conformity encourages an individual to form an independent judgement of a situation. A culture which emphasizes human autonomy rather than fatalistic submission to nature encourages the kind of self-confidence required of the entrepreneur. A culture which emphasizes the heroic aspects of leadership rather than the corrupting effects of power-seeking encourages individuals to undertake ambitious projects which call for a high degree of organization, and so on. Cultural values have always been emphasized in the literature on entrepreneurship: Schumpeter, for example, refers to the dream and will to found a private dynasty, the will to conquer and the joy of creating, while Weber (1930) emphasizes the Protestant ethic and the concept of calling and Redlich (1956) the militaristic values of the 'captains of industry'. Writers on business history almost invariably stress the influence of culture and personality on the behaviour of the entrepreneur.

A common criticism of theories which place considerable weight on cultural characteristics and personality traits is that they are difficult to test. Indeed, it is often suggested that because the behaviour of individual entrepreneurs tends to be unpredictable, theories of entrepreneurship are

untestable. It is, however, quite possible that while the behaviour of individual entrepreneurs cannot be predicted, the behaviour of entrepreneurs as a group is predictable. Furthermore, a theory of entrepreneurship may generate propositions relating to other social phenomena besides the behaviour of entrepreneurs themselves. With certain qualifications, it is possible to develop a model in which both the level of entrepreneurial activity and the functional distribution of income between entrepreneurship and other factors are simultaneously determined.

Given that the entrepreneur specializes in judgemental decision-making, it is possible to formulate a derived demand for entrepreneurial services which varies according to the demands which the business environment places upon judgement. The more complex the environment, the faster the pace of change, and the more radical the structural adjustments that these changes call for, the greater will be the demand for entrepreneurs. A large demand for entrepreneurs will be reflected in substantial profit opportunities for people who can anticipate changes and correctly foresee their consequences. Individual profit opportunities will not be competed away so long as each opportunity can be preempted by a single entrepreneur before others come to form the same judgement as he has done. In the short run, therefore, the successful entrepreneur can earn a monopolistic rent to superior judgement.

In the long run, however, entry into entrepreneurship will tend to compete away any expected return to entrepreneurial activity which exceeds the expected return to non-entrepreneurial activity (after due allowance for different levels of risk and for the non-pecuniary net benefits of the two kinds of activity). The competing away of entrepreneurial rents may not be complete, however, because access to capital may prove a barrier to entry for the reasons explained above.

Long-run entry corresponds to a movement along a long-run supply curve for entrepreneurs. The total supply of entrepreneurs is measured by the number of individuals whose principal activity is to exercise their judgement to allocate resources. The people concerned may be senior salaried managers or the self-employed – given the definition above, it is impossible to identify the entrepreneur simply by his contractual status in employment. An increase in the supply of entrepreneurs is effected by individuals transferring out of manual work and non-entrepreneurial decision-making (i.e. routine management), and from unemployment and leisure, and by net inward migration of entrepreneurs from abroad. The position and elasticity of the entrepreneurial supply curve depends upon the expected return to non-entrepreneurial activity abroad, the distribution of judgemental ability within the indigenous population, cultural attitudes, and barriers to entry and exit which reduce mobility between the entrepreneurial and non-entrepreneurial groups.

Given both the long run supply and long run demand for entrepreneurs, it is possible to visualize a long equilibrium in which the marginal entrepreneur earns an approximately normal return, intra-marginal entrepreneurs earn a quasi-rent to superior judgement, and intra-marginal non-entrepreneurs earn quasi-rents for their non-entrepreneurial abilities. The equilibrium return to entrepreneurship, and the equilibrium number of entrepreneurs, depend upon the parameters of the demand and supply curves, as described above. This equilibrium is a partial equilibrium, conditional upon the returns to non-entrepreneurial activity within the economy. It is also possible to derive a general equilibrium by endogenizing the return to non-entrepreneurial activity.

It should be emphasized, however, that any kind of ‘equilibrium’ in a ‘market for entrepreneurs’ is essentially an analytical fiction because the adjustment of this market to an equilibrium is itself an entrepreneurial task. The decision whether to hire an entrepreneur, and the decision whether to become one, are both entrepreneurial decisions. It is difficult for entrepreneurs to intermediate in the market for entrepreneurs because it is difficult to buy and sell ‘human capital’ of this kind. To introduce a Walrasian auctioneer to coordinate supply and demand decisions in the market for entrepreneurs would be self-contradictory, for it is only because of the absence of the Walrasian auctioneer that entrepreneurs are required in the first place. Thus while the concept of a market

equilibrium for entrepreneurs is a useful analytical device, it is erroneous to suppose that the market for entrepreneurs is ever in a full equilibrium.

Twenty years ago, the study of the entrepreneur was regarded as a 'gap' in economic theory. It is now recognized that this gap cannot be filled without radically changing the nature of the theory itself. The entrepreneur can only be understood properly in the context of an economic model which does full justice to the structural complexity and the evolutionary nature of the economy (Nelson and Winter 1982). Within such a model the 'equilibrium' concept remains a useful analytical device, but one of limited practical relevance. The study of the entrepreneur leads to a vision of economics much wider than that of a subject which parsimoniously derives a consistent set of price and quantity equations. Aspects of human personality – such as self-confidence – acquire a crucial role – and so too does the malleability of the personality under the influence of cultural attitudes. The theory of the entrepreneur, therefore, is not the last step which renders the conventional theory of value complete, but the first step towards an economic theory which forms part of a wider integrated body of social science.

Entrepreneurship

William J. Baumol and Melissa A. Schilling

Abstract

This article describes the recent expansion of research on entrepreneurship, innovation and growth. Although the entrepreneur is widely credited with critical contributions to innovation and growth, the subject of entrepreneurship has virtually disappeared from mainstream theory and standard textbooks. Reasons explaining this gap are indicated. In addition to some brief materials on earlier writings, the rich body of recent work on the subject, both theoretical and empirical, is surveyed, illustrating the wide variety of subjects explored and the insights offered by the new literature.

An entrepreneur is an individual who organizes, operates, and assumes the risk of creating new businesses. There are two types. A replicative entrepreneur organizes a new business firm that is like other firms already in existence. An innovating entrepreneur provides something new – a new product or process, or a new type of business structure, a new approach to marketing, and so on. These innovations need not be productive or beneficial. For example, Richard Cantillon (one of the first great economic theorists) spoke of thieves who are entrepreneurs (Cantillon 1730, pp. 54–5). And Joseph A. Schumpeter, arguably the contributor of the most important analysis of entrepreneurship, included as an entrepreneurial act '.. .the creation of a monopoly position (for example, through trustification).. ..' (Schumpeter 1911, p. 66). Entrepreneurs (interpreted as the self-employed) are estimated to constitute about seven percent of the labour force in the United States (U.S. Bureau of the Census 2004). Most of them are probably replicative, not innovative, entrepreneurs.

It is widely agreed that the entrepreneur plays an important role in economic growth. But the evidence shows little correlation between an economy's number of replicative entrepreneurs and its growth rate. Innovative entrepreneurs do make a substantial difference to a nation's growth rate, having introduced many breakthrough innovations like the telephone and the airplane. The primary social contribution of replicative entrepreneurship is as a means for individuals to escape poverty, because such undertakings require little capital, education or experience. Still, the data show that entrepreneurs, on average, earn less than employees with similar education and experience (Freeman 1978; Astebro 2003; Benz and Frey 2004).

Although economists have recently exhibited a resurgence of interest in entrepreneurship, the entrepreneur nevertheless rarely shows up in contemporary mainstream economic theory.

Early Writings and the Origin of the Term

Until the 20th century, writings in English referred to entrepreneurs as 'adventurers' or 'undertakers' (see, for example, Marshall 1923, p. 172). Apparently, the term 'entrepreneur' was introduced by Cantillon in the French translation of his great work, *Essai Sur la Nature de Commerce en Général* (1730, p. 54), but what is apparently *his* English text uses the word 'undertaker'. The early writings on entrepreneurship were descriptive rather than theoretical. Cantillon's discussion (1730, ch. 11) is brief, focusing on replicative entrepreneurs: '.. .wholesalers in Wool and Corn, Bakers, Butchers, Manufacturers and Merchants of all kinds.. ..' (1730, p. 51). Cantillon's main point, like that of Frank H. Knight (1921), was the task's riskiness: 'These Undertakers can never know how great will be the demand in their City, nor how long their customers will buy of them since their rivals will try all sorts of means to attract customers from them. All this causes so much uncertainty among these Undertakers that every day one sees some of them become bankrupt' (1730, p. 51).

Nearly a century later, Jean-Baptiste Say's (1819) discussion is still brief, but richer. Say seems interested primarily in innovating entrepreneurs, dealing with three types of 'producers': scientists, entrepreneurs and labourers. Using mechanical locks as an example, the scientist investigates '.. .the properties of iron, the method of extracting from the mine and refining the ore.. .' The entrepreneurs deal with '.. .application of this knowledge to a useful purpose.. .,' while the third group – the workers – actually make the product (1819, p. 80). And any successful economy needs all three: 'Nor can [industry] approximate to perfection in any nation, till that nation excel in all three branches' (1819, p. 80).

Thus, Say blames poverty in Africa on the absence of scientists and entrepreneurs. Lack of

entrepreneurs alone can undercut prosperity, even with scientific knowledge abundant, for without the entrepreneur, '.. .that knowledge might possibly have lain dormant in the memory of one or two persons, or in the pages of literature' (1819, p. 81). This is precisely the explanation that one of the present authors proposed for the failure of medieval China and the Soviet Union to translate an abundance of non-military inventions into viable consumer products (Baumol 2002, chs. 5, 14). Say also foreshadows some of Schumpeter's analysis (see below): 'In manufacture.. .if success [in innovation] ensue, the adventurer is rewarded by a longer period of exclusive advantage, because his process is less open to observation' (1807, p. 84).

Finally, Say mentions the spillovers of innovation and their justification for governmental financing: 'The charges of experiment, when defrayed by the government... [are] hardly felt at all, because the burthen is divided among innumerable contributors; and the advantages resulting from success being a common benefit to all, it is by no means inequitable that the sacrifices, by which they are obtained, should fall on the community at large' (1819, p. 85).

Before Schumpeter's breakthrough (see below), the subject was touched upon by economists like J.S. Mill, Alfred Marshall and (a bit later) Knight. Generally, their focus was not on innovative entrepreneurship, and they emphasized management's directing of going concerns rather than establishment of new firms. (But Marshall 1923, p. 172, does digress briefly to mention Matthew Boulton's significant role as an entrepreneur dealing with James Watt's inventions.) Today, however, these discussions would hardly be considered theory. Rather, they are usually narratives containing illuminating observations. They assert that the entrepreneur's payment is a residual after other inputs are compensated, and that compensation is determined by the entrepreneur's ability and the supply of entrepreneurship in the market. They note that entrepreneurs employ themselves, so that unlike other inputs there is no demand function, as for other inputs.

Disappearance of the Entrepreneur from Modern Mainstream Economics

Given the acknowledged importance of the entrepreneur's role, it could be hoped that modern theoretical economics, with its powerful analytic tools, would have produced an extensive entrepreneurship analysis. Instead, the opposite happened – the entrepreneur became the 'invisible man' in mainstream theory. There are at least two reasons for this. First, the most advanced and powerful microeconomic models predominately study timeless static equilibria. But, for the entrepreneur, the transition process is the heart of the story. Schumpeter (1911) shows the entrepreneur as a destroyer of equilibria by constant innovation, while Israel Kirzner (1979) tells how the alert entrepreneur seeks out the arbitrage opportunities presented by disequilibria, thereby moving the economy back toward equilibrium. Such a relentless attack upon both equilibria and disequilibria does not fit a stationary model from which firm creation and invention are excluded.

The second reason for the entrepreneur's disappearance from mainstream theory is that, by definition, an invention is something never available before. So invention is the ultimate heterogeneous product. This impedes the optimality analysis underlying most microeconomic theory. Explicitly or implicitly, an optimality calculation entails a comparison among possible substitute choices, while the innovating entrepreneur normally deals with no well-defined substitutes with quantifiable attributes. In contrast, the standard theory of the firm analyses repetitious decisions of management in fully operational enterprises where the entrepreneur has already completed his job and left to create other firms.

Thus, neoclassical theory is justified in excluding the entrepreneur, because it deals with subjects for which the entrepreneur is irrelevant. That does not mean that no theory of entrepreneurship is needed, or that such a theory is lacking, but it means that a theory of entrepreneurship must be sought elsewhere, and that is what Schumpeter succeeded in doing.

Brief Summary: Schumpeter's Model: The Supply and Earnings of Entrepreneurial Activity

The basic Schumpeterian model (1911) notes that the successful innovative entrepreneur's reward is profit temporarily exceeding that of perfect competition. This attracts rivals who seek to share those profits by imitating the innovation, and thereby erode its super-competitive earnings. To prevent termination of these rewards, the entrepreneur can never desist from further innovation and cannot rest on his laurels.

Perhaps most important, the Schumpeterian analysis shows how the entrepreneur is driven to work without let-up for economic growth. Thus, it clearly reveals the tight association between innovative entrepreneurship and growth.

Allocation Between Productive and Unproductive Entrepreneurship

Some work of one of the present authors (Baumol 2002, ch. 14) tells much of the rest of the story about the supply and allocation of productive entrepreneurship and the key role of evolving institutions. In the economic growth literature, it has often been asserted that an expanded supply of entrepreneurs effectively stimulates growth, while shrinkage in the supply undermines growth. But the standard explanation of the entrepreneurs' appearance and disappearance is shrouded in mystery, with hints about cultural developments and vague psychological and sociological changes. The historical evidence suggests a more mundane explanation: that entrepreneurs are always present but, as the structure of rewards in the economy changes, entrepreneurs switch their activities, moving to where payoffs become more attractive. In doing so, they move in and out of the activities usually recognized as entrepreneurial, exchanging them for other activities that also require enterprising talent but are often distant from production of goods and services. The generals of ancient Rome, the Mandarins of the Tang, Sung, and Ming Chinese empires, the captains of late medieval private and mercenary armies, the rent-seeking contemporary lawyers, and the Mafia Dons – all are clearly enterprising and often successful. And when institutions have changed so as to modify profoundly the relative payoffs offered by the different enterprising activities, the supply of entrepreneurs has shifted accordingly. Here, it is helpful to distinguish two categories of entrepreneurs, the productive and the unproductive entrepreneurs, with the latter, in turn, divided into subgroups such as rent-seeking entrepreneurs and destructive entrepreneurs, including the organizers of private armies or criminal groups. Once there is a pertinent change in the institutions that govern the relative rewards, the entrepreneurs will shift their activities between productive and unproductive occupations, so the set of productive entrepreneurs will appear to expand or contract autonomously. For example, when institutions change to prohibit private armies, entrepreneurs are led to look elsewhere to realize their financial ambitions. If, simultaneously, rules against confiscation of private property and for patent protection of inventions are adopted, entrepreneurial talent will shift into productive, innovative directions.

Recent Studies: Other Disciplines and Empirical Approaches

Outside mainstream economic analysis, research on entrepreneurship has expanded rapidly since the 1980s, particularly that by specialists in management, psychology, and sociology. We focus here on three streams of work that have attracted the most scholarly attention: (*a*) how differences among individuals influence entry into (and success in) entrepreneurship, (*b*) how environment influences entrepreneurship, and (*c*) the strategies and forms of organization used by entrepreneurs.

Differences Among Individuals

There are numerous studies investigating how differences among individuals (in attributes such

as education, age, experience, social position and psychology) are associated with a propensity to become self-employed and the likelihood of success at entrepreneurship. A wide variety of studies have indicated that individuals with higher education than the general population are more likely to become entrepreneurs (Shane 2003). Robinson and Sexton (1994) and others have found that number of years of education is significantly related to likelihood of becoming self-employed, and Bates (1995) found that individuals with a graduate education were significantly more likely to become self-employed. Age appears to have an inverted U-shaped relationship with likelihood of forming a new venture. Entrepreneurship first increases with age because of experience, and then decreases with age because of opportunity costs and uncertainty premiums (Bates 1995; Shane 2003).

A number of studies that look at how experience influences likelihood of starting a business and the success of the new venture have found that general business experience (Evans and Leighton 1989; Robinson and Sexton 1994), experience specific to the industry in which the entrepreneur later founds a business (Aldrich 1999), and prior self-employment (Carroll and Mosakowski 1987) all increase the likelihood that an individual will found a new business. Furthermore, such experience tends to improve new venture performance and survival rates (Gimeno et al. 1997).

Studies have revealed that, in general, social status increases the likelihood of forming a new venture (for example, Stuart et al. 1999). The number and diversity of an individual's social ties also increase the likelihood of founding a company (Aldrich et al. 1987), as well as the success of the venture (Hansen 1995). Psychological factors also influence an individual's likelihood of becoming an entrepreneur (Shane 2003). In particular, extraversion (Babb and Babb 1992), need for achievement (Hornaday and Aboud 1973), risk-taking propensity (Astebro 2003), self-efficacy (Zietsma 1999), overconfidence (Arabsheibani et al. 2000), and creativity (Ames and Runco 2005) have all been shown to be significantly related to an individual's likelihood of becoming an entrepreneur.

Environmental Factors

A number of industry characteristics influence new venture formation. Market size (Pennings 1982) and growth (Dean and Meyer 1992) increase the likelihood of new firm formation, while uncertainty from technological change decreases the rate of business start-ups (Audretsch and Acs 1994). Capital intensity also reduces new firm formation by raising entry costs (Dean and Meyer 1992). The density of firms has an inverted U-shaped relationship with new firm formation (Carroll and Wade 1991). Too few firms in an industry may signal that there is no opportunity worth pursuing, or scarcity of market information. Thus, initial increases in the density of firms in the industry encourage business start-ups (Shane 2003), although high density can increase competition for resources and create an entry barrier.

Not surprisingly, the institutional environment of an industry or region also affects new firm formation. Capital availability (for example, low-cost debt or venture capital) enhances firm formation (McMillan and Woodruff 2002). Higher marginal federal income tax rates decrease self-employment (Gentry and Hubbard 2000) and business tax concessions increase business start-ups (Dana 1987).

Stronger property rights encourage entrepreneurship, presumably because they assure entrepreneurs that they can appropriate the fruits of their efforts (McMillan and Woodruff 2002). Researchers have also investigated the role of university technology-transfer offices on entrepreneurship, with most research indicating that such offices increase rates of new venture formation, particularly when technology-transfer offices are structured to profit from the transfers (Markman et al. 2005). Finally, socio-cultural norms about the desirability of self-employment or the risks of failure are significantly related to rates of business start-ups in a nation or ethnic group (Butler and Herring 1991).

Strategy and Organization

The area of entrepreneurial strategy that has received most research attention is method of financing. Consistent with Knight's (1921) argument that self-financing is needed to overcome

moral hazard problems, most entrepreneurs finance their ventures primarily with their own capital (Aldrich 1999; Shane 2003). However, funds provided by 'angel' investors (wealthy individuals who invest in entrepreneurial companies, usually at an early stage) and venture capitalists are also important. The research on angel investment is sparse, but there is more research on venture capitalst investment. A number of researchers have investigated how venture capitalists choose their investments, mitigate risk, and influence new venture survival and growth (Bygrave and Timmons 1992). Some studies have also examined how entrepreneurs identify opportunities (Shane 2003), their degree of reliance on patent protection (Shane 2001), the effect of entrepreneurs' new product development strategies (Zahra and Bogner 2000), and their breadth of market focus (Bhide 2000; Gimeno et al. 1997).

Finally, there also has been some research on the organization of new ventures how they are formed as legal entities, the performance implication of this choice (Delmar and Shane 2004), and the effect of venture team size and background (Eisenhardt and Schoonhoven 1990). In general, formation as a legal entity and a large, diverse venture team appear to improve new venture performance.

On the State of the Theory of Entrepreneurship

Our discussion demonstrates that the beginnings of a significant theory of entrepreneurship already exist. The analysis uses little mathematics to derive any formal theorems, and its results are primarily qualitative. But this nascent theory of entrepreneurship does tell us about its supply and earnings, its role in the pricing of its products and the role of the price mechanism in its allocation among alternative activities. The Schumpeterian model tells us about the determination of entrepreneurs' profits and the prices of their products, as well as their influence on the supply of their activity. The model of productive and unproductive entrepreneurship tells us more about supply, as well as about the allocation of this resource. The empirical research adds further insight into the factors that increase the likelihood of individuals engaging in, and being successful at, entrepreneurship.

Beyond the stationary analysis of standard microeconomic theory, we see that the entrepreneurship models enable us to deal with such important questions as what features of the structure of the free market economy have caused it to outperform by an order of magnitude the innovation and growth of any alternative economic system. The institutional changes that reallocated much of entrepreneurship from redistributive to productive activities are, according to the model, the key to the answer. And this has profound policy implications both for developing countries seeking desperately to escape their poverty and for developed economies seeking to keep up the pace of their growth.

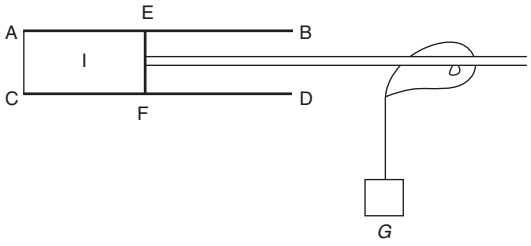
Entropy

Nicholas Georgescu-Roegen

A concept of momentous importance for our understanding of physical reality though it is, entropy is one of the most poorly understood even by many physicists as a keen



Entropy, Fig. 1

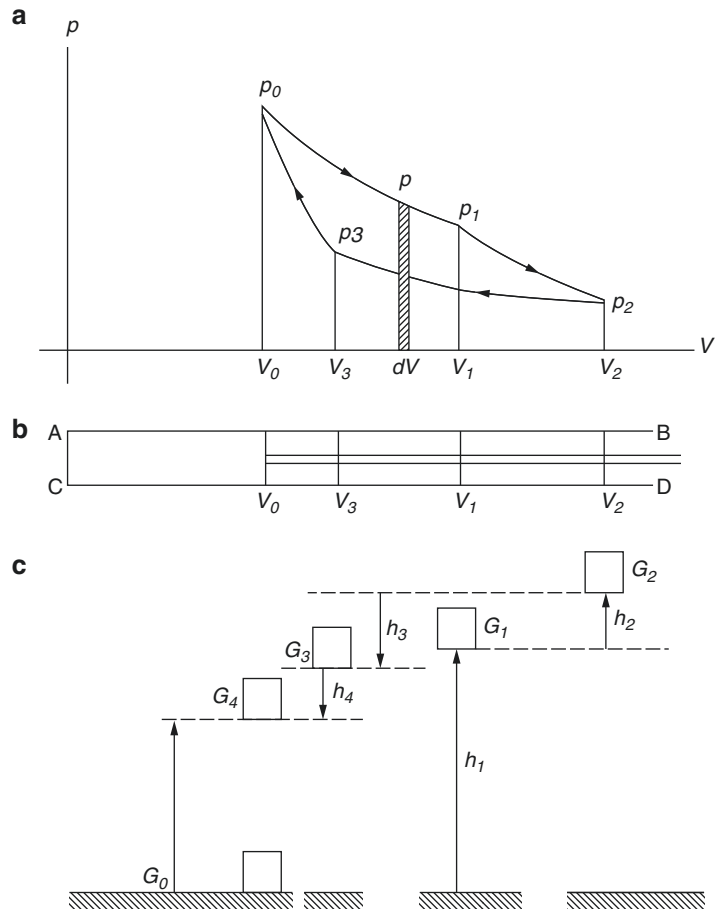
thermodynamicist, D. ter Haar, opined. A 'far-fetched' notion, 'obscure and difficult of comprehension' judged J. Willard Gibbs, the architect of statistical thermodynamics. It was apposite for Lord Snow to argue that some familiarity with the law of entropy, the second law of thermodynamics, separates the educated into two cultures. But this condition is quite curious given that the fountainhead of thermodynamics is anthropomorphic in a far more pronounced degree than that of any other branch of physics. No other physical concept belongs to our ordinary experience as inherently as heat and work or temperature and pressure. Indeed, thermodynamics is at bottom a physics of economic value as Sadi Carnot initiated it in his famous 1824 memoir about our efficient use of energy (Georgescu-Roegen 1971).

An explication of entropy at the ground level being beset with unusual difficulties, over the years the concept has received several, not always logically related, definitions. However, there is an original nature of that concept which can be grasped only by a punctilious description of the so-called Carnot cycle (Georgescu-Roegen 1987). This cycle – the pillar of thermodynamic theory – is a model of unmatched idealization of an engine that converts thermal into potential energy. It consists of a piston-and-cylinder (Fig. 1). The cylinder, ABCD, as well as the piston diaphragm, EF, are made of a perfect thermal insulator; the head of the cylinder, AC, instead is a perfect thermal conductor. The piston-rod turns a noncircular cam which raises or lowers a suspended weight, G. The space AEFC is filled with an ideal gas whose simple properties enable us to represent analytically the working of the engine (Fig. 2a). The model involves several other idealizations. First, the piston moves reversibly, i.e., with an infinitesimally slow speed, an assumption which does away with any friction. And since any such motion would require an infinite time, the point exposes one of the basic anthropomorphic limitations. Second, the piston performs no other work than turning the cam. And the cam on turning does not change its potential energy. Third, when the cycle begins, the volume of the gas is at, say, V_0, and its absolute temperature at T_1. A hot reservoir (a virtually limitless source of thermal energy at the same temperature T_1) is already attached at AC. On expanding, the gas absorbs thermal energy from the reservoir at a rate that keeps its temperature constant throughout. The work thus produced raises the weight from its initial position G_0. Because the internal energy of an ideal gas remains constant if its temperature does not change and because the work only raises the weight, the thermal energy, Q, absorbed by the gas from the reservoir must at any time be equal to the work, W.

Two observations call now for undivided attention. First, the phase considered so far proves that *it is possible to convert thermal energy (heat) from a single source into potential energy (work)*. Hence, in principle, we could sail by tapping the immense energy of the ocean water. Lord Kelvin (1882, I) was not exact therefore when he said in 1852 that '*It is impossible by means of an inanimate material agency, to derive mechanical effect from any portion of matter by cooling it below the temperature of the coldest of the surrounding objects*.' The true reason is not technical (as we have just seen), but still another anthropomorphic limitation: no human can work with a piston that expands beyond any limit; we must bring it back to begin another conversion. But to bring it back we need some energy. Of course, we could use the potential energy of the weight to push the piston back reversibly. That would not do for everything would be just as at the beginning.

There is, however, a technical means to bring the piston back by using less energy than Q. Sadi Carnot (p. 36) revealed the secret in a rather unnoticed law: *The fall of the caloric [thermal energy] produces more motive power [work] at inferior than at superior temperatures*. Let us then

Entropy, Fig. 2



assume that the gas expands only to V_1 which raises the weight to G_1 (Fig. 2). The performed work, W_1 ($=Q_1$), is represented by the area below the segment p_0p_1 of the curve $pV =$ constant which represents the isothermal expansion of the ideal gas. The reason for using a cam is that the work $p\mathrm{d}V$ is not uniform as V increases.

At V_1, an idealized operation takes place: instantaneously the hot reservoir is replaced by a perfect insulator covering AC and a different cam replaces the old. During this second phase the gas expands adiabatically (i.e. without exchanging heat with the outside) to V_2, converting Q_{12} of its internal energy into work, $W_{12} = Q_{12}$. This raises the weight further to G_2. By V_2 the temperature of the ideal gas has decreased to, say, T_2. Another idealized operation now replaces the thermal insulator with a cold reservoir of temperature T_2 and a different cam replaces the previous one. From V_2 on, Carnot's law applies: an energy Q_2 obtained by lowering G_2 to G_3 is transmitted to the reservoir through the intermediary of the gas which contracts so that its temperature and hence its energy remain constant. At V_3 again the cam is exchanged and the reservoir replaced by a perfect insulator over AC. The gas continues then to contract this time adiabatically, from V_3 to V_0. The work W_{34} supplied by the lowering of the weight from G_3 to G_4 is converted into internal energy $Q_{34} = Q_{12}$ because equal temperature changes cause equal changes of the internal energy of an ideal gas.

To sum up: the cycle of the piston is complete, from V_0 back to V_0. Yet the weight is not back at G_0, but at G_4. For the puzzling contrast we should recall the role of the cams in the model. It could

not be otherwise since the final work of the cycle, W, is positive, being represented by the area $p_0p_1p_2p_3$; accordingly,

$$W = Q_1 + Q_{12} - Q_2 - Q_{34} = Q_1 - Q_2 \quad (1)$$

The foregoing analysis proves the correctness of the so-called Carnot's principle, that any heat engine needs two sources of energy of different temperatures. The point is explicit in Planck's amended form of the second law of thermodynamics as given by Lord Kelvin:

> 'It is impossible to construct an engine which will work in a complete cycle, and produce no effect except the raising of a weight and the cooling of a heat-reservoir' (Planck 1897).

Planck thus negated what Wilhelm Ostwald called perpetual motion of the second kind.

From the equations of the curves of Fig. 2a there follows an expression of Carnot's law

$$Q_2/T_2 - Q_1/T_1 = 0. \quad (2)$$

This surprising relation led Rudolf Clausius (in an 1854 essay) to interpret Q/T as *the transformation equivalent-value* of Q at the temperature T. And, as Lord Kelvin had done a few months earlier, he proved that for a reversible cycle

$$N = \sum Q_i/T_i = 0 \text{ or } N = \int \mathrm{d}Q/T = 0. \quad (3)$$

Both based the *theorem* on the first law of thermodynamics, $W = \sum Q/T = 0$ for an isolated system, and on a formulation of the second law. Clausius', which is equivalent to that of Kelvin-Planck, is still the most transparent one: *Heat cannot by itself pass from a colder to a warmer body.*

Clausius also proved the epochal result that, with the convention for signs as in (2), for an *irreversible* cycle

$$\int \mathrm{d}Q/T > 0 \quad (4)$$

In 1865, on the basis of (3) he defined a new thermodynamic function, S, by

$$S_a - S_b = \int_a^b \mathrm{d}Q/T \quad (5)$$

for any reversible path from a state a to b. Then, by (3) and (4), always

$$\Delta S \geq \int \mathrm{d}Q/T, \quad (6)$$

the equality prevailing only for reversible transformations.

At that juncture, Clausius replaced the term, 'transformation' by its Greek equivalent, *entropi*, and ended the memoir by the famous stanza:

1. *The energy of the universe is constant.*
2. *The entropy of the universe tends to a maximum.*

Although S was then defined only for thermal equilibrium, it was one of the greatest novelties ever thought up by a scholarly mind.

Once the idea that heat is not an indestructible fluid but a kind of molecular motion gained credence, to explain thermodynamic phenomena by the laws of mechanics became a vital programme. The most ambitious attempt was that of an 1872 epochal, albeit hard-going, essay by Ludwig Boltzmann (Brush 1966). He argued that if the collisions between molecules follow some (apparently innocuous) rules, the distribution, $f(x,t)$, of their velocities at any time, t, is such that

$$H(t) = \int f \log f \, \mathrm{d}x \quad (7)$$

is never increasing,

$$\mathrm{d}H(t)/\mathrm{d}t \leq 0, \quad (8)$$

the equality prevailing only for thermal equilibrium. Naturally, Boltzmann went on to claim not only that $S = -H$, but that (7) defined entropy for any thermodynamic system as well.

Since to derive an irreversible property from a completely reversible axiomatic basis was as incredible a feat as claiming that the angles of a triangle in an Euclidean plane add to more than two right angles, protests had to come. In 1876, a Boltzmann colleague, Joseph Loschmidt, pointed out that if at any time the velocities of a system satisfying (8) are reversed, we obtain a system for which H increases. And twenty years later, Ernst Zermelo, a pupil of Max Planck, recalled that in 1890 Henri Poincarè had proved that any finite mechanical system must eventually return as close as we wish to any of its *previous* positions (cf. the elementary illustrations in Georgescu-Roegen 1971, pp. 154f). Hence, if H decreases for some time, it must necessarily increase before the return. Boltzmann was at a loss to defend his strong position of 1872 (see Brush 1966). He asserted that if velocities are reversed the entropy most probably would still increase, since his theorem was not based on 'the nature of the forces' but on the immensely greater probability of the initial conditions that yield (8). But there is no reason for these conditions – known as *Stossenanzahl* (statistical postulate) – to be perpetuated from one collision to the next (Georgescu-Roegen 1971, App. C). As to Zermelo's entropy recurrence, Boltzmann dismissed it as irrelevant in practice because of the extremely long time for the return of present conditions (Brush 1966). Loschmidt's objection, however, had a weak point, namely, that systems with reversed velocities do not exist always in actuality. And in favour of Zermelo's, one could imagine that we may be in the middle of a recurrence period begun eons ago.

Pressed by persistent criticism Boltzmann abandoned his purely mechanistic basis of entropy, to concede that his H-theorem 'can never be proved from the equations of motions alone, [it] can only be deduced from the laws of probability' (Boltzmann 1895). Already in 1877, he anchored the law of increasing entropy on the postulate that every state always passes to one of greater probability. Reasonable though the postulate may seem, it is not supported by probability laws: the occurrence of highly improbable bridge hands is subject to no sequential condition (Georgescu-Roegen 1971, VI. 1 and App. F). Then, observing that any state ultimately reaches one of the molecular structures corresponding to thermal equilibrium, and that the number, Ω, of those structures is far greater than that of any other state, Boltzmann proposed that for thermal equilibrium

$S = \log \Omega$, which after the dimensional correction by Max Planck became

$$S = k \log \Omega, \tag{9}$$

where k is now registered as Boltzmann's constant. As has been observed by Planck (1897), the logarithm function must be used in (9) because for a thermal equilibrium composed of two such states we know that $S = S_1 + S_2$ whereas $\Omega = \Omega_1 + \Omega_2$. Later, Boltzmann (1896/8) connected (9) with (7) and (8) by observing that n_i, being the number of molecules in some state i, with $n = \sum n_i$, then the number of possible structural combinations for that system is

$$W = n!/n_1!n_2! \ldots n_m! \tag{10}$$

Hence, granting that every n_i is sufficiently great, by Stirling's asymptotic formula for $n!$ we obtain $\log W = \Sigma n_i \log(n_i/n)$, where by putting $f_i = n_i/n$, by analogy to (7) and (9) Boltzmann put

$$S = -nk\Sigma f_1 \log f_1 = -nkH, \tag{11}$$

still another expression for entropy. At least, this formula fared well with the advent of Planck's quantum theory, which explains why Planck, who at first opposed Boltzmann's position, ultimately changed his mind (1897, seventh edn).

To buttress the probabilistic interpretation of entropy, Boltzmann (1896/8) ultimately brought in the ideas of ordered and disordered states. Herman von Helmholtz had already defined (in 1892) entropy as the measure of disorder, an unfortunate connection as disorder certainly cannot be defined analytically. Curiously, this definition has had amazing success: the entry for 'entropy' in *The Encyclopedia of Philosophy* opens with it.

Because the endeavours to systematize the various ways of looking at entropy could not arrive at

a simple, natural explanation of that notion, writers have moved deeper and deeper into purely formal lucubrations, so that Jacques Hadamard in his 1910 review of J. Willard Gibbs's treatise could say that statistical thermodynamics is only mathematics (cited in Georgescu-Roegen 1971). Yet as early as 1882 Helmholtz placed entropy in an accessible cadre as he showed that the internal energy, U, of an isolated system consists of free (or available) energy, F, and of bound (or unavailable) energy measured by TS. Hence, if we represent U by a rectangle of base T, the entropy would indicate the height for separating the *bound* energy. It was with the introduction of the relation $F = U - TS$ that the importance of the singular concept, entropy, was brought to the surface. It was only thereafter that one could translate Clausius's entropy law into

> The free energy of any isolated system continuously degrades into bound energy.

It is this form that pinpoints the reason for the supreme role of entropy in all nature, as has been recognized by great luminaries such as Sir Arthur Eddington and Albert Einstein. Interestingly, Lord Kelvin who first spoke (in 1852) of 'The Universal Tendency in Nature to the Dissipation of Energy', hardly ever used the term 'entropy'. And Walter Nernst, another illuminator of thermodynamics, even decided not to have recourse to it.

We should next recall that just as the foundation of classical thermodynamics was being laid, Herbert Spencer came forth with some tenets that presaged Darwin's own theory. One was that 'the homogeneous is the hotbed of the heterogeneous', which looks like a characterization of living systems. Lord Kelvin (quoted earlier) as well as Helmholtz thus were not prepared to admit that the entropic degradation applies to animated matter, too. Later Henri Bergson even claimed that life opposes that degradation. Of course, life does not violate the entropy law, for as Erwin Schrödinger was to put it not very long ago, a living creature is not an isolated system: it exchanges entropy with its environment. Yet from the fact that such a phenomenon is not impossible thermodynamically, it does not follow at all that it should also exist. That is why several scholars have argued that in nature there must also be at work an anti-entropy principle – *ektropy*, coined by G. Hirth and adopted by Felix Auerbach, or *anti-chance*, Sir Arthur Eddington's term (Georgescu-Roegen 1971). The dissipative structures, recently set forth by Ilya Prigogine (1980) to portray the entropic process specific to living organisms imply as Prigogine recognizes, a new crowning of the Spencerian tenet.

A real imbroglio involving the entropy concept grew from the seminal work of Claude H. (Shannon and Weaver 1948) on the purely technical problem of communication, which is to find out how many distinct sequences (messages) of a given length can be formed by a code, a set of different single signals. For the communication engineer it is totally irrelevant what each message may mean. However, that meaning must be understood by both the originator and the intended receiver. Knowledge thus passes from the former to the latter; while in transit, it is information (a distinction analogous to the heat being thermal energy in transit).

For messages transmitted in a vernacular language, Shannon found that the ratio of messages per letter is given by the same formula as $-H$ in (11) if the f_i's represent the statistical frequencies of the corresponding alphabet. Seeking a name for his new formula (a measure of the efficiency of the code), Shannon accepted the suggestion of John von Neumann: 'entropy'. But the mere coincidence of formulae was not a basis for justifying the terminological transfer. We would not call 'kinetic energy' the second moment of a distribution just because both formulae are a sum of squares: $\sum \eta_i X_i^2$. With that transfer, the concept of entropy started travelling from one domain to another with hardly any discrimination. One now speaks of the income distribution in country A being greater than in B, although the student interested in B will certainly think otherwise. And the reader is dizzied by the frequent phrases in which 'information', 'knowledge', 'negentropy', intervene pell-mell. Further, O, Onicescu suggested that $\sum f_i^2$ can also serve as 'informational energy', which, of course, could not be related to the real entropy. Most important, in a

vignetted article, 'The Bandwagon', Shannon himself protested without delay the use of 'entropy' beyond the domain of technical communication (Georgescu-Roegen 1975).

The idea that the entropic degradation of anything is in fact a 'loss of information' was set forth earlier by a consummate thermodynamicist, G.N. Lewis (*Science*, 1930). But it was E.T. Jaynes who after the spread of Shannon's theorem set out to erect thermodynamics on that basis alone. In spite of its bizarreness, or perhaps because of it, the idea is still running in some circles. So, in his recent primer (*The Second Law*, 1984), P.W. Atkins was in good order to deliberately omit any reference to entropy and information because of the 'muddleheadedness' of the idea that entropy is not a property, of an engine but of the engineer's mind.

While the concept of entropy was thus converted almost at will, a vital issue found no place in thermodynamics, namely, the macroscopic role of matter. Matter is mentioned but only indirectly, as friction. Prigogine (1955) did extend the domain of thermodynamics from closed (impermeable to matter) systems to open systems, but he considered matter only as a vehicle of energy – the heat carried by a red-hot iron, for instance. No one seems to have derived the important object lesson from Gibbs's proof that the interdiffusion of two gases of the *same* temperature increases entropy. The increase is due to the entropic degradation of matter. To fill this lacuna, a new law of thermodynamics states that

Perpetual Motion of the Third Kind is Impossible

Which means that no closed (not to be confused with 'isolated') system can perform work indefinitely at constant rate. The reason is that macroscopic matter also degrades entropically (Georgescu-Roegen 1980).

With its exotic name and its complicated fate even within the evolution of thermodynamics, entropy has become a word of great alluring power. Occasionally, littérateurs have used it manifestly as a selling point, 'Entropy' by Thomas Pynchon in 1960, *Against Entropy* by Michael Frayn (1967). Clausius certainly did not foresee this development from his coinage of the bizarre word.

Entry and Market Structure

B. Curtis Eaton

Entry – and its opposite, exit – have long been seen to be the driving forces in the neoclassical theory of competitive markets. Long-run equilibrium in such a market requires that no potential entrant finds entry profitable, and that no established firm finds exit profitable. In conjunction with the price-taking assumption, the first condition requires that price be no greater than minimum average cost, $\underline{AC}$, and the second that price be no less than $\underline{AC}$. Hence, in equilibrium, price is equal to $\underline{AC}$. There is very little more to the theory of equilibrium in a competitive market than this simple yet powerful story of no-entry and no-exit.

Surprisingly, considerations of entry and potential competition, so central to the economist's view of competitive markets, played almost no role in oligopolistic and monopolistic markets until the work of Bain (1956) and Sylos-Labini (1956) in the mid–1950s. One important strand of the modern literature on entry combines, in essence, their insights into the role of potential competition in oligopolies with Schelling's (1956) ideas on commitment. This essay focuses on this strand of literature.

In reviewing Bain (1956) and Sylos-Labini (1956), Modigliani (1958) proposed what has come to be known as the *limit-output* (more commonly, *limit-price*) model, which is a formalization of one of the key ideas in these books. One version of this model has been the focal point of much of the recent literature on entry. Consider a market for some undifferentiated good, currently served by *one established firm*, in which demand and cost conditions are unchanging over an infinite time horizon. Now suppose that all potential entrants take the established firm's output today, denoted by X, as the output which it will produce tomorrow and forever – the so-called Sylos postulate. Let $\underline{X}$ denote the smallest value of X such that the maximized profit of a representative potential entrant is non-positive. This value, $\underline{X}$, is called the *limit output* (and the corresponding price the *limit price*) because, given the Sylos postulate, there will be no entry if and only if $X \geq \underline{X}$. (We assume for convenience that zero profit does not induce entry.)

Two important insights are already clear. First, potential competition constrains the ability of the established firm to exploit its position of market power since the no-entry condition ($X \geq \underline{X}$) places a lower bound on industry output in long-run equilibrium. Second, by producing at least $\underline{X}$ units of output, the established firm can deter entry. In one case central to the evolution of the literature, entry deterrence is also always profitable.

Suppose that the established firm's average cost function is nowhere upward-sloping, and that the interest rate is not too high. In this situation, the established firm will always choose to deter entry by producing at least $\underline{X}$. There are two sorts of solutions. If the ordinary monopoly output, M, is greater than or equal to $\underline{X}$, then the monopolist will produce M, and we have what we could call *natural monopoly*, in the positive sense of the term. If $M < \underline{X}$, the monopolist produces X to deter entry strategically, a case of *artificial monopoly*. When $M < \underline{X}$ the monopolist must choose between deterring and accommodating entry. Relative to the deterrence strategy – produce $\underline{X}$ today and forever – accommodation produces larger profit for the one established firm today (since today's output will be M) but smaller profit tomorrow and forever (since price will be no higher than the limit price and the established firm's output will be less than $\underline{X}$). If the rate of interest is not too high, it is obvious that the established firm will choose to deter entry.

The essence of both solutions is a message which the established firm wants to communicate to potential entrants. 'If you enter, then my output will be (no smaller than) $\underline{X}$.' This 'deterrence message' has the property that it deters entry – if it is believed. It raises the obvious credibility question, 'Would the established firm really produce the promised output post-entry'? Much of the recent literature on entry has implicitly or

explicitly focused on this question. Four interrelated insights have emerged.

First, to answer the credibility question we can use Schelling's distinction between threats and commitments (1956). The deterrence message is a commitment if, entry having occurred, it is in the established firm's self-interest to produce $\underline{X}$, or if the production of $\underline{X}$ follows automatically. Otherwise the message is a threat and is not credible. To implement this approach we need a model of oligopoly. Given such a model, all interested parties can compute the post-entry equilibrium, providing a direct answer to the credibility question.

Second, by virtue of being there first, the established firm has the opportunity to make *irreversible decisions* which alter its real economic circumstances in any post-entry oligopoly game. These irreversible decisions can sometimes make the established firm a more aggressive competitor post-entry, and therefore serve to make the deterrence message more believable. That is, the established firm has the opportunity to do some things prior to entry which cannot be undone subsequent to entry, and which affect the profitability of entry. It is convenient to refer to these irreversible decisions as *commitments*. As Spence (1977) observed, since the rate at which output is produced is reversible, producing the limit output prior to entry is not a commitment and therefore has no bearing on the credibility of the deterrence message. However, holding the capacity or capital to do so is – provided that it is specific. By acquiring specific capital, the established firm reduces its marginal cost, making it more aggressive in any post-entry oligopoly game. Inventory (analysed by Ware 1985) is a particularly illuminating commitment since it puts the firm in the position of having zero marginal cost post-entry (until its inventory is exhausted).

The third insight, which arises from the attempt to implement the first two, concerns the *form* of the game which established firms and potential entrants play, and the appropriate *equilibrium concept* which this form seems to imply. Even in the simplest of circumstances, any game involving established firms and potential entrants is a *multi-stage game* played out in real time with two important features: (1) commitments, which inevitably involve *sunk costs*, are made in earlier stages of the game; (2) the net revenues which justify these sunk costs are generated only in later stages. As Brander and Spencer (1983) observe, this form is an unavoidable feature of economic reality. Product development costs, for example, must be sunk prior to production; the costs associated with specific capital goods must be sunk prior to production, and so on.

A rational firm must therefore think of commitments in the way it thinks of other investment decisions. In particular, it must form expectations about how decisions with respect to today's commitments will alter its net revenues tomorrow, and thereafter. In the presence of sunk costs, *rational* or *consistent* expectations are a desirable feature of any equilibrium concept. If firms' expectations are not constrained to be rational, then any outcome is possible – that is, given an outcome, there is a set of expectations which will produce it. Rational expectations are then necessary to constrain results. See, for example, the discussions in Eaton and Lipsey (1979, 1980) and Dixit (1980) on this point. Given this view, Selten's (1975) notion of sub-game perfection is the appropriate equilibrium concept in these entry games.

To convey the flavour of modern theories of entry and to see how rational expectations enter the analysis, it is instructive to write down a simple entry game and to consider the way in which one finds the perfect equilibrium. Most of the recent literature on entry has focused on exercises which involve one established firm and one potential entrant, and which are not a great deal more complex than the following illustration.

Consider an entry game played in three stages. In stage 1, firm 1 (the established firm) chooses the value of some commitment, c_1. In stage 2, knowing the value of c_1, which firm 1 chose in stage 1, firm 2 chooses a value for its commitment, c_2. By appropriate choice of units, we can interpret c_1 and c_2 as costs, which once they are incurred are sunk. These sunk costs might, for example, be expenditures on advertising or on cost-reducing research and development. In stage 3, the two firms play a market game in

which goods are produced and sold and the net revenues which justify the upstream sunk costs are realized.

To find the perfect equilibrium of this game we work backwards.

Stage 3 Given an oligopoly model which determines the equilibrium of the market game, the net revenue to each firm in stage 3 is determined by c_1 and c_2. Denote these net-revenue functions by $\prod_1(c_1, c_2)$ and $\prod_2(c_1, c_2)$ If, for example, the oligopoly model is the Cournot model, then in stage 3 each firm chooses its own quantity to maximize its revenues minus its *avoidable* costs. The net-revenue functions are simply revenues minus avoidable costs in the Cournot equilibrium.

Stage 2 If firm 2 is to have rational expectations, it must know $\prod_2(c_1, c_2)$. This, of course, means that it knows the oligopoly model which determines the equilibrium of the market game. In stage 2, knowing its net-revenue function and the value of c_1, firm 2 chooses c_2 to maximize $[\prod_2(c_1, c_2) - c_2]$. The solution to this maximization problem determines c_2 as a function of c_1 : $c_2 = g(c_1)$.

Stage 1 Rational expectations for firm 1 means that it knows both $g(c_1)$ and $\prod_1(c_1, c_2)$. In stage 1 it chooses c_1 to maximize $[\prod_1(c_1, c_2) - c_2]$ subject to $c_2 = g(c_1)$. The only endogenous variable in this maximization problem is c_1 and the solution to it therefore determines a value for c_1 say c^*_1. Firm 2 then chooses $\Pi_1(c^*_1, c^*_2)$, and in the third stage of the game the firms realize $\Pi_2(c^*_1, c^*_2)$ and $c^* = g(c^*)$.

In this sort of game the established firm may or may not be able to deter entry, and if it is able, it may or may not choose to. Duopoly solutions will, however, be asymmetric. The established firm will rig the duopoly market structure to its own advantage.

Using this approach, or one that is in the spirit of this one, the recent literature on entry has focused on many of the commitments which established firms can and, indeed, must make. Advertising (Cubbin 1981), brand proliferation (Schmalensee 1978), the location of retail outlets (Eaton and Lipsey 1979), patenting (Gilbert and Newbery 1982), learning-by-doing (Spence 1981), the durability of specific capital (Eaton and Lipsey 1980), the exercise of monopsony power (Salop and Scheffman 1983) and, of course, specific capital (Spence 1977; Dixit 1980 and Ware 1984) are just some of the vehicles for commitment which have been considered.

This rich set of games and possible solutions brings us to the fourth insight in this literature. Implicit in this way of thinking about oligopolistic markets, and the role which entry plays in those markets, is much more than a theory of how one established firm strategically positions itself with respect to one potential entrant. There is, in this paradigm, a theory of market structure, a theory which remains largely unexplored.

Envelope Theorem

Eugene Silberberg

Abstract

The envelope theorem appeared in economics following the 1931 Viner–Wong diagram (incorrectly drawn in the original paper). This famous paper indicated that, starting at some minimum cost input combination, the change of average cost when output changed was the same whether or not other inputs were allowed to vary or were held fixed. This puzzling result remained mostly a curiosity until the 1970s when, with the use of a generalization of this diagram, the modern theory of duality was developed. This new approach to comparative statics provided a clearer explanation for the appearance of refutable implications in maximization models.

The origin of this famous theorem is the discussion between Jacob Viner (1931) and his draughtsman Y.K. Wong concerning the relationship between short- and long-run average cost curves. Viner had apparently reasoned that since in the long run average costs should be at a minimum, the long-run average cost (LRAC) curve should not only always be below the short-run average cost (SRAC) curves, but should also pass through the minimum points of each short-run curve. Wong pointed out the impossibility of this joint occurrence, and Viner opted to draw the long-run curve through the minimum points, thereby necessarily passing above sections of the short run curves. It was also puzzling (in the now corrected diagram) that at the point of tangency between the LRAC and a SRAC, the rate of change of average cost with respect to output was the same when capital was fixed as when it was allowed to vary. The puzzle was solved by Samuelson (1947), who showed in a general way why the long-run curve would be the 'envelope' curve to the set of short-run curves. Perhaps the most surprising result of all was that this seeming mathematical curiosity turned out to be the fundamental basis for the development of refutable comparative statics implications in economics.

Unconstrained Maximization Models

The most general comparative statics model with explicit maximizing behaviour is *maximize* $y = f(x, \alpha)$ subject to $g(x, \alpha) = 0$, where $x = (x_1,..., x_n)$ is a vector of decision variables, $\alpha = (\alpha_1,..., \alpha_m)$ is a vector of parameters (though for simplicity, we treat a as a scalar in the discussion below), and g(·) represents one or more constraints. Models at this level of generality, however, imply no refutable implications and are hence largely uninteresting. In particular, there are never refutable implications for parameters that enter the constraint (see, for example, Silberberg and Suen 2000). We therefore initially restrict the

analysis to models of unconstrained maximization:

$$maximize\ y = f(x, \alpha) \tag{1}$$

The necessary first-order conditions (NFOC) are

$$f_i(x, \alpha) = 0\ \ i = 1, ..., n \tag{2}$$

The sufficient second-order conditions (SSOC) are that the *Hessian* matrix $\mathbf{H} = (f_{ij})$ is negative definite. Alternatively, the principal minors of order (size) k of the Hessian determinant $H = |f_{ij}|$ have sign $(-1)^k$. Assuming the sufficient second-order conditions hold, we can in principle 'solve' for the n explicit choice functions $x = x^*(\alpha)$. Of course, since these choice functions are the result of solving the NFOC simultaneously, each individual x_i is a function of *all* the parameters, not just ones which might appears in some f_i.

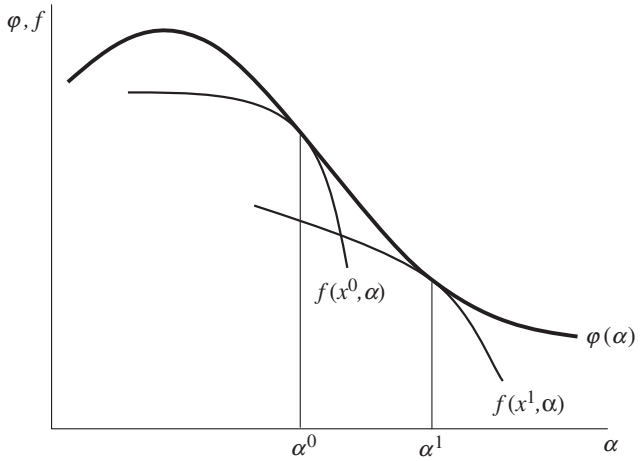
Substituting the x_i^*'s into the objective function yields the *indirect objective function* $\phi(\alpha) = f(x^*(\alpha), \alpha)$, the maximum value of f for given α. Since $\phi(\alpha)$ is by definition a maximum value, $\phi(\alpha) \geq f(x, \alpha)$, but $\phi(\alpha) = f(x, \alpha)$ when $x = x^*$. In Fig. 1, a typical $\phi(\alpha)$ is plotted. For an arbitrary α^0, an $x^0 = x^*(\alpha^0)$ is implied. Consider the behaviour of $f(x, \alpha)$ when the x_i's are held fixed at x^0 as opposed to when they are variable. When $\alpha = \alpha^0$, the 'correct' x_i's are chosen, and therefore $\phi(\alpha) = f(x^0, \alpha)$ at that one point. However, both to the left and to the right of α^0, the 'wrong' (that is non-maximizing) x_i's are chosen, and, since $\phi(\alpha)$ is the *maximum* value of f for given α, $f(x^0, \alpha) \leq \phi(\alpha)$ in any neighbourhood around α^0. This implies that ϕ and f must be tangent at α^0 - (assuming differentiability), and, moreover, f must be either more concave or less convex than ϕ there. Since this must happen for arbitrary α, similar tangencies occur at other values of α. It is apparent from Fig. 1 that $\phi(\alpha)$ is the *envelope* of the $f(x_1, x_2, \alpha)$'s for each α. What surprised most researchers was the discovery that all comparative statics theorems in maximization models are in fact consequences of the relative curvatures of ϕ and f.

From the above discussion, the function $F(x, \alpha) = f(x, \alpha) - \varphi(\alpha)$ has a maximum of zero, with respect to both x and α. Thus we consider the *primal–dual* model

$$maximize\ F(x, \alpha) = f(x, \alpha) - \phi(\alpha) \tag{3}$$

where the maximization runs over x and also α. (In the latter instance, we ask, for given x_i's, what values of the parameters would make these x_i's the maximizing values?) The NFOC with respect to x are the same as in the original model. With respect to α, the NFOC yield the famous 'envelope theorem' which is the tangency of f and ϕ in Fig. 1:

$$F_\alpha = f_\alpha - \phi_\alpha = 0 \tag{4}$$



Envelope Theorem, Fig. 1

In the α dimensions, the second-order conditions are simply

$$F_{\alpha\alpha} = f_{\alpha\alpha} - \phi_{\alpha\alpha} \leq 0. \tag{5}$$

This inequality says that in the α dimensions, f is relatively more concave than ϕ. (When α is a vector, this second-order condition is that the Hessian matrix ($F_{\alpha\alpha}$) is negative semi-definite.)

This is the fundamental geometrical property that underlies all comparative statics relationships. The NFOC (4) are identities when $x = x^*$. That is,

$$\phi_\alpha(\alpha) \equiv f_\alpha(x^*(\alpha), \alpha) \tag{6}$$

Differentiating with respect to α,

$$\phi_{\alpha\alpha} \equiv \sum_1^n f_{\alpha i} \frac{\partial x_i^*}{\partial \alpha} + f_{\alpha\alpha} \tag{7}$$

Rearranging terms, using (5) and invariance to the order of differentiation,

$$\phi_{\alpha\alpha} - f_{\alpha\alpha} \equiv \sum_1^n f_{i\alpha} \frac{\partial x_i^*}{\partial \alpha} \geq 0 \tag{8}$$

This is the fundamental relation of comparative statics. From it, we can derive Samuelson's famous 'conjugate pairs' theorem that refutable implications occur in maximization models when and only when a parameter enters one and only one firstorder condition. For in that case, where say α enters only $f_i = 0, f_{j\alpha} = 0, j \neq i$, and so (8) reduces to one term:

$$f_{i\alpha} \frac{\partial x_i^*}{\partial \alpha} \geq 0 \tag{9}$$

In this case we can say that the response of x_i is in the same direction as the disturbance to the equilibrium (or, in the case of minimization models, in the opposite direction). For example, consider the profit-maximization model

$$\begin{aligned} \textit{maximize } \pi &= f(x, w, p) \\ &= p\theta(x_1, \ldots, x_n) - \sum w_i x_i \end{aligned}$$

Each parameter w_i enters only the ith NFOC, and $f_{x_i w_i} = -1$, so that (9) yields the slope property $\partial x_i^* / \partial w_i \leq 0$; the factor demand functions are downward sloping in their own price.

The envelope theorem also yields the non-intuitive 'reciprocity' conditions. Suppose there are two parameters α and β. Then from invariance of second partial derivatives to the order of differentiation (Young's theorem), $\phi_{\alpha\beta} = \phi_{\beta\alpha}$. Using Eq. (6) above,

$$\sum f_{i\alpha} \frac{\partial x_i^*}{\partial \beta} = \sum f_{i\beta} \frac{\partial x_i^*}{\partial \alpha} \tag{10}$$

When the objective function contains a linear expression such as in the profit maximization model, that is, $w_1 x_1 + \ldots + w_n x_n$, we have $f_{x_i w_i} = -1$ and $f_{x_i w_i} = 0, i \neq j$. In that case, (11) reduces to the simple expression $\frac{\partial x_i^*}{\partial w_j} = \frac{\partial x_j^*}{\partial w_i}$. This result also occurs in consumer theory for the Hicksian demands.

Constrained Maximization Models

Consider now the general comparative statics model with constraints, *maximize* $y = f(x, \alpha)$ subject to $g(x, \alpha) = 0$, where $g(\cdot)$ represents one or more constraints. Assuming just one constraint for the moment, the Lagrangian for this model is $L = f(x, \alpha) + \lambda g(x)$, producing the NFOC

$$L_i = f_i(x, \alpha) + \lambda g_i(x, \alpha) = 0 \; i = 1, \ldots, n \tag{11}$$

$$L_\lambda = g(x, \alpha) = 0 \tag{12}$$

Assuming the SSOC, we can in principle 'solve' for the $n + 1$ explicit choice functions $x = x^*(\alpha)$ and $\lambda^*(\alpha)$. We derive the indirect objective function as before by substituting the x_i^*'s into the objective function producing $\phi(\alpha) = f(x^*(\alpha), \alpha)$, the maximum value of f for given α, now also subject to the constraint. Proceeding as above, since $\phi(\alpha)$ is by definition a maximum value, $\phi(\alpha) \geq f(x, \alpha)$, but $\phi(\alpha) = f(x, \alpha)$ when $x = x^*$. Thus the function $F(x, \alpha) = f(x, \alpha) - \phi(\alpha)$ has a (constrained) maximum of zero, with respect to both x and α. Thus we consider the *primal–dual* model

$$\text{maximize } F(x,\alpha) = f(x,\alpha) - \phi(\alpha) \tag{13}$$

$$\text{subject to } g(x,\alpha) = 0 \tag{14}$$

where the maximization runs over x and also α. The Lagrangian for this model is

$$L = f(x,\alpha) - \phi(\alpha) + \lambda g(x,\alpha) \tag{15}$$

The first-order conditions with respect to x are the same as in the original model. With respect to α, we get the envelope theorem in its most general form,

$$\phi_\alpha = L_\alpha = f_\alpha + \lambda g_\alpha \tag{16}$$

At this level of generality, it is not possible to generate any useful curvature properties of $\phi(\alpha)$. However, consider the case where α does not enter any constraint. In that case, $g_\alpha \equiv 0$ and the NFOC reduce to (4) above, that is, $F_\alpha = f_\alpha - \phi_\alpha = 0$. Moreover, when a does not enter the constraint, the primal–dual model is *an unconstrained maximization in* α. Hence in the α dimensions, the second-order conditions are as before:

$$F_{\alpha\alpha} = f_{\alpha\alpha} - \phi_{\alpha\alpha} \leq 0. \tag{17}$$

Thus in this important class of models, the comparative statics are identical to the models with no constraints. We obtain the inequalities (8) and (9) in the same manner as above.

Consider now an important class of models having the structure maximize $f(x)$ subject to $g(x) = k$, where we suppress all parameters except k, which is the focus of this analysis. The Lagrangian for this model is $L = f(x) + \lambda(k - g(x))$; assuming the NFOC and SSOC are valid, we solve for the explicit choice functions $x = x^*(k)$ and $\lambda^*(k)$. The indirect objective function is $\phi(k) = f(x^*(k))$, the maximum value of f for given k. The envelope theorem (16) yields

$$\phi_k = \lambda^*(k) \tag{18}$$

Suppose the function f represents the value of output, and the constraint describes a limitation on that value due to the scarcity of some resource, measured by the value of k. Then the Lagrange multiplier imputes a 'shadow price', a marginal evaluation of that resource, since $\lambda^*(k)$ is the rate of change of the maximum value of output with respect to a change in the availability of that resource. This is a very widespread use of Lagrangian analysis in economics. For example, the fundamental model from which we derive the cost curves for a firm is, *minimize* $C = \Sigma w_i x_i$ subject to $f(x) = y$, where y is a parameter. Using (17), the Lagrange multiplier in this model is the marginal cost function $\partial C^*/\partial y = \lambda^*(w, y)$.

To further show the powerful nature of this analysis, consider the two-factor, two-goods model that plays an important part of international trade theory:

$$\begin{aligned} &\text{maximize } NNP = p_1 y_1 + p_2 y_2 \\ &\text{subject to} \ : \\ &y_1 = f^1(L_1, K_1) \; y_2 = f^2(L_2, K_2) \; L_1 + L_2 \\ &\quad = L \; K_1 + K_2 = K \end{aligned}$$

where f^1 and f^2 are production functions using labour (L) and capital (K) in each of two industries with outputs y_1 and y_2; output prices p_1 and p_2 and labour and capital endowments L and K are parametric. We can enumerate the salient properties of this model just by inspection, using the above results. The Lagrangian for this model is $L = p_1 y_1 + p_2 y_2 + \lambda_1(f^1(L_1, K_1) - y_1) + \lambda_2(f^2(L_2, K_2) - y_2) + \lambda_L(L - L_1 - L_2) + \lambda_K(K - K_1 - K_2)$. Assuming the NFOC and SSOC hold, we solve the NFOC for the output supply functions $y_1^*(p_1, p_2, L, K)$ and $y_2^*(p_1, p_2, L, K)$, and the Lagrange multipliers, particularly $\lambda_L^*(p_1, p_2, L, K)$ and $\lambda_K^*(p_1, p_2, L, K)$. Substituting $y_1^*(\cdot)$ and $y_2^*(\cdot)$ into the objective function, we get the maximum value of *NNP* for given prices and resource constraints, $\phi(p_1, p_2, L, K)$. Since prices enter the objective function only, and in the classic linear form, (9) immediately yields the envelope relations $\phi_{pi} = y_i^*(\cdot)$. We also note $\phi_L = \lambda_L^*(\cdot)$ *and* $\phi_K = \lambda_K^*(\cdot)$. The primal–dual model is, *maximize* $F = p_1 y_1 + p_2 y_2 - \phi(p_1, p_2, L, K)$ subject to the same constraints above. Since p_1 and p_2 do not enter the constraints, F is concave in p_1 and p_2. Since the first two terms are linear and ϕ enters negatively, ϕ is convex in p_1 and p_2, and thus $\phi_{p_i p_i} = \partial y_i^*/p_i > 0$; the supply curves are upward

E

sloping. Furthermore, from (17), the Lagrange multipliers λ_L^* and λ_K^* are the imputed values of labour and capital. If an additional increment of labour, say, became available, λ_L^* would represent its marginal value product, and hence its implied wage in a competitive economy. Without further assumptions (for example, concavity of the production functions), we cannot determine a sign for how these imputed values change when the resource endowment changes: $\partial \lambda_L^* / \partial L / 0$. The reciprocity relationships are straightforward: $\phi_{p_1 p_2} = \partial \lambda_1^* / \partial p_2 = \partial \lambda_2^* / \partial p_1 = \phi_{p_2 p_1}$, and similarly, $\phi_{LK} = \partial \lambda_L^* / \partial K = \partial \lambda_K^* / \partial L = \phi_{KL}$. We also find $\phi_{p_1 L} = \partial \lambda_1^* / \partial L = \partial \lambda_L / \partial p_1 = \phi_{L p_1}$, and so on. It seems unlikely that Jacob Viner could have imagined what the corrected version of his diagram would eventually lead to!

Environmental Economics

Robert N. Stavins

Abstract

An overview is provided of the economics of environmental policy, including the setting of goals and targets, notably the Kaldor–Hicks criterion and the related method of assessment known as benefit–cost analysis. Also reviewed are the means of environmental policy, that is, the choice of specific policy instruments, featuring an examination of potential criteria for assessing alternative instruments, with focus on cost-effectiveness. The theoretical foundations and experiential highlights of individual instruments are reviewed, including conventional command-and-control mechanisms and market-based instruments.

Q5

The fundamental theoretical argument for government activity in the environmental realm is that pollution is an externality – an unintended consequence of market decisions which affect individuals other than the decision maker. Providing incentives for private actors to internalize the full costs of their actions was long thought to be the theoretical solution to the externality problem. The primary advocate of this view was Arthur Pigou, who in *The Economics of Welfare* (1920) proposed that the government should impose a tax

on emissions equal to the cost of the related damages at the efficient level of control.

A response to the Pigouvian perspective was provided by Ronald Coase in 'The problem of social cost' (1960). Coase demonstrated that, in a bilateral bargaining environment with no transaction costs, wealth or income effects, or third-party impacts, two negotiating parties will reach socially desirable agreements, and the overall amount of pollution will be independent of the assignment of property rights. At least some of the specified conditions are unlikely to hold for most environmental problems. Hence, private negotiation will not – in general – fully internalize environmental externalities.

Criteria for Environmental Policy Evaluation

More than 100 years ago Vilfredo Pareto (1896) enunciated the well-known normative criterion for judging whether a social change makes the world better off: a change is *Pareto efficient* if at least one person is made better off and no one is made worse off. This criterion has considerable normative appeal, but virtually no public policies meet the test. Nearly 50 years later Nicholas Kaldor (1939) and John Hicks (1939) postulated a more pragmatic criterion that seeks to identify 'potential Pareto improvements': a change is welfare-improving if those who gain from the change could – in principle – fully compensate the losers, with (at least) one gainer still being better off.

The Kaldor–Hicks criterion – a test of whether total social benefits exceed total social costs – is the theoretical foundation for the use of the analytical device known as benefit–cost (or net present value) analysis. If the objective is to maximize the difference between benefits and costs (net benefits), then the related level of environmental protection (pollution abatement) is defined as the efficient level of protection:

$$\max_{\{q_i\}} \sum_{i=1}^{N} [B_i(q_i) - C_i(q_i)] \rightarrow q_i^* \qquad (1)$$

where q_i is abatement by source i ($i = 1$ to N), $B_i(\cdot)$ is the benefit function for source i, $C_i(\cdot)$ is the cost function for the source, and q_i^* is the efficient level of protection (pollution abatement). The key necessary condition that emerges from the maximization problem of Eq. 1 is that marginal benefits be equated with marginal costs (on the assumption of convexity of the respective functions).

The Kaldor–Hicks criterion is clearly more practical than the strict Pareto criterion, but its normative standing is less solid. Some have argued that other factors should be considered in a measure of social well-being, and that criteria such as distributional equity should trump efficiency considerations in some collective decisions (Sagoff 1993). Many economists would agree with this assertion, and some have noted that the Kaldor–Hicks criterion should be considered neither a necessary nor a sufficient condition for public policy (Arrow et al. 1996).

Benefit–Cost Analysis of Environmental Regulations

The soundness of empirical benefit–cost analysis rests upon the availability of reliable estimates of social benefits and costs, including estimates of the social discount rate. The present value of net benefits (PVNB) is defined as:

$$PVNB = \sum_{t=0}^{T} \left\{ (B_t - C_t) \cdot (1 + \mathrm{r})^{-t} \right\} \qquad (2)$$

where B_t are benefits at time t, C_t are costs at time t, r is the discount rate, and T is the terminal year of the analysis. A positive PVNB means that the policy or project has the potential to yield a Pareto improvement (meets the Kaldor–Hicks criterion). Thus, carrying out benefit–cost or 'net present value' (NPV) analysis requires discounting to translate future impacts into equivalent values that can be compared. In essence, the Kaldor–Hicks criterion provides the rationale both for benefit–cost analysis and for discounting (Goulder and Stavins 2002).

Choosing the discount rate to be employed in an analysis can be difficult, particularly where impacts are spread across a large number of years involving more than a single generation. In

theory, the social discount rate could be derived by aggregating the individual time preference rates of all parties affected by a policy. Evidence from market behaviour and from experimental economics indicates that individuals may employ lower discount rates for impacts of larger magnitude, higher discount rates for gains than for losses, and rates that decline with the time span being considered (Cropper et al. 1994; Cropper and Laibson 1999). In particular, there has been support for the use of hyperbolic discounting and similar approaches with declining discount rates over time (Ainslie 1991; Weitzman 1994, 1998), but most of these approaches are subject to time inconsistency.

The costs of Environmental Regulations

In the environment context, the economist's notion of cost (or, more precisely, opportunity cost) is a measure of the value of whatever must be sacrificed to prevent or reduce the risk of an environmental impact. A full taxonomy of environmental costs ranges from the most obvious to the least direct (Jaffe et al. 1995).

Methods of direct compliance cost estimation, which measure the costs to firms of purchasing and maintaining pollution-abatement equipment plus costs to government of administering a policy, are acceptable when behavioural responses, transitional costs, and indirect costs are small. Partial and general equilibrium analysis allows for the incorporation of behavioural responses to changes in public policy. Partial equilibrium analysis of compliance costs incorporates behavioural responses by modelling supply and/or demand in major affected markets, but assumes that the effects of a regulation are confined to one or a few markets. This may be satisfactory if the markets affected by the policy are small in relation to the overall economy; but, if an environmental policy is expected to have large consequences for the economy, general equilibrium analysis is required, such as through the use of computable general equilibrium models (Hazilla and Kopp 1990; Conrad 2002). The potential interaction of abatement costs with pre-existing taxes indicates the importance of employing general equilibrium models for comprehensive cost analysis. Revenue recycling (using emission tax or auctioned permit revenues to reduce distortionary taxes) can make the costs of pollution control significantly less than they would otherwise be (Goulder 1995).

In a retrospective examination of 28 environmental and occupational safety regulations, Harrington et al. (2000) found that 14 cost estimation analyses had produced ex ante cost estimates that exceeded actual ex post costs, apparently due to technological innovation stimulated by market-based instruments (see below).

The Benefits of Environmental Regulations

Protecting the environment usually involves active employment of capital, labour, and other scarce resources. The benefits of an environmental policy are defined as the sum of individuals' aggregate willingness to pay (WTP) for the reduction or prevention of environmental damages or individuals' willingness to accept (WTA) compensation to tolerate such environmental damages. In theory, which measure of value is appropriate for assessing a particular policy depends upon the related assignment of property rights, the nature of the status quo, and whether the change being measured is a gain or a loss; but under a variety of conditions the difference between the two measures may be expected to be relatively small (Willig 1976). Empirical evidence suggests larger than expected differences between willingness to pay and willingness to accept (Fisher et al. 1988). Theoretical explanations include psychological aversion to loss and poor substitutes for environmental amenities (Hanemann 1991).

The benefits people derive from environmental protection can be categorized as (*a*) related to human health (mortality and morbidity), (*b*) ecological (both market and non-market), or (*c*) materials damage. The distinction between use value and non-use value is critical. In addition to the direct benefits (use value) people receive through protection of their health or through use of a natural resource, they derive passive or non-use value from environmental quality, particularly in the ecological domain. For example, an individual may value a change in an environmental good because she wants to preserve the good for her

heirs (bequest value). Still other people may envision no current or future use by themselves or their heirs, but still wish to protect the good because they believe it should be protected or because they derive satisfaction from simply knowing it exists (existence value).

How much would individuals sacrifice to achieve a small reduction in the probability of death during a given period of time? How much compensation would individuals require to accept a small increase in that probability? These are reasonable economic questions because most environmental regulations result in very small changes in individuals' mortality risks. Hedonic wage studies, averted behaviour, and contingent valuation (all discussed below) can provide estimates of marginal willingness to pay or willingness to accept related to small changes in mortality risk, and such estimates can be normalized as the 'value of a statistical life' (VSL).

The VSL is *not* the value of an individual life, whether in ethical or technical, economic terms. Rather it is simply a convention:

$$VSL = \frac{MWTP \text{ or } MWTA \text{ (from hedonic wage or } CV)}{Small \text{ risk change}} \tag{3}$$

where *MWTP* and *MWTA*, respectively, refer to marginal willingness to pay and marginal willingness to accept. For example, if people are willing, on average, to pay \$12 for a risk reduction from 5 in 500,000 to 4 in 500,000, Eq. 3 would yield:

$$VSL = \frac{\$12}{0.000002} = \$6,000,000 \tag{4}$$

Thus, VSL quantifies the aggregate amount that a group of individuals are willing to pay for small reductions in risk, standardized (extrapolated) for a risk change of 1.0. It is not the economic value of an individual life because the VSL calculation does not signify that an individual would pay \$6 million to avoid (certain) death this year, or accept (certain) death this year in exchange for \$6 million.

Revealed Preference Methods of Environmental Benefit Estimation

The *averting behaviour method*, in which values of willingness to pay are inferred from observations of people's behavioural responses to changes in environmental quality, is grounded in the household production function framework (Bockstael and McConnell 1983). People sometimes take actions to reduce the risk (averting behaviour) or lessen the impacts (mitigating behaviour) of environmental damages, for example by purchasing water filters or bottled water. In theory, people's perceptions of the cost of averting behaviour and its effectiveness should be measured (Cropper and Freeman 1991), but in practice actual expenditures on averting and mitigating behaviours are typically employed. An additional challenge is posed by the necessity of disentangling attributes of the market good or service.

Recreational activities represent a potentially large class of benefits that are important in assessing policies affecting the use of public lands. The models used to estimate recreation demand fall within the class of household production models. *Travel cost models* (or Hotelling–Clawson–Knetsch models) use information about time and money spent visiting a site to infer the value of that recreational resource (Bockstael 1996). The simplest version of the method involves one site and uses data from surveys of users from various geographic origins, together with estimates of the cost of travel and opportunity cost of time, to infer a demand function relating the number of trips to the site to a function of people's willingness to pay for the experience. *Random utility models* explicitly model the consumer's decision to choose a particular site from among recreation locations, assessing the probability of visiting each location. Such models can be used to value changes in environmental quality by comparing decisions to visit alternative sites (Phaneuf and Smith 2004).

All recreation demand models share limitations. First, the valuation of costs depends on estimates of the opportunity cost of (leisure) time, which is notoriously difficult to estimate. Also, most trips to a recreation site are part of a

multi-purpose experience. In addition, random utility models rely on people's perceptions of environmental quality changes. Finally, like all revealed-preference approaches, recreation demand models can be used to estimate use value only; non-use value cannot be examined.

An alternative approach to assessing people's willingness to pay for recreational experiences is to draw on evidence from *private options to use public goods*. This approach also fits within the household production framework, and is based upon the notion of estimating the derived demand for a privately traded option to utilize a freely available public good. In particular, the demand for state fishing licences has been used to infer the benefits of recreational fishing. Using panel data on fishing license sales and prices, combined with data on substitute prices and demographic variables, Bennear et al. (2005) estimated a licence demand function from which the expected benefits of a recreational fishing day were derived.

Hedonic pricing methods are founded on the proposition that people value goods in terms of the bundles of attributes that constitute those goods. *Hedonic property value methods* employ data on residential property values and home characteristics, including structural, neighbourhood, and environmental quality attributes (Palmquist 2003). By regressing the property value on key attributes, the hedonic price function is estimated:

$$P = f\left(\underset{\sim}{x}, \underset{\sim}{z}, e\right) \tag{5}$$

where P = housing price (includes land); $\underset{\sim}{x}$ = vector of structural attributes; $\underset{\sim}{z}$ = vector of neighbourhood attributes; and e = environmental attribute of concern.

From the estimated hedonic price function of Eq. 5, the marginal implicit price of any attribute, including environmental quality, can be calculated as the partial derivative of the housing price with respect to the given attribute:

$$\frac{\partial P}{\partial e} = \frac{\partial f(\cdot)}{\partial e} = P_e \tag{6}$$

This marginal implicit price, P_e, measures the aggregate marginal willingness to pay for the attribute in question. For purposes of benefit estimation, the demand function for the attribute is required, and so it is necessary to examine how the marginal implicit price of the environmental attribute varies with changes in the quantity of the attribute and other relevant variables. If the hedonic price Eq. 5 is nonlinear, then fitted values of P_e can be calculated as e is varied, and a second- stage equation can be estimated:

$$\widehat{P}_e = g\left(e, \underset{\sim}{y}\right) \tag{7}$$

where $\widehat{P}_e$ = the fitted value of the marginal implicit price of e from the first-stage equation; and $\underset{\sim}{y}$ = a vector of factors that affect marginal willingness to pay for e, including buyer characteristics.

Equation 7, above, has been interpreted as the demand function for the environmental attribute, from which benefits (consumers surplus) can be estimated in the usual way; but there are problems. Most important among these is the question of whether a demand function has actually been estimated, since environmental quality may affect both the demand for housing and its supply, raising the classic identification problem. In addition, informational asymmetries may distort the analysis. Also, because the hedonic property method is based on analysis of marginal changes, it should not be applied to analysis of policies with large anticipated effects.

A related benefit-estimation technique is the *hedonic wage method*, based on the reality that individuals in well-functioning labour markets make trade-offs between wages and risk of on-the-job injuries (or death). A job is a bundle of characteristics, including its wage, responsibilities and risk, among others factors. Two jobs that require the same skill level but have different risks of on-the-job mortality will pay different wages. On the labour supply side, employees tend to require extra compensation to accept jobs with greater risks; and on the labour demand side, employers are willing to offer higher wages to attract workers to riskier jobs. Hence, labour market data on wages and job characteristics can be used to estimate people's marginal implicit price

of risk, that is, their valuation of risk. By regressing the wage on key attributes, the hedonic price function is estimated:

$$W = h\left(\underline{x}, r\right) \tag{8}$$

where $W =$ wage (in annual terms); $\underline{x} =$ vector of worker and job characteristics; and $r =$ mortality risk of job.

The marginal implicit price of risk is calculated as the partial derivative of the annual wage with respect to the measured mortality risk:

$$\frac{\partial W}{\partial r} = \frac{\partial h(\cdot)}{\partial r} = W_r \tag{9}$$

This marginal implicit price of risk is the average annual income necessary to compensate a worker for a marginal change in risk throughout the year, and it varies with the level of risk.

Many of the issues that arise with the hedonic property value method have parallels here. First, there is the possibility of simultaneity: causality between risk and wages can run in both directions. Also, if individuals' perceptions of risk do not correspond with actual risks, then the marginal implicit price of risk calculated from a hedonic wage study will be biased, and imperfections in labour markets (less than perfect mobility) can cause further problems.

Direct application of the method in the environmental realm is limited to occupational (as opposed to environmental) exposures and risks. Yet hedonic wage methods are of considerable importance in the environmental policy realm, because the results from hedonic wage studies have frequently been used through 'benefit transfer' to infer the VSL. In such applications, the hedonic wage method brings with it possible bias, because studies typically focus on risky occupations, which may attract workers who are systematically less risk-averse.

Standard economic theory would suggest that younger people would have higher values for risk reduction because they have a longer expected life remaining before them and thus a higher expected lifetime utility (Moore and Viscusi 1988; Cropper and Sussman 1990). In contrast, some models and empirical evidence suggest that older people may in fact have a higher demand for reducing mortality risks than younger people, and that the value of a life may follow an 'inverted-U' shape over the life cycle, with its peak during mid-life (Shepard and Zeckhauser 1982; Mrozek and Taylor 2002; Viscusi and Aldy 2003; Alberini et al. 2004).

E

Stated Preference Methods of Environmental Benefit Estimation

In the best known stated preference method, *contingent valuation* (CV), survey respondents are presented with scenarios that require them to trade off, hypothetically, something for a change in an environmental good or service (Mitchell and Carson 1989; Boyle 2003). The simplest approach is to ask people for their maximum willingness to pay, but as there are few real markets in which individuals are actually asked to generate their reservation prices, this method is considered unreliable. In a bidding game, the researcher begins by stating a willingness-to-pay number, asks for a yes–no response, and then increases or decreases the amount until indifference is achieved. The problem with this approach is starting-point bias. A related approach is the use of a payment card shown to the respondent, but the range of WTP on the card may introduce bias, and the approach cannot be used with telephone surveys. Finally, the referendum (discrete choice) approach is favoured by researchers. Each respondent is offered a different WTP number, to which a simple yes–no response is solicited.

The primary advantage of contingent valuation is that it can be applied to a wide range of situations, including use as well as non-use value; but potential problems remain. Respondents may not understand what they are being asked to value. This may introduce greater variance, if not bias, in responses. Likewise, respondents may not take the hypothetical market seriously because no budget constraint is imposed. This can increase variance and bias. Yet if the scenario is 'too realistic,' strategic bias may be expected to show up in responses. Finally, the 'warm glow effect' may plague some stated preference surveys: people

may purchase moral satisfaction with large but unreal statements of their willingness-to-pay (Andreoni 1995).

The 1989 Exxon Valdez oil spill off the coast of Alaska led to massive litigation, and resulted in the most prominent use ever of the concept of non-use value and the method of contingent valuation for its estimation. The result was a symposium sponsored by the Exxon Corporation attacking the CV method (Hausman 1993), and the subsequent creation of a government panel – established by the National Oceanic and Atmospheric Administration (NOAA) and chaired by two Nobel laureates in economics – to assess the scientific validity of the CV method. The NOAA panel concluded that 'CV studies can produce estimates reliable enough to be the starting point of a judicial process of damage assessment, including lost passive (non-use) values' (Arrow et al. 1993, p. 4610). The panel offered its approval of CV methods subject to a set of best-practice guidelines.

It is important to distinguish between legitimate methods of benefit estimation and approaches sometimes encountered in the policy process that do not measure willingness-to-pay or willingness-to-accept. Frequently misused techniques include: (*a*) employing, as proxies for the benefits of a policy, estimates of the 'cost avoided' by not using the next most costly means of achieving the policy's goals; (*b*) 'societal revealed preference' models, which seek to infer the benefits of a proposed policy from the costs of previous regulatory actions; and (*c*) cost-of-illness or human-capital measures which estimate explicit market costs resulting from changes in morbidity or mortality. Because none of these approaches provides estimates of WTP or WTA, these techniques do not provide valid measures of economic benefits.

Choosing Instruments: The Means of Environmental Policy

Even if the goals of environmental policies are given, economic analysis can bring insights to the assessment and design of environmental policies. One important criterion is *cost-effectiveness*, defined as the allocation of control among sources that results in the aggregate target being achieved at the lowest possible cost, that is, the allocation which satisfies the following cost-minimization problem:

$$\min_{\{r_i\}} C = \sum_{i=1}^{N} c_i(r_i) \tag{10}$$

$$s.t. \sum_{i=1}^{N} [u_i - r_i] \leq E \tag{11}$$

$$and\ 0 \leq r_i \leq u_i \tag{12}$$

where r_i = reductions in emissions (abatement or control) by source i ($i = 1$ to N); $c_i(r_i)$ = cost function for source i; C = aggregate cost of control; u_i = uncontrolled emissions by source i; and E = the aggregate emissions target imposed by the regulatory authority.

If the cost functions are convex, then necessary and sufficient conditions for satisfaction of the constrained optimization problem posed by Eqs. 10–12 are the following (among others) (Kuhn and Tucker 1951):

$$\frac{\partial c_i(r_i)}{\partial r_i} - \lambda \geq 0 \tag{13}$$

$$r_i \cdot \left[\frac{\partial c_i(r_i)}{\partial r_i} - \lambda\right] = 0 \tag{14}$$

Equations 13 and 14 together imply the crucial condition for cost- effectiveness that all sources (that exercise some degree of control) experience the same marginal abatement costs (Baumol and Oates 1988). Thus, when one examines environmental policy instruments, a key question is whether marginal abatement costs are likely to be being equated across sources.

Command-and-Control Versus Market-Based Instruments

Conventional approaches to regulating the environment – frequently characterized as command-and-control – allow relatively little flexibility in the means of achieving goals. Such

policy instruments tend to force firms to take on equal shares of the pollution-control burden, regardless of the cost. The most prevalent form of uniform command-and-control standards is technology standards that specify the adoption of specific pollution-control technologies, and performance standards that specify uniform limits on the amount of pollution a facility can generate. In theory, non- uniform performance standards could be made to be cost-effective, but the government typically lacks the requisite information (on marginal costs of individual sources).

Market-based instruments encourage behaviour through market signals rather than through explicit directives regarding pollution-control levels or methods. Market-based instruments fall within four categories: pollution charges, tradable permits, market-friction reductions, and government subsidy reductions. Liability rules may also be thought of as a market-based instrument, because they provide incentives for firms to take into account the potential environmental damages of their decisions.

Where there is significant heterogeneity of abatement costs, command-and- control methods will not be cost-effective. In reality, costs can vary enormously due to production design, physical configuration, age of assets, and other factors. For example, the marginal costs of controlling lead emissions have been estimated to range from $13 to $56,000 per ton (Hartman et al. 1994; Morgenstern 2000). But where costs are similar among sources, command-and- control instruments may perform as well as (or better than) market-based instruments, depending on transactions costs, administrative costs, possibilities for strategic behaviour, political costs, and the nature of the pollutants (Newell and Stavins 2003).

In theory, market-based instruments allow any desired level of pollution clean- up to be realized at the lowest overall cost by providing incentives for the greatest reductions in pollution by those firms that can achieve the reductions most cheaply. Rather than equalizing pollution levels among firms, market-based instruments equalize their marginal abatement costs (Montgomery 1972). In addition, market- based instruments have the potential to bring down abatement costs over time by providing incentives for companies to adopt cheaper and better pollution-control technologies. This is because, with market-based instruments, most clearly with emission taxes, it pays firms to clean up a bit more if a sufficiently low-cost method (technology or process) of doing so can be identified and adopted (Downing and White 1986; Maleug 1989; Milliman and Prince 1989; Jaffe and Stavins 1995). However, the ranking among policy instruments in terms of their respective impacts on technology innovation and diffusion is ambiguous (Jaffe et al. 2003).

Closely related to the effects of instrument choice on technological change are the effects of vintage-differentiated regulation on the rate of capital turnover, and thereby on pollution abatement costs and environmental performance. Vintage- differentiated regulation is a common feature of many environmental policies, whereby the standard for regulated units is fixed in terms of their date of entry, with later vintages facing more stringent regulation. Such vintage-differentiated regulations can be expected to retard turnover in the capital stock, and thereby to reduce the cost-effectiveness of regulation. Under some conditions the result can be higher levels of pollutant emissions than would occur in the absence of regulation. Such economic and environmental consequences are not only predictions from theory (Maloney and Brady 1988); both types of consequences have been validated empirically (Gruenspecht 1982; Nelson et al. 1993).

Pollution Charges

Pollution charge systems assess a fee or tax on the amount of pollution that firms or sources generate (Pigou 1920). By definition, actual emissions are equal to unconstrained emissions minus emissions reductions, that is, $e_i = u_i - r_i$. A source's cost minimization problem in the presence of an emissions tax, t, is given by:

$$\min_{\{r_i\}} \; [c_i(r_i) + t \cdot (u_i - r_i)] \tag{15}$$

$$s.t. \;\; r_i \geq 0 \tag{16}$$

The result for each source is:

$$\frac{\partial c_i(r_i)}{\partial r_i} - t \geq 0 \tag{17}$$

$$r_i \cdot \left[\frac{\partial c_i(r_i)}{\partial r_i} - t\right] = 0 \tag{18}$$

Equations 17 and 18 imply that each source (that exercises a positive level of control) will carry out abatement up to the point where its marginal control costs are equal to the tax rate. Hence, marginal abatement costs are equated across sources, satisfying the condition for cost-effectiveness specified by Eqs. 13 and 14, at least in the simplest case of a uniformly mixed pollutant. In the non-uniformly mixed pollutant case, where 'hot spots' can be an issue, the respective cost-effective instrument is an 'ambient charge'.

A challenge with charge systems is identifying the appropriate tax rate. For social efficiency, it should be set equal to the marginal benefits of clean-up at the efficient level of clean-up (Pigou 1920); but policymakers are more likely to think in terms of a desired level of clean-up, and they do not know beforehand how firms will respond to a given level of taxation. An additional problem is that, although such systems minimize aggregate social costs, these systems may be *more* costly than comparable command-and-control instruments *for regulated firms*, because firms pay both their abatement costs *and* taxes on their residual emissions.

If charges are broadly defined, many applications can be identified (Stavins 2003). Coming closest to true Pigouvian taxes are the increasingly common *unit- charge* systems for financing municipal solid waste collection, where households and businesses are charged the incremental costs of collection and disposal. Another important set of charge systems has been *deposit refund systems*, whereby consumers pay a surcharge when purchasing potentially polluting products, and receive a refund when returning the product to an approved centre for recycling or disposal. A number of countries and states have implemented this approach to control litter from beverage containers and to reduce the flow of solid waste to landfills (Bohm 1981; Menell 1990), and the concept has also been applied to lead-acid batteries. There has also been considerable use of *environmental user charges*, through which specific environmentally related services are funded. Examples include *insurance premium taxes* (Barthold 1994). Another set of environmental charges are *sales taxes* on motor fuels, ozone-depleting chemicals, agricultural inputs, and low-mileage motor vehicles. Finally, *tax differentiation* has been used to encourage the use of renewable energy sources.

Tradable Permit Systems

Tradable permits can achieve the same cost-minimizing allocation as a charge system, while avoiding the problems of uncertain firm responses and the distributional consequences of taxes. Under a tradable permit system, an allowed overall level of pollution, E^{-}, is established, and allocated among sources in the form of permits. Firms that keep emission levels below allotted levels may sell surplus permits to other firms or use them to offset excess emissions in other parts of their operations. Let q_{0i} be the initial allocation of emission permits to source i, such that:

$$\sum_{i=1}^{N} q_{0i} = \overline{E} \tag{19}$$

Then, if p is the market-determined price of tradable permits, a single firm's cost minimization problem is given by:

$$\min_{\{r_i\}} \left[c_i(r_i) + p \cdot (u_i - r_i - q_{0i})\right] \tag{20}$$

$$s.t. r_i \geq 0 \tag{21}$$

The result for each source is:

$$\frac{\partial c_i(r_i)}{\partial r_i} - p \geq 0 \tag{22}$$

$$r_i \cdot \left[\frac{\partial c_i(r_i)}{\partial r_i} - p\right] = 0 \tag{23}$$

Equations 22 and 23 together imply that each source (that exercises a positive level of control)

will carry out abatement up to the point where its marginal control costs are equal to the market-determined permit price. Hence, the environmental constraint, E, is satisfied, and marginal abatement costs are equated across sources, satisfying the condition of cost-effectiveness. The unique cost-effective equilibrium is achieved independently of the initial allocation of permits (Montgomery 1972), which is of great political significance.

The performance of a tradable permit system can be adversely affected by: concentration in the permit market (Hahn 1984; Misolek and Elder 1989); concentration in the product market (Maleug 1990); transaction costs (Stavins 1995); non-profit maximizing behaviour, such as sales or staff maximization (Tschirhart 1984); the pre-existing regulatory environment (Bohi and Burtraw 1992); and the degree of monitoring and enforcement (Montero 2003).

Tradable permits have been the most frequently used market-based system (US Environmental Protection Agency 2000). Significant applications include: the emissions trading programme (Tietenberg 1985; Hahn 1989); the leaded gasoline phase-down; water quality permit trading (Hahn 1989; Stephenson et al. 1998); CFC trading (Hahn and McGartland 1989); the sulphur dioxide (SO2) allowance trading system for acid rain control (Schmalensee et al. 1998; Stavins 1998; Carlson et al. 2000; Ellerman et al. 2000); the RECLAIM programme in the Los Angeles metropolitan region (Harrison 1999); tradable development rights for land use; and the European Union's greenhouse gas emission trading scheme.

Market Friction Reduction

Market friction reduction can serve as a policy instrument for environmental protection. *Market creation* establishes markets for inputs or outputs associated with environmental quality. Examples of market creation include measures that facilitate the voluntary exchange of water rights and thus promote more efficient allocation and use of scarce water supplies (Howe 1997), and policies that facilitate the restructuring of electricity generation and transmission. Since well-functioning markets depend, in part, on the existence of well-informed producers and consumers, *information programmes* can help foster market-oriented solutions to environmental problems. These programmes have been of two types. *Product labelling requirements* have been implemented to improve information sets available to consumers, while other programmes have involved *reporting requirements* (Hamilton 1995; Konar and Cohen 1997; Khanna et al. 1998).

Government Subsidy Reduction

Government subsidy reduction constitutes another category of market-based instruments. Subsidies are the mirror image of taxes and, in theory, can provide incentives to address environmental problems. Although subsidies can advance environmental quality (see, for example, Jaffe and Stavins 1995), it is also true that subsidies, in general, have important disadvantages relatives to taxes (Dewees and Sims 1976; Baumol and Oates 1988). Because subsidies increase profits in an industry, they encourage entry, and can thereby increase industry size and pollution output (Mestelman 1982; Kohn 1985). In practice, rather than internalizing externalities, many subsidies promote economically inefficient and environmentally unsound practices. In such cases, reducing subsidies can increase efficiency and improve environmental quality. For example, because of concerns about global climate change, increased attention has been given to cutting inefficient subsidies that promote the use of fossil fuels.

Implications of Uncertainty for Instrument Choice

The dual task facing policymakers of choosing environmental goals and selecting policy instruments to achieve those goals must be carried out in the presence of the significant uncertainty that affects the benefits and the costs of environmental protection. Since Weitzman's (1974) classic paper on 'Prices vs. quantities', it has been widely acknowledged that benefit uncertainty on its own has no effect on the identity of the efficient control instrument, but that cost uncertainty can have significant effects, depending upon the relative

slopes of the marginal benefit (damage) and marginal cost functions. In particular, if uncertainty about marginal abatement costs is significant, and if marginal abatement costs are flat relative to marginal benefits, then a quantity instrument is more efficient than a price instrument.

In the environmental realm, benefit uncertainty and cost uncertainty are usually both present, with benefit uncertainty of greater magnitude. When marginal benefits are positively correlated with marginal costs (which, it turns out, is not uncommon), then there is an additional argument in favour of the relative efficiency of quantity instruments (Stavins 1996). Nevertheless, the regulation of stock pollutants will often favour price instruments, because the marginal benefit function – linked with the stock of pollution – will tend to be flatter than the marginal cost function – linked with the flow of pollution (Newell and Pizer 2003). In theory, there would be considerable efficiency advantages in the presence of uncertainty of hybrid systems – for example, quotas combined with taxes – or nonlinear taxes (Roberts and Spence 1976; Weitzman 1978; Kaplow and Shavell 2002; Pizer 2002), but such systems have not been adopted.

Conclusion

The growing use of economic analysis to inform environmental decision-making marks greater acceptance of the usefulness of these tools in improving regulation. But debates about the normative standing of the Kaldor–Hicks criterion and the challenges inherent in making benefit–cost analysis operational will continue. Nevertheless, economic analysis has assumed a significant position in the regulatory state. At the same time, despite the arguments made for decades by economists, there is only limited political support for broader use of benefit–cost analysis to assess proposed or existing environmental regulations. These analytical methods remain on the periphery of policy formulation. In a growing literature (not reviewed here), economists have examined the processes through which political decisions regarding environmental regulation are made (Stavins 2004).

The significant changes that have taken place over the past 20 years with regard to the means of environmental policy – that is, acceptance of market-based environmental instruments – may provide a model for progress with analysis of the ends – the targets and goals – of public policies in this domain. The change in the former realm has been dramatic. Market-based instruments have moved centre stage, and policy debates today look very different from those of 20 years ago, when these ideas were routinely characterized as 'licences to pollute' or dismissed as completely impractical. Market-based instruments are now considered seriously for nearly every environmental problem that is tackled, ranging from endangered species preservation to regional smog and global climate change. Of course, no individual policy instrument – whether market-based or conventional – is appropriate for all environmental problems. Which instrument is best in any given situation depends upon a variety of characteristics of the environmental problem, and the social, political, and economic context in which it is regulated.

Environmental Kuznets Curve

Arik Levinson

Abstract

Pollution often appears first to worsen and later to improve as countries' incomes grow. Because of its resemblance to the pattern of inequality and income described by Simon Kuznets, this pattern of pollution and income has been labelled an 'environmental Kuznets curve'. While many pollutants exhibit this pattern, peak pollution levels occur at different income levels for different pollutants, countries and time periods. This link between income and pollution cannot be interpreted causally, and is consistent with either efficient or inefficient growth paths. The evidence does, however, refute the claim that environmental degradation is an inevitable consequence of economic growth.

Some forms of pollution appear first to worsen and later to improve as countries' incomes grow. The world's poorest and richest countries have relatively clean environments, while middle-income countries are the most polluted. Because

of its resemblance to the pattern of inequality and income described by Simon Kuznets (1955), this pattern of pollution and income has been labelled an 'environmental Kuznets curve' (EKC).

Grossman and Krueger (1995) and the World Bank (1992) first popularized this idea, using a simple empirical approach. They regress data on ambient air and water quality in cities worldwide on a polynomial in GDP per capita and other city and country characteristics. They then plot the fitted values of pollution levels as a function of GDP per capita, and demonstrate that many of the plots appear inverse-U-shaped, first rising and then falling. The peaks of these predicted pollution-income paths vary across pollutants, but 'in most cases they come before a country reaches a per capita income of $8000' in 1985 dollars (Grossman and Krueger 1995, p. 353).

In the years since these original observations were made, researchers have examined a wide variety of pollutants for evidence of the EKC pattern, including automotive lead emissions, deforestation, greenhouse gas emissions, toxic waste and indoor air pollution. Some investigators have experimented with different econometric approaches, including higher-order polynomials, fixed and random effects, splines, semi- and non-parametric techniques, and different patterns of interactions and exponents. Others have studied different groups of jurisdictions and different time periods, and have added control variables, including measures of corruption, democratic freedoms, international trade openness, and even income inequality (bringing the subject full circle back to Kuznets's original idea).

Some generalizations across these approaches emerge. Roughly speaking, pollution involving local externalities begins improving at the lowest income levels. Fecal coliform in water and indoor household air pollution are examples. For some of these local externalities, pollution appears to decrease steadily with economic growth, and we observe no turning point at all. This is not a rejection of the EKC; pollution must have increased at some point in order to decline with income eventually, and there simply are no data from the earlier period. By contrast, pollutants involving very dispersed externalities tend to have their turning points at the highest incomes, or even no turning points at all, as pollution appears to increase steadily with income. Carbon emissions provide one such example. This, too, is not necessarily a rejection of the EKC; the turning points for these pollutants may come at levels of income per capita higher than in today's wealthiest economies.

Another general empirical result is that the turning points for individual pollutants differ across countries. This difference shows up as instability in empirical approaches that estimate one fixed turning point for any given pollutant. Countries that are the first to deal with a pollutant do so at higher income levels than following countries, perhaps because the following countries benefit from the science and engineering lessons of the early movers.

Most researchers have been careful to avoid interpreting these reduced-form empirical correlations structurally, and to recognize that economic growth does not automatically cause environmental improvements. All of the studies omit country characteristics correlated with both income and pollution levels, the most important being environmental regulatory stringency. The EKC pattern does not provide evidence of market failures or efficient policies in rich or poor countries. Rather, there are multiple underlying mechanisms, some of which have begun to be modelled theoretically.

In theory, the EKC relationship can be divided into three parts: scale, composition, and technique (see Brock and Taylor 2005). If as an economy grows the *scale* of all activities increases proportionally, pollution will increase with economic growth. If growth is not proportional but is accompanied by a change in the *composition* of goods produced, then pollution may decline or increase with income. If richer economies produce proportionally fewer pollution-intensive products, because of changing tastes or patterns of trade, this composition effect can lead to a decline in pollution associated with economic growth. Finally, if richer countries use less pollution-intensive production *techniques*, perhaps because environmental quality is a normal good, growth can lead to falling pollution. The EKC summarizes the interaction of these three processes.

Beyond this aggregate decomposition of the EKC, some attempts have been made to formalize structural models that lead to inverse-U-shaped pollution-income patterns. Many describe economies at some type of corner solution initially, where residents of poor countries are willing to trade environmental quality for income at a faster rate than possible using available technologies or resources. As the model economies become wealthier and their environments dirtier, eventually the marginal utility of income falls and the marginal disutility from pollution rises, to the point where people choose costly abatement mechanisms. After that point, the economies are at interior solutions, marginal abatement costs equal marginal rates of substitution between environmental quality and income, and pollution declines with income (see Stokey 1998). In frameworks of this type, there is typically zero pollution abatement until some threshold income level is crossed, after which abatement begins and pollution starts declining with income.

To date, the practical lessons from this theoretical literature are limited. Most of the models are designed to yield inverse-U-shaped pollution-income paths, and succeed using a variety of assumptions and mechanisms. Hence, any number of forces may be behind the empirical observation that pollution increases and then decreases with income. Moreover, that pattern cannot be interpreted causally, and is consistent with either efficient or inefficient growth paths. Perhaps the most important insight is in Grossman and Krueger's original paper: 'We find no evidence that economic growth does unavoidable harm to the natural habitat' (1995, p. 370). Economists have long argued that environmental degradation is not an inevitable consequence of economic growth. The EKC literature provides empirical support for that claim.

Envy

Peter J. Hammond

Envy is a deadly sin, but then so is avarice or greed, and greed seems not to trouble economists. Envy does, however, perhaps because it is an externality. Different economists have also used the term in different senses. Veblen (1899) avoids the word 'envy', but one feels that some of the pleasure of conspicuous consumption may come from the malicious belief that it induces envy in others. Brennan (1973) uses the term 'malice' to indicate negative altruism – a distaste for the income of others – and 'envy' to indicate that the marginal disutility of another's income increases as their income increases. For other concepts of envy, see Nozick (1974) and Chaudhuri (1985).

Most economists now use the word 'envy' in a narrow technical sense due to Foley (1967), who was much more interested, however, in finding an adequate concept of 'equity'. First, however, one should turn to Rawls (1971), whose *Theory of Justice* has 12 pages of very pertinent discussion.

Rawls on Envy and Justice

Rawls (1971) defines envy in a way which he attributes to Kant, and he is careful to distinguish

'envy' from 'jealousy', which can be thought of as a protective response to envy:

> we may think of envy as the propensity to view with hostility the greater good of others even though their being more fortunate than we are does not detract from our advantages. We envy persons whose situation is superior to ours... and we are willing to deprive them of their greater benefits even if it is necessary to give up something ourselves. When others are aware of our envy, they may become jealous of their better circumstances and anxious to take precautions against the hostile acts to which our envy makes us prone. So understood envy is collectively disadvantageous: the individual who envies another is prepared to do things that make them both worse off, if only the discrepancy between them is sufficiently reduced (p. 532).

This is in section 80, on 'the problem of envy' in which Rawls asks whether his theory of justice is likely to prove impractical because 'just institutions... are likely to arouse and encourage these propensities [such as envy] to such an extent that the social system becomes unworkable and incompatible with human good' (p. 531). This is a positive question; a normative one arises when one recognizes the possibility of 'excusable envy' because 'sometimes the circumstances evoking envy are so compelling that, given human beings as they are, no one can reasonably be asked to overcome his rancorous feelings' (p. 534). In the following section 81, on 'envy and equality', Rawls argues carefully that his 'principles of justice are not likely to arouse excusable... envy... to a troublesome extent' (p. 537). Thereafter, he discusses the conservative contention 'that the tendency to equality in modern social movements is the expression of envy' (p. 538), and Freud's lamentable suggestion that an egalitarian sense of justice is but an adult manifestation of childish feelings of envy and jealousy. Recently, indeed, a particular progressive tax in West Germany has been labelled an 'envy tax' *(Neidsteuer)*, as noted by Bös and Tillmann (1985). Anyway, Rawls is careful to distinguish 'rancorous' envy from the justifiable feelings of resentment at being treated unjustly. While envy may often form the basis of an appeal to justice, the claims that all appeals to justice rely on envy often fail to distinguish envy from resentment. I shall return to this later.

Equity as Absence of 'Envy'

More recently, however, 'envy' has acquired a precise technical sense in economic theory, following the (apparently independent) lead taken by Feldman and Kirman (1974) and by Varian (1974) in analysing a concept of 'equity' due to Foley (1967, p. 75). Apparently Foley was the first to use the term 'envy' in this sense, though only informally: Feldman, Kirman and Varian include it in their titles.

Consider any allocation (x^i_g) (g $= 1$ to n; $i = 1$ to m) of n goods to each of m individuals. Suppose these individuals have preferences represented by ordinal utility functions $U^i(x^i)$ ($i = 1$ to m) of each individual i's own (net) consumption vector x^i. Then individual i is said to *envy* j if $U^i(x^j) > U^i(x^i)$, so that i prefers j's allocation to his own. Notice that this *is* a purely technical definition; it tells us nothing about i's emotional or psychological state, whether i is unhappy because he prefers what j has, or whether i's 'envy' makes him want to harm j. There is no sin in this unemotional economists' concept of envy, but no particular ethical appeal either. Indeed, it might be better to say that 'i finds j's position to be *enviable*', to minimize the suggestions of emotion.

Nevertheless, Foley was concerned to introduce a concept of equity of welfare which overcomes the deficiencies of equality of after-tax income – deficiencies which are obvious when there are different public goods in different areas, different preferences for leisure as against consumption, and different needs as well. Thus Foley proposes the absence of 'envy' as a test of whether an allocation is equitable. Formally, (x^i_g) is *equitable* if $U^i(x^i) \geq U^i(x^j)$ for all pairs of individuals i and j.

Foley (1967) was careful to qualify this test. First, lifetime consumption plans must be considered so that the prodigal do not envy the higher later consumption enjoyed by the thrifty. Second, as he says:

> if a gas station attendant has the desire to be a painter but not the ability, it may be necessary to make the painter's life very unattractive in other ways before the gas station attendant will prefer his own; so unattractive, perhaps, that the painter

> will envy the attendant while the attendant is still envying him. These cases must be interpreted flexibly; either equivalents to the talents must be postulated which the gas station attendant does possess, or reasonable alternatives framed that abstract from the glamour and prestige of certain activities (p. 75).

Foley (1967, p. 76) concludes his discussion of 'equity' as follows:

> If tastes differ greatly, there is very little gained by the analysis since a very wide range of allocations will meet the equity criterion. The definition is offered only as a tentative contribution to a difficult and murky subject and concludes the sketchy discussion this paper will make of welfare economics.

Fairness and Other Extensions of Equity

In a one-good problem of dividing a cake, procedures for achieving 'fair' allocations, without envy and with no cake wasted, were discussed in works such as Steinhaus (1948, 1949), and Dubins and Spanier (1961) before Foley. Fairness with many goods was considered by Schmeidler and Vind (1972), by adding Pareto efficiency to the requirement that nobody should envy anybody else's *net trade vector* (as opposed to the consumption vector, which includes the endowment). Pazner and Schmeidler (1974) and Varian (1974) then came up with examples of economies with production in which there are no fair allocations, because Pareto efficiency requires skilled workers to supply more hours of labour than unskilled workers, and tastes are such that no allocation of consumption then avoids envy. Feldman and Kirman (1974) considered reducing the degree of envy, whereas Pazner and Schmeidler (1978) weakened the notion of equity to 'egalitarian equivalence' – finding an allocation (x^i_g) in which each individual i is indifferent between x^i and a consumption in an 'egalitarian' allocation $(\bar{x}^i{}_g)$ with $\bar{x}^i$ ndependent of i. Of course, in this egalitarian allocation there is no envy. These later developments all seem like attempts to rescue a dubious notion of equality without giving up first-best Pareto efficiency, even though that is surely unattainable anyway in economies with private information.

Envy and Resentment Reconsidered

In the definition of envy, each individual i compares the consumption vector x^j of another with his own, x^i, using i's own utility function U^i. But $U^i(x^j) > U^i(x^i)$ is insufficient for i's envy to be excusable, in Rawls's sense. Indeed, if x^j is preferable for i because j has some special needs met, i's envy is quite unjustifiable. As Sen (1970, ch. 9) points out in his discussion of Suppes's (1966) grading principles of justice, comparisons of x^j and x^i must allow for differences in tastes, needs, and so on. Thus the appropriate comparison in determining what is inequitable is rather whether $U^j(x^j) > U^i(x^i)$. If this is true, we might say that i *resents* j. Absence of resentment then requires all individuals to have equal utility levels; of course, this requires interpersonal comparisons of utility levels, of the kind used to make decisions 'in an original position', behind the 'veil of ignorance', before each individual knows his tastes. The technical sense of envy defined earlier differs from this technical notion of resentment precisely because it ignores the original position; not surprisingly, then, envy has no moral force, whereas resentment may well have.

Complete absence of resentment in this sense is probably too strong; but one should look for there to be no resentment in the weaker sense that no individual can legitimately feel treated unjustly by the institutions that determine his welfare. That, of course, reverts to Rawls (1971), though not necessarily to his particular concept of justice.

French economic periodical issued in three series under different names from 1766 to 1772, 1774 to 1776 and in 1788. Published first as a bimonthly by its founder and first editor, l'Abbé Baudeau, it became a monthly as from January 1767 after Baudeau's conversion to Physiocracy by Mirabeau and Le Trosne. Its contents included contributed articles on economic and political subjects, book reviews, comments and letters to the editor, together with a chronicle of public events of interest to its readership. This provided its format from January 1769, when Du Pont de Nemours took over the editorship. Although censorship problems troubled the journal persistently (as disclosed in the Turgot–Du Pont correspondence, for this reason many issues appeared well after the ostensible month of publication) the first series was terminated by l'Abbé Terray in November 1772, presumably because it contained much vigorous criticism of his abolition of domestic free trade in grain. The first series produced therefore six issues in 1766 as a bi-monthly and 63 monthly issues from January 1767 to March 1772 inclusive. Under the title *Nouvelles Ephémérides ou Bibliothèque raisonnée de l'histoire, de la morale et de la politique*, it was revived by Baudeau after Turgot became Contrôleur-général in 1774, publishing 18 issues in all from January 1775 to June 1776, that is, the month after Turgot's dismissal from the ministry. A third series, *Nouvelles Ephémérides économiques* published three issues from January to March 1788, again under Baudeau's editorship, but his failing mental powers were presumably the reason why this final series ended so quickly.

Although initially set up by Baudeau in imitation of the English *Spectator*, within a year of its inception economics began to dominate its contents and many of the leading Physiocrats, in particular Mirabeau, Baudeau and Du Pont de Nemours, contributed most of the articles. A detailed discussion of its contents is given in Bauer (1894) and in Coquelin and Guillaumin (1854, pp. 710–12). Perhaps the most important piece it contained is Turgot's *Réflexions sur la formation et distribution des richesses* in serial form (*Ephémérides,* 1769, No. 11, pp. 12–56; No. 12, pp. 31–98; and 1770, No. I,

pp. 113–73), although with considerable unauthorized alterations and notes by Du Pont (see Groenewegen 1977, pp. xix–xxi). It also published foreign contributions in French translation, including Beccaria's inaugural lecture with copious notes and comments by Du Pont (*Ephémérides,* 1769, No. 6, pp. 57–152) and a contribution by Franklin on the increasing troubles between England and her American colonies (*Ephémérides,* 1768, No. 8, pp. 159–92). As an early, if not the first, economic journal, the *Ephémérides* remains an important part of economic literature and an indispensable source for those interested in the study of Physiocracy.

The following three articles survey some aspects of the foundations of noncooperative game theory. The goal of work in foundations is to examine in detail the basic ingredients of game analysis.

The starting point for most of game theory is a 'solution concept' – such as Nash equilibrium or one of its many variants, backward induction, or iterated dominance of various kinds. These are usually thought of as the embodiment of 'rational behaviour' in some way and used to analyse game situations.

One could say that the starting point for most game theory is more of an endpoint of work in foundations. Here, the primitives are more basic. The very idea of rational – or irrational – behaviour needs to be formalized. So does what each player might know or believe about the game – including about the rationality or irrationality of other players. Foundational work shows that even what each player knows or believes about what other players know or believe, and so on, can matter.

Investigating the basis of existing solution concepts is one part of work in foundations. Other work in foundations has uncovered new solution concepts with useful properties. Still other work considers changes even to the basic model of decision making by players – such as departures from the expected utility model or reasoning in various formal logics.

The first article, epistemic game theory: beliefs and types, by Marciano Siniscalchi, describes the formalism used in most work on foundations. This is the 'types' formalism going back to Harsanyi (1967–8). Originally proposed to describe the players' beliefs about the structure of the game (such as the payoff functions), the types approach is equally suited to describing beliefs about the play of the game or beliefs about both what the game is and how it will be played. Indeed, in its most general form, the formalism is simply a way to describe any multi-person uncertainty. Harsanyi's conception of a 'type' was a crucial breakthrough in game theory. Still, his work left many fundamental questions about multi-person

uncertainty unanswered. Siniscalchi's article surveys these later developments.

The second and third articles apply these tools to the two kinds of uncertainty mentioned. The second article, epistemic game theory: complete information, concerns the case where the matrix or tree itself is 'transparent' to the players, and what is uncertain are the actual strategies chosen by the players. The third article, epistemic game theory: incomplete information, by Aviad Heifetz, has the opposite focus: it covers the case of uncertainty about the game itself. (Following Harsanyi, the third article focuses on uncertainty about the payoffs, in particular.)

Both cases are important to the foundations programme. Because Nash equilibrium is 'as if' each player is certain (and correct) about the strategies chosen by the other players (Aumann and Brandenburger 1995, Section 7h), uncertainty of the first kind has played a small role in game theory to date. Uncertainty of the second kind is the topic of the large literatures on information asymmetries, incentives, and so on.

Interestingly, though, von Neumann and Morgenstern (1944) already appreciated the significance of both complete and incomplete information environments. Indeed, they asserted that phenomena often thought to be characteristic of incomplete-information settings could, in fact, arise in complete-information settings (1944, p. 31):

> Actually, we think that our investigations – although they assume 'complete information' without any further discussion – do make a contribution to the study of this subject. It will be seen that many economic and social phenomena which are usually ascribed to the individual's state of 'incomplete information' make their appearance in our theory and can be satisfactorily interpreted with its help.

This is indeed true, as work in the modern foundations programme shows. (Some instances are mentioned in what follows.) Overall, the foundations programme aims at a 'neutral' and comprehensive treatment of all ingredients of a game.

Epistemic Game Theory: Beliefs and Types

Marciano Siniscalchi

Abstract

Modelling what each agent believes about her opponents, what she believes her opponents believe about her, and so on, plays a prominent role in game theory and its applications. This article describes Harsanyi's formalism of type spaces, which provides a simple, elegant representation of probabilistic belief hierarchies. A special emphasis is placed on the construction of rich type spaces, which can generate all 'reasonable' belief hierarchies in a given game. Recent developments, employing richer representation of beliefs, are also considered.

John Harsanyi (1967–8) introduced the formalism of type spaces to provide a simple and parsimonious representation of belief hierarchies. He explicitly noted that his formalism was not limited to modelling a player's beliefs about payoff-relevant variables: rather, its strength was precisely the ease with which Ann's beliefs about Bob's beliefs about payoff variables, Ann's beliefs about Bob's beliefs about Ann's beliefs about payoff variables, and so on, could be represented.

This feature plays a prominent role in the epistemic analysis of solution concepts (see epistemic game theory: complete information), as well as in the literature on global games (Morris and Shin 2003) and on robust mechanism design (Bergemann and Morris 2005). All these applications place particular emphasis on the expressiveness of the type-space formalism. Thus, a natural question arises: just how expressive is Harsanyi's approach?

For instance, solution concepts such as Nash equilibrium or rationalizability can be characterized by means of restrictions on the players' mutual beliefs. In principle, these assumptions could be formulated directly as restrictions on players' hierarchies of beliefs; but in practice the analysis is mostly carried out in the context of a type space à la Harsanyi. This is without loss of generality only if Harsanyi type spaces do not themselves impose restrictions on the belief hierarchies that can be represented. Similar considerations apply in the context of robust mechanism design.

A rich literature addresses this issue from different angles, and for a variety of basic representations of beliefs. This article focuses on hierarchies of probabilistic beliefs; however, some extensions are also mentioned. For simplicity, attention is restricted to two players, denoted '1' and '2' or 'i' and '$-i$.'

Probabilistic Type Spaces and Belief Hierarchies

Begin with some mathematical preliminaries. A topology on a space X is deemed Polish if it is separable and completely metrizable; in this case, X is itself deemed a Polish space. Examples include finite sets, Euclidean space $\mathbb{R}^n$ and closed subsets thereof. A countable product of Polish spaces, endowed with the product topology, is itself Polish. For any topological space X, the notation $\Delta(X)$ indicates the set of Borel probability measures on X. If the topology on X is Polish, then the weak* topology on $\Delta(X)$ is also Polish (for example, Aliprantis and Border 1999, Theorem 14.15). A sequence $\{\mu^k\}k \geq 1$ in $\Delta(X)$ converges in the weak* sense to a measure $\mu \in \Delta(x)$, written μ^k *LongRightArrow*;$^{w^*}$ μ, if and only if, for every bounded, continuous function $\psi : X \to \mathbb{R}$, $\int_X \psi d\mu^k \to \int_X \psi d\mu$. The weak* topology on $\Delta(X)$ is especially meaningful and convenient when X is a Polish space: see Aliprantis and Border (1999, Chapter 14) for an overview of its properties. Finally, if μ is a measure on some product space $X \times Y$, the marginal of μ on X is denoted $\text{marg}_x\mu$.

The basic ingredient of the players' hierarchical beliefs is a description of payoff-relevant or fundamental uncertainty. Fix two sets S_1 and S_2, hereinafter called the *uncertainty domains*; the intended interpretation is that S_{-i} describes aspects of the strategic situation that Player i is uncertain about. For example, in an independent private-values auction, each set S_i could represent bidder i's possible valuations of the object being sold, which is not known to bidder $-i$. In the context of interactive epistemology, S_i is usually taken to be Player i's strategy space. It is sometimes convenient to let $S_1 = S_2 \equiv S$; in this case, the formalism introduced below enables one to formalize the assumption that each player observes different aspects of the common uncertainty domain S (for instance, different signals correlated with the common, unknown value of an object offered for sale).

An (S_1, S_2)-*based type space* is a tuple $J = (T_i, g_i)_{i=1,2}$ such that, for each $i = 1, 2$, T_i is a Polish space and $g_i : T_i \to \Delta(S_{-I} \times T_{-i})$ is continuous. As noted above, type spaces can represent hierarchies of beliefs; it is useful to begin with an example. Let $S_1 = S_2 = \{a, b\}$ and consider the type space defined in Table 1. To interpret, for every $i = 1,2$, the entry in the row

Epistemic Game Theory: Beliefs and Types, Table 1 A type space

T_1	a, t_2	a, t'_2	b, t_2	b, t'_2
t_1	1	0	0	0
t'_1	0	0.3	0	0.7
T_2	a, t_1	a, t'_1	b, t_1	b, t'_1
t_2	0	0.5	0.5	0
t'_2	0	0	0	1

corresponding to t_i and (s_{-i}, t_{-i}) is $g_i(t_i)(\{(s_{-i}, t_{-i})\})$. Thus, for instance, $g_1(t_1)\left(\left\{\left(a, t'_2\right)\right\}\right) = 0$; $g_2(t_2)(\{b\} \times T_1) = 0.5$.

Consider type t_1 of Player 1. She is certain that $s_2 = a$; furthermore, she is certain that Player 2 believes that $s_1 = a$ and $s_1 = b$ are equally likely. Taking this one step further, type t_1 is certain that Player 2 assigns probability 0.5 to the event that Player 1 believes that $s_2 = b$ with probability 0.7.

These intuitive calculations can be formalized as follows. Fix an (S_1, S_2)-based type space $J = (T_i, g_i)_{i=1,2}$; for every $i = 1, 2$ define the set X^0_{-i} and the function $h^1_i : T_i \to \Delta\left(X^{-i}_0\right)$ by

$$X^0_{-i} = S_{-i} \text{ and } \forall t_i \in T_i, \; h^1_i(t_i) = \text{marg}_{S_{-i}} g_i(t_i). \tag{1}$$

Thus, $h^1_i(t_i)$ represents the *first-order beliefs* of type t_i in type space T – her beliefs about the uncertainty domain S_{-i}. Note that each $X^0_{-i} = S_{-i}$ is Polish. Proceeding inductively, assuming that $X^0_{-i}, \ldots, X^{k-1}_{-i}$ and $h^1_i, \ldots, h^k_i$ have been defined up to some $k > 0$ for $i = 1,2$, and that all sets X^l_{-i}, $l = 0, \ldots, k-1$ are Polish, define the set X^k_{-i} and the functions $h^{k+1}_i : T_i \to \Delta\left(X^k_{-i}\right)$ for $i = 1, 2$ by

$$X^k_{-i} = X^{k-1}_{-i} \times \Delta\left(X^{k-1}_i\right) \text{ and } \forall t_i \in T_i, \; h^{K+1}_i(t_i)(E) = g_i(t_i)\left(\left\{(s_{-i}, t_{-i}) \in S_{-i} \times T_{-i} : \left(s_{-i}, h^k_{-i}(t_{-i})\right) \in E\right\}\right) \tag{2}$$

for every Borel subset E of X^k_{-i}. Thus, $h^2_1(t_1)$ represents the *second-order beliefs* of type t_1 – her beliefs about *both* the uncertainty domain $S_2 = X^0_2$ and Player 2's beliefs about S_1, which by definition belong to the set $\Delta\left(X^0_1\right) = \Delta(S_1)$. Similarly, $h^{k+1}_i(t_i)$ represents type t_i's $(k+1)$-th order beliefs.

Observe that type t_i's second-order beliefs are defined over $X^0_2 \times \Delta\left(X^0_1\right) = S_2 \times \Delta(S_1)$, rather than just over $\Delta\left(X^0_1\right) = \Delta(S_1)$; a similar statement holds for her $(k+1)$-th order beliefs. This is crucial in many applications. For instance, a typical assumption in the literature on epistemic foundations of solution concepts is that Player 1 believes that Player 2 is rational. Letting S_i be the set of actions or strategies of Player i in the game under consideration, this can be modelled by assuming that the support of $h^2_1(t_1)$ consists of pairs $(s_2, \mu_1) \in S_2 \times \Delta(S_1)$ wherein s_2 is a best response to μ_1. Clearly, such an assumption could not be formalized if $h^2_1(t_1)$ only conveyed information about type t_1's beliefs on Player 2's first-order beliefs: even though type t_1's beliefs about the action played by Player 2 could be retrieved from $h^1_1(t_1)$, it would be impossible to tell whether each action that type t_1 expects to be played is matched with a belief that rationalizes it.

Note that, since X^{k-1}_i and X^{k-1}_{-i} are assumed Polish, so are $\Delta\left(X^{k-1}_i\right)$ and X^k_{-i}. Also, each function h^k_i is continuous.

Finally, it is convenient to define a function that associates to each type $t_i \in T_i$ an entire *belief hierarchy*: to do so, define the set H_i and, for $i = 1, 2$, the function $h_i : T_i \to H_i$ by

$$H_i = \prod_{k \geq 0} \Delta\left(X^k_{-i}\right) \text{ and } \forall t_i \in T_i, \; h_i(t_i) = \left(h^1_i(t_i), \ldots, h^{k+1}_i(t_i), \ldots\right). \tag{3}$$

Thus, H_i is the set of all hierarchies of beliefs; notice that, since each X^k_{-i} is Polish, so is H_i.

Rich Type Spaces

The preceding construction suggests a rather direct way to ask how expressive Harsanyi's

notion of a type space is: can one construct a type space that generates *all* hierarchies in H_i?

A moment's reflection shows that this question must be refined. Fix a type space $(T_i, g_i)_{i=1,2}$ and a type $t_i \in T_i$; recall that, for reasons described above, the first- and second-order beliefs of type t_i satisfy $h_i^1(t_i) \in \Delta(S_{-i})$ and $h_i^2(t_i) \in \Delta\left(X_{-i}^0 \times \Delta\left(X_i^0\right)\right) = \Delta(S_{-i} \times \Delta(S_i))$ respectively. This, however, creates the potential for redundancy or even contradiction, because both $h_i^1(t_i)$ and $\text{marg}_{S_{-i}} h_i^2(t_i)$ can be viewed as 'type t_i's beliefs about S_{-i}'. A similar observation applies to higher-order beliefs. Fortunately, it is easy to verify that, for every type space $(T_i, g_i)_i = 1,2$ and type $t_i \in T_i$, the following *coherency* condition holds:

$$\forall k > 1, \ \text{marg}_{X_{-i}^{k-2}} h_i^k(t_i) = h_i^{k-1}(t_i); \quad (4)$$

To interpret, recall that $h_i^k(t_i) \in \left(X_{-i}^{k-1}\right) = \Delta\left(X_{-i}^{k-2} \times \Delta\left(X_{-i}^{k-2}\right)\right)$. Thus, in particular, $\text{marg}_{S_{-i}} h_i^2(t_i) = h_i^1(t_i)$.

Since H_i is defined as the set of *all* hierarchies of beliefs for Player i, some (in fact, 'most') of its elements are not coherent. As noted above, no type space can generate incoherent hierarchies; more importantly, coherency can be viewed as an integral part of the interpretation of interactive beliefs. How could an individual simultaneously hold (infinitely) many distinct first-order beliefs? Which of these should be used, say, to verify whether she is rational? This motivates restricting attention to coherent hierarchies, defined as follows:

$$H_i^c = \left\{ \left(\mu_i^1, \ \mu_i^2, \ldots\right) \in H_i : \forall k > 1, \ \text{marg}_{X_{-i}^{k-2}} \mu_i^k = \mu_i^{k-1} \right\}. \quad (5)$$

Since $\text{marg}_{X_{-i}^{k-2}} : \Delta\left(X_{-i}^{k-1}\right) \to \Delta\left(X_{-i}^{k-2}\right)$ is continuous, H_i^c is a closed, hence Polish subspace of H_i.

Brandenburger and Dekel (1993, Proposition 1) show that there exist homeomorphisms $g_i^c : H_i^c \to \Delta(S_{-i} \times H_{-i})$: that is, every coherent hierarchy corresponds to a distinct belief over the uncertainty domain and the hierarchies of the opponent, and conversely. Furthermore, this homeomorphism is canonical, in the following sense. Note that $S_{-i} \times H_{-i} = S_{-i} \times \Pi_{k \geq 0} \Delta\left(K_i^k\right) = K_{-i}^k \times \Pi_{l>k} \Delta\left(X_i^l\right)$.

Then it can be shown that, if $\mu_i = \left(\mu_i^1, \ \mu_i^2, \ldots\right) \in H_i^c$, then $\text{marg}_{X_{-i}^k} g_i^c(\mu_i) = \mu_i^{k+1}$ Intuitively, the marginal belief associated with μi over the first k orders of the opponent's beliefs is precisely what it should be, namely μ_i^{k+1}. The proof of these results builds upon Kolmogorov's extension theorem, as may be suggested by the similarity of the coherency condition in Eq. (5) with the notion of Kolmogorov consistency: cf. for example Aliprantis and Border (1999, Theorem 14.26).

This result does not quite imply that all coherent hierarchies can be generated in a suitable type space; however, it suggests a way to obtain this result. Notice that the belief on $S_{-i} \times H_{-i}$ associated by the homeomorphism g_i^c to a coherent hierarchy μ_i may include *in*coherent hierarchies $\nu_{-i} \in H_{-i} / H_{-i}^c$ in its support. This can be interpreted in the following terms: if Player i's hierarchical beliefs are given by μ_i, then she is coherent, but she is not certain that her opponent is. On the other hand, consider a type space $(T_i, g_i)_{i=1,2}$; as noted above, for every player i, each type $t_i \in T_i$ generates a coherent hierarchy $h_i(t_i) \in H_i^c$. So, for instance, if (s_1, t_1) is in the support of $g_2(t_2)$ then t_1 also generates a coherent hierarchy. Thus, not only is type t_2 of Player 2 coherent: he is also certain (believes with probability one) that Player 1 is coherent. Iterating this argument suggests that *hierarchies of beliefs generated by type spaces display common certainty of coherency.*

Motivated by these considerations, let

$$H_i^0 = H_i^c \text{ and } \forall k > 0,$$
$$H_i^k = \left\{ \mu_i \in H_i^{k-1} : g_i^c(\mu_i)\left(S_{-i} \times H_{-i}^{k-1}\right) = 1 \right\}. \quad (6)$$

Thus, H_i^0 is the set of coherent hierarchies for Player i; H_i^1 is the set of hierarchies that are coherent and correspond to beliefs that display certainty of the opponent's coherency; and so on. Finally, let $H_i^* = \cap_{k \geq 0} H_i^k$. Each element of H^* is intuitively consistent with coherency and common certainty of coherency.

E

Brandenburger and Dekel (1993, Proposition 2) show that the restriction g_i^* of g_i^c to H_i^* is a homeomorphism between H^*_i and $\Delta\left(S_{-i} \times H^*_{-i}\right)$; furthermore, it is canonical in the sense described above. This implies that the tuple $\left(H_i^*, g_i^*\right)_{i=1,2}$ is a type space in its own right – the (S_1, S_2)-based *universal type space*.

The existence of a universal type space fully addresses the issue of richness. Since the homeomorphism g_i^* is canonical, it is easy to see that the hierarchy generated as per Eqs. (1) and (2) by any 'type' $t_i = (\mu^1, \mu^2, s) \in H_i^*$ in the universal type space $\left(H_i^*, g_i^*\right)_{i=1,2}$ is t_i itself; thus, since H_i^* *consists* of all hierarchies that are coherent and display common certainty of consistency, the universal type space also *generates* all such hierarchies.

The type space $\left(H_i^*, g_i^*\right)_{i=1,2}$ is rich in two additional, related senses. First, as may be expected, every belief hierarchy for Player i generated by an arbitrary type space is an element of H^*; this implies that every type space $(T_i, g_i)_{i=1,2}$ can be uniquely embedded in $\left(H_i^*, g_i^*\right)_{i=1,2}$ as a 'belief-closed' subset: see Battigalli and Siniscalchi (1999, Proposition 8.8). Call a type space *terminal* if, like $\left(H_i^*, g_i^*\right)_{i=1,2}$, it embeds all other type spaces as belief-closed subsets.

Second, since each function g_i^* is a homeomorphism, in particular it is a surjection (that is, onto). Call a type space $(Ti, gi)_{i=1,2}$ *complete* if every map g_i is onto. (This should not be confused with the topological notion of completeness.) Thus, the universal type space $\left(H_i^*, g_i^*\right)_{i=1,2}$ is complete. It is often the case that, when a universal type space is employed in the epistemic analysis of solution concepts, the objective is precisely to exploit its completeness. Furthermore, for certain representations of beliefs, it is not known whether universal type spaces can be constructed; however, the existence of complete type spaces can be established, and is sufficient for the purposes of epistemic analysis. The next section provides examples.

Alternative Constructions and Extensions

The preceding discussion adopts the approach proposed by Brandenburger and Dekel (1993), which has the virtue of relying on familiar ideas from the theory of stochastic processes. However, the first constructions of universal type spaces consisting of hierarchies of beliefs are due to Armbruster and Böge (1979), Böge and Eisele (1979) and Mertens and Zamir (1985).

From a technical point of view, Mertens and Zamir (1985) assume that the state space S is compact Hausdorff and beliefs are regular probability measures. Heifetz and Samet (1998b) instead drop topological assumptions altogether: in their approach, both the underlying set of states and the sets of types of each player are modelled as measurable spaces. They show that a terminal type space can be explicitly constructed in this environment.

In all the contributions mentioned so far, beliefs are modelled as countably additive probabilities. The literature has also examined other representations of beliefs, broadly defined.

A *partitional structure* (Aumann 1976) is a tuple $(\Omega,(\sigma_i, P_i)_{i = 1,2})$, where Ω is a (typically finite) space of 'possible worlds', every $\sigma_i : \Omega \to S_i$ indicates the realization of the basic uncertainty corresponding to each element of Ω, and every P_i is a partition of Ω. The interpretation is that, at any world $\omega \in \Omega$, Player i is only informed that the true world lies in the cell of the partition P_i containing ω, denoted $P_i(\omega)$. The *knowledge operator* for Player i can then be defined as

$$\forall E \subset \Omega, K_i(E) = \{\omega \in \Omega : P_i(\omega) \subseteq E\}.$$

Notice that no probabilistic information is provided in this environment (although it can be easily added).

Heifetz and Samet (1998a) show that a terminal partitional structure does not exist. This result was extended to more general 'possibility' structures by Meier (2005). Brandenburger and Keisler (2006) establish related non-existence results for complete structures. However, recent contributions show that topological assumptions, which play a key role in the constructions of Mertens and Zamir (1985) and Brandenburger and Dekel (1993), can also deliver existence results in non-probabilistic settings. For instance, Mariotti

et al. (2005) construct a structure that is universal, complete and terminal for possibility structures.

Other authors investigate richer probabilistic representations of beliefs. Battigalli and Siniscalchi (1999) construct a universal, terminal, and complete type space for *conditional probability system*, or collections of probability measures indexed by relevant conditioning events (such as histories in an extensive game) and related by a version of Bayes's rule. This type space is used in (2002) to provide an epistemic analysis of forward induction. Brandenburger et al. (2006) construct a complete type space for *lexicographic sequences*, which may be thought of as an extension of lexicographic probability systems (Blume et al. 1991) for infinite domains. They then use it to provide an epistemic characterization of iterated admissibility.

Non-probabilistic representations of beliefs that reflect a concern for ambiguity (Ellsberg, 1961) have also been considered. Heifetz and Samet (1998b) observe that their measure-theoretic construction extends to beliefs represented by continuous *capacities*, that is non-additive set functions that preserve monotonicity with respect to set inclusion. Motivated by the multiple-priors model of Gilboa and Schmeidler (1989), Ahn (2007) constructs a universal type space for sets of probabilities.

Epstein and Wang (1996) approach the richness issue taking *preferences*, rather than beliefs, as primitive objects. In their setting, an S-based type space is a tuple $(T_i, g_i)_{i=1,2}$, where, for every type t_i, $g_i(t_i)$ is a suitably regular preference over *acts* defined on the set $S \times T_{-i}$. The analysis in the preceding section can be viewed as a special case of Epstein and Wang (1996), where preferences conform to expected-utility theory. Epstein and Wang construct a universal type space in this framework (see also Di Tillio 2006).

Finally, constructions analogous to that of a universal type space appear in other, unrelated contexts. For instance, Epstein and Zin (1989) develop a class of recursive preferences over infinite-horizon temporal lotteries; to construct the domain of such preferences, they employ arguments related to Mertens and Zamir's. Gul and Pesendorfer (2004) employ analogous techniques to analyse self-control preferences over infinite-horizon consumption problems.

Epistemic Game Theory: Complete Information

Adam Brandenburger

Abstract

The epistemic programme can be viewed as a methodical construction of game theory from its most basic elements – rationality and irrationality, belief and knowledge about such matters, beliefs about beliefs, knowledge about knowledge, and so on. To date, the epistemic field has been mainly focused on game matrices and trees – that is, on the non-cooperative branch of game theory. It has been used to provide foundations for existing non-cooperative solution concepts, and also to uncover new solution concepts. The broader goal of the programme is to provide a method of analysing different sets of assumptions about games in a precise and uniform manner.

Epistemic Analysis

Under the epistemic approach, the traditional description of a game is augmented by a mathematical framework for talking about the rationality or irrationality of the players, their beliefs and knowledge, and related ideas.

The first step is to add sets of *types* for each of the players. The apparatus of types goes back to Harsanyi (1967–8), who introduced it as a way to talk formally about the players' beliefs about the payoffs in a game, their beliefs about other players' beliefs about the payoffs, and so on. (See epistemic game theory: incomplete information.) But the technique is equally useful for talking about uncertainty about the actual play of the game – that is, about the players' beliefs about the strategies chosen in the game, their beliefs about other players' beliefs about the strategies, and so on. This survey focuses on this second source of uncertainty. It is also possible to treat both kinds of uncertainty together, using the same technique.

We give a definition of a type structure as commonly used in the epistemic literature, and an example of its use.

Fix an n-player finite strategic-form game $\langle S^1, \ldots, S^n, \pi^1, \ldots, \pi^n \rangle$. Some notation: given sets $X^1,\ldots, X^n$, let $X = \times_{i=1}^n X^i$ and $X^{-i} = \times_{j \neq i} X^j$. Also, given a finite set Ω, write $\mathcal{M}(\Omega)$ for set of all probability measures on Ω.

Definition 1.1 *An $(S^1,\ldots, S^n)$-based **(finite) type structure** is a structure*

$$\langle S^1, \ldots, S^n; T^1, \ldots T^n; \lambda^1, \ldots \lambda^n \rangle,$$

*where each T^i is a finite set, and each $\lambda^i : T^i \to \mathcal{M}\left(S^{-i} \times T^{-i}\right)$. Members of T^i are called **types** for player i. Members of $S \times T$ are called **states (of the world)**.*

For some purposes – see, for example, sections "Conditions for Backward Induction and Conditions for Iterated Admissibility" – it is important to consider infinite type structures. Topological assumptions are then made on the type spaces T_i.

A particular state $(s^1, t^1,\ldots, s^n, t^n)$ describes the strategy chosen by each player, and also each player's type. Moreover, a type t^i for player i induces, via a natural induction, an entire hierarchy of beliefs – about the strategies chosen by the players $j \neq i$, about the beliefs of the players $j \neq i$, and so on. (See epistemic game theory: beliefs and types.)

The following example is similar to one in Aumann and Brandenburger (1995, pp. 1166–7).

Example 1.1 (A Coordination Game) *Consider the coordination game in* Fig. 1.1 *(where Ann chooses the row and Bob the column), and the associated type structure in* Fig. 1.2.

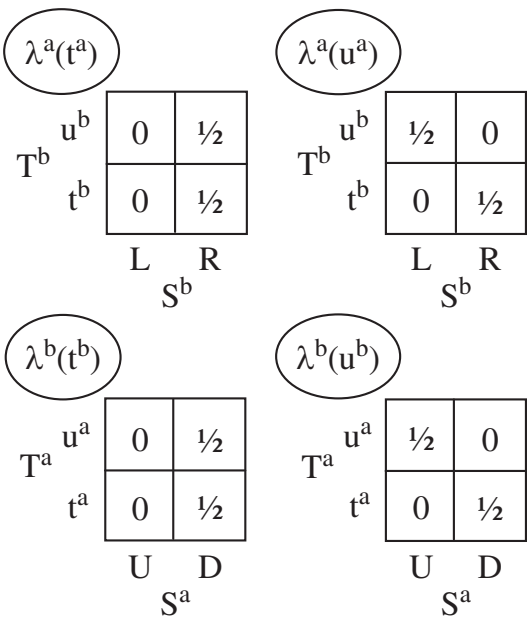
There are two types t^a, u^a for Ann, and two types t^b, u^b for Bob. The measure associated with each type is as shown. Fix the state (D, t^a, R, t^b). At this state, Ann plays D and Bob plays R. Ann is 'correct' about Bob's strategy. (Her type t^a assigns probability 1 to Bob's playing R.) Likewise, Bob is correct about Ann's strategy. Ann, though, thinks it possible Bob is wrong about her strategy. (Her type assigns probability 1/2 to type u^b for Bob, which assigns probability 1/2 to Ann's playing U, not D.) Again, likewise with Bob.

What about the rationality or irrationality of the players? At state (D, t^a, R, t^b), Ann is rational. Her strategy maximizes her expected payoff, given her first-order belief (which assigns probability 1 to R). Likewise, Bob is rational. Ann, though, thinks it possible Bob is irrational. (She assigns probability 1/2 to (R, u^b). With type u^b, Bob gets a higher expected payoff from L than R.) The situation with Bob is again symmetric.

Summing up, the example is just a description of a game situation, not a prediction. A type structure is a descriptive tool. Note, too, that the example includes both rationality and irrationality, and also allows for incorrect as well as correct beliefs (for example, Ann thinks it possible Bob is irrational, though in fact he isn't). These are typical features of the epistemic approach.

Epistemic Game Theory: Complete Information, Fig. 1.1

	L	R
U	2, 2	0, 0
D	0, 0	1, 1



Epistemic Game Theory: Complete Information, Fig. 1.2

Two comments on type structures. First, we can ask whether Definition 1.1 above is to be taken as primitive or derived. Arguably, hierarchies of beliefs are the primitive, and types are simply a convenient tool for the analyst. See epistemic game theory: beliefs and types for further discussion.

Second, note that Definition 1.1 applies to finite games. These will be the focus of this survey. There is nothing yet approaching a developed literature on epistemic analysis of infinite games.

Early Results

A major use of type structures is to identify conditions on the players' rationality, beliefs, and so on, that yield various solution concepts.

A very basic solution concept is iterated dominance. This involves deleting from the matrix all strongly dominated strategies, then deleting all strategies that become strongly dominated in the resulting submatrix, and so on until no further deletion is possible. (It is easy to check that in finite games – as considered in this survey – the residual set will always be non-empty.) Call the remaining strategies the *iteratively undominated* (*IU*) strategies. There is a basic equivalence: a strategy is not strongly dominated if and only if there is a probability measure on the product of the other players' strategy sets under which it is optimal. Using this, IU can also be defined as follows: delete from the matrix any strategy that isn't optimal under some measure on the product of the other players' strategy sets. Consider the resulting sub-matrix and delete strategies that don't pass this test on the sub-matrix, and so on.

The second definition suggests what a formal epistemic treatment of IU should look like. A rational player will choose a strategy which is optimal under some measure. This is the first round of deletion. A player who is rational and believes the other players are rational will choose a strategy which is optimal under a measure that assigns probability 1 to the strategies remaining after the first round of deletion. This gives the second round of deletion. And so on.

Type structures allow a formal treatment of this idea. First the formal definition of rationality. This is a property of strategy-type pairs. Say (s^i, t^i) is **rational** if s^i maximizes player i's expected payoff under the marginal on S^{-i} of the measure $\lambda^i(t^i)$.

Say type t^i of player i **believes** an event $E \subseteq S^{-i} \times T^{-i}$ if $\lambda^i(t^i)(E) = 1$, and write

$$B^i(E) = \left\{t^i \in T^i : t^i \text{ believes } E\right\}.$$

Now, for each player i, let R^i_1 be the set of all rational pairs (s^i, t^i), and for $m > 0$ define R^i_m inductively by

$$R^i_{m+1} = R^i_m \cap \left[S^i \times B^i\left(R^{-i}_m\right)\right].$$

Definition 2.1 *If* $(s^1, t^1, \ldots, s^n, t^n) \in R_{m+1}$, *say there is* ***rationality andm th-order elief of rationality (RmBR)*** *at this state. If* $(s^1, t^1, \ldots, s^n, t^n) \in \cap^{\infty}_{m=1} R_m$ *say there is* ***rationality and common belief of rationality (RCBR)*** *at this state.*

These definitions yield an epistemic characterization of IU: *Fix a type structure and a state* $(s^1, t^1, \ldots, s^n, t^n)$ *at which there is RCBR. Then the strategy profile* $(s^1, \ldots, s^n)$ *is IU. Conversely, fix an IU profile* $(s^1, \ldots, s^n)$. *There is a type structure and a state* $(s^1, t^1, \ldots, s^n, t^n)$ *at which there is RCBR.* Results like this can be found in the early literature – see, among others, Brandenburger and Dekel (1987) and Tan and Werlang (1988).

An important stimulus to the early literature was the pair of papers by Bernheim (1984) and Pearce (1984), which introduced the solution concept of *rationalizability*. This differs from IU by requiring on each round that a player's probability measure on the product of the other players' (remaining) strategy sets be a product measure – that is, be independent. Thus the set of rationalizable strategy profiles is contained in the IU set. It is well known that there are games (with three or more players) in which inclusion is strict.

The argument for the independence assumption is that in non-cooperative game theory it is supposed that players do not coordinate their strategy choices. Interestingly though, correlation is

consistent with the non-cooperative approach. This view is put forward in Aumann (1987). (Aumann, 1974, introduced the study of correlation into non-cooperative theory.) Consider an analogy to coin tossing. A correlated assessment over coin tosses is possible, if there is uncertainty over the coin's parameter or 'bias'. (The assessment is usually required to be conditionally i.i.d., given the parameter.) Likewise, in a game, Charlie might have a correlated assessment over Ann's and Bob's strategy choices, because, say, he thinks Ann and Bob have observed similar signals before the game (but is uncertain what the signal was).

The same epistemic tools used to understand IU can be used to characterize other solution concepts on the matrix. Aumann and Brandenburger (1995, Preliminary Observation) point out that pure-strategy Nash equilibrium is characterized by the simple condition that each player is rational and assigns probability 1 to the actual strategies chosen by the other players. (Thus, in Example 1.1 above, these conditions hold at the state (D, t^a, R, t^b), and (D, R) is indeed a Nash equilibrium.) As far as mixed strategies are concerned, in the epistemic approach to games these don't play the central role that they do under equilibrium analysis. Built into the set-up of section "Epistemic Analysis" is that each player makes a definite choice of (pure) strategy. (If a player does have the option of making a randomized choice, this can be added to the – pure – strategy set. Indeed, in a finite game, a finite number of such choices can be added.) It is the other players who are uncertain about this choice. Harsanyi (1973) originally proposed this shift in thinking about randomization. Aumann and Brandenburger (1995) give an epistemic treatment of mixed-strategy Nash equilibrium along these lines.

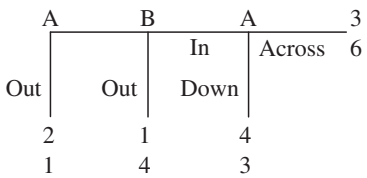
Aumann (1987) asks a question about an outside observer of a game. He provides conditions under which the observer's assessment of the strategies chosen will be the distribution of a correlated equilibrium (as defined in his 1974 paper). The distinctive condition in (1987) is the so-called Common Prior Assumption, which says that the probability assessment associated with each player's type is the same as the observer's assessment, except for being conditioned on what the type in question knows. A number of papers have investigated foundations for this assumption – see, among others, Morris (1994), Samet (1998), Bonanno and Nehring (1999), Feinberg (2000), Halpern (2002), and also the exchange between Gul (1998) and Aumann (1998).

Next Steps: The Tree

An important next step in the epistemic programme was extending the analysis to game trees. A big motivation for this was to understand the logical foundation of *backward induction* (*BI*). At first sight, BI is one of the easiest ideas in game theory. If Ann, the last player to move, is rational, she will make the BI choice. If Bob, the second-to-last player to move, is rational and thinks Ann is rational, he will make the choice that is maximal given that Ann makes the BI choice – that is, he too will make the BI choice. And so on back in the tree, until the BI path is a identified (Aumann, 1995).

For example, Fig. 3.1 is three-legged centipede (Rosenthal, 1981). (The top payoffs are Ann's, and the bottom payoffs are Bob's.) BI says Ann plays *Out* at her first node. But what if she doesn't? How will Bob react? Perhaps Bob will conclude that Ann is an irrational player, who plays *Across*. That is, Bob might play *In*, hoping to get a payoff of 6 (better than 4 from *Out*). Perhaps, anticipating this, Ann will in fact play *Down*, hoping to get 4 (better than 2 from playing *Out*).

Many papers have examined this conceptual puzzle with BI – see, among others, Binmore



Epistemic Game Theory: Complete Information, Fig. 3.1

(1987), Bicchieri (1988, 1989), Basu (1990), Bonanno (1991), and Reny (1992).

A key step in resolving the puzzle is extending the epistemic tools of section "Epistemic Analysis", to be able to talk formally about rationality, beliefs and so on in the tree.

Example 3.1 (Three-Legged Centipede) Figure 3.2 *is a type structure for three-legged Centipede.*

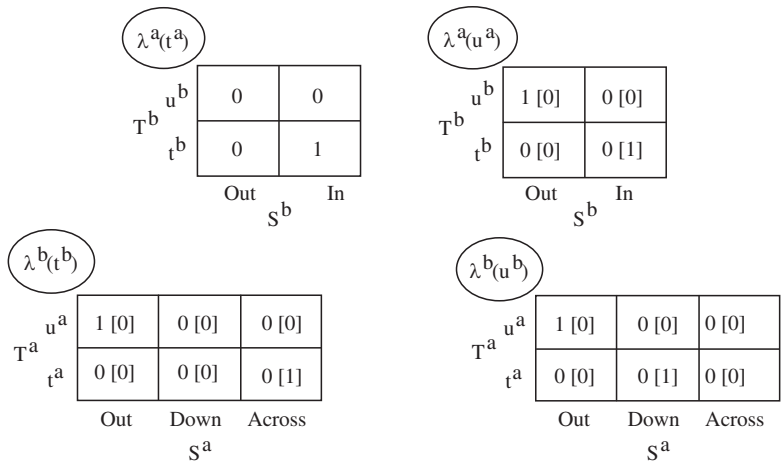
There are two types t^a, u^a for Ann. Type t^a for Ann has the measure shown in the top-left matrix. It assigns probability 1 to (In, t^b) for Bob. Type u^a has two associated measures – shown in the top-right matrix. The first measure (the numbers without parentheses) assigns probability 1 to (Out, u^b) for Bob. In this case, we also specify a second measure for Ann, because we want to specify what Ann thinks at her second node, too. Reaching this node is assigned positive probability (in fact, probability 1) under Ann's type t^a, but probability 0 under her type u^a. So, for type u^a, there isn't a well-defined conditional probability measure at Ann's second node. This is why we (separately) specify a second measure for Ann's type u^a: it is the measure in square brackets. If type u^a, Ann assigns probability 1 to (In, t^b) at her second node.

There are also two types t^b, u^b for Bob. Both types initially assign probability 1 to Ann's playing Out. For both of Bob's types, there isn't a well-defined conditional probability measure at his node. At his node, Bob's type t^b assigns probability 1 to $\{(Across, t^a)\}$, while his type u^b assigns probability 1 to $\{(Down, t^a)\}$.

This is a simple illustration of the concept of a *conditional probability system* (*CPS*), due to Rényi (1955). A CPS specifies a family of conditioning events E and a measure p_E for each such event, together with certain restrictions on these measures. The interpretation is that p_E is what the player believes, after observing E. Even if $p_\Omega(E) = 0$ (where Ω is the entire space), the measure p_E is still specified. That is, even if E is 'unexpected', the player has a measure if E nevertheless happens. This is why CPS's are well-suited to epistemic analysis of game trees – where we need to be able to describe how players react to the unexpected.

Myerson (1991, ch. 1) provided a preference-based axiomatization of a class of CPS's. Battigalli and Siniscalchi (1999, 2002) further developed both the pure theory and the game-theoretic application of CPS's (see below).

Suppose the true state in Fig. 3.2 is (*Down*, t^a, *In*, t^b). In particular, Ann plays *Down*, expecting Bob to play *In*. Bob plays *In*, expecting (at his node) Ann to play *Across*. Ann expects a payoff of 4 (and gets this). Bob expects a payoff of 6 (but gets only 3). In everyday language, we can say that Ann successfully bluffs Bob. (At the state



Epistemic Game Theory: Complete Information, Fig. 3.2

(*Down*, t^a, *In*, t^b), the bluff works. By contrast, at the state (*Down*, t^a, *Out*, u^b), Ann attempts the bluff and it fails.)

But what about epistemic conditions? Are the players rational in this situation? Does each think the other is rational? And so on.

To answer, we need a definition of rationality with CPS's. Fix a strategy-type pair (s^i, t^i), where t^i is associated with a CPS. Call this pair **rational (in the tree)** if the following holds: fix any information set H for i allowed by s^i, and look at the measure on the other players' strategies, given H. (This means given the event that the other players' strategies allow H.) Require that s^i maximizes i's expected payoff under this measure, among all strategies r^i of i that allow H.

With this definition, the rational strategy-type pairs in Fig. 3.2 are (*Down*, t^a), (*Out*, u^a), (*In*, t^b), and (*Out*, u^b).

Next, what does Ann think about Bob's rationality? To answer, we need a CPS-analogue to belief (as defined in section "Early Results"). Ben Porath (1997) proposed the following (we have taken the liberty of changing terminology, for consistency with 'strong belief' below): Say player i **initially believes** event E if, under i's CPS, E gets probability 1 at the root of the tree. (Formally, the conditioning event consists of all strategy profiles of the other players.) Battigalli and Siniscalchi (2002) strengthened this definition to: Say player i **strongly believes** event E if, under i's CPS, E gets probability 1 at every information set at which E is possible. Under initial belief, E also gets probability 1 at any information set H that gets positive probability under i's initial measure (that is, i's measure given the root). This is just standard conditioning on non-null events. But under strong belief, this conclusion holds for any information set H which has a non-empty intersection with E – even if H is null under i's initial measure. This is why strong belief is stronger than initial belief.

Let us apply these definitions to Fig. 3.2. Does Ann initially believe that Bob is rational? Yes. Both of Ann's types initially believe Bob is rational. Type t^a initially assigns probability 1 to the rational pair (*In*, t^b). Type u^a initially assigns probability 1 to the rational pair (*Out*, u^b). In fact, both types strongly believe Bob is rational. Since, under type t^a, Ann's second node gets positive probability (in fact, probability 1) under her initial measure, we need only check this for type u^a. But at Ann's second node, type u^a assigns probability 1 to the rational pair (*In*, t^b).

Turning to Bob, both of his types initially believe that Ann is rational. Type u^b even strongly believes Ann is rational; but type t^b doesn't. This is because, at Bob's node, type t^b assigns positive probability (in fact, probability 1) to the irrational pair (*Across*, t^a).

Staying with initial belief (we come back to strong belief below), we can parallel Definition 2.1 and define inductively **rationality and mth-order initial belief of rationality (RmIBR)** at a state of a type structure, and **rationality and common initial belief of rationality (RCIBR)** (see Ben Porath, 1997). In Fig. 3.2, since all four types initially believe the other player is rational, a simple induction gives that at the state (*Down*, t^a, *In*, t^b) for instance, RCIBR holds.

In words, Ann plays across at her first node, believing (initially) that Bob will play *In*, so she can get a payoff of 4. Why would Bob play In? Because he initially believes that Ann plays *Out*. But in the probability-0 event that Ann plays across at her first node, Bob then assigns probability 1 to Ann's playing across at her second node – that is, to Ann's being irrational. He therefore (rationally) plays *In*. All this is consistent with RCIBR.

Conditions for Backward Induction

Interestingly, this is exactly the line of reasoning which, as we said, was the original stimulus for investigating the foundations of BI. So, there is no difficulty with it – we've just seen a formal set-up in which it holds. The resolution of the BI puzzle is simply to accept that the BI path may not result.

But one can also argue that RCIBR is not the right condition: it is too weak. In the above example, Bob realizes that he might be 'surprised' in the play of the game – that's why he has a CPS, not just an ordinary probability measure. If he realizes he might be surprised, should he abandon his

(initial) belief that Ann is rational when he is surprised? Bob's type t^b does so. This is the step taken by Battigalli and Siniscalchi (2002) with their concept of strong belief. The argument says that we want t^b to strongly believe, not just initially believe, that Ann is rational. Type t^b will strongly believe Ann is rational if we move the probability-1 weight (in square brackets) on (*Across*, t^a) to (*Down*, t^a). But now (*In*, t^b) isn't rational for Bob, so Ann doesn't (even initially) believe Bob is rational. It looks as if the example unravels.

We can again parallel Definition 2.1 and define inductively **rationality and *m*th-order strong belief of rationality (R*m*SBR)**, and **rationality and common strong belief of rationality (RCSBR)** (see Battigalli and Siniscalchi, 2002). The question is then: does RCSBR yield BI?

The answer is yes. *Fix a CPS-based type structure for n-legged Centipede* (Fig. 4.1), *and a state at which there is RCSBR. Then Ann plays Out*. The result follows from Friedenberg (2002), who shows that in a PI game (satisfying certain payoff restrictions), RCSBR yields a Nash-equilibrium outcome. In Centipede, there is a unique Nash path and it coincides with the BI path. Of course, this isn't true in general.

Example 4.1 (A Second Coordination Game) *Consider the coordination game in* Fig. 4.2 *and the associated CPS-based type structure in* Fig. 4.3.

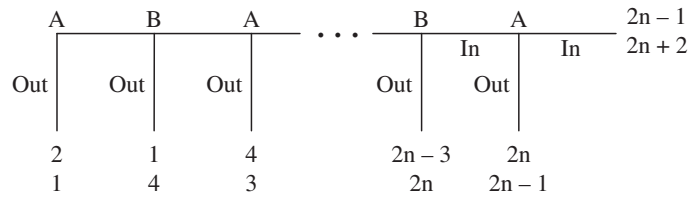
The rational strategy-type pairs are (*Out,* t^a) *and* (*Out,* t^b) *for Ann and Bob respectively. Ann's type* t^a *strongly believes* {(*Out,* t^b)}, *and Bob's type* t^b *strongly believes* {(*Out,* t^a)}. *By induction, RCSBR holds at the state* (*Out,* t^a, *Out,* t^b).

Here, the BI path need not be played under RCSBR. The key is to see that both (*Down*, t^a) and (*Across*, t^a) are irrational for Ann, since she (strongly) believes Bob plays *Out*. So at his node, Bob can't believe Ann is rational. If he considers it sufficiently more likely Ann will play *Down* rather than *Across*, he will rationally play *Out* (as happens). In short, if Ann doesn't play *Out*, she is irrational and so 'all bets are off' as to what she will do. She could play *Down*.

This situation may be surprising, at least at first blush, but there does not appear to be anything conceptually wrong with it. Indeed, it points to an interesting way in which the players in a game can literally be trapped by their beliefs – which here prevent them from getting their mutually preferred (3, 3) outcome.

But one can also argue differently. If Ann forgoes the payoff of 2 she can get by playing *Out* at the first node, then surely she must be playing *Across* to get 3. Playing *Down* to get 0 makes little sense since this is lower than the payoff she gave up at the first node. (This is forward-induction reasoning à la Kohlberg and Mertens, 1986, Section 2.3, introduced in the context of non-PI games. Interestingly, epistemic analysis makes clear that the issue already arises in PI games, such as Fig. 4.2.) But if Bob considers *Across* (sufficiently) more likely than *Down*, he will play *In*. Presumably then, Ann will indeed play *Across*, and the BI path results.

There is no contradiction with the previous analysis because in Fig. 4.3 Ann is irrational once she doesn't play *Out*, so we can't say Ann should then rationally play *Across* not *Down*. To make *Across* rational for Ann, we have to add more types to the structure – specifically, we would want to add a second type for Ann that assigns (initial) probability 1 to Bob's playing *In* not *Out*. This key insight is due to Stalnaker (1998) and Battigalli and Siniscalchi (2002).

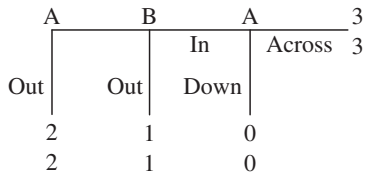


Epistemic Game Theory: Complete Information, Fig. 4.1

Battigalli and Siniscalchi formulate a general result of this kind. They consider a **complete** CPS-based type structure, which contains, in a certain sense, every possible type for each player (a complete type structure will be uncountably infinite), and prove: *Fix a complete CPS-based type structure. If there is RCSBR at the state* $(s^1, t^1, ..., s^n, t^n)$, *then the strategy profile* $(s^1, ..., s^n)$ *is extensive-form rationalizable. Conversely, if the profile* $(s^1, ..., s^n)$ *is extensive-form rationalizable, then there is a state* $(s^1, t^1, ..., s^n, t^n)$ *at which there is RCBR.*

The extensive-form rationalizability strategies (Pearce, 1984) yield the BI outcome in a PI game (under an assumption ruling out certain payoff ties; Battigalli, 1997), so the Battigalli and Siniscalchi analysis gives epistemic conditions for BI.

There are other routes to getting BI in PI games. Asheim (2001) develops an epistemic analysis using the properness concept (Myerson, 1978). Go back to Example 4.1. The properness idea says that Bob's type t^b should view (*Across*, t^a) as infinitely more likely than (*Down*, t^a) since *Across* is the less costly 'mistake' for Ann, given her type t^a. Unlike the completeness route taken above, the irrationality of both *Down* and *Across* (given Ann's type t^a) is accepted. But the relative ranking of these 'mistakes' must be in the right order. With this ranking, Bob is irrational to play *Out* rather than *In*. Ann presumably will play *Across*, and we get BI again. Asheim (2001) formulates a general such result.

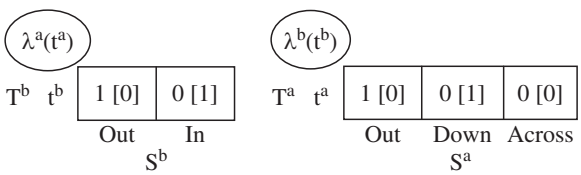


Epistemic Game Theory: Complete Information, Fig. 4.2

Another strand of the literature on BI employs knowledge models rather than belief models. As pointed out in Example 1.1, players' beliefs don't have to be correct in any sense. For example, a type might even assign probability 1 to a strategy-type pair for another player different from the actual one. Knowledge as usually formalized is different, in that if a player knows an event E, then E indeed happens.

Aumann (1995) formulates a knowledge-based epistemic model for PI trees. In his set-up, the condition of common knowledge of rationality implies that the players choose their BI strategies. Stalnaker (1996) finds that non-BI outcomes are possible, under a different formulation of the same condition. The explanation lies in differences in how counterfactuals are treated. These play an important role in a knowledge-based analysis, when we talk about what a player thinks at an information set that cannot be reached given what he knows. Halpern (2001) provides a synthesis in which these differences can be understood. See also the exchange between Binmore (1996) and Aumann (1996), and the analyses by Samet (1996), Balkenborg and Winter (1997), and Halpern (1999).

Aumann (1998) provides knowledge-based epistemic conditions under which Ann plays *Out* in Centipede. The conditions are weaker than in his (1995) paper, and the conclusion weaker (about outcomes not strategies). There is an obvious parallel between this result and the belief-based result on Centipede we stated above (also about outcomes). More generally, there may be an analogy between counterfactuals in knowledge models and extended probabilities in belief models. But, for one thing, completeness is crucial to the belief-based approach, as we have seen, and an analogous concept does not appear



Epistemic Game Theory: Complete Information, Fig. 4.3

to be present in the knowledge-based approach. As yet, there does not appear to be any formal treatment of the relationship between the two approaches.

Next Steps: Weak Dominance

Extending the epistemic analysis of games from the matrix to the tree has been the focus of much recent work in the literature. Another area has been extending the analysis on the matrix from strong dominance (described in section "Early Results") to weak dominance.

Weak dominance (admissibility) says that a player considers as possible (even if unlikely) any of the strategies for the other players. In the game context, we are naturally led to consider *iterated admissibility* (*IA*) – the weak-dominance analogue to IU. This is an old concept in game theory, going back at least to Gale (1953). Like BI, it is a powerful solution concept, delivering sharp answers in many games – Bertrand, auctions, voting games, and others. (Mertens, 1989, p. 582, and Marx and Swinkels, 1997, pp. 224–5, list various games involving weak dominance.)

But, also like BI, there is a conceptual puzzle. Suppose Ann conforms to the admissibility requirement, so that she considers possible any of Bob's strategies. Suppose Bob also conforms to the requirement, and this leads him not to play a strategy, say *L*. If Ann thinks Bob adheres to the requirement (as he does), then she can rule out Bob's playing *L*. But this conflicts with the requirement that she not rule anything out (see Samuelson, 1992).

Can a sound argument be made for IA? To investigate this, the epistemic tools of section "Epistemic Analysis" have to be extended again.

Example 5.1 (Bertrand) Figure 5.1 *is a Bertrand pricing game, where each firm chooses a price in* {*0, 1, 2, 3*}. (*Ken Corts kindly provided this example*.) *The left payoff is to A, the right payoff to B. Each firm has capacity of two units and zero cost. Two units are demanded. If the firms charge the same price, they each sell one unit*. Figure 5.2 *is an associated type structure* (*with one type for each player*).

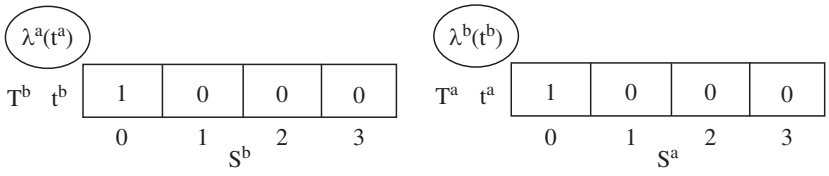
A \ B	3	2	1	0
3	3, 3	0, 4	0, 2	0, 0
2	4, 0	2, 2	0, 2	0, 0
1	2, 0	2, 0	1, 1	0, 0
0	0, 0	0, 0	0, 0	0, 0

Epistemic Game Theory: Complete Information, Fig. 5.1

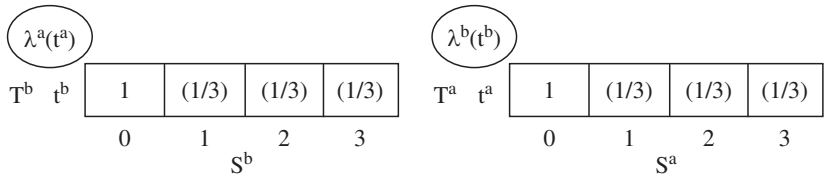
The rational strategy-type pairs are $R_1^a = \{0,1,2,3\} \times \{t^a\}$ *and* $R_1^b = \{0,1,2,3\} \times \{t^b\}$. *Since both types assign positive probability only to a rational strategy-type pair for the other player, we get* $R_m^a = R_1^a$ *and* $R_m^b = R_1^b$ *for all m. In particular, there is RCBR at the state* (*3,* t^a*, 3,* t^b).

But a price of 3 is inadmissible (as is a price of 0). The IA set is just {(1,1)}, where each firm charges the lowest price above cost. (This is a plausible scenario: while pricing at cost is inadmissible, competition forces price down to the first price above cost.)

A tool to incorporate admissibility is *lexicographic probability systems* (*LPS*'s), introduced and axiomatized by Blume et al. (1991a, b). An LPS specifies a sequence of probability measures. The interpretation is that the first measure is the player's primary hypothesis about the true state. But the player recognizes that his primary hypothesis might be mistaken, and so also forms a secondary hypothesis. This is his second measure. Then his tertiary hypothesis, and so on. The primary states can be thought of as infinitely more likely than the secondary states, which are infinitely more likely than the tertiary states, and so on. Stahl (1995), Stalnaker (1998), Asheim (2001), Brandenburger et al. (2006), and Asheim and Perea (2005), among other papers, use LPS's.



Epistemic Game Theory: Complete Information, Fig. 5.2



Epistemic Game Theory: Complete Information, Fig. 5.3

Example 5.2 (Bertrand Contd) Figure 5.3 *is a type structure for Bertrand* (Fig. 5.1) *that now specifies LPS's.*

Each player has a primary hypothesis which assigns probability 1 to the other player's charging a price of 0. But each player also has a secondary hypothesis that assigns equal probability to each of the three remaining choices for the other player. This measure is shown in parentheses. Note that every state (that is, strategy-type pair) gets positive probability under some measure. But states can also be ruled out, in the sense that they can be give infinitely less weight than other states.

What about epistemic conditions? Are the players rational in this situation? Does each think the other is rational? And so on.

To answer, we need a definition of rationality with LPS's. Fix strategy-type pairs (s^i, t^i) and (r^i, t^i) for player i, where t^i is now associated with an LPS. Calculate the tuple of expected payoffs to i from s^i, using first the primary measure associated with t^i, then the secondary measure associated with t^i, and so on. Calculate the corresponding tuple for r^i. If the first tuple lexicographically exceeds the second, then s^i is preferred to r^i. (If $x = (x_1,..., x_n)$ and $y = (y_1,..., y_n)$, then x lexicographically exceeds y if $y_j > x_j$ implies $x_k > y_k$ for some $k < j$.) A strategy-type pair (s^i, t^i) is **rational (in the lexicographic sense)** if s^i is maximal under this ranking.

So $(3, t^a)$ and $(3, t^b)$ are irrational. All choices give each player an expected payoff of 0 under the primary measure. But a price of 2 gives each player an expected payoff of 2 under the secondary measure, as opposed to an expected payoff of 1 from a price of 3. Conceptually, we want $(3, t^a)$ and $(3, t^b)$ to be irrational (because a price of 3 is inadmissible).

What does each player think about the other's rationality? For this, we again need an LPS-based definition. An early candidate in the literature was: Say player i **believes** event E **at the 1st level** if E gets primary probability 1 under i's LPS (Börgers, 1994; Brandenburger, 1992). A stronger concept is: Say i **assumes** E if all states not in E are infinitely less likely than all states in E, under i's LPS (Brandenburger, Friedenberg and Keisler, 2006). In other words, a player who assumes E recognizes E may not happen, but is prepared to 'count on' E versus not-E.

In Fig. 5.3, type t^a doesn't 1st-level believe (so certainly doesn't assume) the other player is rational. Likewise with t^b. Again, this is right conceptually.

Conditions for Iterated Admissibility

Once again we can parallel Definition 2.1 and define inductively **rationality and *m*th-order 1st-level belief of rationality (R*m*1BR)** at a state of a type structure, and **rationality and common 1st-level belief of rationality (RC1BR)**. Likewise, one can define **rationality and *m*th-order assumption of rationality (R*m*AR), and rationality and common assumption of rationality (RCAR).** What do these conditions yield?

In fact, just as we saw in sections "Next Steps: The Tree and Conditions for Backward Induction" that neither RCIBR not RCSBR yields BI, so neither RC1BR nor RCAR yields IA. RC1BR is characterized by the $S^{\infty}W$ concept (Dekel and Fudenberg, 1990), that is, the set of strategies that remain after one round of deletion of inadmissible strategies followed by iterated deletion of strongly dominated strategies. RCAR is characterized by the self-admissible set concept (Brandenburger, Friedenberg and Keisler, 2006). Self-admissible sets may be viewed as the weak-dominance analogue to Pearce (1984) best-response sets.

But while the IA set is one self-admissible set in a game, there may well be others. To select the IA set, a completeness assumption is needed, similar to section "Conditions for Backward Induction": *Fix a complete LPS-based type structure. If there is RmAR at the state* $(s^1, t^1, ..., s^n, t^n)$*, then the strategy profile* $(s^1, ..., s^n)$ *survives* $(m + 1)$ *rounds of iterated admissibility. Conversely, if the profile* $(s^1, ..., s^n)$ *survives* $(m + 1)$ *rounds of iterated admissibility, then there is a state* $(s^1, t^1, ..., s^n, t^n)$ *at which there is RmAR* (Brandenburger, Friedenberg and Keisler, 2006).

This result is stated for R*m*AR and not RCAR. See the next section for the reason. Of course, for a given game, there is an m such that IA stabilizes after m rounds.

IA yields the BI outcome in a PI game (again ruling out certain payoff ties; Marx and Swinkels, 1997), so, understanding IA gives, in particular, another analysis of BI.

Related analyses of IA include Stahl (1995) and Ewerhart (2002). Stahl uses LPS's and directly assumes that Ann considers one of Bob's strategies infinitely less likely than another if the first is eliminated on an earlier round of IA than the second. Ewerhart gives an analysis of IA couched in terms of provability (from mathematical logic).

Strategic Versus Extensive Analysis

Kohlberg and Mertens (1986, Section 2.4) argued that a 'fully rational' analysis of games should be invariant – that is, should depend only on the fully reduced strategic form of a game. (This is the strategic form after elimination of any – pure – strategies that are duplicates or convex combinations of other strategies.) In this, they appealed to early results in game theory (Dalkey, 1953; Thompson, 1952) which established that two trees sharing the same reduced strategic form differ from each other by a (finite) sequence of elementary transformations of the tree, each of which can be argued to be 'strategically inessential'. Kohlberg and Mertens added a fourth transformation involving convex combinations, to get to the fully reduced strategic form.

In decision theory, invariance is implied by (and implies) admissibility. (Kohlberg and Mertens, 1986, Section 2.7, gave the essential idea. See Brandenburger, 2007, for the decision-theory argument.) If we build up our game analysis using a decision theory that satisfies admissibility, we can hope to get invariance at this level too. LPS-based decision theory satisfies admissibility. Indeed, IA, and also the $S^{\infty}W$ and self-admissible set concepts, are invariant in the Kohlberg–Mertens sense. The extensive-form rationalizability concept (section "Conditions for Backward Induction") is not.

There does appear to be a price paid for invariance, however. The extensive-form conditions of RCSBR and (CPS-based) completeness are consistent (in any tree). That is, for any tree, we can build a complete type structure and find a state at which RCSBR holds. But Brandenburger et al. (2006) show the strategic-form conditions of RCAR and (LPS-based) completeness are inconsistent (in any matrix satisfying a non-triviality condition).

A possible interpretation is that rationality, even as a theoretical concept, appears to be inherently limited. There are purely theoretical limits to the Kohlberg-Mertens notion of a 'fully rational' analysis of games.

The epistemic programme has uncovered a number of impossibility results (see epistemic game theory: beliefs and types for some others). We don't see this as a deficiency of the programme, but rather as a sign it has reached a certain depth and maturity. Also, central to the programme is the analysis of scenarios (we have seen several in this survey) that are 'a long way from' these theoretical limits. Under the epistemic approach to game theory there is not one right set of assumptions to make about a game.

Epistemic Game Theory: Incomplete Information

Aviad Heifetz

Abstract

In a game of incomplete information some of the players possess private information which may be relevant to the strategic interaction. Private information is modelled by a *type*

space, in which every type of each player is associated with a belief about the basic issues of uncertainty (like payoffs) and about the other players' types. At a *Bayesian equilibrium* each type chooses a strategy which maximizes its expected payoff given the choice of strategies by the other players' types. Bayesian equilibrium payoffs are often inefficient relative to the equilibrium payoffs that would result had the players been fully informed.

A game of incomplete information is a game in which at least some of the players possess private information which may be relevant to the strategic interaction. The private information of a player may be about the payoff functions in the game, as well as about some exogenous, payoff-irrelevant events. The player may also form beliefs about other players' beliefs about payoffs and exogenous events, about their beliefs about the beliefs of others, and so forth.

Harsanyi (1967–8) introduced the idea that such a state of affairs can be succinctly described by a *type space*. With this formulation, T_i denotes the set of player i's *types*. Each type $t_i \in T_i$ is associated with a belief $\lambda_i(t_i) \in \Delta(K \times T_{-i})$ about some basic space of uncertainty, K, and the combination T_{-i} of the other players' types. The basic space of uncertainty K is called the space of *states of nature*, and $\Omega = K \times \Pi_{i \in I} T_i$, where I is the set of players, is called the space of *states of the world*.

A type space models a game of incomplete information once each state of nature $k \in K$ is associated with a payoff matrix of the game, or, more generally, with a payoff function u_i^k for each player $i \in I$. This payoff function specifies the player's payoff $u_i^k(s)$ for each combination of strategies $s = (s_i)_{i \in I} \in S = \Pi_{i \in I} S_i$ of the players. (In the particular case in which k is associated with a payoff matrix, that is, the game is such that each player has finitely many strategies, the payoffs $u_i^k(s)$ to the players $i \in I$ appear in the entry of the matrix corresponding to the combination of strategies $s = (s_i)_{i \in I}$.) As usual, the set of strategies S_i of player $i \in I$ may be a complex object by itself. For instance, it may be the set of mixed strategies over some set of pure strategies S_i^0. The payoff function of player i in the state of nature k is $u_i^k : S \to \mathbb{R}$.

Obviously, different types of a player may want to choose different strategies. Thus, a *Bayesian strategy* of player i in a game of incomplete information specifies the strategy $\sigma_i(t_i) \in S_i$ that the player chooses given each one of her types $t_i \in T_i$.

Given a profile of Bayesian strategies $\sigma = (\sigma_j : T_j \to S_j)_{j \in I}$ of the players, the expected payoff of player i of type t_i is

$$U_i(\sigma, t_i) = \sum_{(k, t_{-i}) \in K \times T_{-i}} u_i^k\left(\sigma_i(t_i), \sigma_{-i}(t)\right) \times \lambda_i(t_i)(k, t_{-i})$$

where $\sigma_{-i}(t_{-i}) = (\sigma_j(t_j))_{j \neq i}$. If there is a continuum of states of nature and types, the sum becomes an integral:

$$U_i(\sigma, t_i) = \int_{K \times T_{-i}} u_i^k\left(\sigma_i(t_i), \sigma_{-i}(t_{-i})\right) d\lambda_i(t_i)(k, t_{-i})$$

(In this case, the expected payoff function $U_i(\sigma, t_i)$ is well defined if the Bayesian strategies $\sigma_j : T_j \to S_j$ are measurable functions and if the payoff function $u_i : K \times S \to R$ is measurable as well; we omit the details of this technical requirement).

We assume that the players are expected payoff maximizers. Thus, player i prefers the Bayesian strategy σ over σ' if and only if $U_i(\sigma, t_i) \geq U_i(\sigma', t_i)$ for each of her types $t_i \in T_i$. It follows that given a Bayesian strategy profile σ_{-i} of the other players, the Bayesian strategy σ_i is a *best reply* of player i if for any other strategy σ' of hers, $U_i((\sigma_i, \sigma_{-i}), t_i) \geq U_i((\sigma', \sigma_{-i}), t_i)$ for each of her

types $t_i \in T_i$. A *Bayes–Nash equilibrium* or a *Bayesian equilibrium* is a profile of Bayesian strategies $\sigma^* = (\sigma_{i*})_{i \in I}$ such that σ_{i*} is a best reply against σ_{-i*} for every player $i \in I$.

A simple, discrete variant of an example by Gale (1996) may clarify these abstract definitions. There are two investors $i = 1, 2$ and three possible states of nature $k \in K = \{-1, 0, 1\}$. Each investor i only knows her own type

$$t_i \in T_i = \{-10, -6, -2, 2, 6, 10\}.$$

Every type t_i of investor i believes that all of the other investor's types $t_j \in T_j, j \neq i$, are equally likely, so that each of them has probability $\frac{1}{6}$. Moreover, every type t_i believes that the state of nature is $k = 1$ when $t_i + t_j > 0$; that the state of nature is $k = 0$ when $t_i + t_j = 0$; and that the state of nature is $k = -1$ when $t_i + t_j < 0$. Formally, the belief $\lambda_i(t_i)$ of type $t_i \in T_i$ is defined by

$$\lambda_i(t_i)(k, t_j) = \begin{cases} \frac{1}{6} & k \text{ has the same sign as } t_i + t_j \\ 0 & \text{otherwise} \end{cases}$$

The investors cannot communicate their types to one another. They can invest in at most one of two available investment periods. Each investor has three relevant strategies: invest *immediately*, in the first period; *wait* to the second period and invest only if the other investor has invested in the first period; or *never* invest. The payoff of each of the investors depends on the state of nature $k \in K = \{-1, 0, 1\}$ and on her own investment strategy, but not on the investment strategy of the other investor. The payoffs are as follows:

- Investing *immediately* when the state of nature is k yields investor i a payoff of k

$$u_i^k(\text{`}immediately\text{'}, \cdot) = k$$

(The $\cdot$ stands for the investment decision of the other investor $j \neq i$, which, as we said, does not effect the payoff of investor i.)

- If investor i chooses to *wait* to the second period and invest only if the other investor has invested in the first period, investor i's payoff in the state of nature k is

$$u_i^k(\text{`}wait\text{'}, \cdot) = -\frac{3}{4}k.$$

- If the investor *never* invests, her payoff is 0 irrespective of the state of nature:

$$u_i^k(\text{`}never\text{'}, \cdot) = 0.$$

How will the different types behave at a Bayesian equilibrium? The type $t_i = 10$ assesses that by investing immediately her expected payoff is

$$Ui(\text{`}immediately\text{'}, 10) = \frac{1}{6} \times 0 + \frac{5}{6} \times 1 = \frac{5}{6}$$

(immediate investment yields 0 in case $t_j = -10$, and yields 1 in case $t_j = -6, -2, 2, 6, 10$). This is higher than $\frac{3}{4}$, the maximum payoff she could possibly get by waiting for the second period, and higher than the payoff 0 of never investing. So at a Bayesian equilibrium

$$\sigma_i^*(10) = \text{`}immediately\text{'}, \quad i = 1, 2.$$

Next, the expected payoff to the type $t_i = 6$ from immediate investment is

$$Ui(\text{`}immediately\text{'}, 6) = \frac{1}{6} \times (-1) + \frac{1}{6} \times 0 + \frac{4}{6} \times 1 = \frac{1}{2}$$

(immediate investment yields 1 unless $t_j = -10$, in which case the payoff is -1, or $t_j = -6$, in which case the payoff is 0). So investing immediately is preferred for her over never investing. But how about waiting until the second period? That's an inferior option as well, since the types $t_j = -10, -6, -2$ will never invest in the first period (this would yield them a negative expected payoff). So only the positive types $t_j = 2, 6, 10$ could *conceivably* invest immediately, with overall probability reaching at most $\frac{3}{6}$. So waiting to see if they invest yields to the type $t_i = 6$ an expected payoff not higher $\frac{3}{6} \times \frac{3}{4} = \frac{3}{8}$, which is smaller than $\frac{1}{2}$. We conclude that the preferable strategy of $t_i = 6$ at equilibrium is

$$\sigma_i^*(6) = \text{`}immediately\text{'},\ \ i = 1, 2.$$

What about $t_i = 2$? Immediate investment yields her

$$Ui(\text{`}immediately\text{'}, 2) = \frac{2}{6} \times (-1) + \frac{1}{6} \times 0 + \frac{3}{6} \times 1 = \frac{1}{6}$$

(-1 is the payoff when $t_j = -10, -6$; 0 is the payoff when $t_j = -2$; the payoff is 1 otherwise). However, given that the types $t_j = 6,10$ invest immediately at equilibrium, and that the negative types $t_j = -10, -6, -2$ do not invest immediately, the type $t_i = 2$ figures out that by waiting and investing only if the other investor has invested first would yield her an expected payoff

$$Ui(\text{`}wait\text{'}, 2) \geq \frac{2}{6} \times \frac{3}{4} = \frac{1}{4} > \frac{1}{6}$$

($\frac{2}{6}$ is the probability assigned by $t_i = 2$ to the event that $t_j \in \{6, 10\}$ and hence j invests immediately, and $\frac{3}{4}$ is the payoff from the second period investment). Thepreferred strategy of $t_i = 2$ at equilibrium is therefore

$$\sigma_i^*(2) = \text{`}wait\text{'},\ \ i = 1, 2.$$

We can now compute inductively, in a similar way, that also

$$\sigma_i^*(-2) = \text{`}wait\text{'},\ \ i = 1, 2 \sigma_i^*(-6) = \text{`}wait\text{'},\ \ i = 1, 2$$

and that

$$\sigma_i^*(10) = \text{`}never\text{'},\ \ i = 1, 2.$$

Notice that the equilibrium in the example is inefficient. For instance, when the pair of types is $(t_1,t_2) = (2, 2)$ the investment is profitable, but both investors wait to see if the other one invests, and thus end up not investing at all. In this case, behaviour would become efficient if the investors could communicate their types to each other. Indeed, they would have been happy to do so, because their interests are aligned.

Obviously, there are other strategic situations with incomplete information in which the interests of the players are not completely aligned. For example, a potential seller of an object would like to strike a deal with a potential buyer at a price which is as high as possible, while the potential buyer would like the price to be as low as possible. That's why the traders might not volunteer to communicate honestly their private valuations of the object, even if they are technically able to do so. Still, in case the buyer values the object more than the seller, they would both prefer to trade at some price in-between their valuations rather than forgoing trade altogether. Therefore, the traders would nevertheless like to avoid a complete lack of communication. Myerson and Satterthwaite (1983) phrase general conditions under which no Bayesian equilibrium of any trade mechanism is ever fully efficient due to this tension between interests alignment and interests mismatch. Under these conditions, even if the traders are able to communicate their private information, at no Bayesian equilibrium does trade take place in all instances in which there exist gains from trade.

In the above variant of Gale's example we were able to find the unique Bayesian equilibrium using iterative dominance arguments. We have iteratively crossed out strategies that are inferior for some types, which enabled us to eliminate inferior strategies for other types, and so forth. As in games of complete information, this technique is not applicable in general, and there are games with incomplete information in which a Bayesian equilibrium is not the outcome of any process of iterative elimination of dominated strategies (Battigalli and Siniscalchi 2003; Dekel et al. 2007).

Games with incomplete information are discussed in many game theory textbooks (for example, Dutta 1999; Gibbons 1992; Myerson 1991; Osborne 2003; Rasmusen 1989; Watson 2002). Aumann and Heifetz (2002), Battigalli and Bonanno (1999) and Dekel and Gul (1997) are advanced surveys.

Epistemological Issues in Economics

Shaun Hargreaves-Heap and Martin Hollis

Economics has raised such high hopes with its sophisticated techniques that the lack of agreed findings sets a puzzle. It will be suggested here that this lack of agreement reflects an epistemological puzzle, partly of how to recognize a causal law and partly of whether the search should be for causal laws in any case.

Start with the hypothetico-deductive method and the standard idea that economic theory advances when hypotheses confront the empirical evidence, as laid out in textbooks of positive economics, like Lipsey (1980). The backdrop is an empiricist picture of the natural world as an ordered realm, independent of our concepts, beliefs, hypotheses and conjectures about it. Science captures the order by testing our conjectures so as to arrive at causal laws or hypotheses describing what happens next in various initial conditions. Whether or not the world is governed by underlying forces and mechanisms, our knowledge of it, formulated in terms of causal laws, has only the empirical warrant conferred when observation and experiment uphold our generalizations. Scientific method is a matter of generalizing either from a known pattern to the next case (prediction) or from a particular case to a pattern which subsumes it (explanation). Prediction and explanation are thus two sides of the only epistemic coin, experience generalized. The economic world and economic knowledge are then construed on this natural science model.

This very basic empiricism needs supplementing in two ways, if it is to carry conviction. One is to give theory a more explicit role, which it plainly has in the practice of economics, without undermining the claims of prediction to be the only test of truth. A neat source is Friedman (1953), who associates economic theory with 'a language' and 'a body of substantive hypotheses'. The former is 'a set of tautologies' and 'its function is to act as a filing system'. The latter is 'designed to abstract essential features of a complex reality'. Whether the right features have been abstracted and included in the filing system depends solely on thee success of the resulting predictions. This echoes the Logical Positivists' distinction between analytic statements, whose truth relies on the meaning of terms and tells us nothing about the world, and synthetic statements, whose truth depends on the facts. Friedman's 'substantive hypotheses' serve to link pure theory (the 'filing system') to the world, while making sure that empirical facts wear the trousers.

The other supplement is Popper's (1963) account of science as conjectures and refutations. Reflecting that circular theories, like those of Freud and Marx, are always confirmed by experience in the eyes of their holders, he weakens the claim of empirical confirmation as a test of truth. Instead, it is falsifiability which separates science from pseudo-science. Formally, if hypothesis H implies observation O, then O does not prove H, but *not-O* refutes H. So a genuinely scientific theory must state possible empirical conditions in which it would be refuted. A causal law is an empirical hypothesis of sufficient scope and generality, which has risked refutation. In Popper's own eyes, he has made a radical break with traditional empiricism by undermining the value of induction. However, epistemologically, claims to knowledge still face the same old test and the facts of observation are still trumps. (This paragraph refers to Popper's best-known, classic account and not to his more recent writings.)

Later philosophy of science has raised serious difficulties for this empiricist approach to judging a theory. The Quine–Duhem hypothesis has it that a scientific theory is a web, which includes observation sentences and which can only be understood as a whole. Quine (1961), evoking Duhem (1914), argues that traditional empiricism relies on two untenable dogmas. One is that our five senses supply us with 'unvarnished news' as an objective and independent test of hypotheses. The other is that meaningful statements divide cleanly into analytic and synthetic (as defined above). Both dogmas are to be rejected. Our beliefs form a 'seamless web', a 'field of force which touches experience only at the edges'. At the moment of testing they 'face the tribunal of experience together' and, in assessing the verdict, we always have a choice of what to accept, revise or reject (including our own observations). In place of a single hypothesis H implying an unvarnished observation O, we have a set H_1H_2 ... etc. linked to another theory-laden set O_1O_2 ... etc. What we do about it, when we find that we cannot keep both sets, may be governed by criteria like parsimony, elegance or fertility, whose epistemic warrant is open to question and is far removed from any which relies on there being brute facts.

Economics is full of illustrations of the Quine–Duhem hypothesis. The 'money supply' or 'the general price level' are not brute facts. There are a number of different definitions of the money supply and ways of aggregating prices, and the choice of one rather than another will reflect theoretical considerations. The economist works with descriptions of data which already have theoretical order built into them, and this seems inescapable. Likewise, the joint testing of hypotheses is notoriously recognized in economics to be complicated by the role of *ceteris paribus* conditions. Predictions are always issued subject to certain *ceteris paribus* clauses, and if the prediction is falsified, the economist is often able to claim that this is because the *ceteris paribus* conditions were violated, particularly when, as in consumer theory, there are unobservable variables like preference orderings or utility functions to reckon with. So we find that empirical tests in economics are often indecisive. Few neoclassical economists, for example, seem willing to forsake the homogeneity assumption (the absence of money illusion) in consumer theory despite its frequent 'falsification'. Indeed, it looks rather as if, despite the common gestures of respect for Popper, economics is full of those circular theories which are always confirmed by experience in the eyes of their holders. The Quine–Duhem hypothesis is descriptively plausible.

This conclusion would not surprise Kuhn (1970), who argues that even the natural sciences have not progressed in the way expected by an empiricist methodology. Instead, their history is best understood as a discontinuous series of paradigms. By 'paradigms' he usually seems to mean the definitive current practices of the dominant scientific community and sometimes a more loosely specified set of currently shared presuppositions or world views. Paradigms rise and fall for many reasons, but empirical testing is never decisive. Rather, paradigms simply acquire more and more anomalies as contrary empirical evidence accumulates, and it is only when a new paradigm surfaces, which can incorporate the anomalies, that the anomalies become regarded as counter-examples. A paradigm shift then occurs. Feyerabend (1975) has continued this

process of dismantling empiricism, until it is unclear whether theory choice can be a rational process at all. This can be read as an invitation to a sociology of knowledge approach. If there is no good intellectual reason behind theory selection, then we must study the social pressures on and within the scientific communities, which influence the evolution of theory. In economics one might cite the suspicion in some quarters that the dominance of neoclassical economics owes much to its apparent support for a free enterprise system and that its mathematical sophistication is best understood as an exclusionary device typical of a closed profession. But a step into the sociology of knowledge is not the only option.

Lakatos (1978) tries to reaffirm the core of Popper by accepting that the units at stake are whole research programmes rather than single hypotheses, and that the core of the research programme is often defended against falsification by suitable adjustments to the auxiliary hypotheses or 'protective belt'. A research programme is to be judged, however, by whether these revisions to the protective belt are progressive or degenerating. Degenerating ones are *ad hoc* and cover only the anomaly which has precipitated the adjustment, whereas progressive ones provide additional and novel areas of application for the theory. The progressive/degenerative distinction sounds a promising way of reintroducing empirical criteria into the evaluation of a theory, but in practice this designation, like falsification earlier, is prone to vary with the eyes of the beholder. What looks progressive from one theoretical perspective can become *ad hoc* when viewed from another. For a setting to these developments the reader might usefully consult Harré (1972); for a chart of the options, Chalmers (1976); and for a robust post-empiricist philosophy of science, Hesse (1980).

Recent philosophy of science thus makes it unsurprising that economic methodologies inspired by empiricism are alive with controversy. But there are other sources of methodological inspiration. Weber (1922) draws an appealing but cloudy distinction between explaining *(erklären)* and understanding *(verstehen)*. Natural sciences seek to explain by means of causal laws; the humanities seek to understand by reconstructing the actors' world from within. The crux is the idea that the agent's own point of view matters in the social world in a way which does not hold for the natural sciences. Unlike the natural world, the social is *not* an ordered realm independent of our concepts, beliefs, hypotheses and conjectures about it. Our beliefs influence our actions and hence the outcomes we observe in any empirical investigation, whereas subatomic particles have no beliefs to affect outcomes in the natural world. This sets a puzzle for an empiricist methodology, which seeks the causal laws governing an independent realm. How is the social scientist to investigate the world from within and to relate these findings to the demands of objectivity?

Weber's answer is that some of his work is to be done by a process of *'verstehen'* – a key term from the German idealist, 'hermeneutic' (interpretative) tradition. The guiding thought is that what turns behaviour into action is its inward meaning and that institutions similarly are meaningful practices. But 'meaning' is an elusive concept, which threatens to let in more subjective variety than a social scientist can welcome. Weber tries to render *verstehen* more precise by stressing the rationality of action seen through the actor's eyes. He borrows the neoclassical economic concept of rational action. To the objection that real actions are not always rational, even when seen from within, he replies that, by establishing what would be fully rational, one can identify departures from the ideal type as *explananda*. *Verstehen* is not the only method, however. The social sciences seek both adequacy at the level of meaning and adequacy at the causal level, with the 'causal level' said to be one of statistically significant correlations. *Verstehen* is thus finally less of an alternative to *erklären* and more of a heuristic device; but an interesting line has been opened.

Among examples of the use of *verstehen* Weber cites pure mathematics. This suggests a more ambitious thought, one which finds echoes in economics itself. Von Mises (1949, 1960) presents economics as the science of human action and economic theory as the construction *a priori*

of ideal types of rational allocation. This yields an element of *a priori* knowledge contrary to empiricism. Similarly, Hayek (1960) and the new Austrians appeal to Kant and *a priori* knowledge when making their commitment to a methodological individualism grounded in the preconditions of the possibility of free choice.

Although a shift to a Kantian epistemology of pure reason would create more problems than it answers, it could have interesting implications. Consider, for example, Arrow–Debreu general equilibrium theory. It is not plausibly regarded either as a set of empirical hypotheses or as a mere filing system. Its proponents would not accept a sociology-of- knowledge suggestion that it belongs to the initiation rites of the profession. It functions very much as an 'ideal type', used for judging economic performance and making policy recommendations. What claim has to be made for it, if it is to be a reliable benchmark for performance? A Kantian reply is that it has to lay claim to truth, in the sense of stating correctly what would be the outcome of a fully rational allocation of resources throughout an economy. As in mathematics, the Kantian adds, *a priori* truths are hard to come by but are nonetheless what theory aims for. Arrow–Debreu general equilibrium theory makes sense on no other terms.

This is, of course, a contentious approach even to pure mathematics. It is doubly so for economics, owing to the role of rationality in its 'ideal types'. Not everyone would accept that Arrow–Debreu general equilibrium theory embodies an ideally rational allocation. Whether it does depends in part on how 'rationality' is defined. It is standardly given an instrumental definition, with a rational allocation being one which adopts the most efficient means to a given end. One reason for this definition is that it is believed to keep on the safe side of the positive/normative distinction and so to preserve the basic parts of economic theory from value judgements. This does not satisfy advocates of other approaches, especially political economists, who allege that Arrow–Debreu general equilibrium theorem has ideological commitments. A Kantian comment would be that 'ideal type' rationality is bound to involve the rationality of ends as well as of means. An ideally rational allocation of resources is the one which a just or good society would display, and an ideally rational choice is, in the last analysis, a moral choice. A switch to a Kantian epistemology may breach the positive/normative distinction and restore economics to the position of a moral science.

A challenge to the positive/normative distinction opens up deep epistemological questions. But some economists are willing to take the plunge, inspired by Rawls (1971). By defining a just society as one whose allocation of resources rational agents would agree upon in advance of knowing what they would each get out of it personally, Rawls connects economic rationality to moral choice. That makes it possible to ask precise questions about, for instance, the rationality of preferences and which kind of preferences should be satisfied in cases of conflict. The hope might be said to be an *a priori*, normative science with implications both for efficiency and for moral advance. This is to take seriously the thought that to know what would be ideally rational is to know how to do better.

Rawls's epistemological novelty lies in the use of a thought-experiment, inviting readers to think themselves into the shoes of fully rational, self-interested agents, who do not yet know whether they themselves will gain or lose from any arrangement proposed. Their knowledge of what would be rational comes from a proof that each does best to settle for equal basic rights and a maximum distribution of goods. The proof is controversial, but Rawls has certainly given economists new thoughts, especially in welfare economics, and a new line of defence against the charge that pure theorizing about reflective equilibria is only a parlour game.

The article began by suggesting that the lack of many results in economics comparable to the major discoveries in natural science reflected puzzles about causal laws and the value of seeking them. Some of the puzzles are general for all sciences; witness the unfinished arguments started by Quine, Kuhn and others. An initial empiricism seems peculiarly difficult to uphold in economics, however, because one is trying to predict what will be done by agents, who themselves have

beliefs and whose world depends on their expectations.

That makes rationality an epistemologically important yet special concept in economics. But it is unlikely to be a gateway to a simple rationalist epistemology. Whereas an 'ideal type' of frictionless motion is simply a limiting case with a zero coefficient of friction, an 'ideal type' of rational choice is not an abstraction from normal behaviour but a solution to a theoretical problem with a likely normative dimension. Even if economics is still regarded as the search for a different kind of causal law, rather than as an alternative to causal thinking, this difference in kind is great enough to set epistemological problems. Changes in belief change the course of economic events and introduce discontinuities, which make ideal types of rational action unlike timeless models of causal regularities. Rational belief is part of the concept of rationality. So the normative element of the concept of rationality will remain important for economics, even if only for prediction.

Equal Rates of Profit

Christopher Bliss

The concept of equality, or its opposite inequality, implies a comparison, and a comparison must be based on the consideration of a population of cases. Therefore equality or inequality has different implications according to the definition of that population. This general observation applies in particular to rates of profit.

Three different types of comparison of rates of profit will be examined:

(i) We may compare the rates of profit in terms of a fixed *numéraire*, particularly money, which can be obtained over a certain period of time from investment of funds in different lines of activity. We shall refer to equality in this sense as *sectoral equality* of rates of profit. Or,

(ii) We may compare the rate of profit obtainable over a certain period of time in terms of one *numéraire* with that obtainable over the same period of time in terms of another *numéraire*.

In a famous chapter of his *General Theory* (Keynes 1936, Ch. 17), Keynes employs the term 'own rates of interest' to describe these rates of return in terms of different *numéraires*, and we shall borrow the same term and call equality of the rates of return in different numeraires *own rates* equality. Finally,

(iii) We may compare the rate of profit obtainable in terms of the fixed *numéraire*, which may again be money, during one period of time with that obtainable during another later period of time. This comparison include the historically important question of the long-term trend of the rate of interest, whether it will tend to constancy, to increase, or to decline and, if not constant, what will be its eventual limit. We shall refer to equality in this sense as *temporal equality* of rates of profit. (In common with many writers, particularly in the past, we ignore in the present discussion distinctions between the rate of interest and the rate of profit. The main cause of a persistent difference between the two must be sought in the uncertainty from which our analysis abstracts.)

While it is convenient to have discussions of respectively sectoral, own-rate and temporal equality of rates of profit collected together in one article, it will be clear that these are distinct notions and that the investigation of the conditions required for another.

The Theory of Profit

An argument concerning equality of rates of profit might depend importantly on which theory of the rate of profit is invoked. Such is inescapably the case where temporal equality of rates of profit is concerned. However a good deal of our argument concerning sectoral and own rate equality of rates of profit is independent of the exact theory of the determination of rates of profit in general. This unexpected possibility might be realized because equality of rates of profit depends above all upon arbitrage, the tendency for capital to seek the highest return. Indeed in some cases an arbitrage condition alone suffices to demonstrate that rates of profit must be equal.

We shall refer to a state of the economy in which all possibilities of profitable arbitrage have been put into effects, which is a kind of short-period equilibrium, as an *arbitrage equilibrium*. It has sometimes been claimed that profit (where what is intended is a part of profit distinct from a normal rate of return) is essentially a phenomenon of disequilibrium. On this account an arbitrage equilibrium would not only exhibit equal rates of profit, all rates of profit would equal zero. Only the normal rate of return would be realised in an arbitrage equilibrium.

To argue about terminology where weighty issues are involved shows poor judgement. Even if profit is defined to be an excess of return to capital above the return generally available, and even if we exclude temporary rents, it remains to show that no sector can enjoy a permanent profit advantage against which arbitrage is for some reason powerless. If, on the other hand, profit is taken to include temporary rents it is evident that there is really no case for equality. Hence the only interesting question to decide is whether rates of profit defined as net returns to capital divided by the values of capital employed (on average or at the margin) are equal in an arbitrage equilibrium.

Sectoral Equality of Rates of Profit

Nowhere is the power of arbitrage, together with its limitations, better illustrated than in the case of comparisons of profit rates across sectors. The desire of every investor to obtain the highest possible rate of return may reasonably be assumed to equalize the equivalent rates of return on different bonds. Will not a similar principle ensure the equalization of rates of profit in different activities, be they regions or industries?

The answer depends on two important points. First, we must decide how to compare two rates of return, what are the principles of equivalence? Secondly, arbitrage may encounter obstacles. This is true even where bonds are concerned,

and is more important still where we are concerned with different sectors.

Clearly rates of return should be true economic rates including allowances for capital gains, etc. Moreover, two apparently different rates of return may not excite arbitrage if they represent different risks, or different liabilities to taxation, or if the difference is too small to overcome transactions costs. Although they are important in empirical investigations, these detailed considerations may be neglected for our purposes. So we are left with structural obstacles to arbitrage.

When economic theorists assume equal rates of profit in different sectors they are implicitly ignoring questions of industrial structure. (For an excellent treatment of the concept of industrial structure and it implications for profitability, see Hay and Morris 1979, Ch. 7.) It is typically supposed, for example, that capital may be shifted from one sector to another in arbitrarily small quantities. If increasing returns to scale imply that operation at a very small scale will be costly, the putative entrant must choose between staying out of the sector of fighting his way into what must be an oligopolistic market. There is naturally no reason to suppose that the rate of profit enjoyed by those already inside may not exceed that obtainable in a competitive sector of small-scale units.

It would not be necessary to reiterate the foregoing point if it had not apparently been challenged by the late Piero Sraffa in the oft-quoted foreword to his *Production of Commodities by Means of Commodities* (1960). Sraffa's model for the determination of prices is striking for its simplicity and for the fewness of its assumptions. In his forward the author warned his readers against the temptation to assume that his argument depended upon assuming constant returns to scale. In a sense it does not, as that assumption is never directly employed. However equality of rates of profit, sectoral equality according to our present terminology, is assumed. We cannot of course claim that sectoral equality requires constant returns to scale. However it requires some assumptions about the environment, specifically the market environment, in which firms operate, and constant returns to scale and free entry are obvious sufficient conditions for sectoral equality of profit rates.

Equality of Own Rates of Interest

Consider a price system extending through time so that for each period t there is a present price for each of N goods. Such a price system may be represented thus:

$$\begin{matrix} p_{11} & p_{12} & \cdots & p_{1t} & \cdots & p_{1T} \\ p_{21} & p_{22} & \cdots & p_{2t} & \cdots & p_{2T} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ p_{N1} & p_{N2} & \cdots & p_{Nt} & \cdots & p_{NT} \end{matrix} \quad (1)$$

As problems raised by infinite price systems need not concern us here, we suppose that the prices only extend forward to period T. If we imagine that good 1 is money, it will be seen that the money rate of interest in period 1 for a t-period loan may be calculated as follows. One unit of present money costs p_{11} and one unit of money bought now for delivery in period t costs p_{1t}. Hence one unit of money surrendered now buys p_{11}/p_{1t} units of money at t. This corresponds to a rate of interest equal to $p_{11}/p_{1t} - 1$, or $(p_{11} - p_{1t})/p_{1t}$. What was denoted above by the term the money rate of interest can equally be designated the own rate of interest on money, in this case for a t-period loan.

The money rate of interest measures the extra money obtainable by postponing payment as a proportion of the payment deferred. This notion generalises to any good. We may for example measure the extra wheat obtainable by postponing delivery as a proportion of the quantity of wheat delivery deferred. Suppose that wheat prices occupy the second row of (Eq. 1) above. Then the t period own rate of interest for wheat will be equal to $p_{21}/p_{2t} - 1$, or $(p_{21} - p_{2t})/p_{2t}$, which is exactly analogous to the expression of the money rate of interest already derived.

Turning from the rows of (Eq. 1), which correspond to different goods, consider the columns, which correspond to different periods of time. It is easily shown that if the columns are proportional to each other, which is the same as saying that relative prices are the same in all periods, then the own rate of interest for a given duration of loan is the same for all goods. Suppose that the own rate

of interest for good 1 for a deferment from period 1 to period t is r_1t. Then, as we have already seen:

$$r_1t = (P_{11} - p_{1t})/p_{1t} \quad (2)$$

However, by assumption:

$$p_{1t}/p_{1t} = p_{11}/p_{1t} \quad (3)$$

So that:

$$(p_{11} - p_{1t})/p_{1t} = (p_{11} - p_{1t})/p_{1t} \quad (4)$$

Or,

$$r_1t = r_1t \quad (5)$$

Here, constancy of relative prices implies equality of own rates of return, as required. Conversely, variations in relative prices will be reflected in differences in own rates of return.

Under what circumstances is it reasonable to assume constancy of relative prices over time? We shall certainly require the assumption that the economy is stationary in some sense. Suppose for example that as time passes timber becomes more and more scarce relative to demand as forests are depleted or demand grows. Then we would expect the price of timber to rise through time relative to other goods. Similarly, technical progress, unless it be of the simplest labour-augmenting kind, will typically imply changes in relative prices. The transistor, the microchip and other innovations, to cite another example, have certainly caused electric goods to become relatively cheaper.

Consider therefore a stationary state, which may be growing economy, but which is stationary in the sense that in each period it is technically exactly the same as in every other period, except perhaps for scale. As the economy is essentially the same at every moment of time, it makes intuitive sense to suppose that relative prices might be the same at each moment of time, and this intuition is valid in so far as it can be shown that any development of the economy which is stationary, in the sense just described, may be supported by a price system which is itself stationary, in the sense that relative prices are invariant over time[3].

Stationarity of the real economy is sufficient for stationarity of a price system that will support production activities, but does not imply that any such price system will be stationary. Indeed it is an implication of the multiplicity of price systems and interest rates which goes under the name of 'double-switching'. That prices which support stationary production will frequently be neither unique nor themselves stationary. Their non-uniqueness is an immediate implication of double-switching. The existence of non-stationary price systems for these equilibria follows when we note that the average of two systems of equilibrium prices must themselves be equilibrium prices. However the average of two price systems based on different rates of interest produces a rate of interest variable over time, and varying relative prices.

The importance of these findings may be questioned because the price system is required to support not only production (supply) but also consumption (demand). This will make the observation of non-unique prices, and in particular of a history including double-switching, much less probable than a considering of the production side alone might suggest.

It remains to briefly mention Keynes's use of own rates of interest in his *General Theory*, if only to point out that it is not in fact particularly germane to the present discussion of equality of own rates of interest. Keynes's extraordinary argument is concerned with the comparison of money rates of return at the margin to accumulating various assets, which is something like the question of sectoral equality.

We may imagine that as the various assets are accumulated the money rates of return to further accumulation for each of them is forced down, and that the quantities accumulated are such that these marginal returns on all assets are equalized. If we could conceive of the elasticity of the money rate of return for each asset to the stock accumulated (which we may call the return-stock elasticity) as a value independent of other accumulations, which Keynes in effect does, then assets with low return-stock elasticities will accumulate rapidly relatively to assets with higher return-stock elasticities. Keynes's argument claims that money is eventually the asset with the lowest return-stock elasticity, and that this has the implication that, in an economy with a limited supply of money, the money rate of return

(which of course is the own rate of interest of money) will eventually rise to a level which discourages the further accumulation of real assets.

Temporal Equality of Rates of Proit

We now turn to the equality, or inequality as the case may be, of the rates of profit which prevail at different moments of time. There is a longer tradition among economic theorists, which goes back to the classical writers, of explaining the long-run tendency for the rate of profit to fall. This was largely a response to a supposed fall in the rate of interest which the classical economists 'took to be an indisputable fact'. For these older theories the reader is referred to entries on Adam Smith, Marx, Mill, Ricardo and Say. Here we consider only a modern view of the problem. A justification for this division of labour may be sought in the fact that modern theories of the rate of profit are radically different from classical views.

The main source of the difference between modern and classical theories (which in this context should be taken to exclude Marx) is that the former treat technical progress as having regular and continuous effects on the economy, where the latter typically do not. Thus the characteristic classical argument for a falling rate of profit is stagnationist in nature. The decline in the rate of profit is part of the grinding to a halt of a previously progressive economy. In contrast, the modern neoclassical approach locates the explanation of a falling rate of profit in the character of a technical progress conceived as an indefinitely continuing process.

To demonstrate the theoretical issues involved we first show when a declining rate of profit would arise in a neoclassical model with aggregate capital and a constant saving propensity, and then discuss some of the shortcomings of that model as an account of capital accumulation.

Let output, Y, depend upon the input of labour, L, and a capital stock which is homogeneous with the output flow, K, according to a constant returns production function as:

$$Y = F(K, L, t). \tag{6}$$

Let partial derivatives be denoted by subscripts so that, for example, the marginal product of capital is denoted $F_K(K, L, t)$. We denote the rate of profit by r, so that:

$$r = F_K(K, L, t). \tag{7}$$

Time derivatives are shown by a dot over the variable concerned. Differentiating $F_K(K, L, t)$ totally with respect to time we obtain an expression for the time rate of change of the rate of profit as:

$$\dot{r} = F_{KK} \cdot \dot{K} + F_{KL} \cdot \dot{L} + F_{Kt}, \tag{8}$$

Hence for constancy of the rate of profit we must have:

$$F_{KK} \cdot \dot{K} + F_{KL} \cdot \dot{L} + F_{Kt} = 0. \tag{9}$$

which on rearrangement yields:

$$\frac{F_{KK} \cdot K}{F_K} \cdot k + \frac{F_{KL} \cdot L}{F_K} \cdot l + \frac{F_{Kt}}{F_K} = 0, \tag{10}$$

where k and l are respectively the logarithmic rates of growth of capital and labour. Now (Eq. 5) can be expressed more simply as:

$$\sigma_K \cdot k + \sigma_L \cdot l + \gamma = 0; \tag{11}$$

where σ_K and σ_L are respectively the elasticity of the marginal product of capital with respect to K and L, and y is the proportional change in the marginal product of capital due to the passage of time alone. We know that $F_K(K, L, t)$ is homogeneous of degree zero in K and L. Hence:

$$\sigma_K + \sigma_L = 0, \tag{12}$$

and (Eq. 11) reduces to:

$$\sigma_K \cdot (k - 1) + \gamma = 0. \tag{13}$$

This last expression has an intuitive interpretation. As σ_k is the elasticity of the marginal product of capital with respect to capital, it will be negative. It is weighted by $k - 1$, the rate of growth of capital per unit of labour, which will be positive under

normal economic growth. Thus $\sigma K \cdot (k - 1)$ measures the rate at which capital accumulation is pushing down the rate of profit due to the substitution of capital for labour at constant technical knowledge. The second term represents the rate at which technical progress is tending to raise the rate of profit at constant factor proportions, which must be positive term if technical progress is beneficial. Now, unsurprisingly, (Eq. 13) says that, for the rate of profit to remain constant, these two effects must exactly offset.

As it is known that a production function with aggregate capital cannot be derived rigorously except for simple or special production technologies, it may reasonably be asked how fare the above account, of a downward pressure on the rate of profit due to accumulation being offset by an upward pressure due to technical progress, generalizes. In particular, is it generally true that accumulation with constant technical knowledge exerts a downward pressure on the rate of profit?

Given the enormous literature on the theory of capital which has been produced in recent years, it is perhaps surprising that this question remains relatively under investigated. Many discussions of capital accumulation simply beg the question by assuming that the rate of interest would fall continuously through time. Indeed double-switching is most at variance with the traditional neoclassical view of capital accumulation when that assumption is made. However there is no guarantee of a continuous fall of the rate of profit through time, and the demand side of the economy is likely to prohibit a return to a previous and lower income state.

On the other hand, linear models of the type that have been used to illustrate simple stories of capital accumulation can lead to quite eccentric time profiles of consumption being associated with the accumulation of capital (where this is defined simply as an increase in long-term consumption). Hence there is no possibility in general of ruling out erratic developments in the rate of interest over time.

E

Equality

James S. Coleman

Abstract

'Equality' is used to mean equality before the law, equality of opportunity, and equality of result, among other things. These types of equality are not necessarily mutually compatible. Equal distribution of benefits is often taken to be 'natural' (by Rawls, for example), partly because envy is ubiquitous. In welfare economics the presumed diminishing marginal utility of money implies that equality of incomes maximizes welfare, but if interpersonal utility comparisons are impossible no such presumption can be made. As well, the interdependencies between individuals in terms of welfare are such that enforced equalization is likely to reduce overall welfare.

The very use of the term 'equality' is often clouded by imprecise and inconsistent meanings. For example, 'equality' is used to mean equality before the law (equality of treatment by authorities), equality of opportunity (equality of chances in the economic system), and equality of result (equal distribution of goods), among other things. These different meanings often conflict, and are almost never wholly consistent. See Hayek (1960, p. 85, 1976, pp. 62–4) for a discussion of equality before the law and equality of result, and Rawls (1971) for a discussion of equality of opportunity within a theory of distributive justice. Elsewhere I have discussed the difference between equality of opportunity and equality of result in education (Coleman 1975). See also Pole (1978) for a detailed examination of the changing conceptions of equality in American history.

Some order can be brought into the confusion among the different uses of the term 'equality' by first conceiving of a system that constitutes an abstraction from reality. The system consists of:

(a) a set of positions which have two properties:

(i) when occupied by persons, they generate activities which produce valued goods and services;
(ii) the persons in them are rewarded for these activities, both materially and symbolically;

(b) a set of adult persons who are occupants of positions;
(c) children of these adults;
(d) a set of normative or legal constraints on certain actions.

What is ordinarily meant by equality under the law has to do with (b), (c), and (d): that the normative or legal constraints on actions depend only on the nature of the action, and not on the identity of the actor. That is, the law treats persons in similar positions similarly, and does not discriminate among them according to characteristics irrelevant to the action.

What is ordinarily meant by equality of opportunity has to do with (a), (b), and (c): that the processes through which persons come to occupy positions give an equal chance to all. More particularly, this ordinarily means that a child's opportunities to occupy one of the positions (a) do not depend on which particular adults from set (b) are that child's parents. What is ordinarily meant by equality of result has to do with (a.ii): that the rewards given to the position occupied by each person are the same, independent of the activity.

These three conceptions, equality under the law, equality of opportunity, and equality of result can also be seen as involving different relations of the State to the inequalities that exist or spontaneously arise in ongoing social activities. Equality before the law implies that the laws of the State do not recognize distinctions among persons that are irrelevant to the activities of the positions they occupy, but otherwise make no attempt to eliminate inequalities that arise. Equality of opportunity implies that the State intervenes to insure that inequalities in one generation do not cross generations, that children have opportunities unaffected by inequalities among their parents. Equality of result implies a continuous or periodic intervention and redistribution by the State to insure that the inequalities which arise through day-today activities are not accumulated, but are continuously or periodically eliminated.

The relations between the first two kinds of equality differ according to how close a society is to a legally minimalist society or a legally maximalist society. In a society that is legally minimalist, equality before the law is compatible with a high degree of inequality of opportunity – depending on the distribution of opportunity provided by other institutions in society, such as the family. In a legally maximalist society, in which many functions of traditional institutions have

been taken over by institutions that are creatures of the State (e.g., functions of the family taken over by the public school), equality before the law implies a high degree of equality of opportunity. Only in a society in which the law was far more intrusive than found anywhere, and children were taken from their families to be raised 'with equal opportunity' by the State, could it be said that equality before the law would coincide with equality of opportunity.

The relation between equality of opportunity and equality of result is somewhat different, for it implies two different kinds of interventions of the State. Equality of opportunity implies intervention to provide each person with resources that give equal *chances* to obtain the material and symbolic rewards that arise from productive activity, while equality of result implies intervention in the distribution of these rewards, to provide each person with equal *amounts.* The two concepts become indistinguishable only when the State intervenes to insure that each position (in (*a*) above) provides the same set of material and symbolic rewards; and in such a circumstance, 'opportunity' loses meaning altogether.

Is Equality 'Natural'?

There are certain philosophical positions that take equality of result as a 'natural' point, from which all others are deviations. Isaiah Berlin probably states this as well as any other

> No reason need be given for . . . an equal distribution of benefits for that is 'natural', self evidently right and just, and needs no justification, since it is in some sense conceived as being self justified . . . The assumption is that equality needs no reasons, only inequality does so; that uniformity, regularity, similarity, symmetry, . . . need not be specially accounted for, whereas differences, unsystematic behavior, changes in conduct, need explanation and, as a rule, justification. If I have a cake and there are ten persons among whom I wish to divide it, then if I give exactly one tenth to each, this will not, at any rate automatically, call for justification; whereas if I depart from this principle of equal division I am expected to produce a special reason. It is some sense of this, however latent, that makes equality an idea which has never seemed intrinsically eccentric . . . (1961, p. 131).

This quotation describes a view with which Berlin does not necessarily identify himself. In the same paper, he states that 'equality is one value among many ... it is neither more nor less rational than any other ultimate principle ... rational or nonrational' It is, however, the position implicitly taken by John Rawls in his *Theory of Justice,* for the book is addressed to the question, 'When can inequalities (of result) be regarded as just?' Rawls's answer can be paraphrased as 'Only those inequalities are just which make the least well off person better off than that person would be (other things being equal) in the absence of the inequalities.'

Whether equality of result is 'natural' or not, and whether the position of Berlin and Rawls is correct or incorrect, would appear to depend on how the distribution of goods occurs: If goods are initially the property of a single central source (e.g., 'the State'), then Berlin's position and that of Rawls appear correct. If all rights and resources originate with the State (or with the king, as in early political theory), than an equal distribution has some claim to be seen as natural. (If, for example, the revenue from oil discovered on public lands is a major component of GNP, as in some Middle Eastern states, equal distribution constitutes a natural point.) But if goods are seen to arise from the activities of a set of independent actors each with certain initial property rights, and each with a certain amount of zeal and skill, 'equality' (meaning equality of result) is hardly natural, and is inconsistent with the distribution of property rights including rights to the fruits of one's own activity.

Equality, Envy and Resentment

The idea of equality as 'natural' appears also to derive in part from the ubiquity of envy and resentment in society, with the demand for 'equality' as an expression of these feelings which carries legitimacy. A number of sociologists have pointed to this connection. For example, Simmel writes (1922, translated in Schoeck 1969, pp. 236–7):

> Characteristically, no one is satisfied with his position in relation to his fellow beings, but everyone

> wishes to achieve a position that is in some way an improvement. When the needy majority experiences the desire for a higher standard of living, the most immediate expression of this will be a demand for equality in wealth and status with the upper ten thousand.

Simmel follows with an anecdote: at the time of the 1848 revolution, a woman coal-carrier remarked to a richly dressed lady, 'Yes, madam, everything's going to be equal now; *I* shall go in silks and you'll carry coal.'

Helmut Schoeck, in an extensive examination of the role of envy in society, argues that

> social philosophers have largely failed to see how little the individual is concerned with being *equal* to someone else. For very often his sense of justice is outraged by the very fact that he is denied the measure of inequality which he considers to be right and proper (1969, p. 234).

Feelings of envy and resentment constitute a challenge to the existing distribution of *rights* in society, between those held collectively and those held individually. In particular, it is a challenge to the existence of individual property rights. The centrality of property rights for conceptions of equality is seen most clearly in neoclassical economic theory, which assumes a distribution of property rights among a set of independent actors, accompanied by a free market. (See Meade 1964, for a discussion of property rights and the market in relation to equality.) It is to economic theory that I now turn.

The Role of 'Equality' in Economic Theory

The concept of 'equality' has no place in positive economic theory. In this it is unlike the concept of 'liberty', for economic theory is predicated on the assumption of liberty, that is, free choice (subject only to resource constraints) among alternative actions. There is, in the concept of free choice, however, something closer to the idea of equality before the law than to equality of opportunity, and closer to the latter than to equality of result. Equality of result implies a distribution process that is the antithesis of the market.

But normative economics, that is, welfare economics, makes up for the absence of 'equality' from positive economic theory, for the idea of equality of result is a part of the very atmosphere surrounding welfare economics. The question of what policies will maximize social welfare is not often answered directly in terms of equality in the distribution of valued goods, but the idea seems always to hover nearby. The most direct expression of the central importance of equality in welfare economics was probably that of Pigou (1938); see also (Bergson (1966, ch. 9) who reasoned that because money, like everything else, had declining marginal utility, and thus a dollar was worth much less to a person when he had a million others than when it was the only one he had, then the maximum of social welfare could only be achieved when incomes were made equal. (Neither Pigou nor any other welfare economist followed this implication with actual policy recommendations for equality of income, thus raising the question: if the criterion is correct, then why not recommend implementing it?)

The rock on which Pigou's argument is often regarded as foundering is that of interpersonal comparison of utility. To move from the relative importance for one person of a dollar when he is rich and when he is poor to its relative importance to different persons is a move which, as has been often reiterated, cannot be justified on positive grounds. Perhaps the most widely quoted statement to this effect is that of Lionel Robbins (1938):

> But, as time went on, things occurred which began to shake my belief in the existence between so complete a continuity between politics and economic analysis . . . I am not clear how these doubts first suggested themselves; but I well remember how they were brought to a head by my reading somewhere – I think in the work of Sir Henry Maine – the story of how an Indian official had attempted to explain to a high-caste Brahmin the sanctions of the Benthamite system. 'But that,' said the Brahmin, 'cannot possibly be right – I am ten times as capable of happiness as that untouchable over there.' I had no sympathy with the Brahmin. But I could not escape the conviction that, if I chose to regard men as equally capable of satisfaction and he to regard them as differing according to a hierarchial schedule, the difference between us was not one which could be resolved by the same

> methods of demonstration as were available in other fields of social judgement … 'I see no means,' Jevons had said, 'whereby such comparison can be accomplished.'

Edgeworth expressed the same point, 'The Benthamite argument that equality of means tends to maximum happiness, presupposes a certain equality of natures; but if the capacity for happiness of different classes is different, the argument leads not to equal, but to unequal distribution' (1897, p. 114).

Such arguments are ordinarily taken as conclusive within the domain of economics, and with their acceptance, the very programme of welfare economics – not to speak of the foundations for a policy designed to bring equality – is emasculated.

A philosopher might argue, of course, that there is no logical difference between the comparison of utilities of two persons and the comparison of utilities of one person at two different times. Neither, by this argument, is warranted. See, for example, Parfit (1984).

However, Pigou's conclusion has, quite apart from problems of interpersonal comparison of utility, another deficiency. It assumes that each person is an island, and contributes nothing to the welfare of others, nor has his welfare contributed to by others. Yet is is the essence of social and economic systems that there is interdependence, that one person's activities do affect the welfare of others, whether intended or not. One person spends money on loud radios that cause disturbance, while another plants flowers that others enjoy. Or one uses income for training which is productive, benefiting general welfare, while another uses income on drink and becomes alcoholic, requiring public-expense hospitalization.

But if this is so, then maximization of welfare one time period into the future would require that these interdependencies be taken into account. Maximization would occur only if resources were distributed among persons in accordance with the positive impact of their activities on those events which bring welfare to others. But in general persons do not capture the full benefits of their welfare-generating activities, nor do persons pay the full costs of their welfare–diminishing activities.

The matter can also be seen as a problem in input–output economics: What current allocation of resources among productive activities (i.e., among positions in the system as described earlier) will achieve some desired distribution of final consumption? If the aim is to maximize the sum of final consumption ('maximizing welfare'?), it is quite unlikely that either the current allocation necessary to achieve that, or the distribution of final consumption itself, will approach equality. Even if the desired final distribution is equality, and even if that is achievable within the system of activities, it is highly unlikely that the allocation at time *0* necessary to achieve that at time *t* will be equal. And it may well be that the only distribution at time *0* that would achieve equality at time *t* would do so at a low level of welfare, with each having less than if there were inequality at time *t* resulting from a different distribution at time *0*. If Pareto optimality is taken as a self-evident necessary condition for optimal policies, then because of the processes described above, a criterion of equal distribution (either initially or subsequently) would violate the condition. This suggests that Rawls's question was misdirected, and should have been 'when (assuming non-violation of constitutional rights) is *equality* of distribution justified?' and should have been answered, 'Only when there is no unequal distribution that would subsequently make each better off.'

Thus even if Pigou's point that maximizing welfare requires equalizing marginal utilities is accepted, and noncomparability of utilities is ignored, the policy implication of equalizing incomes appears shortsighted in the extreme. Another way of seeing so is by use of Robert Nozick's Wilt Chamberlain example, an example designed to argue against theories of distributive justice which, like that of Rawls, use the resulting distribution of goods ('end state theories', to use Nozick's term) as a criterion.

> Now suppose that Wilt Chamberlain is greatly in demand by basketball teams, being a great gate attraction. (Also suppose contracts run only for a year, with players being free agents.) He signs the following sort of contract with a team: In each home game, twenty five cents from the price of each ticket of admission goes to him. (We ignore the question of whether he is 'gouging' the owners, letting them

> look out for themselves.) The season starts, and people cheerfully attend his team's games; they buy their tickets, each dropping a separate twenty five cents for their admission price into a special box with Chamberlain's name on it. They are excited about seeing him play; it is worth the total admission price to them. Let us suppose that in one season one million persons attend his home games, and Wilt Chamberlain winds up with $250,000, larger even than anyone else has. Is he entitled to this income? (Nozick 1974, p. 161)

Thus as Nozick points out, an equal distribution at one point will lead to an unequal distribution at a later point, due to the very system of activities through which persons satisfy their interests.

There are only three ways to prevent this, all of which, carried to their limit, can be shown to reduce welfare. One is to prevent the economic exchange through which persons spend their quarters as they see fit, for such exchanges may lead to a large accumulation in the hands of the Wilt Chamberlains.

A second is to attack the system of activities itself, the system which generates that matrix of coefficients that transform equality into inequality – that is, shutting down professional basketball, which redistributes income from those with low incomes to those with high incomes. The third way is to allow the exchange, but then to tax the high incomes back down to equality. This effectively eliminates the activity, because if income is an incentive to carry out the activity that is paid for, the Wilt Chamberlains lose all incentive to carry the activity.

Indeed, unless there is a perfect positive correspondence of those activities which are intrinsically pleasurable with those which produce benefits for others, and a perfect negative correspondence with those that produce harm for others, the absence of any extrinsic incentives will lower the welfare for all. The more interrelated the activities of individuals, the greater the reduction in social welfare when extrinsic incentives are absent.

It is true that taxation which is not carried to the limit, but is merely 'progressive', does not eliminate the incentive for activities that bring high income, for these activities continue in societies that have progressive taxation. But this taxation may lead to underprovision of welfare-generating activities. That is, efficiency may be sacrificed to achieve some distributional goals. The potential conflicts between efficiency and equality are discussed in the literature on optimal taxation (e.g., Atkinson and Stiglitz 1980, part II). (A device which is informally used in social systems to reduce the disincentive effect of regimes of taxation and redistribution that shift incomes in the direction of equality is the attachment of social stigma to the receiving of income thus redistributed, for example, stigma associated with being 'on welfare'. The existence of this stigma constitutes a means of informally reconstituting the differential incentives that are reduced by redistribution.)

All three approaches to preventing inequalities from arising out of equality give, at their extreme, the same result: elimination of the very system of activities that generates welfare in the first place; for it is these activities which not only generate welfare, but also transform equality at one time into inequality at a later time.

Thus it becomes clear that the source of inequalities is embedded in the very matrix of social and economic activities through which individuals increase the welfare of themselves and one another. If, through technology for example, this matrix changes in such a way that individuals' satisfaction of wants is more concentrated in a few hands (e.g., by the invention and development of television), then inequalities will necessarily increase.

More generally, the degree of inequality seems related to the degree of interdependence in this matrix of social and economic activities. In a social system that has very low interdependence (e.g., a social system composed largely of subsistence farmers, a condition that was once the case for nearly all societies), the welfare of each in future periods depends largely on his own initial distribution of resources (including zeal and skill). If that distribution is near equality, then near equality is perpetuated into the future, modified only by random events. More important, even if the initial distribution is unequal, the low interdependence of the system of activities

means that these inequalities (also modified by random events) are merely carried forward into the future. In a system with a high degree of interdependence, however, there are a great many configurations which constitute 'inequality-generating' activity structures. In such activity structures, initial distribution of equality will lead to highly unequal distributions. This inequality in turn will lead in the next generation to inequality of opportunity, constrained only by random processes or explicit policies towards non-inheritance of position, i.e., toward equality of opportunity. (In a system in which attention to basketball was directed not to televised professional teams, but to games of the local high school, both the material and nonmaterial rewards among basketball player would be more equally distributed. There would be greater equality of results, which would arise not through a change in the set of persons (*b*), the distribution of children (*c*), or the normative and legal constraints (*d*), but only through a change in the distribution of positions.)

Does this mean that there tends to be a negative relation between the interdependence of activities in a social system (and thus the total social product) and the equality with which the activities of the system distribute the product? If so, this is a discouraging result for those who would prefer a social system in which incomes are not increasingly unequal, for it specifies an opposition between two goals both regarded as desirable.

This question has two parts, a within-generation part and a between-generation part. Within generations, it appears likely that there is a negative relation, that increased interdependence does, except in unlikely activity structure, increase inequality. It is possible that this negative relation is responsible for the rise in redistributive actions of governments as interdependence of economic activities increases.

Between generations, the answer would appear to hinge largely upon the relative rates of increase of interdependence of activities and of equality of opportunity (i.e., non-inheritance of position). The latter can occur through regression to the mean as well as through explicit policy intervention (see Becker and Tomes 1986, for a discussion). If equality of opportunity increases more slowly than interdependence of activities, then (except for unlikely configurations of the activity matrix) there will be a decrease in equality of result among lineages of persons. If equality of opportunity increases more rapidly than the increase in interdependence of activities, there will be an increase in equality of result among lineages, even with a decrease in equality of result within generations.

Altogether, there has been little investigation of the matters discussed above, that is, just how the structure of social and economic activities itself affects inequalities. Such investigations would lead toward taking work on equality partly out of the realm of normative theory, bringing it partly into the realm of positive theory.

Equality of Opportunity

John E. Roemer

Abstract

Whereas the ethic of equality of outcome does not hold individuals responsible for actions that may create inequality of outcomes, equality of opportunity 'levels the playing field' so that all have potential to achieve equal outcomes; inequalities of outcome that then transpire are not compensable at the bar of justice. The influences on the outcome a person experiences comprise *circumstances* (for which he should not be held responsible) and *effort* (for which he should be). Equal-opportunity policy compensates persons for their disadvantaged circumstances, ensuring that, finally, only effort counts in achieving outcomes.

Equality of opportunity is to be contrasted with equality of outcome. While advocacy of equality of outcome has been traditionally associated with left-wing political philosophy, equality of opportunity has been championed by conservative political philosophy. Equality of outcome does not hold individuals responsible for imprudent actions that may, absent redress, reduce the values of the outcomes they enjoy, or for wise actions that would raise the value of the outcomes above the levels of others'. Equality of opportunity, in contrast, 'levels the playing field' so that all have the potential to achieve the same outcomes; whether in the event they do depends upon individual choice.

This traditional political alignment was upset by Ronald Dworkin (1981a, b) who posed the question: if one is egalitarian, then what should one seek to equalize, welfare or resources? He argued, first, that equalizing welfare (outcome) was undesirable, even if interpersonal comparisons of welfare could be made, because doing so would fail to hold individuals accountable for their preferences. The issue of 'expensive tastes' was important for Dworkin; he argued that, if a person were glad he possessed an expensive taste, or identified with it, as opposed to viewing it as an addiction – a taste he would prefer not to have – then society owed him no extra resources to satisfy it. Dworkin argued that egalitarians should advocate the equalization of resources, as opposed to outcomes, but his conception of what comprised resources was broad. Resources consisted in not only transferable goods and wealth but internal talents as well. The question became: what allocation of *transferable* resources would count as equalizing the *entire bundle* of resources across persons, that is, would count as appropriately compensating individuals for their endowment of non-transferable resources? Dworkin's answer was to construct a kind of market for contingent claims behind a thin veil of ignorance in which traders knew their preferences (importantly, over risk) but not what resources they would come to have in the (actual) world. The desirable tax scheme, in the world, would mimic the allocation of transferable resources that would be implemented at the

equilibrium in this market for contingent claims, after the birth lottery occurred (see Roemer 1996, ch. 7, for a formal model).

Dworkin's contribution, importantly, attempted to integrate the issue of responsibility into egalitarian theory – which amounted to taking the most important tool of the political right and harnessing it for use by the political left. In Dworkin's theory, individuals are held responsible for their preferences, and this is implemented through the insurance market behind the veil of ignorance, where traders representing persons use their persons' preferences to enter into insurance contracts. But persons are not held responsible for their resources, including internal talents, and the families into which they are born, and this is implemented through allowing the traders behind the veil to insure against bad luck in the birth lottery in so far as the distribution of these resources is concerned.

Several years later, G. A. Cohen (1989) and Richard Arneson (1989) criticized Dworkin's theory. Cohen argued that 'Dworkin's cut' between preferences and resources, was, for the purpose of ethics, the wrong way to separate characteristics. Suppose a person developed champagne tastes because she grew up in an aristocratic family in which she was never exposed to beer. Was it correct to later deny her the resources to buy champagne to achieve the level of welfare that beer drinkers could achieve more cheaply? Or suppose that a person, who grew up in a disadvantaged home that lacked resources, developed no ambition to develop his talents; indeed, he was satisfied with his unambitious tastes. Should he likewise be held responsible, even though his tastes were the consequence, at least in part, of an indigent childhood?

Arneson argued that Dworkin was right to argue against taking the 'equalisandum' as welfare, but said that replacing it with 'resources' was wrong – rather, it should be replaced with *opportunity for welfare.* What did it mean, then, to equalize opportunities for welfare? In what sense did this differ from 'equalizing resources' à la Dworkin? Arneson struggled to formulate an alternative, but did not succeed in proposing one that was clearly feasible.

Following Arneson and Cohen, Roemer (1993, 1998) proposed a model that would attempt to capture the insights of this philosophical discussion and permit one to compute, for a given situation, the policy that constituted the 'equal opportunity' policy. He separated the influences on the outcome a person experiences into *circumstances* and *effort:* circumstances are attributes of the person's environment for which he should not be held responsible, and effort is the choice variable for which he should be held responsible. An equal-opportunity (EOp) policy is an intervention (such as the provision of resources by a state agency) that makes it the case that all those who expend the same degree of effort end up with the same outcome, regardless of their circumstances. Thus, EOp 'levels the playing field' in the sense of compensating persons for their deficits in circumstances, ensuring that, finally, only effort counts with regard to outcome achievement.

A more precise formulation follows. Suppose there is an *objective* for whose acquisition a planner wishes to equalize opportunities; this might be a wage-earning capacity, a life expectancy, or an income level. Denote the achievement of the objective as a function $u(\alpha, x; \beta)$ where α is the (scalar) level of effort expended by the person, x is the policy of the planner, and β is the vector of circumstances of the person. u is monotone increasing in the argument α – thus, effort enhances the acquisition of the objective. Nevertheless, effort may be subjectively costly for the individual: thus, u is not to be thought of as the usual economist's utility function, in which effort is costly. For example, u might be the wage-earning capacity a person comes to have, where α is the number of years of schooling and β measures family background, natural talent, and so on. The policy x can be chosen from some feasible set of policies X: it might, for example, be the distribution of a resource possessed by the planner. The set of individuals with a given value of β is called a 'type'.

Suppose that, for each ordered pair (x, β) there ensues a distribution of effort in type β denoted by its cumulative distribution function $F(\alpha; x, \beta)$. The distribution of effort, classically, would result from the maximization of a preference order by

the individuals of the type, one in which effort is differentially costly for those individuals. Typically, these distributions F differ across types (β). By hypothesis, individuals are not to be held responsible for their type. We now ask how one should interpret the stricture to choose a policy that equalizes the values of the objective *at constant effort levels* across types. The problem is that the *distribution* of effort in a type is a characteristic of the type and, if individuals are to be compensated for their types, they should likewise be compensated for the characteristics of those distributions. For example, if a disadvantaged type has a distribution of effort with a low mean, that itself should be taken into account in the compensation scheme. Roemer's solution was to propose that the *degree* of a person's effort should be measured by her *rank* in the effort distribution of her type. Thus, define the rank π by

$$\pi = F(\alpha; x, \beta)$$

and define the ' indirect' objective function

$$v(\pi; x, \beta) = u\big(F^{-1}(\pi; x, \beta), x; \beta\big).$$

Then x is an equal-opportunity policy just in case it equalizes the value of objective across types at every degree of effort, that is:

$$\forall \pi \in [0,\ \ 1] \forall \beta,\ \ \beta' v(\pi; x, \beta) = v(\pi; x, \beta'). \quad (1)$$

Here, the process by which the effort distributions F emerge is black-boxed; of course, in actual applications, the black box would be unpacked with the specification of utility functions that individuals maximize to derive their efforts.

In general there will be no policy which equalizes opportunities in the sense of (1). For example, let u be wage-earning capacity, α be years of schooling, β be the educational level of the individual's parents, and x be investment in the education of the individual by the state. Suppose policies can be targeted to types, and there is a per capita social endowment of $\bar{x}$ for education. Suppose we partition the population into a finite set of types, $\{\beta_i |\ i = 1,\ \ \ldots,\ n\}$ where the population frequency of type i is p_i. A feasible policy is a vector $(x_1,\ \ \ldots,\ x_n)$ such that $\Sigma p_i x_i = \bar{x}$. We have as data, as well, the distribution functions $F(\cdot; x,\ \ \beta)$. For this general specification, there will generally not exist a feasible policy satisfying (1).

Some alternative is therefore required. One may proceed as follows. We desire to equalize the values of v across different β's, at each π. As a second-best, we desire to maximize the minimum value of v across different β's, at each π. Thus, define

$$\Phi(\pi; x) = \min_{\beta}\ \ v(\pi, x, \beta).$$

We define a policy x to be *efficient* if

$$\text{there is no } \ x' \in X \quad s.t(\forall \pi)(\Phi(\pi; x') \geq \Phi(\pi; x)), \quad (2)$$

where the inequality sign in (2) is understood to mean that, for some value(s) of π, there is strict inequality. We are interested only in efficient policies. There may, however, be many, even a continuum, of these; and the theory, thus far, gives us no way of choosing among them.

To see this, let us consider a special case in which effort responses within types are insensitive to the policy: thus, we may write those distributions as $F(\alpha;\ \beta)$. Suppose that there are just two types, $\beta = 1$ and $\beta = 2$, indicating the level of education of parents; each type comprises one-half the population. The Department of Education has one unit per capita of an educational resource to be invested in children. A *policy* is an ordered pair $(y,\ 2-y)$, indicating the per capita investment in children of the two types. Suppose that $u(\alpha,\ y;\ \beta) = \alpha^a\ y^c\ \beta^b$ is the value of the objective (perhaps, the child's future wage) where y is the amount of educational resource invested in the child. We will denote a policy by the value of its first component, y. Then

$$\Phi(\pi; y) = \ \ \min_{y}\ \ \left[\left(F^{-1}(\pi; 1)\right)^a y^c, \left(F^{-1}(\pi; 2)^a 2^b (2-y)^c\right].\right. \quad (3)$$

We may compute that the two arguments of the min function in (3) are equalized exactly when

$$y = \frac{2}{1 + \left(\frac{1}{2}\right)^{b/c}\left(\frac{F^{-1}(\pi;1)}{F^{-1}(\pi;2)}\right)^{a/c}}. \tag{4}$$

Now define

$$m = \min_{\pi}\left(\frac{F^{-1}(\pi;1)}{F^{-1}(\pi;2)}\right), M = \max_{\pi}\left(\frac{F^{-1}(\pi;1)}{F^{-1}(\pi;2)}\right). \tag{5}$$

Then any policy

$$y \in \left[\frac{2}{1 + \left(\frac{1}{2}\right)^{b/c} M^{a/c}}, \frac{2}{1 + \left(\frac{1}{2}\right)^{b/c} m^{a/c}}\right] \tag{6}$$

is efficient, and this interval comprises exactly the efficient policies. Thus, there is a continuum of efficient policies.

There has been no general agreement concerning how to narrow the set of efficient policies to a single choice – in other words, how to rank efficient policies from the equal-opportunity viewpoint. Roemer (1998) proposed to choose a single policy by solving the problem:

$$\max_{x} \int_0^1 \Phi(\pi; x) d\pi; \tag{7}$$

Van de Gaer (1993) proposed to solve

$$\max_{x} \min_{\beta} \int v(\pi; x, \beta) d\pi. \tag{8}$$

Each of these proposals is somewhat arbitrary. Fleurbaey and Maniquet (2004) summarize the axiomatic approach to the problem, to which they and others have made substantial contributions. I believe that appeal to the equal-opportunity principle as such cannot resolve the issue; we must bring additional ethical considerations to bear.

How does the theory of equal opportunity fit into social choice theory? There are a number of ways one may answer this question; I believe the most salient point is that the equal-opportunity approach is distinguished from classical social-choice theory in being *non-welfarist.* Welfarism is the view that only the set of vectors of outcome (welfare) possibilities matters for the social decision. To be precise, if we represent individual preferences over social alternatives by utility functions, then the choice of a social alternative should depend only upon the information that is recoverable from the utility possibilities sets of the possible societies. In this sense, welfarism is a consequentialist view. Sen (1979) criticized the welfarist postulate for ignoring the issue of civil rights (the right not to be beaten by another, for instance); Roemer (1996) criticized it, with regard to the theory of distributive justice, for ruling out any theories which mention property rights. The equal-opportunity approach says that one cannot judge the goodness of a social outcome by knowing only the distribution of outcomes; one must also know *how hard people tried* in order to evaluate that goodness – in other words, one must know the correlation of effort with achievement to pass judgement on the fairness of a distribution scheme. Put this way, it is clear that the equal-opportunity approach formalizes a view that is held quite generally by citizens in many countries, to judge from opinion surveys. In judging how just schemes of distribution are, the proverbial man on the street usually wants to know if reward is 'proportionate' to effort expended. Knowing only the distribution of outcomes does not suffice.

Several empirical studies have applied these ideas. In Roemer et al. (2003), the authors asked: in a set of 11 OECD countries, what income-tax regime would equalize opportunities for income acquisition among workers? All workers in a country were assumed to have a quasi-linear utility function over income and labour, with a constant labour-supply elasticity with respect to the marginal tax rate (or the wage). The sole circumstance was taken to be the level of education of the mother of the worker. Young male workers were partitioned into three types, according to whether their mothers had low, medium, or high levels of education. The set of policies, X, was taken to be the set of feasible affine income tax regimes, that is, ones postulating constant marginal tax rates

Equality of Opportunity, Table 1 EOp marginal income tax rates for 11 countries

Country	Observed marginal income-tax rate	EOp marginal income tax rate
Belgium	.53	.54
Denmark	.44	0
France	.31	.58
Great Britain	.36	.71
Italy	.23	.82
Netherlands	.53	.47
Norway	.39	0
Spain	.38	.61
Sweden	.52	0
United States	.24	.65
West Germany	.36	0

Source: Roemer et al. (2003)

and a lump-sum payment to all. The objective was the post-fisc income (not utility) of the individual. Using the EOp objective of (7) turns out to be equivalent to choosing that income-tax regime which maximizes the average post-fisc income of the least advantaged type, those whose mothers did not complete secondary school. Table 1 summarizes the observed marginal tax rates in the countries of the sample and the equal-opportunity tax rates, so computed, under the assumption that the (male) labour-supply elasticity with respect to taxation is – .06.

Countries can be partitioned into three groups: those for which observed tax rates are much greater than the EOp tax rate (West Germany, Denmark, Sweden and Norway), those for which the observed and EOp tax rates are approximately the same (Belgium and the Netherlands), and those for which observed tax rates are much lower than the EOp tax rates (Italy, Spain, France, the United States and Great Britain). The pattern is not particularly surprising given common perceptions of the depth of income-transfer programmes in these countries.

A comment upon the countries in the first category is in order. To say that the EOp tax rate is zero in the northern European countries means that, with the postulated labour-supply effects of taxation, the average post-fisc income of the least advantaged type would be maximized with a lump-sum tax to finance public goods, and no other transfer payments. This comes about precisely because the *pre-fisc* distributions of income across the three types of worker are already very close in these countries. In the other countries in the sample, these pre-fisc distributions are sufficiently far apart that positive marginal tax rates will, despite their incentive effects, increase the average post-fisc income of the least advantaged type.

Should one conclude from Table 1 that, from the equal-opportunity viewpoint, marginal income taxation should be abandoned in northern Europe? Hardly, for the division of workers into only three types is quite coarse. There are many other circumstances besides the education of the mother for which society might wish to compensate citizens. Indeed, the article under discussion studies as well a typology for four of the countries (where data exist) into six types, where workers are typed not only by three maternal education levels but also by two levels of native ability, as measured by performance in IQ tests. It turns out that a positive marginal EOp tax rate is then recommended for Sweden, although Denmark retains its zero tax rate! (With a sufficiently low labour-supply elasticity, this result, too, would be changed.)

Income taxation may not be the instrument of choice to equalize opportunities for income; one naturally thinks of using educational finance policy as a method for compensating children from disadvantaged families. Betts and Roemer (2003) partitioned American male workers who were attending secondary school in the late 1960s into four types, defined by four levels of maternal education. They took *wage-earning capacity* as the objective and state educational investment in the child as the policy instrument, and asked: What distribution of educational finance would have equalized opportunities for wage-earning capacity among these four types of worker? Wage elasticities with respect to educational investment were computed for the four types using data from the US Panel Studies on Income Dynamics (PSID). Based on the assumption of a per capita educational budget of $2500, the recommended allocation is presented in Table 2.

Equality of Opportunity, Table 2 EOp allocation of investment with per capita budget of $2500 per student per annum

Parental ed'n	< 8 years	8 < ed < 12 years	12 years	> 12 years
EOp investment	$5360	$3620	$1880	$1100

Source: Betts and Roemer (2003)

Equality of Opportunity, Table 3 EOp allocation of educational investment, four types, race × maternal education

Type of worker	LB	HB	LW	HW
EOp investment	$8840	$16,260	$2610	$679

Source: Betts and Roemer (2003)

In other words, equal-opportunity investment would allocate almost five times as much to the most disadvantaged type of student as to the most advantaged type. Interestingly, we computed that the average wage of workers under this allocation would have risen by 2.6 per cent over the observed average wage. In other words, there is no observed trade-off between equity and 'efficiency'.

The authors computed that if the allocation of Table 2 had been implemented there would have been very little change in the fraction of black workers who would have risen above the bottom quintile of the wage distribution. They proceeded to compute the EOp policy for a different typology of workers into four types, defined as:

LB: low maternal education, black
HB: high maternal education, black
LW: low maternal education, white
HW: high maternal education, white

The results are presented in Table 3.

For this typology, the investment ratios are huge. Moreover, the total wage bill would fall by 2 per cent under the allocation of Table 3, showing that an equity-efficiency' trade-off does exist with respect to this typology.

At the least, the calculations of Betts and Roemer demonstrate that there is a large difference between an *equal-resource policy,* which invests the same amount in all children, and an *equal-opportunity policy,* which invests in children in such a way as to attempt compensation for differential social circumstances. The United States, with its system of locally financed public education, is in most places less equitable even than the equal-resource policy would be: that is, usually more is invested in the public education of advantaged children than in that of disadvantaged children.

I have earlier distinguished between the equal-opportunity approach and the more classical welfarist approach in welfare economics. A second important distinction is between equal opportunity, as a concept of equity, and meritocracy. Consider the problem of admissions to university or professional school. The equal-opportunity approach would suggest admitting the highest-effort candidates from each of a set of types, distinguished by their levels of advantage in background. The meritocratic approach would suggest admitting those who are most likely to be high achievers. EOp focuses upon fair treatment *among the pool of candidates,* while meritocracy has a double focus: treating the candidates fairly but also considering the quality of services those candidates will, in the future, provide to society at large. (On the other hand, meritocracy is *not* concerned with candidates' effort in its measurement of fair treatment, but only with their ability to perform.) Thus the two approaches are in conflict.

Clearly, the quality of services provided to society at large must count – the unadorned EOp approach cannot in general be the right one. Generally speaking, society should follow a mixture of equal-opportunity and meritocratic policies. To calibrate the right mixture would require, as well as data to calculate the relevant elasticities, a general theory of justice for society at large, in which account is taken not only of fairness to those competing to occupy social positions but

of the welfare of those who eventually consume the products those individuals will produce. In the US debate around affirmative action, one can hear different emphases. With respect to school admissions, most citizens seem concerned with fairness to the candidates, although there is a dispute as to what traits should or should not count in judging fairness; but, with respect to employment, many believe meritocratic principles are primary. Thus, race-based affirmative action policies in universities are under challenge for focusing on the wrong parameters of disadvantage (which, many argue, should be ones of social class, not race), while affirmative-action employment policies are challenged for paying insufficient attention to competence in employing workers.

In the applications discussed above, the policymakers – whether fictitious ones in the minds of scholars or actual ones in social institutions – have generally contemplated only the effects of policies in a single sector, whether it be in education or employment. Calsamiglia (2005) has posed the following problem. Suppose individuals are competing for positions in several sectors simultaneously (in her example, for admission to a university and to an athletic team), and the admissions officer in each sector is attempting to design an equal-opportunity policy for the candidates in his sector alone. Thus, the university admissions officer knows the abilities and circumstances and efforts of candidates for university, and the athletic coach knows the same information as it applies to performance in her sector. Each designs a *local* equal-opportunity admissions policy for his own sector. When will the combination of policies equalize opportunities *globally?* The tension here is that policies in each sector will, if not properly designed, distort the efforts of candidates in other sectors. Calsamiglia demonstrates that, under suitable conditions, locally designed EOp policies aggregate into a global EOp policy if and only if they *equalize rewards to effort* across types in each sector. For example, assigning disadvantaged students who are applying to law school 'extra points' to compensate them does *not* equalize rewards to effort as between them and more advantaged students: rather, one requires a policy which, for each unit of effort expended, increases the probability of admission by the *same amount* across all types of student. One can say, that is, that equalizing rewards to effort is the necessary and sufficient condition for decentralizing the social problem of equalizing opportunities across the board into policy formation at the sectoral level. Whether or not Calsamiglia's insight will be important in policy design depends upon the degree to which individuals are involved in inter-sectoral effort allocation decisions.

Equation of Exchange

Michael D. Bordo

Abstract

One of the oldest formal relationships in economics, the equation of exchange, as a basic accounting identity of a money economy, demonstrates that the sum of expenditures must equal the sum of receipts. It is useful both as a classification scheme for analysing the underlying forces at work in a money economy and as a building block or engine of analysis for monetary theory and in particular for the quantity theory of money. It can also be regarded as a building block for a macro theory of aggregate demand and supply, and used to construct a theory of nominal income.

The equation of exchange (often referred to as the quantity equation) is one of the oldest formal relationships in economics, early versions of both verbal and algebraic forms appearing at least in the 17th century. Perhaps the best known variant of the equation of exchange is that expressed by Irving Fisher (1922):

$$MV = PT. \quad (1)$$

Equation 1 represents a simple accounting identity for a money economy. It relates the circular flow of money in a given economy over a specified period of time to the circular flow of goods. The left-hand side of Eq. 1 stands for money exchanged, the right-hand side represents the goods, services and securities exchanged for money during a specified period of time. M is defined as the total quantity of money in the economy, T as the total physical volume of transactions, where a transaction is defined as any exchange of goods, including physical capital, services and securities for money, P is an appropriate price index representing a weighted average of the prices of all transactions in the economy. Finally, to make the stock of money comparable with the flow of the value of transactions (PT), and to make the two sides of the equation balance, it is multiplied by V, the transactions velocity of circulation, defined as the average number of times a unit of currency turns over (or changes hands) in the course of effecting a given year's transactions.

An alternative variant of the equation of exchange is the income version by Pigou (1927). Empirical difficulties in measuring an index of transactions, and the special price index related to it, led, with the development of national income accounting, to the formulation of Eq. 2:

$$MV = PY \quad (2)$$

where Y represents national income expressed in constant dollars, P the implicit price deflator and V the income velocity of circulation defined as the average number of times a unit of currency turns over in the course of financing the year's final activity.

Equations 1 and 2 differ from each other because the volume of transactions in the economy includes intermediate goods and the exchange of existing assets, in addition to final goods and services. Thus vertical integration and other factors which affect the ratio of transactions to income would also alter the ratio of transactions velocity to income velocity.

A third version of the equation of exchange, the Cambridge cash balance approach (Pigou 1917; Marshall 1923; Keynes 1923), converts the flow of spending into units comparable to the stock of money

$$M = kPY \tag{3}$$

where $k = 1/V$ is defined as the time duration of the flows of goods and services money could purchase, for example, the average number of weeks income held in the form of money balances.

Equations 2 and 3 are arithmetically equivalent to each other but they rest on fundamentally different notions of the role of money in the economy. Both Eqs. 2 and 1 view money primarily as a medium of exchange and the quantity of money is represented as continually 'in motion' – constantly changing hands from buyer to seller in the course of a time period. Equation 3 views money as a temporary abode of purchasing power (an asset) forming part of a cash balance 'at rest'. Consequently, the items included in the definition of money in the transactions and income versions of the equation of exchange are assets used primarily to effect exchange – currency and checkable deposits, whereas the cash balance approach includes, in addition to these items, non-checkable deposits and possibly other liquid assets.

The equation of exchange is useful both as a classification scheme for analysing the underlying forces at work in a money economy and as a building block or engine of analysis for monetary theory and in particular for the quantity theory of money.

As a classification scheme, the equation as a basic accounting identity of a money economy demonstrates the two-sided nature of the circular flow of income – that the sum of expenditures must equal the sum of receipts. The left-hand side of the equation shows the market value of goods and services purchased (dollar value of goods exchanged) and the money received. The equation also relates the stock of money to the circular flow of income by multiplying M by its velocity. Finally, the equation is useful in creating definitional categories – M, V, P, T – amenable both to empirical measurement and to theoretical analysis.

The equation of exchange is best known as a building block for the quantity theory of money. The traditional approach has been to make behavioural assumptions about each of the variables in the equation, converting it from an identity to a theory. The simplest application, dubbed the 'naive quantity theory' (Locke 1691) treated V and T in Eq. 1 as constants, with P varying in direct proportion to M.

A more sophisticated version (Fisher 1911) treats each of M, V and T as being normally determined by independent sets of forces, with V as determined by slowly changing factors such as those affecting the payments process and the community's money holding habits.

The Cambridge cash balance approach, based on Eq. 3, views the quantity theory as encompassing both a theory of money demand and money supply. In this approach the nominal money supply is determined by the monetary standard and the banking system while the nominal quantity of money demanded is proportional to nominal income, with k the factor of proportionality, representing the community's desired holding of real cash balances. k in turn is determined by economic variables such as the rate of interest in addition to the factors stressed by the Fisher approach. The price level (value of money) is then determined by the equality of money supply and demand.

The equation of exchange can also be regarded as a building block for a macro theory of aggregate demand and supply (Schumpeter 1954). If we view MV as aggregate demand and T or Y as aggregate supply, then P would be determined in the familiar Marshallian way.

Finally, the equation can be used to construct a theory of nominal income. According to this

approach (Friedman and Schwartz 1982), nominal income is determined by the interaction of the money supply and a stable demand for real cash balances. The decomposition of a given change in nominal income into a change in the price level and in real output is determined in the short run by inflation (deflation) forecast errors and in the long run by the natural rate of output.

The equation of exchange both as a classification scheme and as a building block for the quantity theory of money can be traced back to the earliest development of economic science.

The pre-classical writers of the 17th and 18th centuries viewed the equation in both senses. Locke (1691), Hume (1752) and Cantillon (1735) each organized his approach to monetary issues using the equation. Locke had a clear statement of the naive quantity theory assuming both V and T to be immutable constants. Hume followed Locke but made a clear distinction between long-run statics and short-run dynamics. In the long run the price level would be proportional to M but, in the short run or transition period, changes in M would produce changes in T. Cantillon had a clear understanding of the relationship between the stock of money and the circular flow of income. Indeed, he was the first to define explicitly the concept of velocity of circulation, viewing V not as a constant but as a variable influenced in a stable way by both technological and economic variables. Furthermore, like Hume, Cantillon distinguished between the long-run equilibrium nature of the quantity theory and short-run disequilibrium. Both Locke and Hume viewed the equation from the perspective of money 'at rest' forming a cash balance whereas Cantillon viewed money as continuously in 'motion'.

John Law (1705) understood the equation of exchange but used it to derive a link between changes in the quantity of M and changes in T.

The classical economists Thornton,et al. followed the Locke/Hume/Cantillon tradition of the quantity theory of money using a verbal version of the equation of exchange in their monetary analysis.

Algebraic versions of the equation first appeared in the 17th and 18th centuries (see Marget 1942; Humphrey 1984). The British writers Briscoe (1694) and Lloyd (1771) both expressed a rudimentary version of Eq. 1, unfortunately omitting a term for velocity. Turner (1819) formulated the equation without breaking PT into separate components. The most complete early statement of the equation was by Sir John Lubbock (1840), who not only included all the items of the equation but (preceding Fisher) distinguished between the quantities and velocities of hard currency, bank notes and bills of exchange. Similar complete algebraic statements of the equation were made by the German writers Lang (1811) and Rau (1841); the Italian Pantaleoni (1889); the Frenchmen Levasseur (1858), Walras (1874) and de Foville (1907); and the Americans Newcomb (1885), Hadley (1896), Norton (1902) and Kemmerer (1907). Of this group Newcomb presented the clearest statement. Newcomb started with the concept of exchange as involving the transfer of money for wealth. Summing up all exchanges in the economy he arrived at his equation of societary circulation:

$$VR = KP \tag{4}$$

where V represents the total value of currency, R the rapidity (velocity) of circulation, K the volume of real transactions, P a price index.

The clearest and best known algebraic expressions of the equation were by the neoclassical economists Irving Fisher (1922) and A.C. Pigou (1917). Fisher (1911, pp. 15–17), directly following Newcomb, defined the equation of exchange as

> a statement, in mathematical form, of the total transaction: effected in a certain period in a given community. . . . [I]n the grand total of all exchanges for a year, the total money paid is equal to the total value of goods bought. The equation thus has a money side and a goods side. The money side is the total money paid, and may be considered as the product of the quantity of money multiplied by its rapidity of circulation. The goods side is made up of the products of quantities of goods exchanged multiplied by their respective prices.

This statement expressed as in Eq. 1 or in an expanded version distinguishing between currency and deposits payable by check,

$$MV + M'V' = PT \tag{5}$$

where M' is defined as checkable deposits and V' their velocity, Fisher then used to analyse the forces determining the price level.

Fisher's approach followed the 'motion' theory tradition of Cantillon with velocity determined primarily by technological and institutional factors. In contrast, Pigou (1917) and other writers in the Cambridge tradition, Marshall (1923) and Keynes (1923), followed the 'rest' approach of Locke and Hume, expressing the equation as

$$1/P = kR/M \tag{6}$$

where R represents total resources enjoyed by the community, k the proportion of resources the community chooses to keep in the form of titles to legal tender, M the number of units of legal tender and P a price index. For Pigou the fundamental difference between his approach and that of Fisher was that by focusing

> attention on the proportion of their resources that people *choose* to keep in the form of titles to legal tender instead of focusing on the 'velocity of circulation' . . . it brings us . . . into relation with *volition* – an ultimate *cause of demand* – instead of with something that seems at first sight *accidental and arbitrary*. (1917, p. 174, emphasis added)

The Cambridge cash balance version of the equation of exchange, by focusing on the demand for money and volition rather than emphasizing mechanical aspects of the circular flow of money, can be viewed as the starting point for the Keynesian approach to the demand for money (Keynes 1936), for modern choice theoretic approaches to money demand (Hicks 1935) and for the modern quantity theory of money (Friedman 1956).

From what appears to have been the first use of the term in economics by James Steuart in 1769, down to the present day, equilibrium analysis (together with its derivative, disequilibrium analysis) has been the foundation upon which economic theory has been able to build up its not inconsiderable claims to 'scientific' status. Yet despite the persistent use of the concept by economists for over 200 years, its meaning and role have undergone some quite profound modifications over that period.

At the most elementary level, 'equilibrium' is spoken about in a number of ways. It may be regarded as a 'balance of forces', as when, for example, it is used to describe the familiar idea of a balance between the forces of demand and supply. Or it can be taken to signify a point from which there is no endogenous 'tendency to change': stationary or steady states exhibit this kind of property. However, it may also be thought of as that outcome which any given economic process might be said to be 'tending towards', as in the idea that competitive processes tend to produce determinate outcomes. It is in this last guise that the concept seems first to have been applied in economic theory. Equilibrium is, as Adam Smith might have put it (though he did not use the term), the centre of gravitation of the economic system – it is that configuration of values towards which all economic magnitudes are continually tending to conform.

There are two properties embodied in this original concept which when taken into account begin to impart to it a rather more precise meaning and a well-defined methodological status. Into this category enters the formal definition of 'equilibrium conditions' and the argument for taking these to be a useful object of analysis.

There are few better or more appropriate places to isolate the first two properties of 'equilibrium' in this original sense than in the seventh chapter of the first book of Adam Smith's *Wealth of Nations.* The argument there consists of two steps. The first is to define 'natural conditions':

> There is in every society . . . an ordinary or average rate of both wages and profits. . . . When the price of any commodity is neither more nor less than what is sufficient to pay . . . the wages of the labour and the profits of the stock employed . . . according to their natural rates, the commodity is then sold for what may be called its natural price. (Smith 1776, I.vii, p. 62)

The key point here is that 'natural conditions' are associated with a general rate of profit – that is, uniformity in the returns to capital invested in different lines of production under existing best-practice technique. In the language of the day, this

property was thought to be the characteristic of the outcome of the operation of the process of 'free competition'.

The second step in the argument captures the analytical status to be assigned to 'natural conditions':

> The natural price . . . is, as it were, the central price, to which the prices of all commodities are continually gravitating. Different accidents may sometimes keep them suspended a good deal above it, and sometimes force them down even somewhat below it. But whatever may be the obstacles which hinder them from settling in this center of repose and continuance, they are constantly tending towards it. (I.vii, p. 65)

This particular 'tendency towards equilibrium' was held to be operative in the *actual* economic system at any given time. It is not to be confused with the familiar question concerning the stability of competitive equilibrium in modern analysis. There the question about convergence to equilibrium is posed in some *hypothetical* state of the world where none but the most purely competitive environment is held to prevail. It is also essential to observe that in defining 'natural conditions' in this fashion, nothing has yet been said (nor need it be said) about the forces which act to determine the natural rates of wages and profits, or the natural prices of commodities. It will therefore be possible to refrain from discussing the *theories* offered by various economists for the determination of these variables in most of what follows. Treatment of these matters may be found elsewhere in this dictionary. Similarly, there will be no discussion here of existence or uniqueness of equilibrium (see existence of general equilibrium).

'Natural conditions' so defined and conceived are the formal expression of the idea that certain systematic or persistent forces, regular in their operation, are at work in the economic system. Smith's earlier idea, that 'the co-existent parts of the universe . . . contribute to compose one immense and connected system' (1759, VII.ii, 1.37), is translated in this later formulation into an analytical device capable of generating conclusions with a claim to general (as opposed to a particular, or special) validity. These general conclusions were customarily referred to as 'statements of tendency', or 'laws', or 'principles' in the economic literature of the 18th and 19th centuries. It is worth emphasizing that there was no implication that these general tendencies were either swift in their operation or that they were not subject at any time to interference from other obstacles. Like sea level, 'natural conditions' had an unambiguous meaning, even if subject to innumerable cross-currents.

To put it another way, the distinction between 'general' and 'special' cases (like its counterpart, the distinction between 'equilibrium' and 'disequilibrium'), refers neither to the immediate practical relevance of these kinds of cases to actual existing market conditions, nor to the prevalence, frequency, or probability of their occurrence. In fact, as far as simple observation is concerned, it might well be that 'special' cases would be the order of the day. John Stuart Mill expressed this idea especially clearly when he held that the conclusions of economic theory are only applicable 'in the *abstract*', that is, 'they are only true under certain suppositions, in which none but general causes – causes common to the *whole class* of cases under consideration – are taken into account' (Mill 1844, pp. 144–5). Marshall, of course, understood their application as being subject not only to this qualification (which he spoke about in terms of 'time'), but also to the condition that 'other things are equal' (1890, I.iii, p. 36). There will be cause to return to this matter below.

To unearth these regularities, one had to inquire behind the scene, so to speak, to reveal what otherwise might remain hidden. Adam Smith had set out the basis of this procedure in an early essay on 'The Principles which Lead and Direct Philosophical Enquiries':

> Nature, after the largest experience that common observation can acquire, seems to abound with events which appear solitary and incoherent. . . by representing the invisible chains which bind together all these disjointed objects, [philosophy] endeavours to introduce order into this chaos of jarring and discordent appearances. (Smith 1795, p. 45)

In short, 'equilibrium', if we may revert to the modern terminology for a moment, became the

central organizing category around which economic theory was to be constructed. It is no accident that the formal introduction of the concept into economics is associated with those very writers whose names are closely connected with the foundation of 'economic science'. It could even be argued that its introduction marks the foundation of the discipline itself, since its appearance divides quite neatly the subsequent literature from the many analyses of individual problems which dominated prior to Smith and the Physiocrats.

Cementing this tradition, Ricardo spoke of fixing his 'whole attention on the permanent state of things' which follows from given changes, excluding for the purposes of general analysis 'accidental and temporary deviations' (1817, p. 88). Marshall, though substituting the terminology 'long-run normal conditions' for the older 'natural conditions', excluded from this category results upon which 'accidents of the moment exert a preponderating influence' (1890, p. vii). J.B. Clark followed suit and held that 'natural or normal' values are those to which 'in the long run, market values tend to conform' (1899, p. 16). Jevons (1871, p. 86), Walras (1874–7, p. 380), Böhm-Bawerk (1899, vol. 2, p. 380) and Wicksell (1901, vol. 1, p. 97) all followed the same procedure.

Not only was the status of 'equilibrium' as the centre of gravitation of the system (the benchmark case, so to speak) preserved, but it was defined in the manner of Smith. The primary theoretical object of all these writers was to explain that situation characterized by a uniform rate of profit on the supply price of capital invested in different lines of production. Walras, whose argument is quite typical, stated the nature of the connection forcefully:

> uniformity of . . . the price of net income [rate of profit] on the capital goods market . . . [is one] condition by which the universe of economic interests is governed. (1874–7, p. 305)

From an historical point of view, the novelty of these arguments which were worked out in the 18th century by Smith and the Physiocrats is not that they recognized that there might be situations which could be described as 'natural', but that they associated these conditions with the outcome of a specific process common to market economies (free competition) and utilized them in the construction of a general economic analysis of market society. Earlier applications of 'natural order' arguments were little more than normative pronouncements about some existing or possible state of society. They certainly made no 'scientific' use of the idea of systematic tendencies, even if these might have been involved. This is particularly apparent in the case of the 'natural law' philosophers, but is also true of the early liberals like Locke and Hobbes. Even Hume, who to all intents and purposes had in his possession all of the building blocks of Smith's position, drew back from the one crucial step that would have led him to Smith's 'method' – he was just not prepared to admit that thinking in terms of regularities, however useful it might prove to be in dispelling theological and other obfuscations (and thus in advancing 'human understanding'), was anything more than a convenient and satisfying way of thinking. The question as to whether the social and economic world was actually governed by such regularities, so central to Smith and the Physiocrats, just did not concern Hume.

Yet the earlier normative connotations of ideas like 'natural conditions', 'natural order', and the like, quite rapidly disappeared when the terminology was appropriated by economic theory. Nothing was 'good' simply by virtue of its being 'natural'. This, of course, is not to say that once the theoretical analysis of the natural tendencies operating in market economies had been completed, and the outcomes of the competitive process had been isolated in abstract, an individual theorist might not at that stage wish to draw some conclusions about the 'desirability' of its results (a normative statement, so to speak). But such statements are not implied by the concept of equilibrium – they are value judgements about the characteristics of its outcomes.

Indeed, contrary to the view sometimes expressed, even Smith's use of deistic analogies and metaphors in the *Theory of Moral Sentiments*, where we read about God as the creator of the 'great machine of the universe', and where we encounter for the first time the famous 'invisible

hand', is no more than the extraneous window-dressing which surrounds a well-defined *theoretical* argument based upon the operation of the so-called 'sympathy' mechanism. Thus, as W.E. Johnson noted when writing for the original edition of Palgrave's *Dictionary*, 'the confusion between scientific law and ethical law no longer prevails', and he observes that 'the term normal has replaced the older word natural' – to be understood by this terminology as 'something which presents a certain empirical uniformity or regularity' (Palgrave 1899, p. 139).

While 'natural conditions' or 'long-run normal conditions' represent the original concept of 'equilibrium' utilized in economic theory, John Stuart Mill's *Political Economy* seems to have been the source from which the actual term equilibrium gained widespread currency (though, like so much else, it is also to be found in Cournot's *Recherches*). More significant, however, is the fact that in Mill's hands the meaning and status of the concept undergoes a modification. While maintaining the idea of equilibrium as a long-period position, Mill introduces the idea that the equilibrium theory is essentially 'static'. The relevant remarks appear at the beginning of the fourth book:

> We have to consider the economical condition of mankind as liable to change … thereby adding a theory of motion to our theory of equilibrium – the Dynamics of political economy to the Statics. (Mill 1848, IV.i, p. 421)

Since he retained the basic category of 'natural and normal conditions', Mill's claim had the effect of adding a property to the list of those associated with the concept of equilibrium. However, over the question of whether this additional property was necessary to the concept of equilibrium, there was to be less uniformity of opinion. Indeed, this matter gave rise to a debate in which at one time or another (until at least the 1930s) almost all theorists of any repute became contributors. The problem was a simple one – are natural or long-period normal conditions the same thing as the 'famous fiction' of the stationary or steady state. Much hinged upon the answer; a 'yes' would have limited the application of equilibrium to an imaginary stationary society in which no one conducts the daily business of life.

On this question, as might be expected, Marshall vacillated. The thrust of his argument (as well as those of his major contemporaries, with the important exception of Pareto) seems to imply that such a property was not essential to his purpose, but as was his habit on so many occasions, in a footnote he qualified that position (1890, p. 379, n.1). In the final analysis, the answer seems to have depended rather more on the explanation given for the determination of equilibrium values, than upon the concept of equilibrium proper. It was not until the 1930s that the issue seems to have been resolved to the general satisfaction of the profession. But then its 'resolution' required the introduction of a new definition of equilibrium (the concept of intertemporal equilibrium) due in the main to Hicks.

However, some further embellishments and modifications were worked upon the concept of equilibrium before the 1930s. Here, two developments stand out. The first concerns the distinction between partial equilibrium analysis and general equilibrium analysis. The second concerns a trend that seems to have developed consequent upon Marshall's treatment of the element of time, which led him to his threefold typology of periods ('market', 'short', and 'long' – we shall leave to one side the further category of 'secular movement'). The upshot of this trend which is decisive, is that it became common to speak of the possibility of 'equilibrium' in each of these Marshallian periods.

The analytical basis for partial equilibrium analysis was laid down in 1838 by Cournot in his *Recherches.* Mathematical convenience, more than methodological principle, seems to have been responsible for his adopting it (see, for example, 1838, p. 127). Though this small volume failed to exercise any widespread influence on the discipline much before the 20th century, it was known and read by Marshall (who spoke of Cournot as his 'gymnastics master'), from whose *Principles* the popularity of partial equilibrium analysis is largely derived (though it would be remiss to overlook Auspitz, Lieben and

von Mangoldt). Unlike the case of Cournot, however, it would be difficult to argue that Marshall came across the method in anything other than a roundabout way (though some have argued that its principal attraction for him lay in its facility in allowing him to express his theory in a manner which required little recourse to mathematics).

When Marshall first introduced the idea of assuming 'other things equal' in the *Principles*, the *ceteris paribus* condition which is taken as the hallmark of the partial equilibrium approach, he seems to have done so not in order to justify the procedure of analysing 'one bit at a time', but in order to make a quite different point – that a long-run normal equilibrium would only *actually* emerge if none but the most general causes were allowed to operate without interference (see, for example, 1890, pp. 36, 366, and 369–70). In other words, the 'other things' that were being held 'equal' were the given data of the theory and the external environment – if the data remained the same and the external environment was freely competitive, then a long-run normal equilibrium would result. Indeed, Walrasian general equilibrium holds 'other things equal' in this sense. To put it another way, in Marshall's initial argument nothing was said about the possibility of assuming the interdependencies between long-run variables themselves to be of secondary importance, as is customary in partial equilibrium analysis.

This latter requirement of Marshallian analysis, the idea of the negligibility of indirect effects when one looks at individual markets (1919, p. 677ff.), seems to have sprung from his habit of presenting equilibrium *theory* in terms of *particular* market demand and supply curves (with their attendant notions of representative consumers and firms). It is here, in fact, that Marshall's presentation of demand and supply theory differs so markedly from its presentation by Walras. To the extent that this is so, it would seem to be better to recognize that the idea of 'partial' versus 'general' equilibrium has more to do with the presentation of a particular theory, and Marshall's propensity to consider markets one at a time, than it has to do with the abstract category of equilibrium with which this discussion is concerned. This view would accord, incidentally, with the fact that the great disputes over the relative merits of these two modes of analysis (for example, that between Walras on the one hand, and Auspitz and Lieben on the other) were fought over the specification of demand and cost functions.

Another modification to the concept of equilibrium that has become more significant in recent literature also makes an appearance in Marshall; though it is not carried as far as it has been in recent literature. The second, third and fifth chapters of the fifth book of Marshall's *Principles* set out the conditions for the determination of what he calls the 'temporary equilibrium', the 'short-run equilibrium' and the 'long-run equilibrium' of demand and supply. The last of these categories, as Marshall makes perfectly clear in the text, corresponds to Adam Smith's 'natural conditions' (1890, p. 347). The first two are to a greater or lesser degree 'more influenced by passing events, and by causes whose action is fitful and short lived' (p. 349). What is striking about Marshall's terminology is the fact that situations which from an analytical point of view would traditionally have been regarded as 'deviations' from long-period normal equilibrium (that is, disequilibria) are explicitly referred to as different cases of 'equilibrium'. This trend has taken on an entirely new significance in recent literature, and has had dramatic consequences for the meaning and status of the concept of equilibrium in economic theory. But just as important in comprehending this development is the introduction of the notion of intertemporal equilibrium into theoretical discourse.

The notion of intertemporal equilibrium (introduced by Hayek, Lindahl and Hicks in the inter-war years and developed in the 1950s by Malinvaud, Arrow and Debreu) warrants special consideration since 'equilibrium conditions' under this notion are defined quite differently from 'natural' or 'long-run normal' conditions. Intertemporal equilibrium defines as its object the determination of nt market-clearing prices (for n commodities over t elementary time periods commencing from an arbitrary short-period

starting point). The chief implication of this definition of equilibrium conditions, and that which sets it apart from long-run normal conditions, is that not only will the price of the same commodity be different at different times but also that the stock of capital need not yield a uniform return on its supply price.

This fundamental change in the concept of equilibrium did not mean that intertemporal equilibrium positions were immediately divested of the status that had been given to 'equilibrium' ever since Adam Smith. In certain circles they continued to be regarded as positions towards which the economic system could actually be said to be 'tending' (or as benchmark cases).

However, once the *sequential* character of this equilibrium concept came to be better understood, it became apparent that there could be no 'tendency' towards it – at least not in the former meaning of that idea. One was either in it, in which case the sequence was 'inessential', or one was not, in which case the sequence was 'essential' (see Hahn 1973, p. 16). And the probabilities overwhelming suggested the latter. Attention was thus turned to the individual points in the sequence; the temporary equilibria, as Hicks had dubbed them (applying the terminology of Marshall in a new context). A whole new class of cases, disequilibrium cases from the point of view of full intertemporal equilibrium, began to be examined. The discipline has now accumulated so many varieties that it is impossible to document them all here. Instead, two broad features of this development may be noted here, the first concerning the role that expectations were thereby enabled to play, the second the common designation now uniformly applied to all such cases: 'equilibrium'.

When equilibrium is interpreted as a solution concept in the sense that *all* solutions to *all* models (for which solutions exist) enjoy equal analytical status and differ only in that they become 'significant', as von Neumann and Morgenstern put it, when they are 'similar to reality in those respects which are essential in the investigation at hand' (1944, p. 32), it is sometimes said that economics has availed itself of a very powerful notion of equilibrium. On this line of argument, Walrasian equilibrium and, say, conjectural equilibrium compete with one another not for the title 'general' (since, in the traditional sense at least, there is no such category), but for the title 'significant'. Furthermore, at any given time they are competing for this title with as many other models as are available to the profession.

It seems to be the case that the status of equilibrium in economic analysis has come full circle since its introduction in the late 18th century. From being derived from the idea that market societies were governed by certain systematic forces, more or less regular in their operation in different places and at different times, it now seems to be based on an opinion that nothing essential is 'hidden' behind the many and varied situations in which market economies might actually find themselves. In fact, it seems that these many cases are to be thought of as being more or less singular from the point of view of modern theory. From being the central organizing category around which the whole of economic theory was constructed, and therefore the ultimate basis upon which its practical application was premissed, equilibrium has become a category with no meaning independent of the exact specification of the initial conditions for *any* model. Instead of being thought of as furnishing a theory applicable, as Mill would have said, to the whole class of cases under consideration, it is increasingly being regarded by theorists as the solution concept relevant to a particular model, applicable to a limited number of cases. The present fashion for replacing economic theory proper by game theory, an approach which could be regarded by no less a theorist than Professor Arrow as contributing only 'mathematical tools' to economic analysis not many years ago (1968, p. 113), seems to exemplify the trend of modern economics.

Equilibrium: An Expectational Concept

Edmund S. Phelps

Economic equilibrium, at least as the term has traditionally been used, has always implied an outcome, typically from the application of some inputs, that conforms to the expectations of the participants in the economy. Many theorists, especially those employing the 'economic man' postulate, have also required the further condition for equilibrium that every participant be optimizing in relation to those correct expectations. However it is the former condition, correct expectations, that appears to be the essential property of equilibrium at least in the orthodox use of the term. Economic equilibrium is therefore not defined in the same terms as physical equilibrium. The rest positions or damped oscillations of pendulums cannot be economic equilibria nor disequilibria since pendulums have no expectations.

Yet it is natural and obvious that the first applications of the equilibrium idea identified some position of rest, or stationary state, as being the equilibrium in the problem at hand. Undoubtedly the term equilibrium, referring to an 'equal weight' of forces pushing capital or what-not *in* as pulling it *out*, owes its origins to the balance of forces prevailing in a stationary situation. But there can also be a *sequence* of positions in which there is a new balance with each new position. There was no reason why equilibria might exist only among stationary states or balanced-growth paths.

Once efforts began to extend economic theory to the case of moving equilibrium paths the

expectational meaning of equilibrium began to be explicit. Two of the pioneers here are Myrdal and Hayek. In his 1927 book on price determination and anticipations (in Swedish) Myrdal addresses the two-way interdependency arising in a dynamic analysis of an on-going economy: present disturbances influence future prices and anticipations of future disturbances affect present prices (the latter relation being Myrdal's main subject). In a 1928 article (in German) on what he called intertemporal equilibrium, Hayek drew the analogy between intertemporal trade and international (or interspatial) trade: prices of the same thing at two different places or times are not generally equal, though they may be pulled up or down together. In a 1929 article (in Swedish) Lindahl studied what is considered to be the first mathematical model of intertemporal equilibrium. This literature is surveyed in Milgate (1979).

The English-speaking world was slow to take up the new line of research. In his *General Theory* of 1936, Keynes speaks grandly of having shown the existence of an (implicitly moving) equilibrium with underemployment, and he does argue that the expectation of falling wages and thus prices makes the slump worse, which suggests he had an expectational notion of equilibrium in mind; but he gives no clues as to what he means by equilibrium, so both the nature and the basis of his claim are left unclear. The new topic of intertemporal equilibrium and the explicit expectational treatment of equilibrium make their English debut in Hicks's *Value and Capital* in 1939. (In the same year Harrod's expectational notion of 'warranted growth', alias equilibrium, and the translation of Lindahl's writings appear.) Hicks makes clear the analytical problem that the analyst and the economic agents alike must solve to find equilibrium: in view of the dependence of future endogenous variables, such as next period's price, on present actions of firms and households, and the dependence of such actions on expectations of those future variables, what expectation would cause the actual outcome to coincide with the expectation? For example, if the actual price P is a function f of the expected price P^e find the value of P^e such that $P^e = f(P^e)$. Thus the fixed-point character of equilibrium from a mathematical standpoint has a human, or real, interpretation. One might say, semi-jocularly, that pendulums have no economic equilibria since their motions, unlike those of trapeze artists, are not a function of expectations, if they have any.

In the postwar period the notion of equilibrium turns up in contexts quite different from that of the inter-war economic theorists. In game theory, begun by von Neumann and Morgenstern, the term equilibrium is used to refer to the theoretical solution to the policies, or play, of two or more players in strategic interaction. If the model postulates optimizing, or expected-utility-maximizing, behaviour by all players, as game theorists' models invariably do, the equilibrium necessarily has the feature that no player can do better acting alone; but lying behind this feature is the essential property that each player has correctly expected the strategy of the others and hence optimized relative to those correct expectations.

In the late 1960s the notion of equilibrium begins to take root in the new territory of non-classical markets – markets without costless and thus complete information. An economy may have markets – the resort hotel market is perhaps a suitable example – in which there are costs in the acquisition or processing of information about prices (and perhaps product specifications) so that arbitrage tendencies are delayed and the classical law of one price operates only with a lag. One well-known portrait of such a market imagines that the national market is composed of Phelpsian islands lacking current-period information about one another's prices. Another image visualizes each firm as an island unto itself with its own stock of customers, who are not knowledgeable about the policies (and perhaps even the whereabouts or existence) of other firms. In such non-Walrasian markets the prevailing prices can be (and usually are) supposed to be market-clearing: no buyer or seller is subjected to rationing (sometimes called non-price rationing by overfastidious writers). However the market will be in *equilibrium* if and only if the prices (and other variables) reflect correct expectations on the part of suppliers and buyers about the prices

prevailing elsewhere – at other islands or other firms; otherwise there is *dis*equilibrium.

An economy may also have markets – one may think of labour markets or markets for rental housing – in which, although information is immediate, the wage or rental setters have to make decisions of some durability, however short-lived, and without advance information about the similar decisions of the other firms. In such quasi-Walrasian markets there may be reasons – having to do with incentives, or efficiency – why wages tend to exceed and rentals lie below the market-clearing level. Yet the market will be in *equilibrium* in the case (if such exists) in which no wage setter or rental setter experiences surprise at the corresponding decisions being made simultaneously (or perhaps somewhat later within the period of the commitment) by the other wage or rental setters; otherwise the market must be in disequilibrium, however long or brief (see Phelps et al. 1970).

Thus the analogy between intertemporal equilibrium and interspatial equilibrium, which was drawn by Hayek and others in their analysis of the former, now seems deeper than it could have at first. The expectational meaning of equilibrium, which is so unavoidably clear in the context of intertemporal equilibrium, where future prices are generally expected future prices, turns out to be just as natural and inevitable in the interspatial context as soon as one gives up the fictive device of the Walrasian auctioneer and thus admit that there are 'other' prices elsewhere, about which there must be expectations, not merely a single market-wide price.

The 1970s witnessed the formal analysis of equilibrium in terms of expectations, or forecasts, of the probability distributions of prices. Lucas, adopting the device of separate market-clearing islands, analysed a model in which there is non-public, or local, information (later called asymmetric information), namely local prices, and these price observations are used to update people's conditional forecasts of the currently unobserved prices elsewhere. There may exist a *rational-expectations* equilibrium in which everyone knows and uses the correct *conditional* expectations of the unobserved prices – that is, the statistically optimal forecasts conditional upon his particular information set. This is equilibrium with a qualification.

In surveying the meaning of equilibrium Grossman has remarked that, in Hicks, 'perfect foresight is an equilibrium concept rather than a condition of individual rationality'. A similar comment applies, with even greater weight, to statistical equilibrium and to its rational-expectations variant. The agents of equilibrium models are not simply rational creatures; they have somehow come to possess fantastic knowledge. The equilibrium premise raises obvious problems of knowledge: why should it be supposed that all the agents have hit upon the true model, and how did they manage to estimate it and conform to it more and more closely? There has always been a strand of thought, running from Morgenstern in the 1930s to Frydman in the present, that holds that we cannot hope to understand the major events in the life of an economy, and perhaps also its everyday behaviour, without entertaining hypotheses of disequilibrium.

Equilibrium-Correction Models

David F. Hendry

Abstract

The equilibrium-correction class of econometric models is surprisingly large, and includes regression equations, autoregressive-error models, autoregressive distributed-lags, simultaneous equations, autoregressive conditional heteroskedastic processes and generalized ARCH, vector autoregressions and dynamic stochastic general equilibrium systems, among others. Moreover, its properties are relatively generic for all members. Following an historical overview of its origins in error corrections and control mechanisms on the one hand and cointegration on the other, its properties are described, leading to an explanation as to why the ubiquitous class of equilibrium-correction models is prone to forecast failure in processes that are non-stationary from location shifts.

Introduction

An equilibrium is a state from which there is no inherent tendency to change. Since we deal with stochastic processes, the equilibrium is the expected value of the variable in an appropriate representation, since that is the state to which the process would revert in the absence of further shocks. Then, we define an equilibrium-correction model (EqCM) as one (*a*) which has a well-defined equilibrium, and (*b*) in which adjustment takes place towards that equilibrium. A key aspect of an EqCM is that deviations from its expected value are attenuated, and eventually eliminated if no additional outside influences impinge. As such, equilibrium-correction models are a very broad class, comprising all regressions, autoregressions, autoregressive-distributed lag (ADL) models, linear simultaneous equations, vector autoregressions (VARs), vector equilibrium-correction systems based on cointegration (VEqCMs), dynamic stochastic general equilibrium systems (DSGEs), autoregressive conditional heteroscedastic processes as in Engle (1982) (ARCH), and generalized ARCH (GARCH, see Bollerslev 1986) processes among others. Their formulation (in levels or differences) determines the equilibrium to which they converge (level or steady state). For example, a random walk without drift is a non-stationary process in levels, but is stationary in differences (its non-integrated representation), and has an expectation of zero, so the differences equilibrium corrects to zero.

We first address the broad nature of the equilibrium-correction class in section "The

Equilibrium-Correction Class", then review the history of equilibrium-correction model formulation in section "Historical Overview", and consider its links to cointegration in section "Equilibrium-Correction and Cointegration". The roles of cointegration and equilibrium correction in economic forecasting are examined in section "Equilibrium Correction and Forecast Failure", in particular the non-robustness of EqCMs to location shifts in the underlying equilibria, and consequently their proneness to forecast failure. Section "Conclusion" concludes.

The Equilibrium-Correction Class

Often it is not realized that the model being used is a member of the equilibrium-correction class, so this section establishes that the models listed above are indeed in the EqCM class. The properties of the class are partly specific to the precise model, but primarily generic, as section "Equilibrium Correction and Forecast Failure" emphasizes. We consider six cases.

Regression as an Equilibrium-Correction Model

Consider a conditional linear equation of the form in (1) for $t = 1; \ldots ; T$:

$$y_t = \beta_0 + \sum_{i=1}^{k} \beta_i z_{i,t} + \varepsilon_t = \beta_0 + \beta' \mathbf{z}_t + \varepsilon_t \quad (1)$$

with $\varepsilon_t \sim \mathrm{IN}\left[0, \sigma_\varepsilon^2\right]$ (normally and independently distributed, mean zero, variance σ_ε^2) independently of the past and present of the k regressors $\{\mathrm{z}_t\}$. Then:

$$\mathrm{E}[(y_t - \beta_0 - \beta' \mathbf{z}_t) | \mathbf{z}_t] = 0 \quad (2)$$

defines the conditional equilibrium, where adjustment to that equilibrium is instantaneous as entailed by (1). Re-expressing (1) in differences ($\Delta x_t = x_t - x_{t\text{-}1}$ for any x) and lagged deviations from (2) delivers the (isomorphic) EqCM formulation:

$$\Delta y_t = \beta' \Delta \mathbf{z}_t - (y_{t-1} - \beta_0 - \beta' \mathbf{z}_{t-1}) + \varepsilon_t \quad (3)$$

where the feedback coefficient is -1. Then (3) is an EqCM where the equilibrium-correction term is ($y_{t\text{-}1}$ - β_0 - $\beta' \mathbf{z}_{t\text{-}1}$). Notice that differencing is a linear transformation, not an operator, in any setting beyond a scalar time series.

The existence of (2) does not require that y_t and $\mathbf{z}_t$ are stationary, provided the linear combination is; and could hold, for example, for growth rates rather than the original levels if y_t and $\mathbf{z}_t$ were differences of those original variables.

Autoregressive-Error Models as Equilibrium-Corrections

Even extending a static regression like (1) by (say) a first-order autoregressive error as in:

$$y_t = \beta_0 + \beta' \mathbf{z}_t + u_t \text{ where } u_t = \rho u_{t-1} + \varepsilon_t \quad (4)$$

leads to:

$$y_t = \beta_0 + \beta' \mathbf{z}_t + \rho(y_{t-1} - \beta_0 - \beta' \mathbf{z}_{t-1}) + \varepsilon_t$$

or:

$$\Delta y_t = \beta' \Delta \mathbf{z}_t + (\rho - 1)(y_{t-1} - \beta_0 - \beta' \mathbf{z}_{t-1}) + \varepsilon_t \quad (5)$$

showing that the common-factor model class (see Sargan 1980; Hendry and Mizon 1978) is also a restricted equilibrium-correction mechanism, constrained by the impact effects (from $\Delta \mathbf{z}_t$) being the same as the long-run effects (from $\mathrm{z}_{t\text{-}1}$).

ADLs as Equilibrium-Correction Models

A first-order autoregressive distributed-lag (ADL) model is:

$$y_t = \beta_0 + \beta_1' \mathbf{z}_t + \beta_2 y_{t-1} + \beta_3' \mathbf{z}_{t-1} + \varepsilon_t \text{ where } \varepsilon_t \sim \mathrm{IN}\left[0, \sigma_\varepsilon^2\right]. \quad (6)$$

The error $\{\varepsilon_t\}$ on (6) is an innovation against the available information, and its serial independence is part of the definition of the model, whereas normality and homoscedasticity are just for convenience. The condition $|\beta_2| < 1$ is needed to

E

ensure a levels' equilibrium solution: Ericsson (2007) provides an extensive discussion. We consider (6) for both stationary and integrated $\{\mathbf{z}_t\}$, the latter denoting that some of the $\mathbf{z}_t$ have unit roots in their levels representations, but are stationary in differences.

First, under stationarity, taking expectations in (6) where $\mathrm{E}[y_t] = y^*$ and $\mathrm{E}[\mathbf{z}_t] = \mathbf{z}^* \; \forall t$.

$$E[(1-\beta_2)y_t - \beta_0 - (\beta_1 + \beta_3)'\mathbf{z}_t] = 0 \tag{7}$$

so:

$$\begin{aligned} y^* &= \frac{\beta_0}{1-\beta_2} + \frac{1}{1-\beta_2}\,(\beta_1 + \beta_3)'\mathbf{z}^* \\ &= \kappa_0 + \kappa_1'\mathbf{z}^*. \end{aligned} \tag{8}$$

Since many economic theories have long-run partial equilibria like (8), they could be modelled by this class. Transforming (6) to differences and the equilibrium-correction term $\left(y - \kappa_0 - \kappa_1'\mathbf{z}\right)_{t-1}$ delivers:

$$\begin{aligned} \Delta y_t = {} & \beta_1'\Delta\mathbf{z}_t \\ & + (\beta_2 - 1)\left(y_{t-1} - \kappa_0 - \kappa_1'\mathbf{z}_{t-1}\right) \\ & + \varepsilon_t. \end{aligned} \tag{9}$$

The immediate impact of a change in z_t on y_t is β_1, and the rapidity with which Δy_t converges to zero, which is its equilibrium outcome under stationarity, depends on the magnitude of $(\beta_2 - 1) < 0$; when both changes and ε_t are zero (their expectations), (7) results.

When y_t and z_t are integrated of order 1 (denoted I(1)), so are stationary in differences, the reformulation in (9) remains valid provided $|\beta_2| < 1$ in which case $\left(y - \kappa_0 - \kappa_1'\mathbf{z}\right)$ is a cointegration relation, as discussed in section "Equilibrium-Correction and Cointegration". Let $\mathrm{E}[\Delta\mathbf{z}_t] = \delta$ (say) so $\mathrm{E}[\Delta y_t] = \kappa_1'\delta = g_y$ where $\mathrm{E}\left[y_t - \kappa_1'\mathbf{z}_t\right] = \mu$, then taking expectations in (9) using (7):

$$g_y = \beta_1'\delta + (\beta_2 - 1)(\mu - \kappa_0) \tag{10}$$

and subtracting (10) from (9) delivers:

$$\begin{aligned} \Delta y_t = {} & g_y + \beta_1'(\Delta\mathbf{z}_t - \delta) \\ & + (\beta_2 - 1)\left(y_{t-1} - \kappa_1'\mathbf{z}_{t-1} - \mu\right) \\ & + \varepsilon_t. \end{aligned} \tag{11}$$

Re-specifying deterministic terms as in (11) plays an important role in EqCMs, both by helping to orthogonalize the regressors, and because of the pernicious effects of shifts in μ, a topic addressed in section "Equilibrium Correction and Forecast Failure". It is so well known that the standard error of the mean of an IID random variable is the standard deviation of the data divided by the square root of the sample size that it hardly bears reiterating: except that it is somehow almost always ignored in this context. The standard error of the intercept in an EqCM equation like (11) should, therefore, be $\hat{\sigma}_\varepsilon/\sqrt{T}$ but is often a hundred times larger in reported empirical models, revealing a highly collinear specification (a similar comment applies to VARs). Moreover, a check on the model formulation follows from using sample means to estimate δ and μ, then checking that g_y has a sensible value, which may be given by theory (for example, no autonomous inflation, so $g_y = 0$).

Finally, if $\beta_2 = 1$, (9) equilibrium corrects in differences. An autoregression is the special case where $\beta_1 = \beta_3 = 0$, so is also an EqCM; and partial adjustment is another special case where now $\beta_3 = 0$.

GARCH as an Equilibrium-Correction Model

As a fourth example, consider a non-integrated GARCH(1,1) process for ε_t, where $\mathrm{E}\left[\varepsilon_t^2 \,|\, I_{t-1}\right] = \sigma_t^2$ when I_{t-1} denotes past information, and:

$$\sigma_t^2 = \omega + \alpha_{t+1}^2 + \theta\sigma_{t-1}^2 \tag{12}$$

with $0 < \alpha < 1$, $0 < \theta < 1$ and $0 < \alpha + \theta < 1$. Let $\sigma_t^2 = \varepsilon_t^2 - v_t$, where $\mathrm{E}[v_t] = 0$, then:

$$\varepsilon_t^2 = \omega + (\alpha + \theta)\varepsilon_{t-1}^2 + v_t - \theta v_{t-1} \tag{13}$$

where the equilibrium is:

$$\sigma_\varepsilon^2 \equiv \mathrm{E}\left[\varepsilon_t^2\right] = \frac{\omega}{1-(\alpha+\theta)}. \tag{14}$$

Substituting $\omega = (1-(\alpha+\theta))\sigma_\varepsilon^2$ from (14) into the equation for σ_t^2:

$$\Delta\sigma_t^2 = (\theta-1)\left(\sigma_{t+1}^2 - \sigma_\varepsilon^2\right) + \alpha\left(\varepsilon_{t+1}^2 - \sigma_\varepsilon^2\right). \tag{15}$$

Thus, the change in the conditional variance σ^2 responds less than proportionally ($\theta < 1$) to the previous disequilibrium between the conditional variance and the long-run variance, perturbed by the zero-mean discrepancy between the previous squared disturbance ε_{t-1}^2 and the long-run variance σ_ε^2, so the model equilibrium corrects to σ_ε^2, consistent with (14). ARCH is simply a special case.

VARs as Equilibrium-Correction Models

The fifth example is an n-dimensional VAR with m lags and an innovation error $\varepsilon_t \sim \mathrm{IN}_n[0, \Omega_\varepsilon]$:

$$\mathbf{X}_t = \pi + \sum_{i=1}^{m} \Pi_i x_{t-i} + \varepsilon_t \tag{16}$$

where the nm eigenvalues of the polynomial $|\mathbf{I}_n - \sum_{i=1}^{m} \mathbf{\Pi}_i L^i|$ in L determine the characteristics of the time series. If all the eigenvalues are inside the unit circle, (16) is stationary (when all the parameters are constant and the initial conditions also satisfy the process). In that case, $\mathbf{\Gamma} = \left(I_n - \sum_{i=1}^{m} \mathbf{\Pi}_i\right)$ is invertible and has all its eigenvalues inside the unit circle, so the process equilibrium corrects to $\psi = \mathbf{\Gamma}^{-1}\pi$. To illustrate for $m = 2$, (16) can be expressed as:

$$\Delta\mathbf{x}_t = (\mathbf{\Pi}_1 - \mathbf{I}_n)\Delta\mathbf{x}_{t-1} - \mathbf{\Gamma}(\mathbf{x}_{t-2} - \psi) + \varepsilon_t \tag{17}$$

where $\mathrm{E}[\Delta x_t] = 0$ by stationarity, so $\mathrm{E}[x_t - \psi] = 0$ is indeed the equilibrium to which x_t converges in the absence of further shocks. Conversely, if all the eigenvalues are unity, x_t is I(1) with $\mathbf{\Gamma} = 0$ in (17), so does not equilibrium correct in levels, but does so in the differences (unless their polynomial has further unit roots, making the process doubly integrated, I(2)). Finally, for a combination of eigenvalues inside and on the unit circle, $\mathbf{\Gamma}$ has reduced rank $0 < r < n$ equal to the number of non-unit eigenvalues, so can be expressed as $\mathbf{\Gamma} = \alpha\beta'$ where α and β also have rank r. Then π in (16) can be decomposed into the unconditional growth rate of x_t, denoted γ, and $\alpha\mu$ such that in place of (17), we have:

$$\Delta\mathbf{x}_t = \gamma + (\mathbf{\Pi}_1 - \mathbf{I}_n)(\Delta\mathbf{x}_{t-1} - \gamma) - \alpha(\beta'\mathbf{x}_{t-2} - \mu) + \varepsilon_t \tag{18}$$

so that $\mathrm{E}[\beta' x_t - \mu] = 0$ and the system converges to that equilibrium when the original variables are I(1), hence $\beta' x_{t-2}$ is an I(0) process which equilibrium corrects to μ. At the same time, $\Delta\mathrm{x}_t$ is an I(0) process which equilibrium corrects to γ, noting that $\beta'\gamma = 0$, whereas x_t drifts.

Linear simultaneous equations systems of time series are a restriction on a VAR, so are also EqCMs.

DSGEs as Equilibrium-Correction Models

As a final brief example, well-defined general equilibrium systems have equilibria. Using Taylor-series expansions around the steady-state values of the discretized representation of a system of differential equations, Bårdsen et al. (2004) show that any dynamic system with a steady-state solution has a linear EqCM representation. Thus, they argue that linearizations of DSGEs imply linear EqCM representations. In principle, these could be in terms of changes only, corresponding to a steady-state path. More usually, level solutions result.

Historical Overview

Equilibrium-correction models are a special case of the general class of proportional, derivative and integral control mechanisms, so have a long pedigree in that arena: for economics examples, see Phillips (1954), Phillips and Quenouille (1960) and Whittle (1963), with the links summarized in Salmon (1988). Explicit examples of EqCMs

E

are presented in Sargan (1964) and were popularized by Davidson et al. (1978), although they were called 'error-correction mechanisms' (ECMs) by those authors. The major developments underlying cointegration in Engle and Granger (1987) established its isomorphism with equilibrium correction for integrated processes, leading to an explosion in the application of EqCMs and the development of a formal analysis of vector EqCM systems in Johansen (1988, 1995). We now review the two stages linking control mechanisms with error correction, then that with equilibrium correction.

Error Correction and Control Mechanisms

Phillips (1954, 1957), in particular, pioneered the application of control methods for macroeconomic stabilization, specifically techniques for derivative, proportional and integral control servomechanisms. In this form of control, a target (say an unemployment rate of five per cent) is to be achieved by adjusting an instrument (say government expenditure), and changes to the instrument, its level, and cumulative past errors may need to be included in the rule to stabilize the target.

That approach is a precursor to the well-known linear-quadratic model in which one optimizes a quadratic function of departures from target trajectories for a linear dynamic system over a finite future horizon (see, for example, Holt et al. 1960; Preston and Pagan 1982). For example, consider the quadratic cost function C_H which penalizes the deviations of a variable x_{t+j} from a pre-specified target trajectory $\left\{x^*_{t+j}\right\}$ subject to costs of adjustment from changes $\Delta x_t = x_t - x_t$ over an H-period horizon commencing at time t:

$$C_H = \sum_{j=0}^{H} c_{t+j} = \sum_{j=0}^{H} \frac{1}{2}\left[\left(x_{t+j} - x^*_{t+j}\right)^2 + \alpha\left(\Delta x_{t+j}\right)^2\right]. \tag{19}$$

To minimize c_{t+j} at time $t + j$, differentiate with respect to x_{t+j}, noting the intertemporal link that $\Delta x_{t+j+1} = x_{t+j+1} - x_{t+j}$ also depends on x_{t+j}, which yields (ignoring the end point for simplicity):

$$\frac{\partial C_H}{\partial x_{t+j}} = \frac{\partial c_{t+j}}{\partial x_{t+j}} + \frac{\partial c_{t+j+1}}{\partial x_{t+j}} = x_{t+j} - x^*_{t+j} \alpha\left(\Delta x_{t+j}\right) - \alpha\left(\Delta x_{t+j+1}\right), \tag{20}$$

so equating to zero for a minimum for any j, and hence for $j = 0$:

$$x_t - x^*_t + \alpha \Delta x_t - \alpha \Delta x_{t+1} = 0.$$

Expressed as a polynomial in leads and lags in the operator L (for $\alpha \neq 0$):

$$\left(L^{-1} - \left(2 + \alpha^{-1}\right) + L\right)x_t = \left(L^{-1} - \lambda_2\right)(1 - \lambda_1 L)x_t = -\frac{x^*_t}{\alpha}. \tag{21}$$

The polynomial in (21) has roots λ_1 and λ_2 with a product of unity (so they are inverses, with λ_1 inside and λ_2 outside the unit circle) and a sum of $(2 + \alpha^{-1})$. Inverting the first factor $(L^{-1} - \lambda_2)$, using $(1/\lambda_2) = \lambda_1 < 1$ and expanding the last term as a power series in L^{-1}expresses x_t as a function of lagged x_s and current and future values of x^*_{t+k}:

$$(1 - \lambda_1 L)x_t = \frac{\lambda_1}{\alpha}\left(1 + \lambda_1 L^{-1} + \lambda_1^2 L^{-2} + \cdots\right)x^*_t = \frac{\lambda_1}{\alpha}\sum_{k=0}^{\infty} \lambda_1^k x^*_{t+k}. \tag{22}$$

Since $(1 - \lambda_1) = \lambda_1/\alpha(1 - \lambda_1)$, let:

$$x^{**}_t = (1 - \lambda_1)\sum_{k=0}^{\infty} \lambda_1^k x^*_{t+k} \tag{23}$$

denote the 'ultimate' target (scaled so that the weights sum to unity as in, for example, Nickell 1985) then from (22) using (23), for $t < H$:

$$\Delta x_t = -(1 - \lambda_1)\left(x_{t-1} - x^{**}_t\right) = (1 - \lambda_1)\Delta x^{**}_t - (1 - \lambda_1)\left(x_{t-1} - x^{**}_{t-1}\right). \tag{24}$$

Thus, x_t adjusts to changes in the ultimate target, and to the previous error from that target, and is an EqCM when $-1 < \lambda_1 < 1$. Mistakes in plans, errors in expectations, and relations between the ultimate target and its determinants all need to be modelled for an operational rule. To hit a moving target requires a feedforward rule, and the role of $\alpha(\Delta x_{t+j})^2$ in (19) is to penalize the controller from making huge changes to x_t when doing so. However, it is difficult to imagine real world adjustment costs being proportional to changes, which in any case then depend on the specification of x_t as logs, levels, proportions or even changes (see, for example, Nickell 1985). Moreover, the entire class is partial adjustment, as (24) shows.

For 1-period optimization (so $H = 0$: see, for example, Hendry and Anderson 1977), only the end point is relevant, so (20) delivers the planned value x_t^p as a function of $x_t^{**} = x_t^*$:

$$\begin{aligned} x_t^p - x_{t-1} &= \frac{1}{1-\alpha}\left(x_t^* - x_{t-1}\right) \\ &= \rho\left(x_t^* - x_{t-1}\right). \end{aligned} \tag{25}$$

When the error on the plan is $\varepsilon_t = x_t - x_t^p$, where $\mathrm{E}[x_t^p \varepsilon_t] = 0$ under rationality, and $x_t^* = \beta' \mathbf{z}_t$ (say), (25) becomes:

$$\begin{aligned} \Delta x_t &= \rho(\beta' \mathbf{z}_t - x_{t-1}) + \varepsilon_t \\ &= \rho\beta' \Delta \mathbf{z}_t - \rho(x_{t-1} - \beta' \mathbf{z}_{t-1}) + \varepsilon_t. \end{aligned}$$

This is a partial adjustment again. The static regression in section "Regression as an Equilibrium-Correction Model" has a more restrictive dynamic structure, but otherwise the properties of the ADL in section "ADLs as equilibrium-correction models" can vary over a wide range (see Hendry 1995, ch. 6).

From Error Correction to Equilibrium Correction

The model in Sargan (1964) was explicitly an ECM for wages and prices (w_t and p_t denote their respective logs), building on previous models of wage and price inflation written as:

$$\Delta w_t = \beta_0 + \beta_1 \Delta p_t + \beta_2 \Delta w_{t-1} + \varepsilon_t. \tag{26}$$

When $\mathrm{E}[\varepsilon_t] = 0$ and the differenced variables are stationary with means $\mathrm{E}[\Delta w_t] = \dot{w}$ and $\mathrm{E}[\Delta p_t] = \dot{p}$, then the long-run steady-state solution to (26) is:

$$\dot{w} = \frac{\beta_0 + \beta_1 \dot{p}}{1 - \beta_2}.$$

As formulated, (26) does not establish any relationship between the levels w_t and p_t, hence these could drift apart. Since economic agents are concerned about the level of real wages, $w_t - p_t$, Sargan postulated the equilibrium:

$$(w - p)_{e,t} = \delta_0 + \delta_1 \Delta p_t + \delta_2' \mathbf{z}_t, \tag{27}$$

where $\mathbf{z}_t$ denotes a vector of additional variables, such as unemployment (u), productivity (q) and political factors. The disequilibrium is:

$$v_t = w_t - p_t - \delta_0 - \delta_1 \Delta p_t - \delta_2' \mathbf{z}_t \tag{28}$$

and, to re-establish equilibrium whenever the levels drift apart, he used the explicit adjustment equation:

$$\begin{aligned} \Delta w_t &= \alpha\left(w_{t-1} - p_{t-1} - (w - p)_{e,t-1}\right) \\ &= \alpha v_{t-1}. \end{aligned} \tag{29}$$

If a relation like (28) is well defined with v_t being I(0) when the levels are I(1), so the differences are I(0), then w_t forms a non-integrated combination with p_t and z_t so these variables are cointegrated (see, among many others, Engle and Granger 1987; Phillips and Loretan 1991; Banerjee, et al. 1993.).

A less restricted specification than (26) entails including the levels terms $(w - p)_{t-1}$ and $\mathbf{z}_{t-1}$ (and their differences), so if contemporaneous variables are excluded:

$$\begin{aligned} \Delta w_t = \pi_0 &+ \pi_1 \Delta p_{t-1} + \pi_2 \Delta w_{t-1} \\ &- \pi_3 (w - p)_{t-1} + \pi_4' \mathbf{z}_{t-1} \\ &+ \pi_5' \Delta \mathbf{z}_{t-1} + u_t. \end{aligned} \tag{30}$$

When $\pi_3 \neq 0$, the long-run levels equilibrium solution to (30) matching (27) is ($\phi_4 = \pi_4/\pi_3$):

$$\mathrm{E}\left[w - p - \varphi_4' \mathbf{z}\right\} = f(\dot{w}, \dot{p}, \dot{\mathbf{z}}).$$

The model in (30) has both derivative and proportional control (e.g., Δp_{t-1} and $(w - p)_{t-1}$) following up Phillips (1954, 1957) (see Salmon 1982). The proportional mechanism ensures the disequilibrium adjustment, based on the (possibly detrended) log-ratio of two nominal levels (see, for example, Bergstrom 1962). The equivalent of g_y in section "ADLs as equilibrium-correction models" should be $\dot{p} + \dot{q}$ in (30) to avoid having 'autonomous wage inflation' independent of all economic forces.

The long-run stability of the 'great ratios' in Klein (1953) was often implicitly assumed to justify such transformations, but had come under question (see, for example, Granger and Newbold 1977, and the discussion in Hendry 1977), although Hendry and Mizon (1978) had argued that what mattered was that the errors in (30) were stationary, not that all the variables were stationary. Granger (1981) related the type of model in (30) to cointegration, and Granger (1986) showed the important new result that one of Δw_t or Δp_t must depend on the equilibrium correction if w_t and p_t were cointegrated: the assumption in (29) is that w_t adjusts to the disequilibrium. If both variables w_t and p_t adjust to the disequilibrium, then p_t is not weakly exogenous for the $\{\pi_i\}$ (see Phillips and Loretan 1991; Hendry 1995). It is primarily because of cointegration that equilibrium-correction models like (30) have proved a popular specification. Engle and Granger (1987) showed that cointegration and proportional EqCM were equivalent, linking time-series approaches more closely with econometric modelling. Davidson and Hall (1991) also linked VARs as in section "VARs as Equilibrium-Correction Models" to target relations as discussed in section "Error Correction and Control Mechanisms" using cointegration analysis, so we now turn to the topic of cointegration in more detail.

Equilibrium-Correction and Cointegration

From the ADL to a VAR

To complete (6), a process is needed for $\{\mathrm{z}_t\}$. Let:

$$\mathbf{z}_t \,|y_{t-1}, \mathbf{z}_{t-1} \sim \mathrm{N}_k\left[\pi_{20} + \pi_{21} y_{t-1} + \pi_{22} \mathbf{z}_{t-1}, \Omega_{zz}\right]. \tag{31}$$

Given (31), the joint distribution is the first-order VAR:

$$\begin{pmatrix} y_t \\ \mathbf{z}_t \end{pmatrix} | y_{t-1}, \mathbf{z}_{t-1} \sim \mathrm{N}_{k+1}\left[\begin{pmatrix} \pi_{10} \\ \pi_{20} \end{pmatrix} + \begin{pmatrix} \pi_{11} & \pi_{12}' \\ \pi_{21} & \pi_{22} \end{pmatrix} \begin{pmatrix} y_{t-1} \\ \mathbf{z}_{t-1} \end{pmatrix}, \begin{pmatrix} \sigma_{11} & \sigma_{12}' \\ \sigma_{12} & \Omega_{zz} \end{pmatrix}\right]. \tag{32}$$

Consequently, to match (6):

$$\mathrm{E}[y_t | \mathbf{z}_t, y_{t-1}, \mathbf{z}_{t-1}] = \pi_{10} + \pi_{11} y_{t-1} + \pi_{12} \mathbf{z}_{t-1} + \sigma_{12}' \Omega_{zz}^{-1} (\mathbf{z}_t - \pi_{20} - \pi_{21} y_{t-1} - \pi_{22} \mathbf{z}_{t-1}), \tag{33}$$

so $\beta_0 = (\pi_{10} - \phi' \pi_{20})$, $\beta_1 = \phi$, $\beta_2 = \pi_{11} - \phi' \pi_{21}$ and $\beta_3 = (\pi_{12} - \phi' \pi_{22})$ when $\varphi = \Omega_{zz}^{-1} \sigma_{12}$, and $\sigma_\varepsilon^2 = \sigma_{11} - \sigma'_{12} \Omega_{zz}^{-1} \sigma_{12}$. When $\mathbf{z}_t$ is weakly exogenous for $(\beta_0, \ldots, \beta'_3)$, the model in (31) can be ignored when analysing (6); also $\pi_{21} = 0$ then ensures the strong exogeneity of $\mathbf{z}_t$ for $(\beta_0, \ldots, \beta'_3)$.

Sufficient conditions for stationarity of (32) are that all the eigenvalues λ_i of the matrix of the $\{\pi_{ij}\}$ are inside the unit circle, but a more realistic setting allows for unit roots in π_{22}. On that basis, we now investigate the properties of the VAR in (32) letting $\mathbf{x}_t' = (y_t : \mathbf{z}_t')$ as in (16).

Cointegration

Linear combinations of I(1) processes are usually I(1) as well: differencing is still needed to remove the unit root. Sometimes integration cancels between series to yield an I(0) outcome and

thereby deliver cointegration. Cointegrated processes in turn define a 'long-run equilibrium trajectory' for the economy, departures from which induce 'equilibrium correction' to move the economy back towards its path. A rationale for integrated–cointegrated data is that economic agents use fewer equilibrium corrections than there are variables they need to control. We can see that effect as follows.

Consider the bivariate VAR:

$$\begin{aligned} x_{1,t} &= \pi_{10} + \pi_{11}x_{1,t-1} + \pi_{12}x_{2,t-1} + \varepsilon_{1,t} \\ x_{2,t} &= \pi_{20} + \pi_{21}x_{1,t-1} + \pi_{22}x_{2,t-1} + \varepsilon_{2,t}, \end{aligned} \tag{34}$$

where $(\varepsilon_{1,ts}, \varepsilon_{2,t})$ are bivariate independent normal. To determine when the system is I(1) and if so, whether or not some linear combinations of variables are cointegrated, rewrite (34) as:

$$\begin{aligned} \begin{pmatrix} \Delta x_{1,t} \\ \Delta x_{2,t} \end{pmatrix} &= \begin{pmatrix} \pi_{10} \\ \pi_{20} \end{pmatrix} \\ &+ \begin{pmatrix} (\pi_{11} - 1) & \pi_{12} \\ \pi_{21} & (\pi_{22} - 1) \end{pmatrix} \begin{pmatrix} x_{1,t-1} \\ x_{2,t-1} \end{pmatrix} \\ &+ \begin{pmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \end{pmatrix} \end{aligned} \tag{35}$$

or as (a special case of (18)):

$$\Delta \mathbf{x}_t = \pi + \mathbf{\Pi}\mathbf{x}_{t-1} + \varepsilon_t. \tag{36}$$

Three cases are of interest. First $\pi = 0$, so (36) is a vector random walk without any levels relationships, and so $\mathbf{x}_t$ is I(1) with $\Delta\mathbf{x}_t$ being I(0) and equilibrium correcting to π. Secondly, if $\mathbf{\Pi}$ has full rank, then $\mathbf{x}_t$ is I(0) and equilibrium corrects to $\mathbf{\Pi}^{-1}\pi$. The most interesting case is when Π is reduced rank so can be expressed as:

$$\mathbf{\Pi} = \alpha\beta' = \begin{pmatrix} \alpha_{11} \\ \alpha_{12} \end{pmatrix} (\beta_{11} \quad \beta_{12}),$$

where we will normalize $\beta_{11} = 1$. Then in (35):

$$\begin{aligned} \begin{pmatrix} \Delta x_{1,t} \\ \Delta x_{2,t} \end{pmatrix} &= \begin{pmatrix} \pi_{10} \\ \pi_{20} \end{pmatrix} \\ &+ \begin{pmatrix} \alpha_{11} \\ \alpha_{12} \end{pmatrix} (1 \ \beta_{12}) \begin{pmatrix} x_{1,t-1} \\ x_{2,t-1} \end{pmatrix} + \begin{pmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \end{pmatrix} \\ &= \begin{pmatrix} \pi_{10} \\ \pi_{20} \end{pmatrix} + \begin{pmatrix} \alpha_{11} \\ \alpha_{12} \end{pmatrix} (x_{1,t-1} + \beta_{12}x_{2,t-1}) + \begin{pmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \end{pmatrix} \end{aligned} \tag{37}$$

which is an EqCM with $(x_{1,t-1} + \beta_{12}x_{2,t-1})$ stationary. Thus, cointegration entails EqCM and vice versa when the feedback relation is I(0). However, prior to Granger (1981) the EqCM literature did not visualize a single cointegration relation affecting several variables, and thereby making them integrated, but instead just took the non-stationarity of the observed data as due to the behaviour of the non-modelled variables. Consequently, system cointegration 'endogenizes' data integrability in a consistent way, and so represents a significant step forward. The extensive literature on cointegration analysis also addresses most of the estimation and formulation issues that arise when seeking to conduct inference in integrated-cointegrated processes: much of this is summarized in Hendry and Juselius (2001), to which the interested reader is referred for bibliographic perspective.

Equilibrium Correction and Forecast Failure

Recent research on the impact of structural breaks, particularly location shifts, on cointegrated processes has emphasized the need to distinguish equilibrium correction, which operates successfully only within regimes, from error correction, which stabilizes in the face of other non-stationarities (see, for example, Clements and Hendry 1995). The assumptions concerning the stationarity, or otherwise, of the entity to be controlled in section "Error Correction and Control Mechanisms" were rarely explicitly stated, but suggest an implicitly stationary system (or perhaps steady-state growth). In such a setting,

equilibrium-correction or cointegration relationships prevent the levels of the variables from 'drifting apart', and so improve the properties of forecasts.

Practical work, however, must allow the data generation process to be non-stationary both from unit roots (that is, I(1) or possibly I(2)) and from a lack of time invariance. When data processes are non-stationary even after differencing and cointegration, equilibrium-correction mechanisms tend to suffer from forecast failure, defined as a significant deterioration in forecast performance relative to in-sample behaviour. Since most empirical model forms are members of the EqCM class, this is a serious practical problem.

To illustrate, reconsider the special case of (18) with just one lag, written as:

$$\Delta \mathbf{x}_t = \gamma + \alpha(\beta' \mathbf{x}_{t-1} - \mu) + \varepsilon_t. \tag{38}$$

The shift of interest here is $\nabla\mu^* = \mu^* - \mu$, where μ^* denotes the post-break equilibrium mean (reasonable magnitude shifts in γ, α and $\mathbf{\Omega}_\varepsilon$ rarely entail forecast failure). Denote the forecast origin as time T, then following a change to μ^* immediately after forecasting, the next outcome is:

$$\begin{aligned} \Delta \mathbf{x}_{T+1} &= \gamma + \alpha(\beta' \mathbf{x}_T - \mu^*) + \varepsilon_{T+1} \\ &= \gamma + \alpha(\beta' \mathbf{x}_T - \mu) + \varepsilon_{T+1} - \alpha\nabla\mu^* \end{aligned} \tag{39}$$

where $-\alpha\nabla\mu^*$ is the unanticipated break, and becomes the mean forecast error for known parameters. Importantly, the 1-step ahead forecast at $T + 1$ using an unchanged model suffers the same mistake:

$$\begin{aligned} &E[\Delta \mathbf{x}_{T+2} - (\gamma + \alpha(\beta' \mathrm{x}_{T+1} - \mu))] \\ &\quad = -\alpha\nabla\mu^* \end{aligned} \tag{40}$$

so the shift in the equilibrium mean induces systematic mis-forecasting. The impact on multi-step forecasts of the levels is even more dramatic, as the mean forecast error increases at every horizon, eventually converging to $\alpha(\beta'\alpha)^{-1}\nabla\mu^*$, which can be very large (see Clements and Hendry 1999). Thus, EqCMs are a non-robust forecasting device in the face of equilibrium-mean shifts, a comment which therefore applies to all members of this huge class of model, including GARCH (as noted earlier), where the pernicious shift is in the unconditional variance σ_ε^2 in (15).

To avoid forecast failure, more adaptive methods merit consideration. One generic approach to improving robustness to location shifts is to difference the forecasting device (although that may well worsen the impact of large measurement errors at the forecast origin). Differencing can be before estimation, as in a double-differenced VAR, or after, as in differencing the estimated EqCM to eliminate the equilibrium mean and growth intercept. Such devices perform as badly as the EqCM in terms of forecast biases when a break occurs after forecasts are announced (see Clements and Hendry 1999), and have a larger error variance. The key difference is their performance when forecasting after a break has already occurred, in which case the EqCM continues to perform badly (as shown above in (48)), but a DEqCM becomes relatively immune to the earlier break. Taking (47) as an example, an additional difference yields:

$$\begin{aligned} \Delta^2 \mathbf{x}_{T+1} &= \Delta(\gamma - \alpha\mu^*) + \alpha\beta' \Delta \mathrm{x}_T + \Delta\varepsilon_{T+1} \\ &= -\alpha\nabla\mu^* + \alpha\beta' \Delta \mathrm{x}_T + \Delta\varepsilon_{T+1} \end{aligned}$$

so there is no benefit when forecasting immediately after the break (as $\Delta\mu^* = \mathrm{r}\mu^*$), whereas (48) becomes:

$$\Delta^2 \mathbf{x}_{T+2} = \alpha\beta' \Delta \mathbf{x}_{T+1} + \Delta\varepsilon_{T+2}$$

since $\Delta\mu^* = 0$. Thus, there is no longer any systematic failure. The same comment applies to double-differenced devices, although Hendry (2006) shows how to improve these while retaining robustness.

A further consequence is that, when a location shift is not modelled, since most econometric estimators minimize mis-fitting, the coefficients of dynamic models will be driven towards unity, which induces differencing to convert a location shift into a 'blip'. Thus, estimates that apparently manifest 'slow adjustment' may just reflect unmodelled breaks.

An alternative approach to avoiding forecast failure would be to construct a genuine error-correction model, adjusting more or less rapidly to wherever the target variable moves: for example, exponentially weighted moving averages do so for some processes. In essence, either the dynamics must ensure correction or the target implicit in the econometric model must move when the regime alters. This last result also explains why models in differences are not as susceptible to certain forms of structural break as equilibrium-correction systems (again see Clements and Hendry 1999), and in turn helps to account for many of the findings reported in the forecasting competitions literature. When the shift in question is a change in a policy regime, Hendry and Mizon (2005) suggest approaches to merging robust forecasts with policy models.

Conclusion

Equilibrium-correction models have a long pedigree as an 'independent' class, related to optimal control theory. However, their isomorphism with cointegrated relationships has really been the feature that has ensured their considerable popularity in empirical applications. In both cases, part of the benefit from the EqCM specification came from expressing variables in the more orthogonalized forms of differences and equilibrium-correction terms, partly from the resulting insights into both short-run and long-run adjustments, partly from discriminating between the different components of the deterministic terms, and partly from 'balancing' regressors of the same order of integration, namely I(0).

Unfortunately, science is often two steps forward followed by one back, and that backwards step came from an analysis of EqCMs when forecasting in the face of structural breaks. Unmodelled shifts in the equilibrium mean (and less so in the growth rate) induce forecast failure, making EqCMs a non-robust device with which to forecast when data processes are prone to breaks, as many empirical studies suggest they are (see, for example, Stock and Watson 1996). Since cointegration hopefully captures long-run causal relations, and ties together the levels of I(1) variables, eliminating its contribution should not be undertaken lightly, hence the suggestion in section "Equilibrium Correction and Forecast Failure" of using the differenced version of the estimated EqCM for forecasting.

Equity

Allan M. Feldman

Depending on the user's inclinations, 'equity' can mean almost anything; this user will adopt a meaning which has been followed by economists and other social scientists since the late 1960s (see particularly Foley 1967), a meaning close to equality or fairness.

Although 'equality' is less ambiguous than 'equity', it too has many definitions: Jefferson's adage that 'all men are created equal' clearly does not mean that they all have the same talents, skills, inherited and acquired wealth; it only means that they share, or ought to share, certain narrowly defined legal rights and political powers. However, in a simple economic model, equality can

be made simple. If we assume that society is comprised of a certain set of n individuals who produce among themselves certain quantities of various goods, we can speak of an equal division of the goods: an allocation that would give each person exactly $1/n$ of the total of each good. Economists would agree that this is equality (at least on the consumption side). Most would also agree that it is an undesirable state of affairs, if for no other reason than that no two people would ever want to consume exactly the same bundle of goods. They would be equal, but not especially happy. Moreover, getting society to that equal allocation would require transferring wealth from the more productive individuals to the less productive, and the transfer mechanism itself would destroy incentives to produce.

So equality in its extreme form – an equal consumption bundle for every consumer – is an obviously unworkable idea, and needs to be weakened. We shall say in this assay that individual i *envies* individual j if i would rather have j's consumption bundle than his own. Formally, let $u_i(\cdot)$ represent individual i's utility function, and x_i represent his consumption bundle. (For now, production is ignored.) Then i envies j if $u_i(x_j) > u_i(x_i)$. This is now a more- or-less standard usage by economists, who have ignored wiser and older counsel, for example, J. S. Mill, who calls envy 'that most odious and anti-social of all passions' (*On Liberty*, ch. 4). Mill would presumably not endorse an economic analysis founded on envy.

Following Varian (1974) we define an allocation as *equitable* if under it no individual envies another; that is, if

$$u_i(x_i) \geq u_i\left(x_j\right) \text{ for all } i \text{ and } j.$$

Obviously, the equal allocation is equitable. But equity does not share equality's obvious disadvantage of forcing all to consume the same no matter what their tastes. If Adam loves ȧpples and Eve loves oranges, and if God has endowed them with a total of one apple and one orange, then the equal allocation (half an apple and half an orange for each) is clearly foolish, but the equitable allocation (one apple for Adam and one orange for Eve) makes good sense.

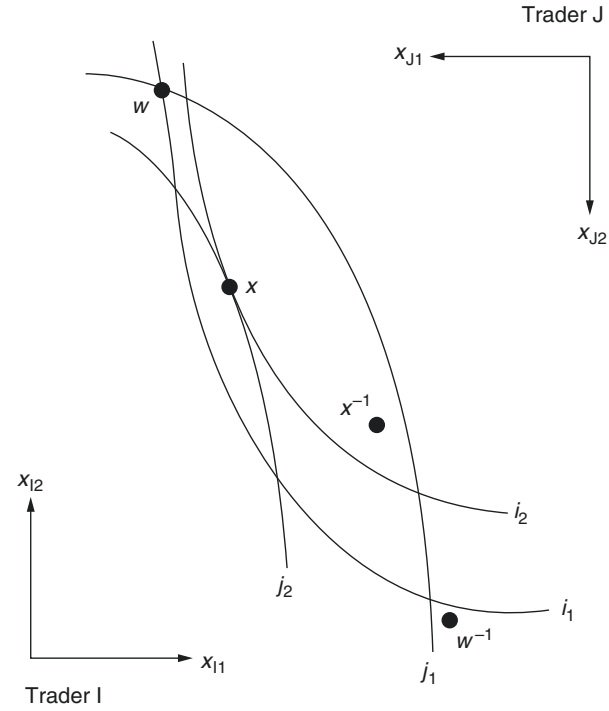
But the notion of equity has an obvious disadvantage, aside from its being founded on that odious passion. For instance, the economist's model, which reduces person i to a utility function $u_i(\cdot)$ and a bundle of goods x_i, ignores the fact that life is full of things not captured in $u_i(\cdot)$ or x_i, for instance, non-transferable attributes like beauty, health and family. Even if the division of economic goods is equitable, i will probably envy j his looks, or his good health. This problem was alluded to by Kolm (1972). A well-meaning economist who follows his equity theory to its bitter end will conclude that the beautiful should be disfigured, and the well made sick.

Less obvious disadvantages of the idea of equity require references to Pareto efficiency, the foundation of modern welfare economics. An allocation y is *Pareto superior* to an allocation x if all individuals prefer y to x. (This assumes, of course, a constant set of individuals who are making the judgement.) If y is Pareto superior to x, the move from x to y is a *Pareto move*. An allocation x is *Pareto optimal* if there is no y that is Pareto superior to it.

Several authors (e.g. Kolm 1972) have established that in an economy where there is no production, there exist allocations that are both equitable and Pareto optimal. To find one, start at the equal allocation and move the economy to a competitive equilibrium. By the first fundamental theorem of welfare economics, a competitive equilibrium is Pareto optimal. Since the equilibrium is based on the equal allocation, every individual has the same budget. But if i has the same budget as j, he cannot envy the bundle j buys since he could have bought it himself. So this theorem creates a link between equity and the more traditional, more fundamental notion of Pareto optimality.

But it is a weak link. Pazner and Schmeidler (1974) and Varian (1974) consider an economy with production, where i's utility depends not only on his consumption bundle x_i, but also on the number of hours he works q_i. However, production attributes are non- transferable. If person i is ten times as productive as j, there may be no Pareto optimal distribution of consumption goods and of work hours that is also equitable.

Equity, Fig. 1



Think of an economy of which you are a part and Luciano Pavarotti is a part. You would have to train for 10 lifetimes before you could sing an aria like he does, and therefore there may be no possibility of arriving at an allocation of consumption and work effort among all that is both equitable and Pareto optimal.

Various possible solutions to this quandary have been suggested (e.g. in Pazner 1976, and Pazner and Schmeidler 1978). For instance, consider an economy where 'everybody shares an equal property right in everybody's time'. This may lead to the existence of allocations that are both equitable and optimal, but it makes Pavarotti a slave to everyone who is less gifted. Or, as another possible solution, consider an *egalitarian equivalent* allocation. This is one such that the utility distribution it produces could be generated by a theoretical economy in which all consumers are assigned identical consumption bundles. Pazner and Schmeidler (1978) show that egalitarian equivalent allocations that are also Pareto optimal exist, even in economies with production. But this idea is also unworkable; it is simply too airy.

Turn back to an economy without production. It is true that there will exist, under general assumptions, allocations that are both equitable and Pareto optimal in the pure exchange economy. But Feldman and Kirman (1974) show two disturbing facts: First, even if traders start at the equal allocation, and they make a Pareto move to the core (the solution set for frictionless barter), they may end up at an inequitable allocation. Second, if traders start at an equitable allocation, and make a Pareto move to a competitive equilibrium they may end up at an allocation where someone envies someone else. The 'green sickness' springs up where once there was equity.

The Edgeworth box diagram below illustrates the second possibility. In Fig. 1, x_{11} and x_{12} represent quantities of goods 1 and 2 belonging to trader I; x_{J1} and x_{J2} represent quantities belonging to J. Also, i_1 and i_2 are two of trader I's indifference curves: j_1 and j_2 and two of trader J's indifference curves; $w = (w_i, \ w_j)$ is the initial

allocation; $w^{-1} = (w_j, w_i)$ is the allocation which switches the bundles between I and J. Note that w^{-1} is found by reflecting w through the centre of the box. Now w is equitable since the indifference curves through it pass above w^{-1}, and the move from w to x is a competitive equilibrium trade that makes both better off. But $x = (x_i, x_j)$ is not equitable, since i_2 passes below $x^{-1} = (x_j, x_i)$, which means that trader I envies J when they are at x.

In an interesting extension of the Feldman and Kirman result, Goldman and Sussangkarn (1978) show with generality that in 2 person, 2 good exchange economies there exist allocations x such that (a) x is equitable in the non-envy sense but (b) x is not Pareto optimal and (c) every y which is Pareto superior to x is inequitable! This is formal proof of Johnson's assertion (*The Rambler*, No.183) that 'envy is almost the only vice which is practicable at all times, and in every place; the only passion which can never lie quiet from want of irritation'.

The concept of equity as non-envy is still alive among prominent economists; for instance, Baumol (1982) applies non-envy to an analysis of rationing. This in spite of the fact that recent history suggests the average man fares better under regimes that are less committed to elimination of envy through redistribution of goods, and in spite of the serious theoretical objections raised to the concept as outlined above. Should we care about equity? The temptation to pronounce judgement on what is equitable and what is not may be irresistible. But economic theory suggests that the pursuit of equity in the sense of non-envy will lead to some peculiar and unpalatable results.

Equivalence Scales

Arthur Lewbel and Krishna Pendakur

Abstract

An equivalence scale is a measure of the cost of living of a household of a given size and demographic composition, relative to the cost of living of a reference household (usually a single adult), when both households attain the same level of utility or standard of living. Equivalence scales are difficult to construct because household utility cannot be directly measured, which results in economic identification problems. Applications of equivalence scales include measurement of social welfare, economic inequality, poverty, and costs of children; indexing payments for social benefits, life insurance, alimony, and legal compensation for wrongful death.

History

Providing two different households with the same standard of living, making them equally well off, requires some definition of well-being. In the early literature on equivalence scales, a household's well-being was defined in terms of needs, such as having a nutritionally adequate diet.

Engel (1895) observed that a household's food expenditures are an increasing function of income and of family size, but that richer households tend to spend a smaller share of their total budget on food than poorer households. He therefore proposed that this food budget share could be a measure of a household's welfare or standard of living. The resulting Engel equivalence scale is defined as the ratio of incomes of two different sized households that have the same food budget share. This is essentially the method used by the US Census Bureau to measure poverty. The bureau first defines the poverty line for a typical household as three times the cost of a nutritionally adequate diet, then uses food shares (Engel scales) to derive comparable poverty lines for households of different sizes and compositions, and finally adjusts the results annually by the consumer price index to account for inflation (see Fisher 1997).

Given two households that differ only in their number or age distribution of children, Rothbarth (1943) equivalence scales are similar to Engel scales. They can be defined as the ratio of incomes of the two households when each household purchases the same quantity of some good that is only consumed by adults, such as alcohol, tobacco, or adult clothing.

Modern equivalence scales measure well-being in terms of utility, using cost (expenditure) functions estimated from consumer demand data via revealed preference theory. Engel or Rothbarth scales are equivalent to valid cost function based equivalence scales only under strong restrictions regarding the dependence of demand functions on characteristics such as age and family size, and on the links between demand functions and utility for these different household types.

One strand of the equivalence scale literature focuses on the former issue, and so deals primarily with the empirical question of how best to model the dependence of household Marshallian demand functions on demographic characteristics. Examples are Sydenstricker and King (1921), Prais and Houthakker (1955), and Barten (1964) scales, in which a different Engel type scale is constructed for every good people purchase, roughly corresponding to a different economies of scale measure for each good. Other examples are Gorman's (1976) general linear technologies, Lewbel's (1985) modifying functions, and Pendakur's (1999) shape invariance.

The second, closely related literature, focuses on the joint restrictions on both preferences and interpersonal comparability of utility required for measuring the relative costs of providing one household with the same utility level as another. Examples include Jorgenson and Slesnick (1987), Lewbel (1989), Blackorby and Donaldson (1993), and Donaldson and Pendakur (2004; 2006).

Definition

Consider a consumer (an individual or a household) with a vector of demographic characteristics $\mathbf{z}$ and nominal total expenditures x that faces the M vector $\mathbf{p}$ of prices of M different goods. The consumer chooses a bundle of goods to maximize utility given a linear budget constraint. Define the cost (expenditure) function $x = C(\mathbf{p}, u, \mathbf{z})$ which equals the minimum expenditure required for a consumer with characteristics $\mathbf{z}$ to attain utility level u when facing prices $\mathbf{p}$. $C(\mathbf{p}, u, \mathbf{z})$ is a conditional cost function in the sense of Pollak (1989) because it gives the expenditure necessary to attain a utility level u, conditional on the consumer having characteristics $\mathbf{z}$.

Equivalence scales relate the expenditures of a consumer with characteristics $\mathbf{z}$ to a consumer with a reference vector of characteristics $\bar{\mathbf{z}}$. The reference vector of characteristics may describe, for example, a single, medically healthy, middle-

aged childless man. The equivalence scale is defined by $D(\mathbf{p}, u, \mathbf{z}) = C(\mathbf{p}, u, \mathbf{z})/C(\mathbf{p}, u, \mathbf{z})$. Equivalent-expenditure $X(\mathbf{p}, x, \bar{\mathbf{z}})$ is defined as the expenditure level needed to bring the well-being of a reference household to the level of well-being of a household with characteristics $\mathbf{z}$, so $X(\mathbf{p}, x, \mathbf{z}) = x/D(\mathbf{p}, u, \mathbf{z}) = C(\mathbf{p}, u, \bar{\mathbf{z}})$ where u is replaced by the indirect utility function, that is, $x = C(\mathbf{p}, u, \mathbf{z})$ solved for u.

Identification

In economics, a parameter is said to be 'identified' if its numerical value can be determined given enough observable data. Here we show why identification of equivalence scales requires either strong untestable assumptions regarding preferences or unusual types of data. Equivalence scales depend on utility, which cannot be directly observed and so must be inferred from consumer demand data, that is, from the quantities that consumers buy of different goods in varying price regimes and at various income levels. The observable (Marshallian) demand functions for goods derived from a conditional cost function $C(\mathbf{p}, u, \mathbf{z})$ are the same as those obtained from $C(\mathbf{p}, \varphi(u, \mathbf{z}), \mathbf{z})$ for any function $\varphi(u, \mathbf{z})$ that is strictly monotonically increasing in u. By revealed preference theory, demand data identifies the shape and ranking of a consumer's indifference curves over bundles of goods, but not the actual utility level associated with each indifference curve. Changing φ(u, $\mathbf{z}$) just changes the utility level associated with each indifference curve.

Therefore, given any $C(\mathbf{p}, u, \mathbf{z})$ derived from demand data, the consumer's true cost of attaining a utility level u is $C(\mathbf{p}, \varphi(u, \mathbf{z}), \mathbf{z})$ for some unknown function 9, so true equivalence scales are $D(\mathbf{p}, u, \mathbf{z}) = C(\mathbf{p}, \varphi(u, \mathbf{z}), \mathbf{z})/C(\mathbf{p}, \varphi(u, \bar{\mathbf{z}}), \bar{\mathbf{z}})$. This is the source of equivalence scale non-identification. We cannot identify $D(\mathbf{p}, u, \mathbf{z})$ because the change from z to $\mathbf{z}$ has an unobservable affect on D through φ. The problem is that revealed preferences over goods identify one set of indifference curves for households of type $\mathbf{z}$ and another set for households of type $\mathbf{z}$, but we have no way of observing which indifference curve of type $\bar{\mathbf{z}}$ yields the same level of utility as any given indifference curve of type $\bar{\mathbf{z}}$.

Given only goods demand data, Blundell and Lewbel (1991) show that changes in equivalence scales that result from price changes can be identified, but the levels of equivalence scales are completely unidentified, because for any cost function C and any positive number d, there exists a $\varphi(u, \mathbf{z})$ function that makes $D(\mathbf{p}, u, \mathbf{z}) = \mathrm{d}$. Changes in D resulting from price changes can be identified because the ratio $D(\mathbf{p_1}, u, \mathbf{z})/D(\mathbf{p_0}, u, \mathbf{z})$ equals a ratio of ordinary identifiable cost of living (inflation) indices.

Identification of equivalence scales therefore requires either additional information or untestable assumptions regarding preferences over characteristics $\mathbf{z}$ and hence regarding φ. There are also other identification issues associated with equivalence scales. For example, different members of a household may have different standards of living, so a single level of utility that applies to the entire household to be compared or equated to anything may simply not exist. Lewbel (1997) lists additional equivalence scale identification issues.

Identification from Demand Data

Let w^j be the fraction of total expenditures a household spends on the jth good (its budget share) and let $\mathbf{w}$ be the vector of budget shares of all purchased goods. Shephard's Lemma states that $\mathbf{w} = \omega(\mathbf{p}, u, \mathbf{z}) = \nabla_{\ln p} \ln C(\mathbf{p}, u, \mathbf{z})$, the price elasticity of cost. Let $w_f = \omega_f(\mathbf{p}, u, \mathbf{z})$ indicate the food equation. Engel's method notes that since ω_f is monotonically declining in utility u, w_f may be taken as an indicator of well-being. If, in addition, w_f indicates the same level of well-being for all household types $\mathbf{z}$, then the expenditure levels which equate the food share w_f, across household types are the equivalent-expenditure function, whose ratios give the equivalence scale. Monotonicity of ω_f in u is observable, but the second restriction concerning utility levels for different types of households refers to φ and so is not testable.

The Rothbarth approach is similar. Let $q_a = h_a(\mathbf{p}, u, \mathbf{z})$ indicate the quantity demanded

for a good consumed only by adults, such as alcohol. If h_a is increasing in utility (a testable restriction), q_a may be taken as an indicator of the well-being of adult household members. If, in addition, q_a indicates the same level of adult wellbeing for adults living in all types of households (untestable), then the expenditure levels which equate q_a across household types are the equivalent-expenditure function, whose ratios again give the (Rothbarth) equivalence scale.

Lewbel (1989) and Blackorby and Donaldson (1993) consider the case where the equivalence scale function is independent of utility, which they call 'independence of base' (IB) and 'equivalence-scale exactness' (ESE), respectively. In this case there is a function Δ such that $D(\mathbf{p}, u, \mathbf{z}) = \Delta(\mathbf{p}, \mathbf{z})$ and $C(\mathbf{p}, u, \mathbf{z}) = C(\mathbf{p}, u, \bar{\mathbf{z}})\Delta(\mathbf{p}, \mathbf{z})$. The special case where $D(\mathbf{p}, u, \mathbf{z})$ is also independent of $\mathbf{p}$ yields Engel scales.

Given IB/ESE, Shephard's Lemma implies that $\omega(\mathbf{p}, u, \mathbf{z}) = \omega(\mathbf{p}, u, \bar{\mathbf{z}}) + \mathbf{n}(\mathbf{p}, \mathbf{z})$, where $\mathbf{n}(\mathbf{p}, \mathbf{z}) = \nabla_{\ln \mathbf{p}} \ln \Delta(\mathbf{p}, \mathbf{z})$. Since households with the same equivalent expenditure have the same utility, and since in this case, equivalent expenditure is given by $x/\mathbf{A}(\mathbf{p}, \mathbf{z})$, we may write the relation as $\mathbf{w}(\mathbf{p},x,\mathbf{z}) = \mathbf{w}(\mathbf{p},x/\Delta(\mathbf{p}, \mathbf{z}), \bar{\mathbf{z}}) + \mathbf{n}(\mathbf{p}, \mathbf{z})$, where $\mathbf{w}(\bullet)$ is the Marshallian budget share vector. Here, $\Delta(\mathbf{p}, \mathbf{z})$ 'shrinks' the budget share functions in the expenditure direction, and the amount of 'shrinkage' identifies the equivalence scale. Pendakur (1999) shows that this 'shape invariance' expression equals the testable implications required for IB/ESE. The untestable restriction, which uniquely defines $\varphi(u, \mathbf{z})$ (up to transformations of u that do not depend on $\mathbf{z}$) is that all households with the same value of $x/\Delta(\mathbf{p}, \mathbf{z})$ have the same level of utility. Blackorby and Donaldson (1993) show when cost functional forms uniquely identify IB/ESE. Donaldson and Pendakur (2004, 2006) consider identification for equivalence scales with more general functional forms.

Other Sources of Identification

Equivalence scale identification depends on how we define utility or well-being. Identification is not a problem if what we mean by making households equally well off refers to some observable characteristic such as nutritional adequacy of diet. As an alternative to revealed preference, identification may be based on surveys that ask respondents to either report their happiness (and hence utility) on some ordinal scale, or ask, based on introspection, how their utility or costs would change in response to changes in household characteristics. An early example is Kapteyn and Van Praag (1976), who estimate equivalence scales based on surveys where households rank income levels as 'excellent', 'sufficient', and so on. Identification requires comparability of these ordinal utility measures across consumers. Happiness studies by psychologists and experimental economists may prove useful for validating these types of subjective responses regarding utility, especially with recent neuroeconomic results measuring brain activity associated with pleasure, regret, and economic decision-making (see, for example, McFadden 2005).

Another possible source of identification is when consumers can choose $\mathbf{z}$, and we can collect information relevant to these choices. Assuming $\mathbf{z}$ is chosen to maximize utility can provide information about how utility varies with $\mathbf{z}$, and hence may restrict the set of possible φ transformations. With enough information regarding how $\mathbf{z}$ is chosen one could identify 'unconditional' cost or utility functions over both goods and $\mathbf{z}$ and thereby identify the dependence of φ on $\mathbf{z}$. Pollak (1989) refers to the use of unconditional versus conditional data to calculate the cost of demographic changes as 'situation comparisons' versus 'welfare comparisons'.

Traditional equivalence scales assign a single level of utility to a household, implicitly assuming that all household members have the same utility level and hence ignoring the effects of the within-household distribution of resources. Features of this intra-household allocation of resources can be identified and estimated with demand data. Given the indifference curves and resource shares of each household member, instead of trying to calculate the cost of making an individual as well off as a household, one may instead calculate the cost of putting the individual on the same indifference

curve when living alone that he attained as a member of a household. Whereas the former calculation requires a welfare comparison, the latter calculation only involves comparing the same individual in two different price and income environments. Browning, Chiappori and Lewbel (2006) call this type of comparison an 'indifference scale', and provide one set of conditions under which such scales can be non-parametrically identified.

Applications of Equivalence Scales

Equivalent expenditures and equivalence scales may be used for social evaluation, for example, inequality and poverty analysis. Given an equivalence scale, *di,* and household expenditure, *xi*, for each person *i* in a population, one constructs equivalent expenditure for each person: $x_i^e = x_i/d_i$. Expenditure data are observed at the level of the household, but x_i^e is constructed for each individual. By construction, the population distribution of equivalent expenditures is equivalent in welfare terms to the actual distribution of expenditures across households. Therefore, one can use this 'as if' distribution for constructing population measures of poverty or inequality, or for calculating the welfare implications of tax and transfer programmes.

Equivalence scales can also be used to calibrate social benefits payments and poverty lines. For example, if the social benefit rate (or poverty line) $\bar{x}$ is agreed upon for a single household type, for example, a single childless adult, then one could use equivalence scales to set rates for other household types $\mathbf{z}$ as $D(\mathbf{p}, u, \mathbf{z})\bar{x}$ where u is the utility level of the reference type with expenditures $\bar{x}$. Some statistical agencies flow information in the other direction: poverty lines are constructed for each household type, which can then be use to construct an implicit 'poverty relative' equivalence scale. If scales are IB/ESE, this provides enough information to identify equivalence scales for all households.

Other applications of equivalence scales are for life insurance, alimony, and wrongful death calculations (see Lewbel 2003), and for indirectly measuring the cost of children based on equivalence scales for households of different sizes.

Ergodic Theory

William Parry

To begin in the middle; for that is where ergodic theory started, in the middle of the development of statistical mechanics, with the solution, by von Neumann and Birkhoff, of the problem of identifying space averages with time averages. This problem can be formulated as follows: If $x_t(-\infty < t < \infty)$ represents the trajectory (orbit) passing through the point $x = x_0$ at time $t = 0$ of a *conservative dynamical system*, when can one make the identification

$$(*)\ \lim_{T\to\infty} (1/T)\int_0^T f(x_t)\mathrm{d}t = \int_\Omega f\,\mathrm{d}m/m(\Omega)$$

for suitable functions defined on the *phase space* Ω of the system?

There are many things to be explained here. For example one might imagine a 'large' number of particles contained in a box, which collide with one another and with the sides of the box according to the usual laws of elastic collision. Each of these particles has three coordinates of position and three coordinates of velocity so that the state of the system is describable by $6n$ coordinates if n is the number of particles. Newtonian laws, of course, provide a history and future for each of these points in $6n$ dimensional space. The same laws imply the law of conservation of energy, so that in principle dynamical systems may be studied with the assumption that energy is constant for each trajectory of a conservative system. Thus in $(^*)$ we take the phase space Ω to be that hypersurface of $6n$ dimensional space where the total energy has a given (constant) value, and m is the hypersurface volume (measure) associated with the Liouville invariant volume whose existence is guaranteed by the conservativity of the system. In general $m(\Omega)$ is a finite quantity.

The left-hand side of $(^*)$ is the time average along a trajectory for a function (observable) f and the right-hand side is the phase or space average.

Von Neumann proved a mean convergence version of $(^*)$ and shortly after G. D. Birkhoff proved $(^*)$ as stated, for *almost all* states, in both cases under the assumption that the system (restricted to Ω) is *ergodic*, a notion, we shall explain presently. (Cf. von Neumann 1932a; Birkhoff 1931.) It was soon realized that both versions of $(^*)$ (the ergodic theorems) could be formulated and proved in a more abstract setting and indeed one can say that this abstraction and the subsequent mathematics thereby generated is ergodic theory proper.

Let (Ω, m) represent an abstract space with a finite measure. (There is no loss in generality in assuming $m(\Omega) = 1$, as we shall do.) Let T_t represent a family of transformations indexed by time (in various contexts, the real numbers, the integers) such that $T_{t+s} = T_t \circ T_s$. Assume that this family is measurepreserving ($mT_tB = mB$, for all 'measurable' sets). The study of T_t as t varies through its index set, provides a model for an evolutionary system, such as the dynamics in phase space described earlier, in which measure (volume) is preserved. The system is said to be *ergodic* if Ω cannot be decomposed into two disjoint invariant measurable sets

$$A, B(A \cup B = \Omega, A \cap B = \varnothing, T_tA = A, T_tB = B \text{ all } t)$$

of positive measure.

In a strict sense, the time-average space-average problem was not *solved* by von Neumann and Birkhoff, as far as the classical dynamical system given at the outset is concerned, for the question of whether this system *is* ergodic was left open and it is only recently (Sinai 1963) that progress has been made in this direction.

Most workers in ergodic theory concern themselves with measure-preserving transformations T_t indexed by the integers, so that with $T_1 = T$, T_t is the iteration of T repeated t times. Results in this context invariably lead to results for real continuous time.

Having freed itself from a particular (albeit important) dynamical system, ergodic theory or more particularly the theory of measure-preserving transformations began to encounter a rich diversity of problems:

(i) When does a measurable transformation, non-singular with respect to a given measure, preserve an equivalent finite (or even σ-finite) measure?
(ii) Are there analogues of the ergodic theorems for Markov processes?
(iii) Where do we find examples of measure-preserving (or non-singular) transformations in other branches? If they are non-singular answer question (i). If they are measure-preserving are they ergodic? If so, interpret the ergodic theorems for them.
(iv) Is it possible to (at least partially) classify the myriad examples coming from other branches of mathematics?

One should notice that in posing these problems ergodic theory became a *global* analysis in two senses: The phase space dynamical system described at the beginning of this entry is global in that *all* solutions of a differential equation are involved. Ergodic theory then moves on to treat all other problems having a dynamical character in which an invariant measure appears.

Concerning (ii) one should note that a measure-preserving transformation T gives rise to an isometric operator $Lf = f^\circ\ T$ on various Banach spaces, the most important being $L^1(m)$. In a similar way a Markov process gives rise to a semi-group of positive contractions. For such operators there is a variety of ergodic theorems generalizing the classical results of Birkhoff and von Neumann. As an example there is the powerful general ergodic theorem (Chacon and Ornstein 1960): If L is a positive contraction on $L^1(m)$ and f, $g \in L^1(m)$ then

$$\sum_{k=0}^{n} L^n f \Big/ \sum_{k=0}^{n} L^n g$$

converges almost everywhere on the set where the denominator is persistently positive.

Here we have an instance of ergodic theory providing a powerful tool for statistics. This should hardly be surprising, however, as even the classical Birkhoff ergodic theorem has an immediate impact on stochastic processes, for one can always associate a measure-preserving transformation with, say, a sequence of independent and identically distributed random variables in such a way that the strong law of large numbers is an easy corollary of Birkhoff's theorem.

Markov and other stochastic processes have played and continue to play a central role in the development of ergodic theory. In recent years a modelling procedure for understanding hyperbolic dynamical systems based on Markov chains

has led to profound results in the area of differentiable statistical mechanics. Thus statistical ideas are exchanged, measure for measure, with those of ergodic theory.

Concerning (iii) here are some examples:

(a) *An 'irrational flow'*. Here $\Omega = \{(z, w)$: z, w complex $| z | = | w | = 1\}$, $T_t(z, w) = (e^{2\pi i\alpha t}z, e^{2\pi i\beta t}w)$, α, β are real with α, β irrational. m is an ordinary Lebesgue measure.

(b) *A skew product*. Here (Ω, m) is the same as in (a).

$$T(z, w) = \left(e^{2\pi i\alpha}z, zw\right), \quad \alpha \, irrational.$$

(c) *An automorphism of a torus*. Again (Ω, m) is the same as in (a).

$$T(z, w) = \left(z^2w, zw\right).$$

(d) *A translation of a homogeneous space*. G is a locally compact Lie group and H is a closed subgroup such that the homogeneous space $G/H = \{gH$: $g \in G\}$ is compact. $\Omega = G/H$ and m is a Haar measure. The transformation T is defined as a translation.

$$T(g, H) = agH$$

for a given element $a \in G$.

(e) *A geodesic flow*. Here we consider an n-dimensional Riemannian manifold M with unit length tangent vectors υ located at points of M. Such a vector υ defines a unique geodesic curve on M. Ω is the totality of such υ and $T_t\upsilon$ is the unit tangent vector obtained by allowing υ to flow along its geodesic at unit speed after time t. The measure m may be taken to be the natural one associated with Liouville's measure.

(f) *A Hamiltonian dynamical system*. Instead of defining this we mention that (e) above and the n particle phase space system at the beginning of this article are both examples of such a system.

(g) *The evolutionary shift associated with a Markov chain or more particularly of a Bernoulli (independent) sequence of trials*.

For the Bernoulli case Ω consists of points $w = \{w_n\}_{-\infty}^{\infty}$ where w_n represents the outcome of an experiment (heads or tails, for example, in the tossing of a coin) at time n. m is the probability which guarantees the independence of these trials, and T is the shift in time $Tw = w'$ where $w'_n = w_{n+1}$.

(h) *A stationary Gaussian (normal process)*.

(i) *The continued fraction transformation*. Here Ω consists of the irrational numbers between 0 and 1. m is 'Gauss's' measure whose density is $1/\log 2\,(1 + x)$ and $Tx = 1/x \bmod 1$.

An alternative account of ergodic theory, which admittedly ignores the history of the subject, could be given which is based on the above examples (and many others). It would motivate the subject by the questions: What do these examples have in common? What concepts underlie them? However, only a posteriori would these questions lose their artificiality.

The first four examples (a), (b), (c) and (d), all arise from algebraic or homogeneous space structures and even (e) falls into this category under certain conditions on the curvature of the manifold. In general, (e) arises from differential geometry. The Bernoulli example (g) (or more generally a Markov chain) arises from probability theory as does (h). The example (i) occurs in the study of continued fractions.

These examples (under suitable conditions) are flows and transformations which display varying degrees of ergodicity or *mixing* and ergodic theoretical techniques reveal important information about them. For example, in Furstenberg, (1961) (b) was used to give a proof of the famous theorem of Weyl that $\alpha n^2 + \beta n + \gamma \bmod 1$ is uniformly distributed in the unit interval [0, 1] as n varies (as long as α or β is irrational). The example (c) was closely analysed as a prototype of *hyperbolicity* prior to the development of Anosov and Axiom A dynamical systems. The examples covered by (e) (and the related *horocycle flows*) are central to the study of hyperbolic geometry and to the theory of unitary representations of semi-simple Lie groups. The examples (g), (h) provide the most important classes of stationary stochastic processes and are intimately related to Brownian

motion. Example (i) is of vital importance in number theory.

Question (iv) was first approached (von Neumann 1932b; Halmos and von Neumann 1942) using spectral techniques. Two measure-preserving transformations *S, T* are said to be (spatially) *isomorphic* if there is an invertible measure-preserving transformation ϕ between their respective spaces such that $\phi S = T\phi$ a.e. (almost everywhere). Isomorphism implies that the unitary spectral characteristics are indistinguishable (i.e. *spectral* equivalence), but not vice versa. The main result obtained characterized all ergodic measure-preserving transformations with a pure point spectrum. For such transformations *S, T* identity of point spectrum implies spatial isomorphism and such transformations are (isomorphically) precisely the ergodic translations of compact metric abelian groups.

A similar theory was developed in Abramov (1962) for so-called transformations with quasi-discrete spectrum. Example (b) provides an example of this type of transformation. They had been studied earlier by Anzai. The works of Auslander, Green and Hahn (1963) and Parry (1971) provide further developments in this direction. A completely analogous theory is modelled on the 'rigid' examples of *nilflows* and *unipotent affines* on nil manifolds. The rigidity here refers to the phenomenon of measure isomorphisms *necessarily* being algebraic in character. The most recent work concerning rigidity in ergodic theory (Ratner 1982) finds this, and related phenomena, in horocycle flows.

So far we have given a condensed account of only one strand in isomorphism theory. The most active work has occurred in connection with examples of an entirely different and *random* character.

This work began with the problem of deciding whether two Bernoulli shifts (which are necessarily spectrally isomorphic) are spatially isomorphic. The first breakthrough occurred with Kolmogorov's introduction of entropy theory into the subject (Kolmogorov 1958). As modified in (Sinai 1959) entropy is a numerical invariant of isomorphism (i.e. if *S, T* are isomorphic then their entropies *h(S), h(T)* coincide). This fact provides a multitude of Bernoulli transformations which are not isomorphic. The basic ideas originate with Shannon and McMillan, but they required significant adaptation before they could be used in ergodic theory. The new entropy theory developed apace in the hands of, principally, Russian mathematicians in the 1960s and received its biggest impetus from the American mathematician Ornstein, who in 1968 proved that two Bernoulli transformations with the same entropy are isomorphic (cf. Ornstein 1970). From that time the subject has grown exponentially, with ever more transformations shown to be (isomorphic to) Bernoulli transformations. Such transformations have to have (to say the least) positive entropy and their *intrinsic* random character is in marked contrast to the rigid examples referred to earlier which are *deterministic* (with zero entropy).

Entropy plays very little role in the looser classification theory which allows velocities (along trajectories) to vary. There are continuous (real) time and discrete versions of this theory and as early as 1943 Kakutani had conjectured that all ergodic systems are *Kakutani equivalent*, using the current nomenclature for this loose equivalence (Kakutani 1943). Although this conjecture turned out to be false (in fact entropy ensures the existence of at least three Kakutani inequivalent systems), Feldman (1976) and Katok (1977) showed that remarkably dissimilar systems are equivalent according to this notion. In Ornstein and Weiss (1984) it is shown that a modification of Kakutani's conjecture is true. In this connection a grand theory of equivalence relations in ergodic theory has been developed in Rudolph (1984). This is ergodic theory with its head in the clouds.

From a more earthly point of view ergodic theory in the 1960s, through the developments of entropy theory and stimulated by Anosov (1967) and Smale (1967), began to connect with the newly flourishing field of differentiable dynamical systems.

Examples (c) and (f) are, respectively, prototypes of Anosov diffeomorphisms and flows. Their principal feature here is their global hyperbolic structure. Dynamicists are particularly interested in such systems as they are *structurally stable*, a concept which became something of a

dogma in the 1960s and 1970s, as some mathematicians went so far as to assert that any real and persistent system must be structurally stable. (A structurally stable system is, roughly speaking, one which retains its principal features after a small perturbation.) This important concept was modified by Smale when he introduced Axiom A systems and proved that the latter are Ω-stable (structural stability relative to non-wandering sets). Smale thereby axiomatized a vast category of new dynamical systems and presented us with an approach which unified Anosov systems, gradient like dynamical systems and his so-called 'horse shoes'. For these systems Smale proved his spectral decomposition theorem, which describes the non-wandering set of an Axiom A system in much the same way as one describes the irreducible block behaviour of a non-negative matrix, in the theory of Markov chains (Smale 1970). The *basic* sets of an Axiom A system received further scrutiny in terms of Markov partitions by Sinai (Anosov case) and Bowen (Axiom A case).

Bowen was a key figure in the fruitful convergence of ergodic theory and differentiable dynamical systems because of his profound expertise in both subjects. In a series of papers he provided deep analyses of Axiom A diffeomorphisms and flows (roughly speaking, hyperbolic dynamics) from the point of view of symbolic dynamics and periodic orbits (Bowen 1977). His work connected happily with the direction Ruelle and Sinai were taking in statistical mechanics (Sinai 1972; Ruelle 1978). Together they laid the foundations for statistical mechanics on manifolds.

The subject then has gone full circle to its origins, but on the way it encountered a dazzling variety of iteration problems from other areas, viz. maps of the unit interval (Collet and Eckmann 1980), boundary measures associated with Fuchsian groups (Patterson 1976; Sullivan (1979), analytic maps of the Riemann sphere or complex plane (Rees 1982), to name but three.

As to recent developments in statistical mechanics the one-dimensional lattice gas has received the most attention. Here one considers a shift transformation (as in the case of a Markov chain) initially in the absence of any probability but supplemented with a natural topology which reflects the connectivity of the transformation. Such a shift is called a *topological Markov chain* (or *shift of finite type)*.

Then one considers an action potential describable in terms of a continuous function. Under a stronger (Lipschitz) condition it turns out that there is always a unique shift invariant probability (called an *equilibrium state)* given by a variational principle involving the *pressure* of the potential.

A key tool in this theory is the *transfer* matrix or operator associated with the potential and under suitable (aperiodic and irreducible) conditions, iterations of this operator will force arbitrary probabilities to converge to the equilibrium state.

The one-dimensional lattice gases provide models for simple gases and also for statistical mechanics on manifolds. The results above have analogues (when appropriate conditions are imposed) for differential or even topological dynamical systems (Pesin 1977). Moreover, at least for hyperbolic systems, one can view topological Markov chains with their potentials, equilibrium states, closed orbits, transfer operators and pressures as (in a technical sense) building schemes for these systems.

A recent new area of ergodic theory which stands outside the developments just sketched is concerned with the application of ergodic theory and topological dynamics to combinatorial number theory. The motivation for this recent work was Szemeredi's proof of a conjecture of Erdos and Turan. The conjecture, which emanated from a result of van der Waerden's, states that if $a_1 < a_2 < \cdots$ is an increasing sequence of positive integers and if θ_N denotes the number of these integers less than N, then for every $k > 0$ there is an arithmetic progression in the sequence of length k, as long as $\theta_N/N > \epsilon$ infinitely often (for some $\epsilon > 0$).

Furstenberg (1977) provided an ergodic theoretical proof of this result and of many other results with the same 'flavour'. His technique involved building a sequence $\{x_n\}$ of zeros and

ones ($x_n = 1$ when and only when n is in the sequence), and embedding this sequence in a shift space. The details, which are quite intricate, involve the proof of a multiple recurrence theorem:

If T is a measure-preserving transformation on (X, m) and if $m(A) > 0$ then for every positive integer k

$$m\left(A \cap T^n A \cap T^{2n} A \cap \cdots \cap T^{kn} A\right) > 0$$

for infinitely many integers n.

Although this area is somewhat askew to the other developments outlined above, it needs to be mentioned because of the great research potential it possesses.

Where are the likely growing points for the subject? Here is a list of guesses. Some of them are wild; others are safe; and they are not all of equal weight:

(1) Applications to combinatorial number theory (Furstenberg 1977);
(2) Problems involving a mixture of prime number theory and ergodic theory inspired perhaps by Vinogradov's theorem that $p\alpha$ mod 1 is uniformly distributed when p runs through the primes and α is irrational;
(3) Greater understanding of the connections between the prime number theorem and the prime orbit theorem (Hejhal 1976; Parry and Pollicott 1983);
(4) Further developments of cohomology theory in ergodic theory (Schmidt 1977);
(5) Developments in *restricted* classification theories of processes; in particular a solution of Williams's problem (Williams 1973); in particular a solution of the stochastic version of the theory of Adler and Marcus (1979);
(6) Developments from Ornstein's and Weiss's modified Kakutani problem in the theory of von Neumann algebras;
(7) Which ergodic translations, affines and flows are rigid?
(8) A greater understanding of turbulence (Ruelle and Takens 1971).

Ergodicity and Nonergodicity in Economics

Ulrich Horst

Abstract

A random economic system is called ergodic if it tends in probability to a limiting form that is independent of the initial conditions. Breakdown of ergodicity gives rise to path dependence. We illustrate the importance of ergodicity and breakdown thereof in economics by reviewing some work of non-market interactions. This includes microeconomic models of endogenous preference formation, macroeconomics models of economic growth, and models of social interaction.

A stochastic system is called ergodic if it tends in probability to a limiting form that is independent of the initial conditions. Breakdown of ergodicity gives rise to path dependence. Path-dependent features of economics range from small-scale technical standards to large-scale institutions. Prominent examples include technical standards, such as the 'QWERTY' standard typewriter keyboard and the 'standard gauge' of railway track. Ergodicity and breakdown thereof is of particular relevance to models of social interaction. We illustrate this importance, summarizing some work on endogenous preference formation, dynamic population games, and models of nonmarket interaction.

Endogenous Preference Formation

In his pioneering paper on endogenous preference formation, Föllmer (1974) developed an equilibrium analysis of large exchange economies where the conditional excess demand $z(x^a, p)$ of the agent $a \in \mathbf{A}$ given a price system p is subject to a random shock x^a and where the probabilities $(\pi_a)_{a \in \mathbf{A}}$ governing this randomness have an interactive structure.

In a benchmark model where the *states* x^a are independent across agents, the distribution μ of the vector of states $x = (x^a)_{a \in \mathbf{A}}$ takes the product form $\mu = \Pi_{a \in \mathbf{A}} \pi_a$, and the law of large numbers yields

$$\lim_{n\to\infty} \frac{1}{|\mathrm{A}_n|} \sum_{a \in \mathbf{A}_n} z(x^a, p) = \int z(x^a, p)\mu(dx)\mu - \text{almost surely} \qquad (1)$$

for an increasing sequence of finite populations $\{\mathbf{A}_n\}_{n \in \mathbf{N}}$. Under standard conditions on $z(x^a, \cdot)$ there exists a unique price system p^* for which per capita excess demand is small in economies with many agents, that is, for which

$$\int z(x^a, p^*)\mu(dx^a) = 0. \qquad (2)$$

The assumption of independence of states can be dropped as long as μ is *ergodic*, that is, as long as (1) holds. However, when preferences are interactive, the probabilities π_a specifying the dependence of the individual states on the states of others do not necessarily determine the *joint* distribution μ of all the states. This effect can best be illustrated by means of an 'Ising economy' where the agents are indexed by the two dimensional integer lattice ($\mathbf{A} = \mathbf{Z}^2$), the set of possible states is $\{-1, 1\}$, and where the conditional distribution of agent a's state depends on all the other states x^{-a} only through the states x^b of his four nearest neighbours $b \in N(a) := \{\hat{a} \in \mathbf{A} : |a - \hat{a}| = 1\}$. The distribution also depends on some constant $h \in \mathbf{R}$ which assigns an intrinsic value to private states and on a non-negative quantity J that measures the strength of social interactions. Specifically,

$$\pi_a(x^a; x^{-a}) = \frac{\exp\left\{x^a h + x^a \sum_{b \in N(a)} J x^b\right\}}{\exp\left\{x^a h + x^a \sum_{b \in N(a)} J x^b\right\} + \exp\left\{-x^a h - x^a \sum_{b \in N(a)=1} J x^b\right\}}. \qquad (3)$$

A probability measure μ on $S = \{x = (x^a)_{a \in \mathbf{A}}: x^a \in \{-1, +1\}\}$ is called a *global phase* if its one-dimensional marginal distributions are consistent with the microscopic data given by the individual characteristics $(\pi_a)_{a \in \mathbf{A}}$, that is, if

$$\mu(x^a = \pm 1 | x^{-a}) = \pi_a(\pm 1; |x^{-a}). \qquad (4)$$

An ergodic phase μ can be *equilibrated* if there exist prices p^* for which (2) holds. For independent preferences ($J = 0$) global phases and, hence, equilibrium prices are always determined uniquely by the agents' characteristics. However, if the distribution of states depends only on the states of others ($h = 0$) and the interaction is sufficiently strong, that is, if J exceeds some critical value, two ergodic global phases μ_+ and μ_- exist. In this case aggregate behaviour cannot be inferred from looking at microscopic characteristics alone. Moreover, there is typically no price system that equilibrates both phases *simultaneously*. Thus, randomness in preferences becomes a source of uncertainty about market clearing prices.

Stochastic Strategy Revision in Population Games

The pioneering work by Blume (1993) puts Föllmer's model into a dynamic framework of interactive choice and exploits the link of discrete choice models with Gibbs distribution theory. It is

mainly concerned with the aggregate behaviour in population games of bounded rational play, looking for 'Nash-like play in the aggregate rather than at the level of an individual player'. In Blume's model choice opportunities arise randomly according to individual players' Poisson 'alarm clocks'. When a choice opportunity arises for player $a \in \mathbf{A}$ at time t, his choice x_t^a results in an instantaneous payoff $G(x_t^a, x_t^b)$ from each neighbor $b \in N(a)$ and in a total payoff

$$\sum_{b \in N(a)} G(x_t^a, x_t^b). \tag{5}$$

The conditional probability $\pi_a(x_t^a; x_t^{-a})$ with which player $a \in \mathbf{A}$ selects an action x_t^a at time t, given the current states x_t^{-a} of all the other agents takes the form (3) with $h = \beta\hat{h}$ and $J = \beta\hat{J}$. Here $\beta \geq 0$ specifies the strength of interaction. For $\beta = 0$ the agents choose the actions with equal probability while a best response dynamics corresponds to the limiting case when β tends to infinity. The constants $\hat{h}$ and $\hat{J}$ are determined *endogenously* by the payoff matrix G through (5). Specifically,

$$\pi_a(x_t^a; x_t^{-a}) = \frac{\exp\left\{\beta\left[x_t^a\hat{h} + x_t^a\sum_{b \in N(a)}\hat{J}x_t^b\right]\right\}}{\exp\left\{\beta\left[x_t^a\hat{h} + x_t^a\sum_{b \in N(a)}\hat{J}x_t^b\right]\right\} + \exp\left\{-\beta\left[x_t^a\hat{h} + x_t^a\sum_{b \in N(a)}\hat{J}x_t^b\right]\right\}}.$$

These *flip rates* generate a continuous time Markov process X on S which describes the evolution of the agents' choices through time. A probability measure μ is called an *ergodic measure* for X if the distribution of choices does not change over time and empirical averages converge to a deterministic limit if the initial state is chosen according to μ. The process X is called *ergodic* if it has a unique ergodic measure. It is well known from the theory of interacting particle systems that the set of all ergodic probability measures for X is given by the ergodic global phases corresponding to the local specification (3). As a result, Blume's stochastic strategy revision process is ergodic if $\hat{h} \neq 0$ and $\hat{J} \geq 0$. This is the case if G describes a two person coordination game. Ergodicity breaks down for games with symmetric payoff matrices ($\hat{h} = 0$) when the interaction gets too strong. In this case, the long-run average choice depends on the starting point. The long-run macroscopic behaviour is as unpredictable as equilibrium prices in Föllmer's model by looking at microscopic characteristics only.

Non-ergodic Economic Growth

The evolution of individual choices in Blume (1993) is described by a *continuous* time Markov process with *asynchronous* updating. In local interaction models with *synchronous* updating, the dynamics of individual behaviour is typically described by a Markov chain whose transition operator takes the product form

$$\prod(x_t;\cdot) = \prod_{a \in \mathbf{A}} \pi_a(\cdot; \{x_t^b\}_{b \in (a)}). \tag{6}$$

Thus, the distribution of the state x_{t+1}^a in period $t + 1$ depends on the neighbours' states $\{x_t^b\}_{b \in N(a)}$. in period t. The long-run dynamics of such Markov chains plays an important role in macroeconomic models of economic growth.

The substantial differences in output levels and growth rates across countries have long been a major focus of macroeconomic research. A hallmark of the stochastic growth model pioneered by Brock and Mirman is the convergence of economies with identical preferences and production functions to a common level of aggregate output. Yet many analyses of long-run output movements have concluded that per capita production is not equalizing across countries. To explain this divergence, Durlauf (1993) studies a dynamic model of capital accumulation of an economy with an infinite set $\mathbf{A}$ of interacting companies where local technological externalities

affect the process of production. Each company $a \in \mathbf{A}$ chooses a capital stock sequence $\{K_t^a\}_{t\in}$ that maximizes the present value of future profits, and the technique-specific production functions generate output

$$Y_t^a = f\left(K_{t-1}^a, x_t^a, F\left(x_t^a\right)\right) \tag{7}$$

where $x_t^a \in \{0,1\}$. Technique $x_t^a = 1$ is more productive, but comes at a higher fixed cost: $F(1) > F(0)$. Local technological complementarities affect the production as the distribution of x_t^a depends on the techniques implemented by the nearest neighbours $b \in N(a)$ in the previous period. The dynamics of production technologies is then described by an interactive Markov chain of the form (6). Assuming that past choices of technique 1 improve the current relative productivity of the technique and that the high-productivity state $x_t^a = 1$ for all $a \in \mathbf{A}$ is an equilibrium, Durlauf (1993) shows that the high-productivity state is the only longrun outcome if the complementarities are weak enough: there exists $0 < \theta < 1$ such that

$$\lim_{t\to\infty} \mathrm{P}\left[x_t^a = 1 \middle| x_0^a = 0\right] = 1 \text{ if } \pi_a\left(1; \left\{x_{t-1}^b\right\}_{b\in N(a)}\right) \times \geq \underline{\theta}.$$

Even when one starts with all low-production industries, an economy eventually coordinates on the high-production technology when negative feedbacks from lowproduction technologies are sufficiently weak. Powerful negative complementarities, on the other hand, can generate a non-ergodic growth path. In fact, there exists $0 < \overline{\theta} < \underline{\theta} < 1$, such that

$$\lim_{t\to\infty} \mathrm{P}\left[x_t^a = 1 \middle| x_0^a = 0\right] < 1 \text{ if } \pi_a\left(1; \left\{x_{t-1}^b\right\}_{b\in N(a)}\right) \times \leq \overline{\theta}.$$

If the complementarities are too strong, industries fail to coordinate on highproductivity equilibria, and economies may get trapped in low-productivity equilibria.

Models of Social Interaction – Mean-Field Interaction

Much of the literature on social interactions assumes very special interaction structures such as nearest neighbour interactions as in Blume (1993), or Durlauf (1993) or mean-field interaction. If agents care about the average behaviour throughout the whole population, the analysis is most naturally done in the context of an infinity of agents, as in Brock and Durlauf (2001). These authors analyse aggregate behavioural outcomes when individual utility exhibits social interaction effects. In the simplest setting agents take actions xa from the binary action set $\{-1, +1\}$ and their utilities consists of three components:

$$U^a(x^a, m^a, \varepsilon(x^a)) = u(x^a) + Jx^a m^a + \varepsilon(x^a), \tag{8}$$

Here m^a denotes agent a's expectation about the average choice of all the other agents. The second term in the utility function may thus be viewed as a social utility expressing an agent's desire for conformity ($J > 0$). The quantity $u(x^a)$, on the other hand, represents the private utility associated with a choice while $\varepsilon(x^a)$ is a random utility term independent of other agents' utilities and extreme-value distributed with parameter $\beta > 0$. The extreme-value distribution assumption for the random utility term yields conditional choice probabilities π_a of the form (3) if we replace the dependence of *actual* actions by a dependence on *expected* actions. When agents have homogeneous expectations about the behaviour of others ($m^a \equiv m$), then

$$\pi_a(x^a; m) = \frac{\exp\{\beta(u(x^a) + Jx^a m)\}}{\exp\{\beta(u(1) + Jm)\} + \exp\{\beta(u(-1) - Jm)\}}. \tag{9}$$

In the limit of an infinite economy all uncertainty about the average action vanishes because the agents' choices are conditionally independent given their expectations about aggregate behaviour. The average action is $tanh(\beta h + \beta Jm)$ where

$h = \frac{1}{2}(u(1) - u(-1))$. If the agents have rational expectations the average satisfies the fixed point condition

$$m = \tanh(\beta h + \beta J m). \tag{10}$$

This equation has a unique solution if $h \neq 0$ and β is large enough. For large enough β the uniqueness property breaks down if $h = 0$, in which case (10) has three roots.

Models of Social Interaction – Local and Global Interaction

When agents care about both the average action and the choices of neighbours, the equilibrium analysis becomes more involved. Horst and Scheinkman (2006) provide a general framework for analysing systems of social interactions with an infinite set of locally and globally interacting agents located on an integer lattice (for example, $\mathbf{A} = \mathbf{Z}^2$), continuous action spaces and random preferences. Specifically, they consider utility functions of the form

$$u^a(x, \theta^a) = U\left(x^a, \{x^b\}_{b \in N(a)}, \rho(x), \theta^a\right)$$

where $\rho(x)$ denotes the average choice associated with the action profile x, and the random variables θ^a specify the distribution of taste shocks. While the distinction between local and global interactions is unnecessary for models with finitely many agents, it is important for the analysis of infinite economies. The continuity of the utility functions $u^a(\cdot, \theta^a)$ in the product topology on the configuration space requires, implicitly, that the dependence of an agent's utility function on another agent's action decays sufficiently fast as the distance from that other agent grows. Thus, if preferences depend on average actions, utility functions are typically discontinuous. To overcome this problem, Horst and Scheinkman (2006) separated the local and global impact of an action profile $x = (x^a)_{a \in \mathbf{A}}$ on individual preferences by viewing the average action as an additional parameter, ρ, of a *continuous* utility function on an *extended* state space. The parameter ρ can be seen as the agents' common expectation about the average behaviour. Under standard curvature conditions on U an equilibrium x^ρ exists for any such expectation ρ. If some form of spatial homogeneity prevails and under a weak interaction condition that restricts the influence of an agent's choice on the optimal decisions of others, x^ρ is unique. Furthermore, there exists a unique ρ that coincides with the average action $\rho(x^\rho)$ associated with x^ρ. In this case the agents correctly anticipate the average behaviour, and x^ρ turns out to be the unique equilibrium. The weak interaction condition also guarantees spatial ergodicity: the equilibrium of the infinite system is the limit of equilibria of finite systems when the number of agents grows to infinity; see Horst and Scheinkman (2005) for details.

Dynamic Models of Social Interaction

When dynamic models of social interaction are studied the analysis is often confined to the case of backward-looking myopic dynamics, either as a simple explicit dynamic process with random sequential choice or as an equilibrium selection procedure. Rational expectations equilibria of economies with local interactions are studied in Bisin et al. (2006). While agents interact locally in these models, they are forward-looking. Their choices are optimally based on the past actions in their neighbourhood as well as on their anticipations of the future actions of their neighbours. The resulting population dynamics can be described by an interactive Markov chain of the form (6) but the transition probabilities πa are *endogenously* specified in terms of the agents' policy functions. Bisin et al. (2006) also allow for local and global interactions and combine spatial and temporal ergodicity results. The dynamics on the level of aggregate behaviour is deterministic (spatial ergodicity) and the distribution of individual choices settles down in the long run (temporal ergodicity) when the interaction is weak enough. The analysis, however, is confined to one-sided interactions. It is an open problem to fully embed the theory of social interactions into a dynamics analysis of equilibrium.

Erhard, Ludwig (1897–1977)

Ralf Dahrendorf

Erhard was a man who had his moment in history and grasped it. As head of the Economic Department of the administration which preceded the creation of the Federal Republic of Germany, he was the author of the decision to combine the currency reform of 1948 with the abolition of rationing, and of restrictive regulations concerning production, distribution and capital movements. Many have argued that Germany's 'economic miracle' (and not less the political miracle) owes much to these decisions which at the time were regarded as either unrealistic or indefensible by many, including the Occupation Powers.

In a sense, Erhard's life before 1948 was a preparation for this moment, and his career afterwards a continuation of its theme. Born in Fürth in Franconia into a small business family, Erhard studied economics after World War I and joined an economic research institute. His teachers were, on the one hand, Wilhelm Rieger, first director of the Nuremberg Commercial College, and, on the other, Franz Oppenheimer, economist and sociologist in Frankfurt, whose influence on Erhard went much deeper. In the Sixties Erhard described Oppenheimer's importance for him in this way: his own economic policy was in a sense the redirection of Oppenheimer's 'liberal socialism' to 'social liberalism'. During World War II he wrote a memorandum sketching his project for a market economy in ways which left no doubt that he foresaw and wished for the defeat of the Nazis. This was one reason why he was appointed Bavarian Minister of Economic Affairs in 1945, and in 1947, head of the small special unit which prepared the currency reform of 1948. When Konrad Adenauer formed the first Federal Government, Erhard became Minister of Economic Affairs, a post which he held until he succeeded Adenauer as Federal Chancellor in 1963. It was as Economics Minister that Erhard preached and implemented the concept of 'social market economy', a market economy tempered by basic social policies, for which the Federal Republic has become famous. Erhard's Chancellorship was undistinguished; in 1966, his own party, the Christian Democratic Union (CDU) forced him to resign. However, his effect on Germany's economic institutions and the prevailing mould of economic thought is profound and lasting.

Alexander Erlich was born in St Petersburg on 6 December 1913 and died on 7 January 1985. He moved to Poland with his family in 1918. In 1914, his father Henryk Erlich, a leader in the Socialist movement in Poland, was executed. In the same year, after university studies in Berlin and Warsaw, Erlich emigrated to the United States, where he earned a Ph.D. at the New School for Social Research and joined the faculty of Columbia University in 1955. From 1966 until his retirement in 1981 Erlich was professor of economics at Columbia, teaching in the economics department, the Russian Institute and the Institute for East Central Europe. Professor Erlich was revered by his students for his unstinting help and encouragement and respected by his colleagues for his breadth of knowledge and understanding of socialist economics.

Alexander Erlich's main contribution to the economics of socialism is his work on the critical issue of industrialization policy in the USSR in the 1920s. To this issue, Erlich brought an unusual blend of sophisticated economic reasoning and penetrating political analysis. His major thesis concerning Soviet policy in this period is that the structural disproportions in the Soviet economy were so deep that virtually any policy would have had negative side effects on reconstruction. Specifically, Erlich argued throughout his career that the economic policies of both the left *and* the right opposition were equally problematic. While the left analysis was correct in pointing out that future growth was limited after 1925 by the existing high-capacity utilization and scarce investment funds, Preobrazhenskii and others were wrong in underestimating the reaction of the peasantry to an industrialization policy that would squeeze peasant incomes. On the other hand, the right opposition did not appreciate the implications of high-capacity utilization for continued growth through small profit margins and high turnover of consumer goods and light manufacturers. The right, and Bukharin in particular, were seen by Erlich to be naive on the intensity of the conflict between consumption and investment once existing capacity was fully utilized. This, his major work, exhibits a detailed knowledge of the Soviet experience and a dispassionate and rigorous analysis of policy choices that set the standard for such work in the field.

Errors in Variables

Vincent J. Geraci

The Historical Ambivalence

This entry surveys the history and recent developments on economic models with errors in variables. These errors may arise from the use of substantive unobservables, such as permanent income, or from ordinary measurement problems in data collection and processing. The point of departure is the classical regression equation with random errors in variables:

$$y = X^*\beta + u$$

where y is a $n \times 1$ vector of observations on the dependent variable, X^* is a $n \times k$ matrix of unobserved (latent) values on the k independent variables, β is a $k \times 1$ vector of unknown coefficients, and u is a $n \times 1$ vector of random disturbances. The matrix of observed values on X^* is

$$X = X^* + V$$

where V is the $n \times k$ matrix of measurement errors. If some variables are measured without error, the appropriate columns of V are zero vectors. In the conventional case the errors are uncorrelated in the limit with the latent values X^* and the disturbances u; and the errors have zero means, constant variances, and zero autocorrelation. In observed variables the model becomes

$$y = X\beta + (u - V\beta).$$

Since the disturbance $(u - V\beta)$ is correlated with X, ordinary least squares estimates of β are biased and inconsistent. The errors thus pose a potentially serious estimation problem. In regard to systematic errors in variables, they will not be discussed, since they raise complex issues of model misspecification which lie outside the scope of this entry.

Errors in variables have a curious history in economics, in that economists have shown an ambivalent attitude toward them despite the universal awareness that economic variables are often measured with error and despite the commitment to economics as a science. Griliches (1974) suggested that much of the ambivalence stems from the separation in economics between data producers and data analysers. If so, why have not economists made a greater effort to cross the breach? Griliches (p. 975) further suggested that 'another good reason for ignoring errors in variables was the absence of any good cure for this disease'. If so, why have not economists made greater use of the econometric techniques developed since Griliches wrote his survey?

We propose an alternative explanation: the way of economic thinking, epitomized by utility theory and consumer maximization, has promoted a neglect of measurement errors. Bentham (1789, ch. IV) was a pioneer of measurement theory in the social sciences in his attempt to provide a theory for the measurement of utility. He went so far as to recommend that the social welfare of a given policy be computed by summing up *numbers* expressive of the 'degrees of good tendency' across individuals. Bentham's notion of cardinal utility met rightfully with great resistance. Pareto (1927, ch. III) pressed the dominant view: the economic equilibrium approach, by producing empirical propositions about consumer demand in terms of observables (quantities, prices, incomes), is to be favoured over theories connecting prices to utility, a metaphysical entity. Thus, theory – here optimization by rational consumers in a competitive market – overcame a fundamental measurement problem.

We do not wish to quarrel with the neoclassical equilibrium approach to the study of demand, although some economists wonder whether the assumptions of the theory have sufficient validity to warrant their acceptance (as part of the

maintained hypothesis) in so many empirical demand studies. Rather, our point is that the great successes of this theory, and analogous successes of similar theories about other economic behaviour, have implanted a subconscious bias toward the substitution of economic theory (assumptions) for difficult measurement. In consequence, many economic models do not have an adequate empirical basis, cf. Leontief (1971) and Koopmans (1979).

Whatever the reasons for their neglect, errors in variables have been hard to keep down. Substantive unobservables such as permanent income, expected price and human capital continue to work their way into economic models and raise measurement issues. Friedman's (1957) permanent income model has served as a prototype for the errors-in-variables setup:

$$c_p = ky_p$$
$$y = y_p + y_t$$
$$c = c_p + c_t$$

where c = consumption, y = income, subscript 'p' = permanent, subscript 't' = transitory, and k is a behavioural parameter. Friedman (p. 36) clearly recognized the connection of the model expressed in observed c and y to the errors-in-variables setup; in his words, 'The estimation problem is the classical one of "mutual regression" or regression "when both variables are subject to error"'.

In the next two sections, early and recent developments on economic models with random errors in variables will be surveyed. Then, we will speculate on the future use of errors-in-variables methods.

Early Econometric Developments

Frisch (1934) was the first econometrician to face squarely the problem of errors in variables. In a brave book addressing model search, multicollinearity, simultaneity, and errors in variables, he decomposed the observed variables into a systematic (latent) part and a random disturbance part. His complicated correlation approach, sometimes resembling common factor analysis, did not satisfactorily resolve the errors-in-variables problem, but he raised fruitful questions. While Koopmans (1937), Geary (1942), Hurwicz and Anderson (1946), Reiersöl (1950), and a few others followed up on Frisch's endeavour, interest in the problem waned by the start of the 1950s. The famous Cowles Commission may have unintentionally buried the errors-in-variables problem when the chief investigators put it aside in order to make progress on the simultaneity problem. Applied economists, in their zeal to employ the new simultaneous equations model, ignored the limitations in their data despite the warning cry of Morgenstern (1950). Sargan (1958), Liviatan (1961), Madansky (1959), and a few others made contributions in the 1950s and 1960s, but for the most part errors in variables lay dormant. Widely used econometrics textbooks aggravated matters by highlighting the lack of identification of the classical regression equation in the absence of strong prior information such as known ratios of error variances. Neglect by the theorists led to the widespread use of *ad hoc* proxies in practice.

Recent Econometric Developments

Zellner (1970) sparked a revival of interest in errors in variables. He attained identification of the permanent income prototype by appending a measurement relation that predicted unobservable permanent income in terms of *multiple causes* (e.g. education, age, housing value), to accompany the natural *indicator* relation in which observed current income is a formal proxy for permanent income. Goldberger (1971, 1972b) stimulated the revival by showing how models with substantive unobservables could be identified and estimated by combining all of the measurement information in a set of multiple equations that arise from multiple indicators or multiple causes. He also drew out the connections among the errors-in-variables model of econometrics, the confirmatory factor analysis model of

psychometrics, and the path analysis model of sociometrics. On the applications side, Griliches and Mason (1972) and Chamberlain and Griliches (1975) studied the important socioeconomic problem of estimating the economic returns to schooling, with allowance for unobservable 'ability'. With Goldberger and Griliches leading the way, the econometric literature on errors in variables flourished in the 1970s.

Multiple Equations

For the permanent income prototype, Zellner's multiple cause relation and indicator relation formed a two-equation measurement system that could be appended to the structural consumption equation. For this three-equation model, Zellner (1970) provided an efficient generalized least squares estimator, and Goldberger (1972a) added a maximum likelihood estimator. This errors-in-variables framework, which can be applied to many situations in which an unobservable appears as an independent variable in an otherwise classical regression equation, has been very useful. Example applications have included Aigner's (1974) study of labour supply in which the wage is an unobservable, Lahiri's (1977) study of the Phillips curve in which price expectations is an unobservable, and Geraci and Prewo's (1977) study of international trade in which transport costs is an unobservable.

Jöreskog and Goldberger (1975) generalized the framework to situations in which there are more than two observed dependent variables. Their model combined prior constraints on the reduced-form coefficients (of the type that arise in econometric simultaneous equations models) with prior constraints on the reduced-form disturbance covariance matrix (of the type that arise in psychometric factor analysis models). For this model which contains multiple indicators and multiple causes (MIMIC) for a single unobservable, they developed a maximum likelihood estimator. Applications of the MIMIC framework have included Kadane et al's (1977) study of the effects of environmental factors on changes in unobservable intelligence over time, and Robins and West's (1977) study of unobservable home value. The framework could be extended to endogenous causes, as Robinson and Ferrara (1977) demonstrated.

Simultaneity

The MIMIC model assumes unidirectional causation. Suppose instead that unobservables appear in a simultaneous equations model. This case calls for less 'outside information' than the single-equation case, since coefficient overidentification, as it would exist in the hypothetical absence of measurement errors, may compensate for the underidentification associated with errors. This idea had appeared in early unpublished works by Hurwicz and Anderson (1946); Goldberger resurrected it in 1971. Geraci (1974), Hausman (1977), and Hsiao (1976) subsequently developed identification analyses and estimators for the simultaneous equations model with errors, taking account of the 'disturbance' covariance restrictions induced by the error structure as well as the usual coefficient restrictions. Many of their results have an instrumental variables interpretation. For illustration, an indicator for an unobservable in a simultaneous equations system is a valid instrumental variable for a given structural equation if the unobservable either (a) does not appear in that equation or (b) appears but has an associated error variance that is identified using information from some other part of the system. Once the latter linkage is recognized, the model well may be identifiable and hence estimable. A notable application has been Griliches and Chamberlain's series of studies on the economic returns to schooling. They employed a triangular model with structural disturbances specified as a function of unobservables (common factors). In various ways their models incorporated simultaneity, multiple indicators, and multiple causes.

Dynamics

Maravall and Aigner (1977), Hsiao (1977), and Hsiao and Robinson (1978) extended the errors-in-variables analysis to dynamic economic models. Among their findings, dynamics are a 'blessing' for identification in that autocorrelation of exogenous variables may provide additional

information; and, upon taking a discrete Fourier transform of the data, many of the results for the contemporaneous model can be carried over to the dynamic model. In the same vein, Geweke (1977) developed a maximum likelihood estimator for the dynamic factor analysis model by reprogramming, in complex arithmetic, Jöreskog's (1970) maximum likelihood algorithm which had developed into the widely used LISREL software package. Geweke applied this estimator to investigate manufacturing sector adjustments to unobservable product demand. Singleton (1977) extended this factor analysis approach to study the cyclical behaviour of the term structure of interest rates. His framework allowed estimation of the model without specifying the causes of the unobservable real rate of interest and price expectations, thus isolating the classic Fisher hypothesis for testing.

As the preceding survey indicates, the recent econometric literature contains many theoretical results on the identification and estimation of structural models that contain substantive unobservables and measurement errors. (For a further survey, see Aigner et al. 1984.) The literature also contains some interesting applications, but not many. Are more forthcoming?

Prospects

We have an uneasy feeling about the state of empirical economics. The development of formal economic theory and associated econometric technique has proceeded at an extraordinary pace. At the same time, what do economists know empirically? Many reported inferences hinge upon model assumptions whose validity remains to be assessed, and the gap between econometric technique and available data seems to be growing. None the less, there are grounds for some optimism.

Although few in number, the applications of errors-in-variables methods in the 1980s have been striking in their relevance to central economic issues. For example, Attfield (1980) has made the permanent income model a more complete explanation of consumption by incorporating unobservable liquid assets, rateable value, and windfall income. His model is a special simultaneous equations model with errors, in which identification of the individual structural equations can be established on a recursive basis. Geweke and Singleton (1981) also have taken up the permanent income model, adapting the classical latent variables model to this time series context and thereby generating some new tests of the permanent income hypothesis. As another example, Garber and Klepper (1980) have defended the competitive model of short-run pricing in concentrated industries through an explicit accounting for errors in measuring cost and output changes. They concluded that short-run price behaviour may appear to be related to market structure primarily because of estimation biases due to the measurement errors. As a final example, Stapleton (1984) has shown that the symmetry restrictions on structural parameters imposed by demand theory can be used to identify a linear model's parameters when measurement errors in price perceptions exist. This study is noteworthy in two respects. First, it shows how price, that bedrock of economic theory, may be measured erroneously. Second, economic theory is used to permit the explicit treatment of errors in variables.

These recent empirical works indicate the potential of errors-in-variables methods to lend fresh insights into important economic issues, and should stimulate more use of these methods. There are other encouraging signs as well. Recent studies using micro data have shown increasing attention to measurement error problems. In the macro area the rational expectations hypothesis has raised economists' consciousness of the difference between key conceptual variables of economic theory (i.e. permanent income, expected price, ex ante real rate of interest) and the available measurements. With respect to applications of errors-in-variables methods in economics, the stock is not great but the flow is encouraging.

Estate and Inheritance Taxes

Wojciech Kopczuk

Abstract

This article briefly describes features of real-life estate and inheritance taxes, economic arguments for and against these types of taxation and empirical evidence on economic distortions associated with such instruments.

Keywords

Bequests; Capital gains and losses; Charitable contributions; Estate taxation; Gift taxation; Inheritance taxation; Progressive and regressive taxation; Redistribution of income and wealth; Tax avoidance; Taxation of income; Wealth accumulation

Taxes imposed on intergenerational transfers are among the oldest types of taxation, apparently dating back at least to the Roman Empire (Pechman, 1987). There is substantial variation in their design in actual tax systems. The tax may be imposed on the donor or the donee side: it can apply either to the total estate (the total value of assets left by the decedent) or it can apply separately to transfers received by each beneficiary. This distinction matters when there are multiple beneficiaries and the tax is not simply proportional, or if the inheritance tax interacts with other forms of taxation (such as income tax). Further sources of variation in how these types of tax appear around the world include differences in how family members are treated, deductions allowed, treatment of certain categories of assets, treatment of capital gains and interaction with other types of tax. Two additional types of tax are closely associated with estate and inheritance taxation. First, some countries impose additional tax on transfers that skip generations. Such transfers would otherwise avoid taxation at death of an intermediate generation and hence would provide tax savings. Second, taxes on *inter vivo* gifts are imposed to protect the base of estate taxation (this is not their sole purpose, however: they also reduce the incentive for income shifting across individuals subject to different individual income tax brackets).

Most developed countries impose some form of taxation of intergenerational transfers; the exceptions are Canada, Australia and New Zealand. European countries usually impose inheritance taxes. See Gale and Slemrod (2001) for more details.

Estate Taxation in the United States

In the United States, estate and gift taxes are 'integrated', that is, gifts over the lifetime influence computation of the estate tax burden at death. On top of federal taxation, many states impose their own taxes (in some cases inheritance rather than estate), although since the 1970s most states have changed their taxes to only 'soak up' federal credit for state taxation without imposing any incremental tax liability for those who are subject to the federal tax. The modern federal estate tax was introduced in 1916, although many states imposed their own taxes before that and the federal government made two earlier attempts to tax estates (during the Civil War and the Spanish–American War). The structure of estate taxation changed often before the Second World War, when the top marginal tax rates hit 77 per cent. Marginal tax rates were not reduced until the early 1980s, when the top rate was cut to 55 per

cent. Further reductions are taking place as a part of the phase-out of estate tax initiated in 2001 that is supposed to culminate in a repeal in 2010. The repeal is a part of the set of provision that sunset in 2011, and hence the future of this tax is uncertain at the time of this writing. The US estate tax has always been characterized by a large tax exemption. At the peak in 1976, slightly over seven per cent of adult deaths corresponded to taxable estates, but, other than during the period of the growth in the reach of the tax in the 1960s and 1970s induced by 'bracket creep' (brackets not indexed for inflation), only two per cent or less of all estates were subject to the tax. Revenue collected by this tax has always been relatively small, constituting one to two per cent of total federal revenue after the Second World War.

Arguments for and Against Estate and Inheritance Taxation

A number of arguments are often given in favour of this type of taxation:

- Administrative convenience – taxation occurs at the time when assets have to be valued anyway, thereby reducing the burden of compliance relative to other forms of wealth taxation.
- Presumed lack of distortions if bequests are mostly 'accidental', that is, when taxpayers save for their own lifetime consumption rather than for bequests (see Kopczuk, 2003, for a critique of this argument).
- Redistribution (although, Kaplow, 2001 suggests that income taxation may be sufficient for redistribution).
- Backstop to avoidance of income taxes.
- Providing equality of opportunities and breaking down concentration of wealth.
- 'Carnegie effect' – inherited wealth is a 'bad' because it makes children unproductive members of society (see Holtz-Eakin, Joulfaian and Rosen, 1993, for supporting empirical evidence).
- Providing incentives for charity.

These are countered by the following:

- Distortions introduced by estate taxation.
- Theoretical arguments for zero capital taxation in the long run (recently challenged in the context of the estate tax by Farhi and Werning, 2007).
- Horizontal inequity due to unequal treatment of 'savers' and 'spenders' (see for example McCaffery, 1994).
- Easy tax avoidance.
- Gift externality (providing an argument for subsidizing transfers).

A broader overview of the normative issues can be found in Gale and Slemrod (2001) and Kaplow (2001).

Economic Distortions

Among the types of economic distortions often discussed in this context are effects on saving, investment and labour supply, tax avoidance and damage that is potentially done to small (family) firms when the owner dies (see Brunetti, 2006, for weakly supporting evidence that survival of small businesses is affected by the presence of this tax; note, though, that small firms already enjoy significant preferences in the US tax code). A related argument involves forcing taxpayers to pursue 'deathbed' planning and implications of the tax for 'widows and orphans' (see Kopczuk, 2007). Because of the presence of a deduction for charitable contributions in the United States, an important topic is the effect of the estate tax on charitable contributions. Some of the more important empirical findings regarding US estate tax are discussed in what follows.

Estate tax avoidance is thought to be very easy. Cooper (1979) suggested that a motivated tax planner could easily reduce tax liability very significantly, if not altogether. Others have challenged this view: for example, Schmalbeck (2001) argues that most avoidance strategies involve losing control over assets. There is some evidence in support of both views. Anecdotal evidence of widespread estate tax avoidance is

easy to obtain, and the existence of a large estate tax planning industry is a prima facie evidence that a lot of effort goes into such planning. At the same time, it has been established that some simple tax avoidance strategies are not pursued enough from the tax minimization point of view. McGarry (1999) and Poterba (2001) show that taxpayers do not take full advantage of annual gift tax exemption (annual gifts of less than $11,000 per donee are exempt from taxation). Kopczuk (2007) shows that significant adjustments take place following the onset of a terminal illness, thereby revealing that not enough planning took place earlier in life. Kopczuk and Slemrod (2003) argue that the widespread reliance by married decedents on the unlimited marital deduction implies that taxpayers do not take full advantage of tax savings from splitting an estate. This is so despite the existence of trust instruments that allow for separating tax planning from other considerations such as taking care of the surviving spouse. On the other hand, while gifts do not seem to be fully utilized as a tax-planning device, they are nevertheless responsive to tax considerations, as demonstrated by Bernheim, Lemke and Scholz (2004) and Joulfaian (2004).

A number of papers have focused on estimating the responsiveness of estates to tax rates. Kopczuk and Slemrod (2001), Holtz-Eakin and Marples (2001) and Joulfaian (2006) all found small but positive elasticities implying that higher marginal tax rates lead to lower estate values. Kopczuk and Slemrod (2001) and Joulfaian (2006) rely on estate tax data and therefore cannot distinguish between tax avoidance and the effect on wealth accumulation. Holtz-Eakin and Marples (2001) use actual wealth, but their results are based on a relatively low-wealth sample and hence are hard to generalize from. Due to the nature of estate taxation, these studies are based on cross-section, repeated cross-section or time series, and hence the econometric assumptions that underlie them are strong.

The estate tax is a part of the tax code, and considering it in isolation is not appropriate. Poterba and Weisbenner (2001) find that over 50 per cent of the value of estates over $10 million are unrealized capital gains that would escape taxation at death due to step-up provisions (capital gains unrealized at the time of death are not subject to the capital gains tax, and the base for the recipient is stepped up to the current value of the asset). Auten and Joulfaian (2001) find that lower estate tax rates reduce capital gains realizations, and thus exacerbate the lock-in effect. The estate tax constitutes a backstop to this type of avoidance and a repeal of the tax would require a modification of the step-up rule. Bernheim (1987) questioned whether the estate tax raises any net revenue once its interaction with other taxes is taken into account.

The effect of estate taxes on charitable contributions is theoretically ambiguous due to offsetting income and substitution effects. Most studies find that higher marginal estate tax rates stimulate charitable giving, but the magnitude of the overall effect, accounting for both price and wealth effects, remains controversial: Joulfaian (2005) provides a recent overview of the empirical literature.

Other than dealing with tax avoidance (the issue that may be better handled by fixing the income tax), the strongest arguments in favour of the tax are based on its role in redistribution, breaking up concentration of wealth and providing equality of opportunities. Kopczuk and Saez (2004) use historical estate tax return data to provide estimates of wealth concentration over the course of the 20th century, and discuss the role that the estate tax might have played in shaping trends in concentration. Piketty and Saez (2007) document the contribution of the estate tax to overall progressivity. Understanding how estate taxation influences the distribution of wealth should be the top priority for anyone interested in an honest assessment of its value as a policy instrument.

E

Estimation

Marc Nerlove and Francis X. Diebold

Point estimation concerns making inferences about a quantity that is unknown but about which some information is available, e.g., a fixed quantity θ for which we have n imperfect measurements $x_1,\ldots,x_n$) The theory of estimation deals with how best to use the information (combine the values $x_1,\ldots,x_n$) to obtain a single number, estimate, for θ, say $\widehat{\theta}$. Interval estimation does not reduce the available information to a single number and is a special case of hypothesis testing. This entry deals only with point estimation.

Justification for any particular way of combining the available information can be given only in

terms of a *model* connecting the x's to θ. For example, in the case of imperfect measurements $x_1,\ldots, x_n$, we could regard the *errors,* $x_i - \theta$, $i = 1,\ldots, n$ as independent outcomes of a random process so that the joint distribution of the x's depends on θ:

$$p(x_1, \ldots, x_n|\theta) = \prod_1^n f(x_i - \theta).$$

In general, a *statistical model* represents the data, observations $x_1,\ldots,x_n$, x, where the x's may be vectors of quantities, as having arisen as a drawing from a joint distribution depending on some unknown parameters $\theta = (\theta_1,\ldots, \theta_k)'$. For example, consider $x_1,\ldots,x_t$, where x_t, is identically and independently distributed according to a univariate normal distribution with mean μ and variance σ^2 (Cramer 1946). The "location parameter," μ, and the "scale parameter, " σ^2, are unknown but, because they determine the distribution from which the data are supposed to arise, the latter may be used to form a point estimate of the vector $\theta = (\mu,\sigma^2)'$, e.g., $\widehat{\theta} = \left(\overline{x}\Sigma_1^T x_i/T, s^2 = \Sigma_1^T(x_i - \overline{x})^2/T\right)'$, the properties of which may be discussed in terms of various criteria and the properties of the family of probability distributions $p(x|\ \theta)$ from which the data are assumed to come. An *estimator* is a *function* of the observations; an *estimate*is the value of such a function for a particular set of observations. The theory of point estimation concerns the justification for estimators in terms of the properties of the estimates which they yield relative to specified criteria.

General treatments of the theory of point estimation may be found in Lehmann (1983), Cox and Hinkley (1974), Rao (1973) and Zellner (1971), *inter alia*.

Econometric estimation problems usually concern inferences about the parameters of conditional rather than unconditional distributions. For example, if the observations $(y_1, x_1,\ldots, (y_n, x_n)$, are assumed to represent a drawing from a multivariate normal distribution with mean vector μ and variance-covariance matrix Σ , then the *conditional distribution of y* given *x,* $p(y \mid x, \theta)$, is univaraite normal with mean $\theta_1 = \mu_1 + \sigma_{12}\sigma_{22}^{-1}(x - \mu_2)$ and variance $\theta_2 = \sigma_{11} - \sigma_{12}\sigma_{22}^{-1}\sigma_{21}$, where

$$\mu = (\mu_1, \mu_2) \text{ and } \sum = \begin{bmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{21} & \sigma_{22} \end{bmatrix}.$$

Note that θ_1 is a linear function of x which depends upon the parameters of the originally assumed joint distribution; this function is called the *regression* of y on *x. regression analysis* deals with the general problem of estimating such functions which characterize conditional distributions, usually those derived from normal distributions.

A standard method, and the one most common in econometrics, for obtaining estimators is the method of *maximum likelihood*. Consideration of this method provides a good introduction to alternative principles of estimation. Let the data $x = (x_1,\ldots, x_n)'$ be fixed and regard $p(x \mid \theta)$ as a function of θ it is then called the *likelihood*. The value of $\widehat{\theta} = \widehat{\theta}\,(x_1,\ldots,x_n)$ which maximizes $p(x \mid \theta)$, if it is exists and is unique, is called the maximum-likelihood estimator, or estimate (MLE). (For a general survey, see Norden 1972–1973, or Lehmann 1983.) The MLE of a continuous function $g(\theta)$ is $g(\widehat{\theta})$ *where* $\widehat{\theta}$ is the MLE of θ. Other desirable properties of the MLE are asymptotic as $n \to \infty$. Under regularity conditions: (1) The MLE is weakly *consistent*, i.e., $\lim n \to \infty \Pr\left(|\ \widehat{\theta}_n - \theta\right| < \in) = 1$ for all $\in > 0$. (2) The MLE is *asymptotically normal*, i.e. the distribution of $\widehat{\theta}$ appropriately normalized, $\sqrt{n}\left(\widehat{\theta}_n - \theta\right)$, tends to the normal distribution, with mean O and variance-covariance matrix $[I(\theta)]^{-1}$ where

$$I(\theta) = -E\left[\partial^2 \log p(x|\theta)/\partial\theta\partial\theta'\right].$$

I(θ) is called the information matrix and shows the information a single observation contains about the parameter θ. (3) The MLE is *asymptotically efficient* in the sense that if θ^* is any other estimator such that $\sqrt{n}\left(\widehat{\theta}_n - \theta\right)$ tends in distribution to the normal with mean zero and variance-covariance matrix $\sum(\theta)$, the matrix $[\sum(\theta) - I^{-1}(\theta)]$ is positive semi-definite. For example, in the case of one parameter this means

that no other asymptotically normal estimator has, as $n \to \infty$, a smaller variance than the MLE. The conditions for asymptotic normality do ensure, with probability tending to one, a solution to the *likelihood equation* $\partial \log p(x|\theta)/\partial\theta = 0$, which is consistent and asymptotically normal and efficient. The problem is that there may be more than one solution, but only one can be the MLE. When the number of parameters to be estimated (elements of the vector θ) tends to infinity with n, the MLE's for some may exist but may not be consistent (Neyman and Scott 1948).

Solutions to the likelihood equation are not the only estimators which may be consistent, asymptotically normal and efficient, but comparison with the MLE, assuming correct specification of $p(x|\theta)$, is facilitated by the fact that all have a normal distribution as $n \to \infty$. For fixed n, the distributions of different estimators are difficult to determine and may, indeed, be quite different. Moreover, when the distributions underlying the data are misspecified, the MLE's generally no longer have these optimal properties (White 1982; Gourieroux et al. 1984), although other, weaker, optimality properties remain. Apart from specification problems, however, the likelihood function provides an important and useful summary of the data, and point estimates and hypothesis testing procedures based on it are often justified in this way (Fisher 1925; Barnard et al. 1962; Edwards 1972).

The 'accuracy' of an estimator $\widehat{\theta}$ of a scalar parameter θ may be measured (defined) in a variety of ways: by its expected squared or absolute error, relative error, or by $\Pr\{|\widehat{\theta} - \theta| \leq \alpha\}$ for some α. Any choice is arbitrary; for convenience expected squared error is the usual choice. Some justification for a particular choice may be provided in terms of a *loss function* $L(\theta, \widehat{\theta})$ *or the expected loss* $EL(\theta, \widehat{\theta})$ *or risk function* of *statistical decision theory*. Choice of estimators may be justified in terms of the extent to which the choice minimizes risk or some aspect thereof. Both the *sampling theory* and *Bayesian* approaches to estimation can be interpreted in these terms.

A very weak property that any estimator should have is that no other estimator exists which dominates it in the sense that the latter leads to estimates having uniformly lower expected loss irrespective of θ. Estimators satisfying this criterion are called *admissible*.

In the sampling theoretic approach, emphasis is placed on finding estimators which have desirable properties in terms of relative frequencies in hypothetically repeated samples. For example, we might require that the distribution of an estimator be centred on the true parameter value, i.e., $E(\widehat{\theta} - \theta) = 0$. *Such estimators are called unbiased*. Among all unbiased estimators we presumably would prefer one yielding estimates with a distribution concentrated about the mean. Such minimum variance unbiased estimators (MVU) play a key role in the theory of estimation. Specifically, the famous Rao-Blackwell Theorem states that if an unbiased estimator $\widehat{\theta}$ is a function of a complete sufficient statistic for θ then it is MVU. A statistic, say T, is said to be sufficient for θ if the conditional distribution of the observations given T is independent of θ. Completeness is also a property of the distribution functions for the observations; (a family P of distributions (of T) indexed by a parameter θ is said to be complete if there is no 'unbiased estimator of zero' other than $\Phi(x) \equiv 0$.) Note that choosing an estimator so as to minimize the expected squared error of the estimate it yields is equivalent to minimizing the unweighted sum of the variance and the squared bias. From a decision theoretic point of view, it may be better to accept an estimator with a small bias if such an estimator has a smaller risk.

In the sampling theoretic approach, emphasis is given to the distribution of estimates yielded by a specified estimator. The likelihood approach, on the other hand, emphasizes the distribution of the observations, given a parametrically specified distribution, under alternative values of these parameters. Concern is primarily with the maximum value of the likelihood function with respect to the parameters and its curvature near the point at which the global maximum occurs, but some approaches stress the relevance of the likelihood function in other neighbourhoods (Barnard et al. 1962; Edwards 1972). The Bayesian approach carries concern with the entire

likelihood function further: estimation and inference are based on the posterior density of the unknown parameters of the distribution generating the observations. This posterior density is proportional to the likelihood function multiplied by a prior density of the parameters, i.e., a weighted average of likelihoods for different parameter values where the weights are determined by prior (subjective) beliefs. (See BAYESIAN INFERENCE.)

In the Bayesian approach, both observations and parameters are taken to be stochastic. Let $p(x_1, \theta)$ be the joint probability density function for an observation vector, x, and a parameter vector θ; then $p(x_1, \theta) = p(x|\theta)p(\theta) = p(\theta|x)p(x)$, where $p(\xi|\eta)$ denotes the conditional density of ξ given η and $p(\xi)$ denotes the marginal density of ξ. Thus $p(\theta|x)$ *is proportional to* $p(\theta)$ $p(x|\theta)$ by the factor

$$p(x) = \int p(\theta)p(x|\theta)\mathrm{d}\theta.$$

$p(\theta|x)$ is the *posterior* distribution of $^{\theta}$ after having observed the data; $p(\theta)$ is the *prior* distribution of θ and $p(x|\theta)$ is the *likelihood*. Alternatively, consider the weighted average risk (as defined above):

$$\int EL\left(\theta, \widehat{\theta}\right) w(\theta)\mathrm{d}\theta,$$

with weights $w(\theta)$ such that

$$\int w(\theta)\mathrm{d}\theta = 1.$$

When $L(\theta, \widehat{\theta}) = (\widehat{\theta} - \theta)^2$, the estimator which minimizes such a weighted average risk is

$$\widehat{\theta}(x) = \int \theta w(\theta)p\left(\theta w(\theta)p(x|\theta)\right. \mathrm{d}\theta \int w(\theta)p(x|\theta) \times \mathrm{d}\theta.$$

If the *weights* $w(\theta)$ are taken to be the values of the marginal density $p(\theta)$, the mean of the posterior Bayes distribution minimizes the expected squared error of the estimates when both the variation of data and the uncertainty with respect to θ are taken into account: $\widehat{\theta}$ *posterior* distribution of θ.

As is the expected value of θ based on the $n \to \infty$, it may be shown that the influence of the prior distribution diminishes until in the limit it disappears; then, under general circumstances, the minimization of mean square error in the Bayesian framework yields the MLE. The principal difficulty in the Bayesian approach is the choice of a reasonable prior for θ, $p(\theta)$. (For a comprehensive discussion, see Zellner 1971.)

Instead of minimizing the expected loss, one may minimize the maximum loss. Estimators which do are called *minimax*; the theory is developed in Wald (1950).

There are three general approaches to choice of a prior in Bayesian analysis. First, the prior may be obtained empirically (Maritz 1970). For example, suppose that the problem is to estimate the percentage of defective items in a particular batch. Assuming such batches were produced in the past suggests a prior based on the proportion of defective items observed in previous batches. This kind of 'updating' forms the basis for the celebrated Kalman filter. Second, the prior may be viewed as representing a 'rational degree of belief' (Jeffreys 1961). What represents a 'rational degree' is not specified, but the idea leads directly to the use of priors that represent knowing little or nothing, so-called *non-informative priors*. However, total ignorance has proved difficult to capture in many cases. A third approach is that the prior represents a subjective degree of belief (Savage 1954; Raiffa and Schlaifer 1961). But, of whom? and how arrived at? Minimax-estimation theory offers one possible approach for it leads to the minimum mean-square-error Bayes estimator, i.e., the mean of the posterior distribution of the parameters, when the prior is least favourable in the sense of making expected loss the largest for whatever class of priors is chosen.

Related to this problem is the more general question of *robust estimation*. In order to make sense of any data, it is necessary to assume something. For example, the justification for using the sample mean to estimate the mean of the distribution generating the data is often the assumption that that distribution is normal or nearly so. In that

case, the sample mean is not only asymptotically efficient but uniformly MVU, minimax, admissible, etc. But suppose that the distribution is Cauchy (having roughly the same shape as the normal but with very thick tails); then, the sample mean has the same distribution as any individual observation, its accuracy does not improve with n and it is not even a consistent estimator. At least, within the class of distributions which include the Cauchy, the properties of the sample mean, and similarly ordinary least squares, are quite sensitive to the true nature of the underlying distribution of the data. We say that such estimators are not *robust*. Complete discussions are contained in Huber (1981) and Hampel et al. (1985).

To conclude, three estimation problems of special concern in economics are discussed: (1) classical linear regression; (2) non-linear regression, and (3) estimation of simultaneous structural equations.

The classical theory of linear regression deals with the following problem: Let X be an $n\ k$ matrix of nonstochastic observations (n for each variable $(x_1,\ldots, x_k)$, β be a k 1 vector of parameters (one of which becomes an intercept if $x_1 \equiv 1$, say), and y be an n 1 vector of stochastic variables such that $y - x\beta = \in \sim N\ (0,\ \Sigma)$. The *ordinary least-squares estimates* (OLS), $\widehat{\beta} = (X'\ X)^{-1}X'y$ are MLE and MVU when $\Sigma = \sigma^2$ When this is not true, although the OLS estimates are unbiased and consistent, they are not asymptotically efficient or minimum variance. The *generalized least squares estimates* (GLS), $\widehat{\beta}\,(X'\ \Sigma^{-1}\ X)^{-1}X'\ \Sigma^{-1}$ are efficient, but of course Σ and therefore $\Sigma^{-1,}$ is generally unknown. Often, however, a consistent estimate of Σ is available, leading to *feasible*, or *estimated*, GLS estimates.

Many problems in economics lead to non-linear relationships. Linear regression may be a good (local) approximation to such relationships if the data do not vary too widely. Moreover, many non-linear relationships may be transformed into linear ones (e.g., the Cobb-Douglas production function). Often, however, the data are sufficiently variable to make a linear relationship a poor approximation and no linearizing transformation exists. The general non-linear regression model is $y = f(X,\ \beta,\ \in)$ or more frequently $y = f(X,\ \ \beta) + \in$. Leastsquares or maximum-likelihood estimates may still be obtained, but the first-order conditions for a minimum or a maximum will generally be non-linear, frequently ruling out analytic expressions for the estimates. Consider the problem of minimizing the sum of squared residuals, $(y - f(X,\ \beta))'$ $(y - f(x,\beta))'$ with respect to β (non-linear least squares); numerical methods for solving this problem are of the general form: $\widehat{\beta}_{i+1} = \widehat{\beta}_i - s_i P_i$ ∇_i, where $\widehat{\beta}_i$ = the value of the estimator parameter vector at iteration i, s_i = the step size at iteration i, P_i = the direction matrix at iteration i, and ∇_i = the gradient of the objective function at iteration i. The matrix P_i, determines the direction in which the parameter vector is changed at each iteration; it is generally taken to be the Hessian matrix evaluated at the current value of the parameter vector or some approximation to it. Let $g(\beta)$ be the objective function; then

$$P_i = \left[\partial^2 g(\beta)/\partial\beta\partial\beta\prime \middle| \beta = \widehat{\beta}_i\right]^{-1}$$

is the Hessian. A justification for this choice is obtained from the second-order (quadratic) approximation to the objective function in the neighborhood of the current estimate. For a detailed treatment of this problem as well as constrained non-linear estimation see Quandt (1983). The statistical properties of non-linear estimators are discussed by Amemiya (1983).

Economic theory teaches us that the values of many economic variables are often determined simultaneously by the joint operation of several economic relationships, for example, supply and demand determine price and quantity. This leads to a representation in terms of a system of simultaneous structural equations (simultaneous equations model, or SEM). The problem of how to estimate the parameters of an SEM has occupied a central place in econometrics since Haavelmo (1944). A linear SEM is given by, $By_i\ \Gamma x_t = \mathrm{u}_{\mathrm{t}}$, $t = 1,\ldots, T$ where B is $G \times G$, Γ is $G \times K$, y_t is $G \times 1$, x_t is $K \times 1$, and u_t is $G \times 1$. u_t is assumed to be zero mean with variance-covariance matrix Σ often normally distributed, independently and

identically for each t. Thus the u_t are serially independent. It is also assumed that plim $\Sigma_1^T x_{it}u_{jt}/T = 0$ all $i = 1,\ldots, K$ and $j = 1,\ldots,G$ and plim $X'X|T$ is a positive definite matrix, where $X = (x_1,\ldots, x_T)'$. If B is non-singular this system of *structural equations*, as they are called, may be solved for the so called 'endogenous' variables, y_t, in terms of the 'exogenous' variables x_t: $y = \Pi x_t + v_t$ *where* $\Pi = -B^{-1}\Gamma$, $v_t = B^{-1}u_t$, so that $Ev_t = 0$;and $Ev_t v'_t = B^{-1}\ \Sigma\ (B^{-1})' = \Omega$. *It is, in general, not possible to determine* B, Γ and Σ from knowledge of the *reduced form* (*RF*) parameters Π and Ω there are, in principle, many structural systems compatible with the same RF. Given sufficient restrictions on the structural system, however, knowledge of the RF parameters can be used, together with the assumed restrictions, to determine the structural parameters. The SEM is then said to be *identified*.

For *linear* structural equations with *normally distributed* disturbances, the conditions for* identification may be derived from the condition that for any system $B^*y_t + \Gamma^*x_t = u_t^*$ *for which* u_t and u_t, are identically distributed, where $B^* = FB$, $\Gamma^* = F\,\Gamma$and $u_t^* = Fu_t$, then $F \equiv fI$ is implied by the restrictions, where f is any positive scalar (Hsiao 1983).

Methods of estimating the parameters of SEMs may be put into two categories: (1) *limited-information* methods which estimate parameters of a subset of the equations, usually a subset consisting of a single equation, taking into account only the identifying restrictions on the parameters of equations in that subset, and (2) *full-information* methods which estimate all of the identifiable parameters in the system simultaneously and therefore take into account all identifying restrictions. Full- or limited-information methods may be based on either least-squares or maximum-likelihood principles. ML-based methods yield estimates which are invariant according to the normalization rule (choice of f).

For systems or single equations in SEMs for which there are restrictions just sufficient to identify the parameters of interest, estimates may be based on *indirect least squares*, that is, derived directly from the reduced form parameters estimated by applying OLS to each equation of the RF; such estimates are ML. If the restrictions are just sufficient to identify the parameters of each equation, the resulting estimates are *full-information maximum-likelihood* (FIML) estimates. When an equation is over-identified, in the sense that there are more than enough restrictions to identify it, *two-stage least squares* (2SLS) or *limited-information maximum likelihood* (LIML) may be applied equation by equation to each equation which is identified. Provided the model is correctly specified, such estimates are consistent and asymptotically unbiased but not asymptotically efficient, because some restrictions are neglected in the estimation of some parameters. An analog of 2SLS, *three-stage least squares* (3SLS), yields estimates which are asymptotically equivalent to FIML and therefore efficient.

Amemiya (1983) extends all of these methods to non-linear systems. Sargan (1980) discusses identification in non-linear systems.

Ethics and Economics

Marc Fleurbaey

Abstract

In recent decades, an important corpus of theories in normative economics (social choice theory, the theory of fair allocation, and inequality and poverty measurement in particular) has developed in which formal analytical tools of economic theory are mobilized in order to relate basic principles of social ethics to precise criteria for the evaluation of social states of affairs. The efficacy of arguments based on veil-of-ignorance devices has been questioned and the scope of impossibility theorems has been circumscribed, leaving the stage to a variety of constructive proposals in several fields of application (voting, resource allocation, public policy, social indicators).

Economics, as a discipline connected to policy decisions, has always been involved in the analysis of social objectives and of their underlying ethical values.

More recently, an important corpus of theories has been developed in which the formal analytical tools of economic theory are mobilized in order to relate basic principles of social ethics to precise criteria for the evaluation of social states of affairs. This corpus is not yet fully unified, and is still replete with debates and open questions, but the outlook of the field is rapidly evolving.

Economics is also connected to individual ethics, as economic decisions by households and firms sometimes involve issues of morality and responsibility toward partners and co-traders. Experimental economics has revealed that altruism, fairness and reciprocity considerations are a key component of strategic interactions between individuals. Ethical issues for firms relate to 'business ethics' and 'corporate social responsibility'.

Normative Versus Positive Economics

'Positive economics' seeks to understand and explain economic mechanisms, whereas 'normative economics' deals with the assessment of policies or states of affairs. While this distinction is useful, one must not be misled into believing that a clear-cut separation is obtained in practice. Positive economics is naturally inclined to focus on ethically important social and economic issues. Moreover, forecasting the consequences of various policies belongs to its realm and, even though this is in principle a purely positive task, it is practically relevant when it is associated with normative conclusions. Meanwhile, normative economics contains many results which merely consist in a logical analysis of the content of given concepts or the relations between concepts. In such work the economist can largely put his own value judgements aside. As Samuelson (1947, p. 220) aptly wrote, 'it is a legitimate exercise of economic analysis to examine the consequences of various value judgments, whether or not they are shared by the theorist'. The role of ethical judgements in economics has received valuable scrutiny in Sen (1987), Hausman and McPherson (2006) and Mongin (2006).

Wariness about value judgements has often led economists to shun issues of distribution and to focus on efficiency as encapsulated in the Pareto principle. In particular it is tempting to think that a Pareto improvement (that is, a new situation that everyone in the population prefers to the status quo) cannot be questioned since, by definition, everyone would approve it. But focusing on Pareto improvements does not protect from controversy. The most pressing reason is that there are important ethical values, especially regarding the distribution, which are not captured by the Pareto principle. As a consequence, there may exist a non-Pareto improving reform that is much better for social welfare than any Pareto improvement. In particular, in the presence of large inequalities, focusing on Pareto improvements implicitly amounts to condoning the status quo, as noted in Arrow (1951). A second reason is that people's immediate preferences, which are relied upon in applications of the Pareto principle, may not correctly represent people's interests. The difficult issue of defining individual interests is examined below.

The Pareto criterion, on the other hand, is very restrictive because it applies only when unanimity of preference is obtained. New Welfare Economics (surveyed in Chipman and Moore 1978) and cost–benefit analysis have developed less restrictive criteria dealing with potential Pareto improvements (that is, reforms that would be Pareto improving if certain transfers from the gainers to the losers were performed in addition, even though they are not actually implemented). Such criteria have been condemned by many authors, from Arrow (1951) to Blackorby and Donaldson (1990), for being inconsistent (they can produce cyclic social preferences), and also

unethical because they may approve reforms that seriously hurt the worst-off sub-populations (because the transfers that could compensate the losers may not be actually made). More sophisticated versions of cost–benefit analysis (Drèze and Stern 1987) rely on consistent and distribution-sensitive social welfare functions.

The Branches of Normative Economics

Four main branches of normative economics can be distinguished. The first – the theory of social choice, sparked off by Arrow (1951) with a provocative impossibility theorem – examines the properties of functions that define an ordering of a set of alternatives (policies, social states, candidates) on the basis of the ordinal non-comparable (ONC) preferences of the population over these alternatives. In economics individual ONC preferences, which can be retrieved from observable choices, are usually considered the natural informational basis. However, the theory of social choice has been extended (following Sen 1970a) to cover the possibility of incorporating more information about individual utilities. This theory has achieved a thorough understanding of the properties of voting rules (surveyed in Brams and Fishburn 2002; Pattanaik 2002) and of the informational requirements about individual utilities of various social welfare functions (surveyed in d'Aspremont and Gevers 2002; Bossert and Weymark 2004). The second – the theory of fair allocation, initiated by Kolm (1972) – studies the allocation of resources among individuals with heterogeneous tastes and abilities, in terms of fairness criteria such as no-envy (no agent should prefer another's bundle), lower bounds (for example, no agent should prefer the equal-split allocation), solidarity (for example, no agent should be hurt by an increase in available resources), among others (see survey in Moulin and Thomson 1997). The third – the theory of inequality and poverty measurement, originally anchored to the Gini coefficient and the Lorenz curve – focuses on income distributions and has developed after Kolm (1969), Atkinson (1970) and Sen (1973) into an axiomatic theory of indices, dominance criteria (that is, criteria ascertaining that a distribution dominates another for a family of indices), and, more recently, statistical tests to be performed on samples. Surveys of this field can be found in Atkinson and Bourguignon (2000) and Silber (1999). The fourth – the theory of axiomatic bargaining and cooperative games, initiated by Nash (1950) and Shapley (1953) – analyses how to find a fair compromise in utility possibility sets, under different assumptions about coalition formation. A synthesis on axiomatic bargaining is available in Thomson (1999).

Three other branches must be mentioned, which can be viewed perhaps as sub-branches of the main ones. Connected to social choice theory, Harsanyi's impartial observer argument (1953) and aggregation theorem (1955), offered in defence of utilitarianism, have generated an important literature and some debates (see Broome 1991; Weymark 1991; Roemer 2002). Sen's (1970b) and Gibbard's (1974) liberal paradoxes have also triggered debates about how to formalize rights and incorporate them in the theory of social choice (see in particular Gaertner et al. 1992; Arrow et al. 1997, ii, part IV). The theory of axiomatic cost and surplus sharing, which lies somewhere between cooperative games and fair allocation, studies the allocation of cost or surplus shares across individuals not as a function of their preferences but as a function of their actions (demands or contributions). It is surveyed in Moulin (2002).

The various branches have developed more or less independently but, if one puts aside the theory of cooperative games and the theory of cost-surplus sharing, they can all be formally described as seeking to rank alternatives of various sets X on the basis of the population's utility functions $U_1, \ldots, U_n$, and possibly other personal characteristics such as abilities and needs. The theory of social choice usually considers only one given set X and in Arrow's initial version, retains information only about individual ONC preferences; the theory of fair allocation takes the Xs to be sets of feasible allocations and usually seeks only to identify a subset of optimal allocations in each X on the basis of ONC preferences; the theory of

inequality and poverty indices usually takes X to be the set of income distributions and focuses on a special aspect of distributions instead of a general notion of social welfare, although it sometimes establishes a link between special indices and social welfare functions; the theory of axiomatic bargaining usually ignores the structure of the sets X and directly examines the utility possibility sets $\{(U_1(x),..,U_n(x))|x \in X\}$. This formal similarity between the various branches is favourable to cross-fertilizing. One observes that the frontiers between these fields, which are largely due to the contingent circumstances of their creation, are progressively vanishing, to be replaced by more substantial differences in principles, such as whether ONC preferences provide morally sufficient information about individual well-being.

Cross-fertilizing with political philosophy is also an essential part of the history of the field. Rawls's (1971) theory of justice, borrowing many features from economics, has had a profound influence in return in at least three ways. It has rekindled interest for equality and the maximin principle among economists; it has popularized the idea that putting individuals behind a 'veil of ignorance' concerning their own circumstances, as in Harsanyi's impartial observer argument (with differences in assumptions and conclusions which have aroused controversies between these two authors and commentators), is a way to define justice; it has also provided an implicit justification of the theory of fair allocation by defining justice in terms of equality of resources (even if by resources he meant 'primary goods', that is, all-purpose goods rather than ordinary commodities), firmly rejecting interpersonal comparisons of utility across individuals with incommensurable preferences. Dworkin's (2000) theory of equality of resources makes a clear reference to the no-envy criterion and combines it with the veil of ignorance in a hypothetical insurance market in which individuals can insure against bad personal characteristics. Social policy should then, according to this theory, mimic the hypothetical insurance premiums and indemnities by suitable taxes and transfers. Sen's (1992) theory of capabilities proposes to shift the focus from resources to functionings, a general notion of individual achievement, and to seek equality of capability sets, that is, the sets of functionings that are accessible to individuals. Arneson (1989) and Cohen (1989) have also proposed to focus on opportunities rather than achievements on the ground that individuals should be viewed as responsible for seizing the opportunities that are offered to them. These recent theories of justice have generated an increased interest in normative economics for the notions of freedom and responsibility (see, for example, Roemer 1998, and, for surveys, Fleurbaey and Maniquet 2006; Peragine 1999; Barberà et al. 2004a, b). Among many other philosophical contributions that have been influential in normative economics, one must also mention Parfit's (1984) thought-provoking essay on utilitarianism, identity and population issues.

The Measurement of Individual Well-Being

With reference to the traditional social welfare function $W(U_1, \ldots, U_n)$, it is convenient to decompose the problem of defining a criterion for the evaluation of social states into two sub-problems, namely, the problem of assessing each individual situation and the problem of constructing a synthetic measure for the whole population. This decomposition, however, does not imply that the former is any less normative than the latter. The measurement of individual well-being is not just an empirical exercise and raises many ethical issues.

First, in such measurement one must consider whether one should take account of individuals' political and social preferences or only of their tastes about their personal situation. It appears that these two kinds of preferences belong to different levels of social evaluation. Political and social preferences are relevant in the democratic debate about general principles, while personal tastes belong to the concrete evaluation of social situations. Mixing the two levels may yield absurd consequences. In particular, making the allocation of resources directly depend on the satisfaction of individual political preferences may produce grossly unfair distributions, for instance when a

simple summation of utilities representing heterogeneous political preferences induces the altruist to transfer their resources to the malevolent. As Sen (1977) nicely put it, one must not confuse the aggregation of 'judgments' with the aggregation of 'interests'. It is worth emphasizing that, concerning judgement aggregation, the contribution of normative economics is not limited to studying voting procedures with the goal of neutrally aggregating judgements, because it may play an active role in shaping those judgements. Indeed, by scrutinizing issues in *interest* aggregation it clarifies the substance of the debates and may help in the formation of personal *judgements* on these matters. It may thereby make a useful contribution in the deliberation process and the construction of a consensus.

When dealing with the aggregation of 'interests', personal tastes themselves are not necessarily appropriate as a basis for ranking social states, since they may be influenced by unjust social pressures and conditioning, or based on mistaken beliefs. It may then appear preferable to try to guess what individual tastes would be if formed in correct conditions. Practical procedures eliciting such authentic preferences have yet to be invented, but one may observe that 'safety belt' policies are commonplace and are usually justified by reference to people's well-considered interests.

A more radical questioning of the reference to personal tastes comes with the observation that, even in absence of conditioning or bad information, those with demanding tastes do not necessarily deserve more resources than those with more modest wishes. Should individuals not assume responsibility, in some cases, for their 'expensive tastes' (Dworkin 2000)? The emergence of principles of freedom and responsibility in recent theories of justice has in fact revealed how important such considerations have always been in the selection of relevant dimensions of individual well-being. Even the standard principle of consumer sovereignty according to which every individual is the best judge of his own interests implies that the social criterion will let the allocation of personal resources be managed under the individual's sole responsibility and will at most cater to a synthetic measure of his satisfaction.

More importantly, if individuals are considered responsible for how they transform ordinal satisfaction into numerical utility, then social evaluation can disregard their utility functions and take care of their ONC preferences only. The focus of Arrovian social choice and of the theory of fair allocation on ONC preferences instead of utilities can hereby find a justification in terms of individual responsibility, in addition to more traditional arguments about the difficulty to compare subjective utility across individuals. Similarly, in Sen's theory of capabilities, the social criterion deals with capability sets and disregards what combinations of functionings individuals choose in those sets. The normative appreciation of what individuals should be held responsible for (or be left free to handle by themselves) and what they should not is a difficult domain of philosophical debating to which economists are not necessarily well equipped to contribute. But economic models are very convenient to examine the consequences of various choices in this matter and it is instructive to relate various policy choices to underlying attributions of responsibility to the target population (see, for example, Roemer 1998).

The important divide between welfarist and non-welfarist approaches is largely connected to this issue. A welfarist approach retains subjective utility (interpreted in terms of happiness or in terms of satisfaction) as the ultimate metric of well-being. A non-welfarist approach will typically discount subjective utility and take account of objective achievements, resources, opportunities or rights, although Sen's theory, for instance, does retain utility as one relevant functioning among others. Critiques of welfarism invoke not only the (at least partial) responsibility of individuals for their subjective utility, but also the idea that there are some objective dimensions of achievement which matter independently of their effect on satisfaction. For instance, a physical disability may justify help even if the concerned individual has perfectly adapted to his situation in terms of subjective utility. Or granting basic rights and freedoms may be viewed as so essential to the constitution of a community of morally

autonomous agents that they should be granted uniformly, independently of their potentially unequal effect on individuals' various utility functions. More generally, fairness in the allocation of resources typically involves non-welfarist concerns. For instance, the axiomatic theory of bargaining, as recalled above, disregards the economic allocations and focuses exclusively on utility possibility sets. This has counter-intuitive consequences. Consider problem 1 which consists in deciding with which probability Ann or Bob will win a ten-dollar prize, and problem 2 which also consists in deciding winning probabilities, except that if Ann wins she gets ten dollars whereas if Bob wins he only gets one dollar. Nash's bargaining solution (which maximizes the product of utility gains) selects the fifty–fifty solution for both problems, whereas it would seem more reasonable to give Bob a greater probability of winning in the second case. See Roemer (1996) for a detailed criticism of welfarism in axiomatic bargaining.

The welfarist–non-welfarist distinction, however, is mainly philosophical and the economist can always reinterpret the utility index U_i as an index of capability, opportunity or objective advantage instead of subjective utility, without changing much to the formal analysis of normative criteria. What is more important for economic analysis is whether the relevant data about individual situations consist in a numerical index permitting comparisons across individuals or in ONC preferences only (a third possibility, considered in the theory of multidimensional inequality, is when individual situations are described by vectors of numerical indices, with no synthetic index or ordering). In the first case, one has a kind of 'formal welfarism' and the standard framework of social welfare functions is readily available. In the second case (as well as the third), one may eventually be able to construct a comparable index, but such an index is not given a priori and its construction must be justified.

The indexing problem is considered a vexing issue for non-welfarist theories of justice such as Rawls's (involving an index of primary goods) or Sen's (involving an index of capabilities). Indeed, it appears that if this index is personalized so as to espouse each individual's preferences, it is then a utility representation of preferences and one is back into the welfarist framework. The alternative is to impose a uniform index to all individuals, but this is tantamount to adopting a special view of how to weight the various goods (or capabilities), that is, a dogmatic or perfectionist definition of the good life. At this point economic analysis is helpful because it shows that a non-welfarist approach can nonetheless respect individual preferences. Consider the simple case of an exchange market with identical prices at the various allocations under consideration. Then, on the assumption that individuals are free to choose their consumption in their budget set, indexing their well-being by the market value of their consumption is congruent with their preferences over consumption bundles, although it is certainly non-welfarist since across individuals there is no relation between utility and wealth. More generally, with each preference ordering one can always associate an index function which is ordinally equivalent to the welfarist measure of utility without coinciding with it, as noted in Roemer (1996). In conclusion, between the pure welfarist approach and the 'perfectionist' non-welfarist approach, there is room for 'Paretian' non-welfarist approaches which respect individual preferences. This distinction can be formally described as follows. In the problem of ranking alternatives on the basis of the profile $(U_1, \ldots, U_n)$, the welfarist approach relies on the utility values $(U_1(x), \ldots, U_n(x))$ at each alternative x; the perfectionist approach ignores individual preferences, imposes an index U^* and evaluates x in terms of $(U^*(x), \ldots, U^*(x))$; the 'Paretian' non-welfarist approach retains the ONC preferences represented by $U_1, \ldots, U_n$ and constructs an ordering of alternatives obeying the Pareto principle (additional examples are provided below).

Another issue for economic analysis is whether the social state must be described in terms of consequences or in terms of procedures. Most of normative economics is still largely consequentialist, but the growing focus on opportunities, rights and freedom of choice definitely enlarges the scope of analysis beyond narrow consequentialism. So far, the studies of rights and freedom

have remained rather abstract, dealing with the general definition of rights, the foundations of a measure of individual freedom and the analysis of distributions of opportunity sets, but there is some interest for more concrete economic settings (on these various approaches, see, for example, Laslier et al. 1998; Pattanaik et al. 2004). Contractarian theories of justice, which analyse justice norms as being shaped by individuals' interests in mutual cooperation, also appeal to game theorists. For instance, Binmore (1994–8) relates various degrees of egalitarianism and libertarianism to different time horizons of social interaction, arguing that the latter prevails in the long run.

The Definition of Social Criteria

When a suitable index of well-being $U_1, .. ., U_n$ is given, as in the welfarist or the perfectionist approaches, the only problem that remains is to choose a social welfare function W from the menu offered by the theory of social choice. For instance, the sum-utilitarian function

$$W(U_1(x), \ldots, U_n(x)) = U_1(x) + \ldots + U_n(x)$$

displays no aversion to inequality in utilities, the maximin function

$$W(U_1(x), \ldots, U_n(x)) = \min\{U_1(x), \ldots, U_n(x)\}$$

has an infinite aversion, while the product (or Nash) function

$$W(U_1(x), \ldots, U_n(x)) = U_1(x) \ldots U_n(x)$$

is an example of an intermediate function. With a small or zero inequality aversion over utilities, as with the utilitarian function, priority is given to individuals with a high marginal utility, independently of their utility level, whereas with a high-inequality aversion, as with the maximin, priority is given to the worst-off (in terms of utility level), even if they have a low marginal utility.

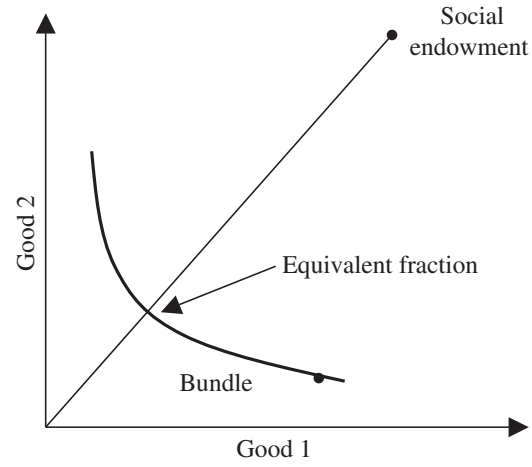
In the choice of an appropriate degree of inequality aversion, it is often thought that the veil of ignorance provides a helpful guide. In the simple version of this device (Harsanyi, Rawls), the observer simply imagines that she could become any individual of the considered society. One may introduce variations about whether this implies taking on all the personal characteristics of each possible individual or simply some of them (his ability, his preferences). In more complex versions of the scheme (Dworkin's hypothetical insurance, or Rawls's original position under some interpretations), individuals may all be put behind the veil and be left free to bargain or make transactions. The attraction of the veil of ignorance comes from the obvious fact that it guarantees the impartiality of decisions. But impartiality is a very weak requirement and any symmetric social welfare function such as those listed above is impartial. The important issue in the choice of a social welfare function is not that it must be impartial, but how averse to inequality it should be. In this respect, the veil-of-ignorance device appears actually ill-suited. It links inequality aversion to the degree of risk aversion of the observer. A very risk-averse observer will come close to some maximin criterion, whereas a risk-neutral observer will adopt a utilitarian kind of rule. If she maximizes her expected utility, her decision will at any rate be structurally utilitarian in some metric. How this translates into a choice of social welfare function W depends on the specific form of the ignorance veil (that is, what personal characteristics are inherited by the observer when she becomes a particular individual). In Dworkin's hypothetical insurance, expected-utility maximizers will adopt insurance contracts that will produce utilitarian kinds of allocations. It is hard to find a reason why risk aversion about the possibility to becoming different persons should determine distributive judgements about actually existing individuals. One could as well imagine other devices, such as living all the lives of the population, one after the other, in a reincarnation process. Again, one does not see why intertemporal preferences over sequences of reincarnations should be especially relevant for distributive judgements over coexisting individuals. The attraction of the veil of ignorance may perhaps come from the mistaken belief that

impartiality is all there is to social justice. But the theory of social choice clearly shows that impartiality is just a minimal requirement. The multiplicity of impartial observer devices (lottery, reincarnation.. .) proves that each of them is just one way among many others to achieve impartiality, and presumably none of them reaches a comprehensive view of justice (on these issues, see, for example, Roemer 2002).

If one forgets the veil and genuinely thinks about inequality aversion in terms of fairness between existing individuals, one still faces a moral dilemma, since typically the social welfare functions that do not give full priority to the worst-off have the repugnant feature that a very small gain to many well-off individuals can always, if these individuals are sufficiently numerous, outweigh a large loss to a badly-off person. On the other hand, the maximin function always prefers giving a very small gain to the worst-off, no matter how costly this may be to all the other individuals. The way out of this dilemma has yet to be invented.

Aggregating Preferences

Let us now turn to the case in which ONC preferences are the only relevant data about individual utilities. Arrow's impossibility theorem of social choice suggests that there is a conflict between the Pareto principle and impartiality in this context, in contrast to the context of the previous paragraph in which many social welfare functions were simultaneously increasing and symmetric in utilities. But this alleged conflict occurs only when one requires the social ranking of two alternatives to depend only on how individuals rank them, to the exclusion of any other alternative. This 'independence' requirement is very restrictive and precludes using information about individual preferences such as their marginal rate of substitution, how they compare their current bundle to natural benchmarks, and so on. The theory of fair allocation actually features many fairness criteria (such as no-envy or lower bounds) which violate this requirement by examining extended portions of indifference curves in order to evaluate an allocation.



Ethics and Economics, Fig. 1

Consider the following example. A certain quantity of divisible goods has to be distributed. At any allocation in which all individuals receive a personal bundle, evaluate every individual's bundle by the fraction of the social endowment that is equivalent according to this individual's preferences (see Fig. 1).

This is a standard way of representing individual preferences by an index function, and such indexes can then serve as arguments of a social welfare function W. This exemplifies a Paretian and impartial way to aggregate individual ONC preferences. This example has an interesting life of its own in the literature. It is briefly examined in Arrow (1951, p. 31), and rejected on the ground that it violates the above independence requirement. This observation, however, could as well suggest abandoning the requirement. A variant of the example is mentioned in Kolm (1969). It is invoked by Samuelson (1977) in order to show that it is possible to construct a Bergson–Samuelson social welfare function on the sole basis of ONC preferences. As explained in Samuelson (1947), such a function is a mapping

$$E(x) = W(U_1(x), \ldots, U_n(x))$$

where $U_1, .. ., U_n$ are suitable indices representing individual preferences. (That the construction depends only on ONC preferences is verified by the fact that the same function E can be written

with other, ordinally equivalent, indices $V_1, .., V_n$ provided W is correspondingly adapted – some commentators have identified W instead of E as the fixed Bergson–Samuelson function, thereby concluding that Samuelson must have been wrong.) Eventually, it is used by Pazner and Schmeidler (1978) in the definition of the concept of egalitarian equivalence, which has become quite important in the theory of fair allocation (an allocation is egalitarian-equivalent if it is Pareto-equivalent to a resource egalitarian allocation).

This example shows a simple way to aggregate preferences: first construct an index and then apply a standard social welfare function. The Borda rule, in the voting context, is another example of the same vein. The selection of the index need not be arbitrary and the above example, for instance, refers to fractions of the social endowment and thereby makes sure that individuals who prefer their bundle to the equal-split are always considered better-off than those in the opposite situation. There are less simple aggregation methods. Consider for instance the index

$$U_i^p(x_i) = e_i(U_i(x_i), p) - p\omega_i,$$

where x_i and ω_i denote i's personal bundle and endowment, e_i his expenditure function, p a price vector. At every feasible allocation x (that is, such that $x_1 + ... + x_n \leq \omega_1 + ... + \omega_n$) and for every price vector p, one has

$$U_1^p(x_1) + \ldots + U_n^p(x_n) \leq \sum_i (px_i - p\omega_i) \leq 0,$$

while a feasible allocation x^* is a competitive equilibrium associated to price vector p^* if and only if one has $U_i^{p*}\left(x_i^*\right) = 0$ for all i. Therefore, for any inequality-averse social welfare function W, the function

$$E(x) = \max_{p \in s} W(U_1^p(x_1), \ldots, U_n^p(x_n)),$$

(where S is the simplex of appropriate dimension) exactly selects the competitive equilibria as the best allocations in the set of feasible allocations. This function, which bears some similarity to cost–benefit criteria without sharing their drawbacks, is slightly more complex than the previous examples as it makes the evaluation of individual situations depend on a price vector that itself depends on the whole allocation. Observe how even the maximin criterion, which is just a particular case of inequality-averse social welfare function, can rationalize a competitive equilibrium, no matter how unequal the endowments are. This is due to the deduction of the value of endowments in the index U_i^p, which is justified if individuals are held responsible for their endowments, so that one is not interested in individual total consumptions but only in the value difference between their consumption and their endowment.

Even though such constructions are based on ONC preferences, they always involve some kind of interpersonal comparison (of the relevant indexes) in order to determine who should be given priority in the allocation of resources (for a synthesis on interpersonal comparisons in general, see Fleurbaey and Hammond 2004).

Hard Issues

A few hard ethical issues have already been described. There are many others. Consider, for instance, Fig. 2. It describes two individuals' utility under three different policies, depending on a random state. Policy B is better than A, since for the same *ex post* distribution of utilities it provides a less unequal distribution of prospects *ex ante*. And Policy C is better than B, since for the same distribution of *ex ante* prospects it guarantees an equal distribution of utilities *ex post*.

However, a social criterion that computes the expected value of social welfare will be indifferent between A and B, while a criterion satisfying the Pareto criterion with respect to expected utilities will be indifferent between B and C. Harsanyi's utilitarian criterion, which satisfies both properties, is indifferent between the three policies. The search for a better criterion in this context is still going on (see, for example, Ben Porath et al. 1997).

Ethics and Economics, Fig. 2

Policy A

	State (or effort) 1	State (or effort) 2
Individual 1	1	1
Individual 2	0	0

Policy B

	State (or effort) 1	State (or effort) 2
Individual 1	1	0
Individual 2	0	1

Policy C

	State (or effort) 1	State (or effort) 2
Individual 1	0	1
Individual 2	0	1

A similar difficulty plagues the theory of equal opportunities, since, in spite of essential differences, there is an obvious similarity between random prospects and opportunities. In the same figure, replace the random states by effort levels exerted by the individuals. Then one can read the rows as depicting opportunity sets for the individuals. Under this new interpretation, Policy B is still better than Policy A because opportunity sets are less unequal, and Policy C is even better because it perfectly equalizes the opportunity sets. None of the social criteria in the literature displays this pattern of preference, because each of them focuses either on the distribution of *ex ante* opportunities or on the *ex post* neutralization of the effect of variables for which the agents are not responsible (this issue is discussed in Fleurbaey and Maniquet 2006).

Another issue is the comparison of social welfare across different populations. The theory of social choice is curiously restricted, in its standard formulation, to the ranking of options for a given population (with a specific ranking for each possible profile of preference of this population). But economic analysis is recurrently asked to compare standards of living across time (measurement of growth) or space (international comparisons). The framework of social choice should then be extended in order to rank not just allocations but pairs (allocation, population) involving populations with different preferences and different sizes. Interestingly, there are contexts in which size should be a neutral matter (for example, comparison of living standards between big and small countries) and other contexts (demographic policy) for which a theory of the optimal size is needed. Optimal demography is a famously hard domain. Classical utilitarianism, which is based on the total sum of utilities, has the unappealing feature that a population with arbitrarily low average welfare is always better, if it is sufficiently large, than any given population (Parfit 1984). The criteria proposed by Blackorby et al. (2005) (see also Broome 2004) avoid this 'repugnant conclusion' by computing individual welfare as the surplus $U_i - U^*$ over some positive threshold of utility U^* and then apply a social welfare function to these surpluses. The U^* threshold corresponds to the minimal welfare level that an individual must reach in order for his addition to society to be an improvement. Such criteria may thus induce judgements that a given population would be better off without its members whose utility is below the threshold, even when these

members have positive utility. There is again a dilemma here.

This is just a sample of those hard ethical issues about social evaluation that economic analysis may never be able to render easy, but is able to clarify and to which it does, sometimes, give inventive solutions.

EU European Semester

Marco Scipioni
Post-Doctoral Fellow, Johns Hopkins University School of Advanced International Studies Bologna Center, Bologna, Italy

Abstract

The European Semester is an EU effort to better coordinate member states' economic policies. Coordination of national fiscal and economic policy has long been considered essential for the tenability of a monetary union lacking the federal features of taxing and spending. The European Semester coordinates national economies by setting collective deadlines for the submission, analysis and discussion of national budgetary plans as well as the various forms of economic coordination that the EU has accumulated through time, from the Macroeconomic Imbalance Procedure (an agreement amongst EU members to prevent risky macroeconomic policy) to Europe 2020 (the EU's growth strategy).

In policy terms, the European Semester provides more evidence for those who saw the Economic and Monetary Union (EMU) developing through soft coordination, as some of the most notable outputs are Council

recommendations addressed to member states. However, more intrusive tools such as the Stability and Growth Pact (the agreement by which all EU member states commit to maintaining the value of the euro through fiscal responsibility) are now framed within the Semester schedule. Importantly, the design of this framework exemplifies a broader shift in EU economic governance from an ex post monitoring of member states' preferences to an effort to ex ante shape their adoption. This occurs by scheduling EU discussions before national ones, thus aiming to inform and shape the latter, and by imposing synchronised submission of different policy documents, thus forcing member states to be consistent in their commitments across policy areas. This might raise questions as to the limits of EU action, particularly in the light of subsidiarity concerns.

While the Semester is now part of the official jargon of EU and member states' economic policy, commitment to such processes in the absence of external pressures (e.g. crisis) has been questioned, as recorded by falling implementation rates. Further, while the first years of the Semester were associated with weak economic growth, the picture has recently turned more positive. That said, there seems to be limited effect on macroeconomic imbalances, one of the main stated objectives of the framework.

The European Semester represents the most recent EU effort to better coordinate member states' economic policies. Coordination of national fiscal and economic policy has long been considered essential for the tenability of a Union lacking the federal features of taxing and spending. This is crystallised in the Treaties, where reference is made to the need for member states to 'regard their economic policies as a matter of common concern' and to 'coordinate them within the Council' (European Union 2012: Art. 121), and for euro area countries to 'strengthen the coordination and surveillance of their budgetary discipline' and 'to set out economic policy guidelines for them, while ensuring that they are compatible with those adopted for the whole of the Union and are kept under surveillance' (European Union 2012: Art. 136). Academic commentators have described policy coordination as 'supranational rules or norms which are agreed by all member states, leave primary responsibility for the policy area with national authorities, but set limits on their discretion' (Begg et al. 2003: 66). The rationale and extent of such coordination, beyond the narrow fiscal policy targets included in the Maastricht Convergence Criteria (that is, the criteria which EU member states need to meet in order to be accepted to the euro), has been subject to much debate. Alesina et al. argued 'explicit coordination of monetary and fiscal policy is not necessary, if the monetary and fiscal authorities (independently) follow appropriate

and prudent policies' (Alesina et al. 2001: 7). Issing reinforced this point by adding that close coordination between monetary and fiscal authorities risks blurring respective competences and therefore weakening accountability mechanisms (Issing 2002). Eichengreen and Wyplosz argued that efforts at consolidating budget implied by the Stability and Growth Pact (SGP) (the agreement by which all EU member states commit to maintaining the value of the euro through fiscal responsibility) would consume politicians' political capital to tackle structural reforms, significantly limiting their growth prospects as well as their capacities to jointly stimulate the economy – in other words, more budgetary surveillance might entail less economic coordination (Eichengreen and Wyplosz 1998). Collignon highlighted that, considering that economic policies are kept at the state level, 'one cannot expect that purely independent decisions will necessarily result in the efficient provision of collective goods', and hence might become detrimental to a common undertaking such as the single market (Collignon 2001). Pisani-Ferry further pointed out that in a decentralised system such as the EMU, 'where decision makers are numerous and diverse [. . .] discretionary co-ordination inevitably implies high transaction costs' (Pisani-Ferry 2002: 9), thus revealing the added benefit of coordination.

In practice, the European Semester aims at coordinating national economies by putting collective deadlines on the submission, analysis and discussion of national budgetary plans as well as the various forms of coordinated monitoring that the EU has accumulated through time. It is a 'semester' as after a period of EU-level coordination (approximately from November to May each year), a period of national coordination follows.

This entry first puts the European Semester in the context of the efforts to build and strengthen economic coordination at the EU level. Second, it looks at continuities and changes in the Semester as compared to previous economic coordination exercises. Third, it provides a description of the European Semester and places it in the context of the EMU reforms undertaken since 2010. Fourth, it looks at the early assessments of its results. The fifth section concludes the entry.

The Rationale Behind the European Semester

Scholars and policy-makers alike have intensely debated the nature of the relationships between monetary policy on the one hand and fiscal and economic policies on the other, in the context of Economic and Monetary Union (EMU). Early policy proposals on monetary union in the 1970s regarded these two poles as inseparable and foresaw nothing short of 'budget aggregates' decided at the EU level (Pisani-Ferry 2006: 824–825). Since the creation of EMU, monetary policy has been fully delegated to the European Central Bank (ECB), member states have cooperated on budgetary policy with binding rules envisaging an institutional hierarchy as well as monitoring and sanctioning powers at the EU level (the SGP), while other economic policies (e.g. structural reforms, employment policies) have been subject to a mixture of policy coordination forms where no sanctions were in order and policy outputs that mainly materialised in recommendations (e.g. the Broad Economic Policy Guidelines, BEPGs: non-legally binding recommendations guiding annual economic policy in member states).

Once a decision to create a monetary union is taken, there remains a choice for either a centralised or decentralised budget that can automatically stabilise the euro-area (De Grauwe 2016). Due to political reasons (Hodson 2009), a centralised budget has not been feasible in the EU. That leaves only the national budgets to stabilise business cycle shocks (De Grauwe 2016: 214–217). Here, policy-makers hit a conundrum. On the one hand, fiscal policies remain their only tool to deal with negative shocks. On the other, unconstrained budgetary policies represent a risk for the monetary union in terms of negative spillovers in interest rates from highly indebted countries to others and regarding ECB independence. Begg et al. (2003: 67–68) summarise the political economy rationale for economic coordination as

aiming to solve two problems. First, negative externalities are likely to stem from excessive government deficits in the context of currency union, which are then spread onto other member states in the form of a 'higher unified interest rate' (for a critique, see Eichengreen and Wyplosz 1998: 76–77). The second relates to the provision of independence and ultimately the credibility of the central bank in the context of a multiplicity of different fiscal policies. If markets presume that the central bank will ultimately come to rescue states with high deficit and unsustainable public debt, its credibility is at risk. To solve both these issues, cooperation and coordination provide some form of collective insurance (Schelkle 2005).

The EMU solution to the dilemmas posed by its institutional configuration was to establish some form of pre-accession convergence (the Maastricht Convergence Criteria), to tie continued membership of the EMU to some form of adherence to budgetary rules (the excessive deficit procedure within the Treaty and its further specification within the SGP), and to coordinate economic policies (see Treaty obligations in Art. 2(3), Art. 5(1) TFEU). Since Maastricht, the EU has consistently decided to reduce economic divergence and the creation of excessive budgetary deficits in some countries for the purpose of common interest. It has done so by setting EU-wide rules, and at the same time issuing guidelines to nudge member states towards commonly agreed objectives for macroeconomic policies and structural reforms.

Economists diverge as to how effective such a solution was. Indeed, besides the 'lack of planning to deal with financial stability' and 'lack of transparency of the ECB', Giavazzi and Wyplosz identify 'the poor articulation between monetary policy and national fiscal policy' as one of the three main flaws in the construction of the EMU (2015: 723–724). De Grauwe (2010c: 3) holds that such asymmetric institutional architecture (centralised for monetary policy, decentralised for economic ones) has been problematic since its inception. Further, such an asymmetrical arrangement 'disregards elementary principles of political economy' inasmuch as it confounds the appropriate level where political power should be exercised (De Grauwe 2010b: 3). While monetary policy has been fully supranationalised, De Grauwe states powers over tax and spending should remain at the national level because that is where accountability mechanisms are grounded. Such arrangements do not and cannot work, De Grauwe argues, simply because states have no incentives to comply and draw their legitimacy from their electorates, not EU institutions. The emphasis on ownership that emerged in EU official documents in the mid-2000s (see next section), can be regarded as a surrogate to overcome such fundamental political economy problems. The basic idea is that the more governments buy into the reform process, the less likely they will be to back down from that path in the face of organised interests or electorate opposition. Confirming this importance, Directorate-General for Economic and Financial Affairs (DG ECFIN) Director Marco Buti has recently declared 'the take-away, from my perspective, is not that fiscal rules per se proved their inadequacy within the crisis. Rather, the main lesson is that fiscal rules operate in a certain institutional and political environment, which has to be conducive to sensible implementation' (Buti 2016: 186).

A Brief History

The first manifestations of economic coordination were the Broad Economic Policy Guidelines (BEPGs), included in the Treaty of Maastricht, and now based on Article 121 TFEU. The BEPGs' main objective was to maintain and foster economic convergence, thus limiting the potential impact of asymmetric economic cycles and shocks in the context of a currency union. In terms of scope, the BEPGs provided recommendations to member states on structural reforms and macroeconomic policies, 'ranging from budgetary policy and wage developments to labour market reform and financial-market integration' (Deroose et al. 2008: 828). The alignment of the Lisbon Agenda (the agreement amongst EU member states to make the EU the leading knowledge-driven economy by 2010) into the

BEPGs in 2000 provoked a significant expansion of the scope of issues considered, as well as the perception that their all-encompassing nature was to the detriment of priority and focus, overcomplicating the process, and ultimately diluting its success (Deroose et al. 2008). The absence of peer pressure amongst member states and a general lack of commitment further contributed to the widespread perception that the BEPGs had limited effect (Deroose et al. 2008). This was paralleled by a negative assessment of the Lisbon Strategy (Kok 2004).

The European Semester itself was first proposed in a 2004 Commission's Communication wherein the opportunity represented by the failure of SGP implementation was seized upon to suggest 'a revision of the economic policy calendar' (Commission 2004: 7). Notably, to strengthen the coordination between member states' economies and to facilitate the monitoring role of EU bodies, the Commission proposed an 'EU semester' to be followed by a national one where budgets would be prepared. Such sequencing would have allowed 'the BEPGs and the Opinions on the [Stability and Convergence] programmes to be taken into account in the preparation of national budgets by governments' (Commission 2004: 7). In the eyes of the Commission, coordination under the Semester would have had several merits: reorienting the SGP-related programmes from 'description' to 'strategic planning'; increasing the national 'ownership' of EU economic coordination as interactions between the two levels intensified; strengthening legitimacy because of the deeper involvement of national parliaments in the policy-making process. Since these early proposals it has been possible to notice a gradual shift towards consensus-building before measures are enacted, and away from what is increasingly perceived as ultimately toothless monitoring. Ownership issues were contemplated at the time, and are still paramount in the Semester (Zuleeg 2015). The focus on ownership derives from IMF past experiences in structural reform, which indicated that the degree to which local policy and political elites buy into reform programmes is determinant to their success (Bird and Willett 2004).

How Does It Work?

The crisis that exploded in Europe in 2010 alerted policy-makers to the need to equip the Union with a single framework to coordinate all the activities related to the reformed EU economic governance. The coordination through the Semester of the correction of macroeconomic imbalances, unsustainable budgetary positions, as well as competitiveness and growth strategies is an answer to the lessons of the crisis as well as the longer-term EU project of coordinating *en bloc* member states' growth strategies. The crisis has revealed how an exclusive focus on a reduced basket of indicators (i.e. mainly budget deficits) was not conducive to macroeconomic stability. Having a framework where a larger pool of indicators is discussed and possibly coordinated was regarded as a step forward from past policies.

Officially started in January 2011, the European Semester cycle kicks off between November and December each year when the Commission releases the Annual Growth Survey (AGS), which spells out the priorities to meet the jobs and growth agenda of Europe 2020, and targets the EU as a whole for the following year (Fig. 1). The AGS builds on three elements: an evaluation of Europe 2020 Strategy, the Macroeconomic Report and the Joint Employment Report. At the same time, the Alert Mechanism Report (AMR) is released, which is part of the constant monitoring of the Macroeconomic Imbalance Procedure (MIP: an agreement amongst EU members to prevent risky macroeconomic policy) (Commission 2014: 7). In addition, the Commission issues opinions on draft budgetary plans. These opinions are then discussed in the Council, while the European Parliament (EP) is involved in the Economic Dialogue on discussions over the AGS. In December/January the Commission and member states have bilateral meetings, while euro-area member states approve their budgets. In January, the Commission can carry out inspections in the member states to verify anomalies that emerged during monitoring. At the same time, the Council adopts recommendations on the euro-area and conclusions on the AGS and AMRs. In March, the European Council

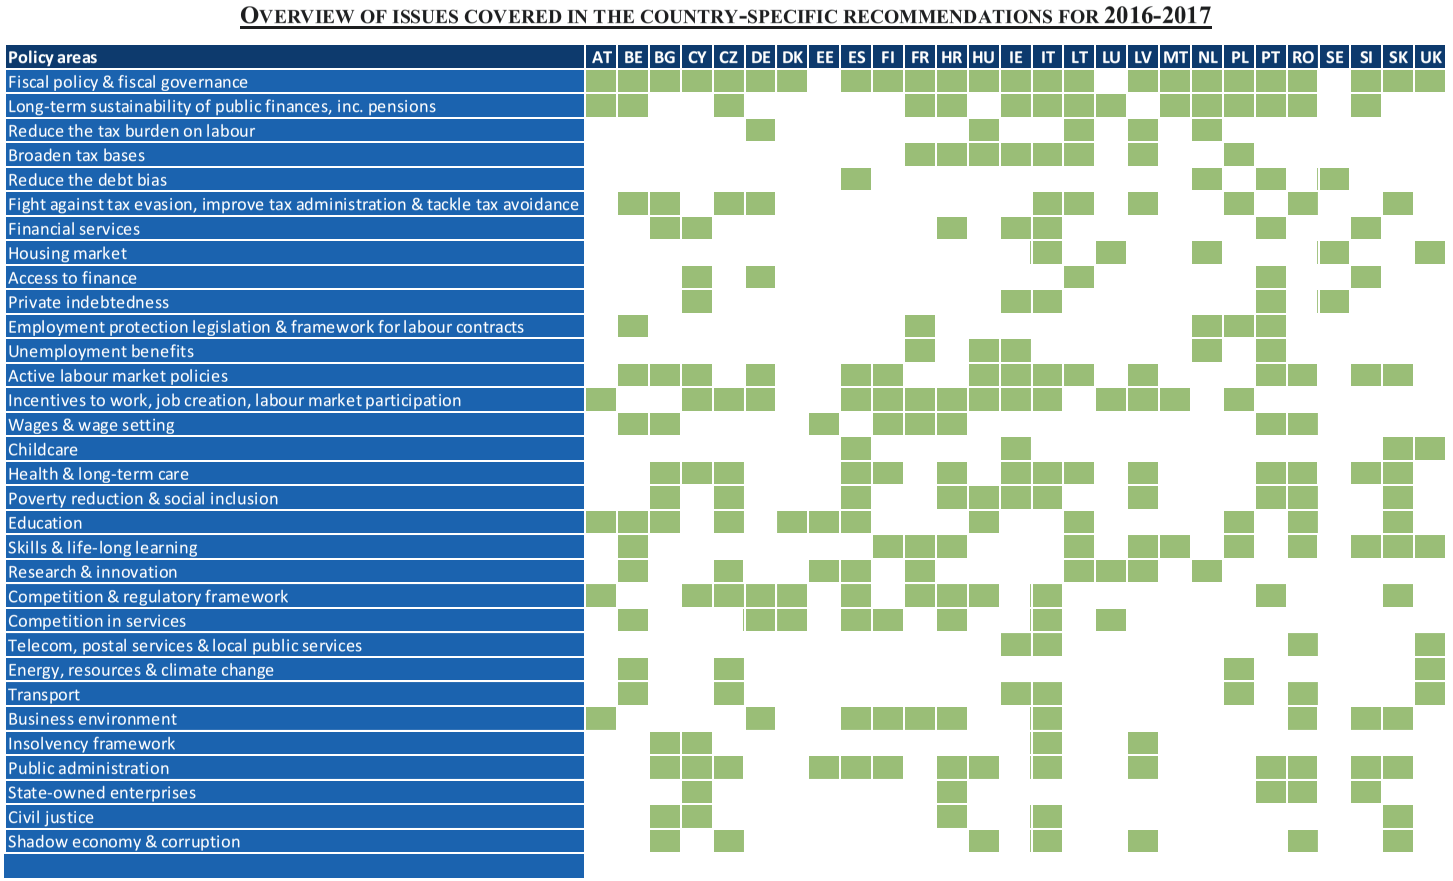
Source: EP 2016a, © European Union, 2016. http://www.europarl.europa.eu/RegData/etudes/ATAG/2014/528767/IPOL_ATA(2014)528767_EN.pdf

adopts the economic priorities on the basis of the AGS. Following suit, the Commission again has bilateral meetings with member states which focus on their submission of National Reform Programmes (NRPs: the local implementation plan of EU objectives) and Stability and Convergence Programmes (SCPs: the individual country's budgetary plans for the coming years, connected with the member states' obligations under the SGP). The National Reform Programmes are compiled by the member states under their Europe 2020 commitments and should be in line with the BEPGs and EGs as well as the Annual Growth Survey (AGS). In May, the Commission releases the Country Specific Recommendations (CSRs) which encompass both economic and budgetary policies and draw on member states' performance for the previous year. At this point, the Commission starts discussions with the EP. Between June and July the Council first debates the CSRs and then the European Council endorses them. The cycle comes to an end in September, when euro area member states submit to the Commission the draft budgets for the following year, while in October the EP discusses the new AGS. The submission of draft budgets should allow the Commission to check their consistency with commitments made in the Stability Programmes previously submitted. It should be noted that there is a differentiation at the heart of the process between euro- and non-euro members, reflecting the various arrangements present in the instruments that the Semester encapsulates (e.g. SGP, MIP). Finally, countries that are under specific surveillance programmes are excluded from the regular CSRs activities, as is currently the case for Greece, and was for Cyprus (between 2013 and 2015), Ireland (2012–2013), and Portugal (2012–2013).

As already mentioned, the Semester has an encompassing nature, which derives from hosting basically every mechanism that the EU has developed so far regarding fiscal, budgetary and economic coordination (see Table 1 below for a recent overview). For instance, the 2015 European Semester started with an AGS focused on three pillars: 'boost for investment' (connected with the other flagship project of an Investment Plan for Europe, which focuses on investment in infrastructure), 'structural reforms', and 'fiscal responsibility'. Examples of specific CSRs are: stepping up efforts to fight tax fraud and evasion in Spain and Italy, increasing tax revenues by harmonising VAT in Germany and introducing tax incentives to strengthen home ownership in the Netherlands (EP 2014). What is the added value of synchronising such a wide array of policy issues? Ideally, to lead member states to a consistent approach under the several coordination schemes present in the EU which cut across policy areas. At a minimum, this means coherence between structural reforms and their budgetary implications. In parallel, synchronisation would facilitate effective monitoring by magnifying inconsistencies between policies (Fig. 2).

As shown in Table 1 below, the numbers of SGP-related recommendations have slightly decreased in absolute terms but remain fairly stable as a share of the total; the MIP-related too have remained fairly stable in absolute numbers but, due to the decreasing overall numbers, have increased in overall share; the most dramatic decrease, however, is in the Integrated Guidelines (which set out the framework for the Europe 2020



EU European Semester, Fig. 2 Overview of issues covered in the EU CSRs for 2016–2017. http://ec.europa.eu/europe2020/pdf/csr2016/csr2016-overview-table_en.pdf (© European Union, 1995–2017)

strategy and reforms at Member State level), which have more than halved in absolute terms and nearly so in relative terms.

As pointed out by the EP, failure to implement recommendations might result in different kinds of sanction, depending on the legal basis of the individual recommendations. For this reason, it may be misleading to encapsulate the European Semester as either soft or hard law, as the framework displays features of both (EP 2016a). Although finding an explicit legal recognition in EU secondary legislation (the Six Pack), this 'overarching framework' (to use the Commission's words; 2014: 10) is only as legally binding and only envisages the possibility of sanctions (two elements frequently used to distinguish soft/hard law policies) as its components are.

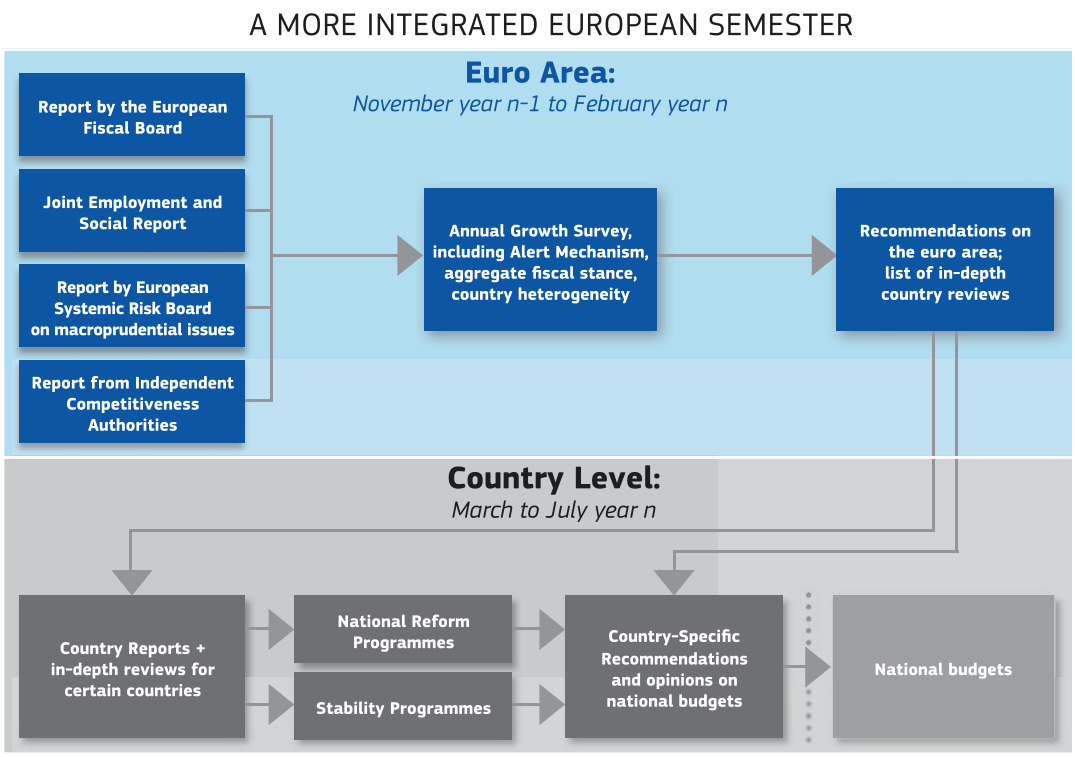
Finally, the Semester can be conceived as having two sources of legitimacy. The first is the involvement of the EP through the Economic Dialogue (albeit in a loose fashion), which might be regarded as enhancing legitimacy by the sheer fact of being directly elected. The second is the fact that, after a European Semester, a national semester is envisaged, where member states are supposed to internally debate the measures to be adopted by their parliaments. The Commission has also recently tightened deadlines during the EU-level of the Semester with the stated aim of conferring more time to national-level discussion on economic reforms and budgets.

The Track Record So Far

Looking at implementation, commentators agree that the picture is disappointing (Darvas and Leandro 2015; Gros and Alcidi 2015; Zuleeg 2015). Member states have made 'full' or 'substantial' progress in decreasing shares of the total recommendations addressed to them between 2012 and 2014 (from 12.3% to 6.4%), while the percentage of measures that were either only limitedly or not implemented increased from 28.8% to 48.1% (Gern et al. 2015: 8). In other words, there is an increasing risk of irrelevance for the entire exercise. Other studies have quantified the level of implementation, finding that 'reform efforts' had been spent only on 40% of recommendations in 2011 (Darvas and Leandro 2015: 10), decreasing to 29% by 2014. Euro-area member states, subject to tighter coordination and monitoring, performed only limitedly better, and for instance in 2014 implemented 31% of recommendations, as compared to 23% of countries outside the Eurozone. Further, implementation is analogous to what was achieved under a parallel OECD framework, which casts doubt on the merits of an operation which has become the flagship initiative for economic coordination in the EU (Darvas and Leandro 2015: 11–13).

Commentators have adduced several reasons for such a deficient implementation, including weak institutional architecture, softening of external pressures as the crisis abated, lack of national ownership of the reform agenda, unfeasible and poorly specified economic objectives. Such implementation gaps have pushed some economists to argue that 'procedures culminating in sanctions in the case of persistent non-compliance' should be introduced to safeguard the 'functioning of the EMU as a whole' (Gern et al. 2015: 24). However, it should be noted that experience with the emphasis on sanctioning as a deterrent for non-compliance has been mixed in the case of SGP (De Grauwe 2010a; Hodson 2014), and it is not clear why this case should be different. Others have regarded such implementation gaps as the ultimate evidence of the need for a 'systemic governance reform' and called for, *inter alia*, a 'fiscal capacity' that member states could tap into provided that they met 'contractual' obligations to be devised by the Commission in the context of the European Semester (Zuleeg 2015: 12, 14). However, the empirical evidence for such a move towards more binding coordination is mixed. Comparing recommendations belonging to the SGP and those of the MIP and other policies (the former two are legally binding, not the latter), studies have found that while the older and more tightly coordinated SGP marginally outperform the others, the 44% implementation rate on average for the period 2012–2014 is not cause for celebration (Darvas and Leandro 2015: 13–14).

In 2015, the Semester was reshuffled into a 'Revamped European Semester' after taking



EU European Semester, Fig. 3 A more integrated European Semester. https://ec.europa.eu/priorities/sites/beta-political/files/5-presidents-report_en.pdf (© European Union, 1995–2017)

stock of mixed implementation records (Commission 2015). EU officials seem to have converged on the idea that less is better, meaning that addressing fewer recommendations to member states might be easier for EU bodies to monitor and for national administrations to implement (Gern et al. 2015: 5). The reforms aim at creating even tighter integration for euro-area member states, as well as gaining more political traction at the domestic level (with an eye to the unresolved issue of ownership). Institutionally, two new advisory bodies are created – a new European Fiscal Board (EFB) and a system of Competitiveness Authorities (Fig. 3).

Commentators have highlighted that while frequent reference is made to 'euro-area aggregate fiscal stance', it is not clear how an 'optimal aggregate fiscal stance should be determined' (Darvas and Leandro 2015: 6). The emphasis on the aggregate fiscal stance comes from ECB invitations and is conceived by the Commission's officials as 'the sum of country policies' (Buti 2016). The Commission argues that there is a 'clear sub-optimal repartition of the fiscal adjustment across countries', but 'those who do not have fiscal space want to use it; those who have fiscal space do not want to use it' (EP 2016b: 2). However, there seems to be little official indication as to how this adjustment should take place (EP 2016b), and policy instruments are still lacking for 'stabilising economic cycles' or forcing 'countries to run larger budget deficits' (Darvas and Leandro 2015). The recommendation to Germany to use the available fiscal space to boost investment was the only divisive one between member states sitting in the Council and the Commission in 2016 (Council 2016), but a decisive one in terms of helping alleviate the internal imbalances of the Union. This reflected (and re-confirmed) the difficulty of EU coordination to push for a measure that was widely regarded as collectively beneficial in the face of

domestic opposition. Further, Deroose and Griesse observe a higher rate of implementation in 'areas where market pressure requires an imminent policy response' (Deroose and Griesse 2014: 1, 6), which casts doubt on whether the positive effects of the Semester are due to coordination or external pressure.

Looking at 2017–2018, the Commission has recently forecast a neutral stance until 2018. In its opinion, member states should run an expansionary fiscal policy, while also taking into account the ECB monetary policy (EP 2016b). Giavazzi regards the very concept of euro area aggregate fiscal stance as a response to the ECB hitting one of the limits of monetary policy, meaning the decision to impose a zero percent interest rate (Giavazzi 2016). Tabellini argues that the crisis has shown that the current setting of the EU, where full financial integration as well as stability is sought for but there is no common fiscal policy or tools to manage aggregate demand, is untenable (Tabellini 2015). In this vein, the emphasis on the aggregate fiscal stance would probably be regarded as ineffective, as one of the main lessons from the crisis was that the EU needs nothing short of a fiscal union to provide 'fiscal stabilisation for the euro-area as a whole' and 'resources to withstand systemic financial crisis' (Tabellini 2016). While a euro-area aggregate fiscal stance that targets, for instance, 'country-specific demand deficiencies' might be adequate to deal with fiscal stabilisation, its suitability to deal with systemic financial crisis is more contested (Monacelli 2016; Wyplosz 2011). In any case, this neglects the crucial question of how such coordination could come about, taking into consideration that coordination initiatives so far have yielded mixed results.

While the Commission seems positive regarding the implementation of the European Semester (Darvas and Leandro 2015: 25), others have outlined a series of criticisms. A line of criticism that often emerges in commentaries relates to the unclear selection criteria upon which recommendations are made, or prioritised (EP 2012: 9). The basic point of a cycle was that recommendations could be followed up year on year. However, commentators have noticed an unevenness of the themes featuring in successive waves of recommendations. For instance, social and labour market policies have been maintained in some countries but not others from one cycle to another despite ostensible lack of progress in all of them (Gern et al. 2015). Others have observed an overall reduction in recommendations for social inclusion, education and skills, without an apparent justification (Zuleeg 2015: 11). Others have criticised the lack of focus on specific areas with significant potential for negative spillovers, such as financial sector vulnerabilities and environmental issues (Gern et al. 2015: 12), or standards on tax compositions (Darvas and Leandro 2015: 21).

Whether the Semester contributes to a more sustainable EMU is complex to assess, but looking at some fundamental macroeconomic variables since the start of the framework might provide an initial indication. Euro area GDP growth increased to 2% in 2015 after weak if not negative performance since 2011, particularly when compared to international competitors such as the USA. Euro area unemployment rates decreased in 2015 to 10.9 after an upward trend in the preceding 3 years. Euro area member states continued to consolidate their public balances (reaching −2.1% in 2015) and brought down their public debt after years of an upward trajectory. These aggregate indicators, however, mask significant disparities and varying trends within the Eurozone, which jeopardise EMU sustainability (Hodson 2016: 154–157). It is in this highly uneven context that commentators have wondered why, in contrast with all previous years, 'a recommendation on the need for symmetric intra-euro adjustment [. . .] was not included in the 2015 recommendations' (Darvas and Leandro 2015). DG ECFIN forecasts limited progress until 2018, with four countries still with unemployment rates above 10% (down from six), GDP growth constant and deficits still above the SGP criteria in two countries (down from three) (Commission 2016b: 1; for a similar analysis, see OECD 2016a). Recent studies have shown that core-periphery dynamics of unsynchronised business cycles which marked the run-up to the adoption of the euro have softened but remain present for a subset of member states (Spain, Portugal, Ireland and Greece)

(Campos and Macchiarelli 2016). Considering that remedying these asymmetries was one of the main goals of economic coordination, as it is regarded as one of the main factors contributing to making the EMU unsustainable, this suggests that coordination has had limited effects so far.

The first years of operation have confirmed that national governments are reluctant to fully buy into the process of coordination (Gern et al. 2015: 5). This shows that lack of ownership, to which the Semester should have been an answer, is still at the forefront. More transparency and timely information on implementation have been suggested as possible solutions with a view to increasing the take up at national level. According to commentators (Gern et al. 2015: 6), increased transparency could be achieved by making more explicit the theoretical premises upon which recommendations to member state are made. More involvement of national parliaments is regarded as instrumental in delivering ownership, but implementation so far suggests that efforts at better including them have largely failed (Gern et al. 2015: 9). Other commentators have pointed out that the only way out from the current situation of lack of ownership and the consequent implementation gap, as well as sovereign and legitimacy issues, is nothing less than an 'economic government', even though there is ample recognition that this 'is not on the cards politically' (Zuleeg 2015: 7). The EP has tried to increase ownership by raising awareness of the process, for instance by inviting national finance ministers to hearings in the EP's Economic and Monetary Affairs Committee as part of Economic Dialogues set up by the Semester (EP 2014).

Conclusions

As the overarching framework including both hard and soft EMU policies, the European Semester is noteworthy for its design. First, by scheduling EU policy discussions before national ones it aims to inform and shape the latter, and within the Eurozone this takes an intrusive form because of, *inter alia*, the budgetary implications of the Two Pack (which involves closer monitoring of the deficits of euro area member states). Second, by imposing synchronised submission of different policy documents, it forces member states to be consistent in their commitments across policy areas, which in turn facilitates monitoring by EU institutions. This exemplifies a broader shift in EU economic governance from an ex post monitoring of member states' preferences to an effort to ex ante shape their adoption. In this regard, it should be remembered that the Semester, by including a wide range of mechanisms such as Europe 2020 and the MIP, now covers a broad spectrum of issues, ranging from energy policy to civil justice. Besides the Semester, the Commission 'considers that ex ante coordination should concern only major national economic reform plans and that it should take place at an early stage before the measures are adopted' (Commission 2013: 3). Because of such methods, timing and scope, the Semester raises questions as to the limits of EU action, introducing a degree of tension between economic policy coordination and subsidiarity concerns.

To conclude, the Semester should be judged by its outcomes. Two simple questions might help in this assessment. Has the Semester facilitated the achievement of the SGP, MIP and Europe 2020 objectives? Has it made monitoring more effective? The answer seems to be negative to the former, as implementation of recommendations related to all three regimes has been falling since the start of the process – this in the context of decreasing numbers of recommendations, which in turn helps answer the second question. This fact suggests that policy-makers are converging on the idea that having less demanding monitoring duties is better for both national and European administrations. It also reduces the complexity of the process and avoids duplications. Eventually, it is hoped that focusing on a smaller number of priorities will improve ownership of the reforms, even if experiences in this regard have been disappointing so far. Regarding coordination, the take-home message is that, while the principle of timely and close cooperation has now entered the official jargon of EU and member states' economic policy, commitment to such processes in the absence of external pressures (e.g. the euro area crisis) has been questioned (Gros and Alcidi 2015). This

resonates with evidence from outside the EU of low responsiveness to coordination recommendations in the absence of external pressures, as revealed by the limited success of the OECD advice to some member states (e.g. Austria, Finland, France, Germany, the Netherlands) to undertake further expansionary fiscal policies to support growth than were currently planned (OECD 2016b, c).

According to the Commission, the innovations in EMU governance since 2010 – including the Semester – aim at helping 'foster growth convergence and the achievement of the goals of the Europe 2020 strategy [,] and preventing the build-up of large macroeconomic imbalances'. Regarding growth convergence, the Commission has recently pointed out that 'GDP growth in the euro area has remained slow compared to past recoveries and is not expected to pick up in the coming years', and that 'the cumulated growth of GDP since the end of the recession differs substantially across Member States' (Commission 2016b: ix, 4). As a consequence, the overarching objective of the Union, as stated in the Treaty, of 'balanced economic growth' does not appear particularly strengthened by coordination through the Semester. Regarding Europe 2020, one should note that, despite the reduction in the numbers of recommendations, this has not led to more compliance. Finally, regarding macroeconomic imbalances (EP 2016c), the Commission this year looked sanguine by noticing that 'fewer Member States have economic imbalances than a year ago' (Commission 2016a). However, since 2012 the countries featuring excessive imbalances have increased year after year (Italy and Hungary have been in that category since 2014), while the Commission has been confirming imbalances in Finland, Germany, Ireland, the Netherlands, Spain and Sweden since at least 2014.

Blanchard et al. observed that the more complex agreements are, the harder respective gains are to identify, and the more measures to be taken by all actors differ and have varying contribution to the collective goal, the more difficult effective coordination is to achieve (Blanchard et al. 2013). The Semester might be suffering from similar problems, as with the multiplication of policy instruments, the extended remit of policies under consideration, and the complexity reached by some of the components of the Semester (SGP, MIP), it is possible to argue that it is becoming increasingly difficult for member states to identify the individual gains from such exercises, understand others' contributions and have a clear sense of the overall benefit of the exercise.

JEL Classifications

B31

Head of the Freiburg School of German neoliberalism and founder of the yearbook *Ordo,* Eucken was born at Jena on 17 January 1891. Eucken earned his doctoral degree at Bonn (1913). After the *Habilitation* in Berlin (1921), he was professor of economics at Tübingen (1925) and Freiburg (1927–50). He died on 20 March 1950 in London, during a lecture series at the London School of Economics.

Eucken's works mark the return to (neo)classical theory in German economics after the dominance of the Historical School. He stressed, however, the theorist's task to explain reality and rejected model-building if it was purely an intellectual game. Eucken's outstanding analytical contributions include a masterly explanation of the German inflation and currency depreciation on quantity-theoretical grounds (1923), a capital theory (1934) building on Böhm-Bawerk and Wicksell and, in particular, his theory of economic systems (1940) and of economic policy (1952).

Eucken's theory of economic policy starts from the distinction between the *economic order*, the legal and institutional framework of economic activity, and the *economic process,* the daily transactions of economic agents. Under laissez-faire the state neither shapes the economic order nor intervenes in the economic process; in a centrally planned economy the state dominates both. Eucken conceived a *Wettbewerbsordnung* (competitive system) different from both systems: Government should abstain from directly intervening into market processes, but it has to shape the economic order by guaranteeing, through *Ordnungspolitik,* the 'constituent principles' of the market economy (monetary stabilization, free entry, private property, freedom of contract, liability, consistency in economic policy and, primarily, maintaining competition). Subsidiary are the 'regulatory principles': monopoly regulation, social policy, process stabilization policy. Eucken's theory laid the ground for West Germany's 'social market economy'.

Euler Equations

Jonathan A. Parker

Abstract

An Euler equation is a difference or differential equation that is an intertemporal first-order condition for a dynamic choice problem. It describes the evolution of economic variables along an optimal path. It is a necessary but not sufficient condition for a candidate optimal path, and so is useful for partially characterizing the theoretical implications of a range of models for dynamic behaviour. In models with uncertainty, expectational Euler equations are conditions on moments, and thus directly provide a basis for testing models and estimating model parameters using observed dynamic behaviour.

An Euler equation is an intertemporal version of a first-order condition characterizing an optimal choice as equating (expected) marginal costs and marginal benefits.

Many economic problems are dynamic optimization problems in which choices are linked over time, as for example a firm choosing investment over time subject to a convex cost of adjusting its capital stock, or a government deciding tax rates over time subject to an intertemporal budget constraint. Whatever solution approach one employs – the calculus of variations, optimal control theory or dynamic programming – part of the solution is typically an Euler equation stating that the optimal plan has the property that any marginal, temporary and feasible change in behaviour has marginal benefits equal to marginal costs in the present and future. On the assumption that the original problem satisfies certain regularity conditions, the Euler equation is a necessary but not sufficient condition for an optimum. This differential or difference equation is a law of motion for the economic variables of the model, and as such is useful for (partially) characterizing the theoretical implications of the model for optimal dynamic behaviour. Further, in a model with uncertainty, the expectational Euler equation directly provides moment conditions that can be used both to test these theoretical implications using observed dynamic behaviour and to estimate the parameters of the model by choosing them so that these implications quantitatively match observed behaviour as closely as possible.

The term 'Euler equation' first appears in text-searchable JSTOR in Tintner (1937), but the equation to which the term refers is used earlier in economics, as for example (not by name) in the famous Ramsey (1928). The mathematics was developed by Bernoulli, Euler, Lagrange and others centuries ago jointly with the study of classical dynamics of physical objects; Euler wrote in the 1700s 'nothing at all takes place in the universe in which some rule of the maximum . . . does not appear' (Weitzman 2003, p. 18). The

application of this mathematics in dynamic economics, with its central focus on optimization and equilibrium, is almost as universal. As in physics, Euler equations in economics are derived from optimization and describe dynamics, but in economics variables of interest are controlled by forward-looking agents, so that future contingencies typically have a central role in the equations and thus in the dynamics of these variables.

For general, formal derivations of Euler equations, see calculus of variations or dynamic programming. This article illustrates by means of example the derivation of a discrete-time Euler equation and its interpretation. The article proceeds to discuss issues of existence, necessity, sufficiency, dynamics systems, binding constraints and continuous-time. Finally, the article discusses uncertainty and the natural estimation framework provided by the expectational Euler equation.

The Euler Equation

Consider an infinitely-lived agent choosing a control variable (c) in each period (t) to maximize an intertemporal objective: $\sum_{t=1}^{\infty} \beta^{t-1} u(c_t)$ where $u(c_t)$ represents the flow payoff in t, $u' > 0$, $u'' > 0$, and β is the discount factor, $0 < \beta < 1$. The agent faces a present-value budget constraint:

$$\sum_{t=1}^{\infty} R^{1-t} c_t \leq W_1 \tag{1}$$

where R is the gross interest rate ($R = 1 + r$ where r is the interest rate) and W_1 is given.

By the theory of the optimum, if a time-path of the control is optimal, a marginal increase in the control at any t, dc_t, must have benefits equal to the cost of the decrease in $t + 1$ of the same present value amount, $-Rdc_t$:

$$\beta^{t-1} u'(c_t) dc_t - \beta^t u'(c_{t+1}) R dc_{t+1} = 0.$$

Reorganization gives the Euler equations

$$u'(c_t) = \beta R u'(c_{t+1}) \text{ for } t = 1, 2, 3 \ldots \tag{2}$$

This set of Euler equations consists of nonlinear difference equations that characterize the evolution of the control along any optimal path. We considered a one-period deviation; several period deviations can be considered, but they follow from sequences of one-period deviations and so doing so does not provide additional information ($u'(c_t) = \beta^2 R^2 u'(c_{t+2})$). These equations imply that the optimizing agent equalizes the present-value marginal flow benefit from the control across periods.

The canonical application of this problem is to a household or representative agent: call c consumption, u utility, and let $W_1 = \sum_{t=1}^{\infty} R^{1-t} y_t$, the present value of (exogenous) income, y. In this case, Eq. (2) imply the theoretical result that variations in income do not cause consumption to rise or fall over time. Instead, marginal utility grows or declines over time as $\beta R 1$; for $\beta R = 1$, consumption is constant.

Existence, Necessity and Sufficiency

In general, to ensure that the Euler equation characterizes the optimal path, one typically requires that the objective is finite (in this example, $u' > 0$) and that some feasible path exists.

Further, since Euler equations are first-order conditions, they are necessary but not sufficient conditions for an optimal dynamic path. Thus, theoretical results based only on Euler equations are applicable to a range of models. On the other hand, the equations provide an incomplete characterization of equilibria. In the example, only by using the budget constraint also can one solve for the time path of consumption; its level is determined by the present value of income.

Dynamic Analysis

More generally, complete characterization of optimal behaviour uses the Euler equation as one equation in a system of equations. For example,

replacing the budget constraint (Eq. (1)) with the capital-accumulation equation

$$K_{t+1} = f(k_t) - c_t + (1-\delta)k_t \qquad (3)$$

where k is capital, $f(k)$ is output, $f' > 0$, $f'' < 0, f(0) = 0$, $\lim_{k \to 0} f_1 > \beta^{-1} - (1-\delta)$, and $\lim_{k \to \infty} f_1 < \beta^{-1} - (1-\delta)$, and adding the constraints k_1 given, $k_t \geq 0$, and $c_t \geq 0$, gives the basic Ramsey growth model. The constant real interest rate of Eq. (2) is replaced by the marginal product of capital in the resulting Euler equation

$$u'(c_t) = \beta(1 - \delta + f'(k_{t+1}))u'(c_{t+1}). \qquad (4)$$

Equations (3) and (4) form a system of two differential equations with two steady states that has been widely studied as a model of economic growth. Linearization shows that the interesting ($k > 0$) steady state is locally saddlepoint stable, and there is a unique feasible convergence path that pins down the dynamic path of consumption and capital.

Binding Constraints

The above Euler equations are interior first-order conditions. When the economic problem includes additional constraints on choice, the resulting Euler equations have Lagrange multipliers. Consider adding a 'liquidity constraint' to our example: that the household maintain positive assets in every period s:

$\sum_{t=1}^{s} R^{1-t} y_t - \sum_{t=1}^{s} R^{1-t} c_t \geq 0$ for all s. In this case, the program is more easily solved in a recursive formulation. Equation (2) holds with a single Lagrange multiplier, $\lambda_{t+1} \geq 0$, on the constraint that assets are positive in $t+1$ since prior to $t+1$ assets levels are unaffected by the choice of c_t and in period $t+1$ the present value of future consumption is unchanged by the one-period deviation considered:

$$u'(c_t) = \beta R u'(c_{t+1}) + \lambda_{t+1}.$$

The multiplier λ_{t+1} has the interpretation of a shadow price. When the constraint does not bind, $\lambda_{t+1} = 0$, the interior version of the Euler equation holds, and the marginal-benefit-marginal-cost interpretation is straightforward. When the constraint binds, the interpretation still holds, but almost tautologically: the change in utility of an extra marginal unit of consumption in t is equal to the change in utility from the marginal decreases in consumption in $t+1$ plus the shadow price (in terms of marginal utility) of marginally relaxing the constraint on c_t. For example, if $\beta R = 1$ and $y_t = \bar{y}\ \ \forall t \neq 2$ and $y_2 = y < \bar{y}$, then $\lambda_{t+1} = 0 \quad \forall t \neq 2\ ,\ \lambda_3 = u'\left(\frac{y+R\bar{y}}{1+R}\right) - u'(\bar{y}) > 0$, and $c_1 = c_2 = \dfrac{y + R\bar{y}}{1+R}, c_t = \bar{y} \quad \forall t \geq 3$. This example illustrates that, relative to the unconstrained equilibrium $(c_t = \bar{y} - r(\bar{y} - y))$, the constraint can postpone consumption ($t = 1, 2$ relative to $t \geq 3$), create a causal link from an increase in income to consumption ($t = 2$ to 3), and can lower consumption in unconstrained periods ($t = 1$).

Continuous Time

In general, continuous-time models have differential Euler equations that are equivalent to the difference-equation versions of their discrete-time counterparts. In the example, replacing $t+1$ with $t + \Delta t$, $c_{t+\Delta t} = c_t + \Delta t$, expanding $u'(c_t + \Delta c_t)$ around c_t, and letting $\Delta t \to 0$ gives:

$$\frac{\dot{c}_t}{c_t} = \sigma_t(r + 1 - \beta)$$

where $\sigma_t = -\frac{u'(c_t)}{c_t u''(c_t)}$. While the marginal-costs-marginal-benefit interpretation of the equation is less obvious in continuous time, it is still clear that consumption rises or falls with the difference between the interest rate (r) and the discount rate ($\beta - 1$), and more obvious that the strength of this response is governed by σ_t, which for this reason is called the elasticity of intertemporal substitution.

Generalized Euler Equations

Dynamic games can also lead to 'generalized' Euler equations. For example, Harris and Laibson (2001) considers a modification of the example as a game among agents at different times who disagree because their preferences are not time consistent due to hyperbolic discounting. At any s, an agent has objective: $u(c_t) + \beta\sum_{\tau=1}^{\infty}\delta^{\tau}u(c_{s+r})$, where $0 < \delta < 1$. Defining recursively $W_{t+1} = R(W_t - c_t)$, the generalized Euler equation is

$$u'(c_t) = R''Effectivediscount\ factor''\left[\underbrace{\beta\delta\left(\frac{\partial c_{t+1}(W_{t+1})}{\partial W_{t+1}}\right) + \delta\left(1 - \frac{\partial c_{t+1}(W_{t+1})}{\partial W_{t+1}}\right)}\right]u'(c_{t+1}).$$

where $c_{t+1}(W_{t+1})$ is the optimal consumption choice made in $t + 1$ as a function of W_{t+1}. The effective discount rate is a function of the (endogenous) marginal propensity to consume wealth in $t + 1$.

Uncertainty

Models that contain uncertainty lead to expectational Euler equations. Add to the discrete-time example that the agent believes income y_s for $s > t$ to be stochastic from the perspective of period t. The Euler equation becomes

$$u'(c_t) = \beta R\hat{E}[u'(c_{t+1})|I_t] \tag{5}$$

where $\hat{E}[.|I_t]$ represents the agent's expectation given information set I_t. The stochastic version of the consumption Euler equation has an analogous interpretation to that under certainty: the household equates *expected* (discounted) marginal utility over time.

Taking a second-order approximation to marginal utility in $t + 1$ around c_t and re-organizing gives

$$\hat{E}\left[\frac{c_{t+1} - c_t}{c_t}|I_t\right] = \sigma_t\left(1 - (\beta R)^{-1}\right) + \frac{1}{2}\varphi_t E\left[(c_{t+1} - c_t)^2|I_t\right]$$

where $\varphi_t = -\frac{c_t u'''(c_t)}{u''(c_t)}$ is the coefficient of relative prudence (see for example Dynan 1993). It is now *expected* consumption growth that rises with the real interest rate and falls with impatience. Additionally, for $\varphi_t > 0$, risk leads to precautionary saving: higher expected consumption growth (much like liquidity constraints).Finally, actual consumption growth is also driven by the realization of uncertainty about current and future income.

Testing and Estimation

An expectational Euler equation is a powerful tool for testing and estimating economic models in large samples, because, along with a model of expectations, it provides orthogonality conditions on which estimation can be based. Only randomization, as under experimental settings, delivers such a clean basis for estimation without near-complete specification of an economic model, including the sources of uncertainty.

Considering our main example, define $\varepsilon_{t+1} = u'(c_{t+1}) - (\beta R)^{-1}u'(c_t)$. Hall (1978) pointed out that Eq. (5) implies that $\hat{E}[\varepsilon_{t+1}z_t|I_t] = \hat{E}[\varepsilon_{t+1}|I_t] = 0$ for *any* z_t in the agent's information set, I_t. Under the assumption of rational expectations, mathematical expectations can be used in place of the agent's expectations. Thus, this equation predicts that observed changes in discounted marginal utility are unpredictable using I_t, or that marginal utility is a martingale, a strong theoretical prediction that Hall (1978) tests. Hansen and Singleton (1983) use a version of the stochastic Euler equation with a portfolio choice as the basis for estimation (and testing) of the

parameters of the representative agent's parameterized utility function.

Following these papers (and others), large-sample testing and estimation of Euler equations under the assumption of rational expectations has played a central role in the evaluation of dynamic economic models. Most research applies the generalized method of moments (GMM) of Hansen (1982) using the restrictions on the moments of time series implied by the expectational Euler equation. Considering a $J \times 1$ vector of z_t's, $\mathbf{z}_t$, and, based on our example, define the column vector $\mathbf{g}(c_{t+1}, c_t, \mathbf{z}_t) = (\beta R u'(c_{t+1}) - u'(c_t))\mathbf{z}_t$, so that we have the J moment restrictions $E[\mathbf{g}(c_{t+1}, c_t, \mathbf{z}_t)] = 0_{J\times 1}$. For example, letting $u'(c_t) = c_t^{-(1/\sigma)}$ and assuming that second moments exist and the model is covariance stationary, the time-series average of $\mathbf{g}(c_{t+1}, c_t, \mathbf{z}_t)$ should converge to $E[\mathbf{g}(c_{t+1}, c_t, \mathbf{z}_t)]$ for the true σ, β and R. The GMM estimates of σ, β and R are those that minimize the difference (according to a given metric) between the observed empirical moments and their theoretical counterparts, $0_{J\times 1}$.

This general approach has the advantage that complete specification of the model is not necessary. In our example, the stochastic process for income need not be specified nor the stochastic process for consumption determined (which can be quite demanding in terms of computer programming and run-time). That said, more complete specification can give more theoretical restrictions and thus more power in asymptotic estimation. Gourinchas and Parker (2002), for example, uses numerical methods to bring more theoretical structure to bear in estimation. Further, more complete specification can allow one to use small-sample distribution theory and thus avoid the approximations inherent in using asymptotic distribution theory for inference in finite samples. A recent cautionary example is provided by the literature showing that standard asymptotic inference can be highly misleading in large samples with 'weak instruments'.

Euler's Theorem

Peter Newman

Keywords

Adding-up problem; Calculus of variations; Euler equations; Euler's Theorem; Homogeneous functions; Lagrange multipliers

JEL Classifications

C6

Euler's Theorem on homogeneous functions is one of those useful pieces of multivariable calculus that has tended not to receive the attention in mathematical textbooks that its importance in economic theory warrants. An analogous case is Lagrange multipliers, though there the analysis in most textbooks falls far short of the rigour and depth that are needed for fruitful economic applications, as it often does of Euler's other discovery of direct importance in economics, the so-called Euler equations in the calculus of variations (for a critical discussion, see Young 1969). With Euler's Theorem there are no such worries, however, and the discussion in a work like that of Courant (1936, vol. 2, pp. 108–10) is quite adequate.

Once the necessary notation and terminology is established, the statement of the theorem follows easily. Given any real number k, let F be a real-valued function defined on some non-empty subset S of vectors $x \in R^n$.Then F is said to be *homogeneous of degree k* (*h.d.k.*) if the equation

$$F(tx) = t^k F(x) \tag{1}$$

holds for every x $\in S$ and every real number t.

Let f be a differentiable function defined on a non-empty open subset $G \subset R^n$, and denote the *gradient* of f at x, that is, the n-dimensional vector of its partial derivatives f_i evaluated at x, by $\nabla f(x)$. The inner product of any two vectors a and b is written $\langle a,b \rangle$.

Euler's Theorem The differentiable function f is homogeneous of degree k if and only if the following Euler relation holds for every $x \epsilon G$,

$$\langle x, \nabla f(x) \rangle = kf(x) \tag{2}$$

For a proof, see Courant (1936). Notice that this theorem *characterizes* homogeneous functions, that is, any function satisfying (2) for all x must satisfy (1), hence be *h.d.k.* A simple but often useful corollary of the theorem is that, if f is r-times differentiable and $m \leq r$, then each of its partial derivatives of order m is homogeneous of degree $k - m$, so that each f_i is *h.d.*$(k-1)$, each f_{ij} is *h.d.*$(k-2)$, and so on. Since homogeneous functions crop up almost everywhere in economics, Euler's Theorem is a standard tool with innumerable applications. So it is slightly odd that what was apparently its first use occurred so late, and that it was not by an established mathematical economist. In his review of Wicksteed (1894), A.W. Flux (1894) pointed out that Wicksteed could have saved himself a great deal of trouble if he had simply cited Euler's Theorem instead of, in essence, proving it all over again. It was indeed in the controversy over the so-called adding-up problem in the theory of distribution that Euler's Theorem first gained notoriety. For details of the adding- up problem, see Steedman (1987); here only a few of the main points will be lightly sketched in.

Assume that the firm wishes to minimize the cost of producing a scalar output s by the use of factors $x_1, x_2, \ldots, x_n = x$ bought at competitive prices $p_1, p_2, \ldots, p_n = p$. Under standard assumptions the first order conditions for this minimization yield

$$p_i = \lambda f_i(x) \tag{3}$$

where $i = 1, 2, \ldots, n$ and λ is the associated Lagrange multiplier. This multiplier is of course the marginal cost of output, a fact which can be guessed at from (3) on purely dimensional grounds alone. Assume now that the production function f, where $\eta = f(x)$, is homogeneous of some unknown degree k.

Then, substituting from (3) into (2) and remembering the meaning of $\nabla f(x)$,

$$\lambda^{-1} \langle x, p \rangle = kf(x). \tag{4}$$

If there is competition in the product market as well, that is, free entry, then in long-run equilibrium marginal cost will equal the price q of the product, so that (4) becomes

$$\langle x, p \rangle = kqf(x). \tag{5}$$

The left-hand side of (5) is total factor payments. If constant returns prevail f is *h.d.*1 and so $k = 1$. All is well, since the right-hand side is then total revenue, equal to the sum of factor payments. If on the other hand $k < 1$, so that returns to scale

are decreasing, (5) shows that there will be something left over after all the purchased inputs have been paid.

What this residual really means is not clear. Some writers have interpreted it to be the returns (rent) to some non-marketed factor internal to the firm. But in that case why isn't the factor sold by its owner to the firm (after all, we are in long-run equilibrium, so that quasi-rents do not apply)? Or is there no external market for the factor?

This is not the place to go into such qsts, but it may be suggested that the incompleteness resides more in the theory than in either the markets or the factor payments. If $k > 1$ there are increasing returns to scale, and (5) then suggests that there will not be enough revenue to meet total factor payments. But with increasing returns the hypothesis of perfect competition in the product market has to be abandoned, so the passage from (4) to (5) is illegitimate and (5) does not hold.

Euro

Adam S. Posen

Abstract

The euro has been a limited success at home, but it has not challenged the dollar as a global reserve currency. This reflects the limited impact of the euro on member economies. While European financial markets and trade are far more integrated than before adoption of the euro, that is the result of broader international trends. Factors inhibiting growth in the eurozone's real economy prevent truly deep financial integration as well, despite the removal of currency risk. The euro has delivered price stability and credible monetary policy, but not induced the convergence and reform necessary to improve European economic performance.

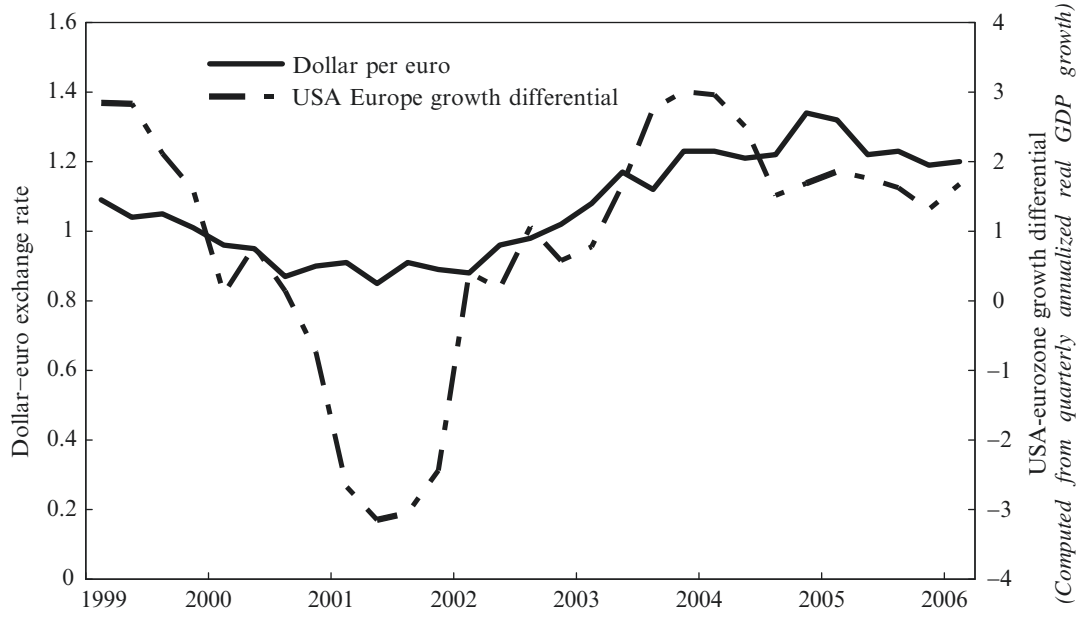
JEL Classification

F

The launch of the euro, the European Union's currency (at least for 12 of the 27 current members), on 1 January 1999, was a birth long foretold. From at least the 1992 Maastricht Treaty onwards, its creation was at the forefront of the European overall integration agenda, and the meeting of criteria for eurozone entry dominated macroeconomic policymaking in Western Europe. The academic and policy discussion of European Monetary Union's (EMU) potential advantages and disadvantages began even earlier (see Canzoneri et al. 1992; De Cecco and Giovannini 1989; De Grauwe 2000; Cecchini 1988; as well as the seminal European Commission 1990. Most of these studies concerned how best to make EMU work, taking the goal as a given, or assessing the optimality of the EU as a currency area.) New international reserve currencies, as the euro has begun to be, do not come along every day, or even every century. New currencies in general are launched usually out of



Euro, Fig. 1 Dollar-euro exchange rate and real GDP growth differential, 1999–2006 (Source: IMF, IFS Statistics)

need, due to replacement of a currency of hyperinflation-eroded value or to political fragmentation or secession; when currency unions are formed, they are usually done as pegs to a previously existing anchor currency of the largest and/or most stable member economy. The voluntary adoption of the euro by sovereign but not politically unified nations, and its replacement of already stable currencies (notably the Deutschmark), is thus an extraordinary monetary experiment and policy undertaking.

While the euro certainly has had no shortage of champions among economists – including beyond Euroland's borders the economists Bergsten (1997), Eichengreen (1999), Mundell (1998), and Portes and Alogoskoufis (1991) – many monetary economists observing the euro have tended to be sceptical: first of the virtues of the goal of monetary integration in Europe itself, then of the project's political viability, and then of its economic sustainability, in turn asserting that the euro was a solely political project. (Notable examples of this scepticism include, on the political side, Currie et al. 1992; Walters 1990; and, famously, Feldstein 1997; and on the economic side Arestis and Sawyer 2001; De Grauwe 1996; Dornbusch 1989; Giavazzi and Spaventa 1990; and Weber 1991. See also the essays by eurosceptics in the face of mounting contrary evidence collected in *Cato Journal* 2004.) Only as the euro passed its eighth birthday in wide usage, remained well past parity with the US dollar (see Fig. 1) and experienced a strong cyclical recovery in the eurozone has sentiment changed. Increasingly, the question is being raised whether the euro might appreciate against the dollar for an extended period, be the beneficiary of substantial international portfolio adjustments, or even begin to supplant the dollar as the dominant global reserve currency. (Recent examples include Chinn and Frankel (2004, 2007); Obstfeld and Rogoff 2004; and Summers 2004.) The euro's viability in its own large economic area may not be sufficient to set it on a path to monetary leadership, but its existence now presents an alternative for capital markets to turn to should the dollar's own appeal diminish.

The waiting for US missteps for the euro to rise in importance, however, is a critical commentary on the limitations of the euro's importance to the eurozone member economies' performance in and of itself. When the euro was first proposed, a number of studies claimed that monetary

integration would bring significant direct benefits to the economic performance of member states. Emerson et al. (1992) estimated that the elimination of transaction costs from moving to a single European currency would yield direct benefits of up to 0.4 % of EU GDP; the European Commission (1996) estimated cost savings of 1.0 % of GDP simply from eliminating transaction costs. The European Commission (1990) made the case that the reduction of nominal and real exchange rate uncertainty would lead to significant growth in intra-EU trade and investment. Financial markets in particular were expected to benefit from the introduction of the euro – McCauley and White (1997) and the European Commission (1997) forecast a rapid deepening and liquidity increase in European bond and lending markets, and perhaps even a 'decoupling' of European interest rates from those of the United States.

While empirical investigations to date of these effects remain mixed in interpretation, there is no question that the real economic effects of the euro's launch on the eurozone member countries have been something of a disappointment. In particular, European financial markets and trade integration are far deeper today than they were before the adoption of the euro, yet how much this represents the effect of the euro on EU integration as opposed to the broader international trends towards global integraton that benefited non-euro members as well is in doubt (see Forbes 2005; Lane and Wälti 2006; Mann and Meade 2002; and Rey 2005). The eurozone's interest rates remain asymmetrically affected by US interest rates, at least through the early 2000s, as established by Chinn and Frankel (2004). The effect of the euro on price convergence and on macroeconomic discipline cannot be all that substantial if on net there has been limited visible improvement in either of these areas (see the assessments of price convergence in Bradford and Lawrence (2003, 2004); and Rogers 2003 and of macroeconomic discipline in Posen (2005a, b). It seems that the euro has proven on net 'irrelevant' to real growth performance of large Continental European economies, neither a harm nor a boon to them, as Posen (1998) forecast it would be.

The External Opportunities and Shortfalls for the Euro

The degree to which the euro comes into wider usage beyond intra-eurozone transactions, for example as an invoicing currency in world trade, is a major issue because of the eurozone's already large share of world output and trade (roughly comparable to that of the United States) and of the established 'domestic' monetary stability of the eurozone. Size does matter for international currency purposes. Yet insufficient integration and depth of European financial markets as well as lagging economic performance remain constraints on the euro's wider adoption and usage. Also important is the lack of coherent institutional representation for the eurozone in international monetary forums. Compared with the EU's one voice in global trade negotiations, the inability of the eurozone to speak as a single entity is striking, especially given the unconsolidated overrepresentation of the eurozone in the Bretton Woods institutions.

History also plays a role, however, in the global demand for currencies and their strength. Inertia and incumbency clearly contributed to the lingering of the British pound in a significant share of international reserves well after the Second World War. Yet the combination of macroeconomic mismanagement and growth underperformance in the United Kingdom from the 1920s to the 1980s eroded that role, and it is worth remembering that the passing of international monetary leadership from the pound to the dollar in the mid-twentieth century was in large part driven by these factors undermining the pound's reserve status. The steady accumulation of international debt by the United States since 1991 could contribute to a similar switch now that the euro is available. An extended dollar depreciation, the natural reaction to a multi-year series of widening US current account deficits, could induce a persistent portfolio diversification into euros by private and official holders of dollars.

In Washington, Frankfurt and Brussels, however, the widespread governmental opinion remains that the euro will not close the gap in usage with the dollar until the eurozone closes the gap with the US economy in per capita GDP

growth and employment on a sustained basis (Fig. 1 shows the growth differential of the USA over the eurozone). In a typical official expression of this sentiment, Quarles (2005, 40) finds that 'too much attention is being focused on exchange rate[s]... and too little on what seems... of far greater importance: namely, the more effective functioning of economies with regards to growth in output and employment'. Successive US governments have viewed both the short-term international adjustment process and the longer-term role of the euro vis-à-vis the dollar as driven by the gap in growth rates between the USA and Europe – with the burden on European economies to catch up by raising their growth rates. EU officials' disappointment with the degree of structural reforms catalysed by the introduction of the euro echoes this view, as does the promotion of the Lisbon Agenda announced in March 2000 for promotion of growth in the EU.

Such an external relative focus overlooks one achievement of the launching of the euro – ending the succession of devaluations, competitive depreciations and currency crises that had beset the members of the Exchange Rate Mechanism (ERM) prior to 1999. Certainly, the experiences of intra-European depreciations upon countries leaving the ERM, especially those of 1992–3, and their impact on economic performance and political outcomes in member states were in the forefront of European policymakers' minds when the run-up to the euro was under way in the late 1990s. And, despite the divergence in histories of some eurozone members, inflation and inflation expectations have remained stable and low in the eurozone. That could have been expected to assist in trade promotion among the already interdependent eurozone economies (see currency unions).

Still there has been little or no expansion in trade as a result of the adoption of the euro – among other evidence, the share of total eurozone exports destined for other members of the eurozone did not increase with the introduction of the currency, as would have been likely if the common currency had promoted trade (Baldwin 2005 provides an excellent analytical summary of the evidence on this score). As shown in Rogers (2003), the bulk of convergence in traded-goods prices within the eurozone occurred between 1990 and 1994, in response to the creation of the single market, and not after 1999 and the introduction of the euro. As for the global dimension, there has been little change in the share of foreign exchange transactions denominated in euros globally from that previously denominated in Deutschmarks. Similarly, the use of the euro as an invoicing currency is somewhat higher than that for the eurozone home currencies prior to EMU, but remains far from universal within Europe or even comparable to the dollar's usage (with the regional exception of some of the newest members of the European Union).

Even the spreading use of the euro in the EU's new members in the east has been far less than many might have expected. A critical part of this outcome has been the insistence on the part of the European Central Bank (ECB) that all prospective eurozone members go through the full Maastricht Treaty-specified process for qualification, including not just fiscal discipline and nominal convergence but also a two-year period in the 'waiting room' of a new ERM-II mechanism. Early, expedited or unilateral adoption of the euro in EU member countries has in fact been discouraged by the ECB (with the exception of Estonia's pre-existing currency board with the euro). Arguably, this has as much to do with the ECB's desire for perceived control over monetary developments, given the ECB's Bundesbank-esque 'two pillar' strategy (of looking at both monetary growth and inflation goals when setting policy), and for keeping decision-making in the ESCB manageable, as with maintaining necessary discipline on eurozone members (see European Central Bank). The ECB has also been explicitly opposed to 'euroization' (dollarization with euros) by non-EU member countries, again partly for monetary control reasons, albeit acknowledging its contribution to stability in the post-conflict Balkan economies.

The Limited Impact of the Euro on the Eurozone Financial Integration and Performance

The euro has delivered monetary stability in the face of a long list of economic shocks and a large

initial decline against the dollar, only to rebound strongly since Autumn 2001 (see Fig. 1). Europe has failed to follow the creation of the euro with the complementary policy reforms that were widely expected, however. This leaves an underlying tension between the constraints on national economic policy measures such as those in the Stability and Growth Pact on fiscal policy (see stability and growth pact) and the national frustrations with poor economic performance – a tension that raises recurrent doubts in eurosceptic financial markets about the sustainability of the euro itself, despite its lack of obvious vulnerabilities or viable exit options for any member country.

The euro was widely expected to transform two aspects of the eurozone economies: the integration and depth of their financial markets, and the conduct of their macroeconomic policies. Particularly with regard to the former, there has been beneficial change at least partly attributable to the euro's introduction and acceptance. Money market integration, which is critical to the implementation of a single monetary policy for the eurozone, given the need to transmit monetary policy in a decentralized fashion across the member economies, has succeeded. It took European money markets less than a month in 1999 to 'learn' how the new operational framework functioned, and to eliminate most of the volatility and cross-border dispersion in overnight interest rates. The evidence of integration in the unsecured lending rates in the European money market is similarly clear. Rey (2005) finds that government bond markets have seen intra-eurozone interest rate spreads virtually disappear, and benchmark securities of different countries have begun to emerge. Corporate bond markets went from 'almost non-existent' prior to EMU to 150 billion euro of issuance in 2003, and the euro swap market has become the largest financial market in the world.

Eurozone financial markets, however, still have a long way to go to become a global competitor with those based in London or New York. Factors in the non-financial economy, such as legal differences, obstacles to more rapid real growth, transaction costs, and institutional gaps in financial supervision combine to keep the eurozone from achieving truly deep, integrated financial markets, despite the removal of currency risk. Thus, there remains a striking contrast between the repo (repurchase of safe assets at central banks) and unsecured market in the degree of cross-national differences in interest rates due to the ongoing lack of harmonization in legal and procedural treatment of financial instruments in the eurozone countries. The costs of making cross-border securities transfers within the eurozone can still be ten times more than the cost of securities transfers within a given eurozone country.

Given the surge in capital flows across borders worldwide, following the recovery from the 1997–98 Asian financial crisis, almost half of which were in the form of portfolio investment, one would expect greater influence of market opinion about assets in a given currency or region upon the actual allocation of capital between regions. It seems that prospects for economic growth drive the relative demand for a region's assets, mostly by determining where trade and investment expands, which then in turn sets the pace of stock market integration of that region with the rest of the world. Given the medium-term outlook for European growth, this appears to militate against an increase in investment and therefore in integration (and influence) of European capital markets, which might be partially offset by some diversification incentives. In the long run, though, a slow growth rate in Europe would also translate into a smaller share of global GDP, and less incentive for central banks to hold euro-denominated reserves. In this context, Forbes (2005) and Lane and Wälti (2006) independently investigate whether the euro's launch prompted greater co-movement of stock prices within the eurozone across national borders, indicating greater financial integration as a result of EMU. Both investigations find that stock market correlations of eurozone member markets with the United States increased after the introduction of the euro more than those between the eurozone countries.

Prospects for the Euro

The euro therefore occupies something of a halfway house. In terms of its purely technical

functions it has been a resounding success, with no problems in acceptance at home or abroad, or in the payments system, and there has been convergence in key eurozone money market interest rates. There has also been evidence of stable low-inflation expectations for the varied eurozone membership as a whole, which remains an outstanding achievement of European central banking. None of the broader forecasts of economic doom or internal political conflict predicted by (mostly American) Chicken Littles came to pass, and those predictions look less credible than they ever did. European financial markets have significantly deepened and added liquidity since the advent of the euro, particularly for fixed-income securities. The sheer size of the eurozone economy as well as the ongoing adjustment of the world economy to US current account deficits propel the euro towards a prominent global role.

At the same time, however, European relative economic performance and growth potential will continue to fall short of that of many other advanced economies and large emerging markets for the foreseeable future. The adoption of the euro and the associated convergence process have failed to induce, let alone produce, the needed transformation in European economic structures, policies and performance. In most scenarios, a collapse of the dollar in coming years, or even an ongoing orderly adjustment involving higher US long-term interest rates and lower net imports, will have at least as great a contractionary effect on the eurozone as it will on the US economy – even if the Asian currencies take on their share of the adjustment burden. And if the Asian currencies, notably the Chinese yuan and Japanese yen, play their part, reserve switches accruing to euro-denominated securities, and their political benefits, will diminish along with the euro's share in the adjustment process. And as yet there has been little evidence of a change in global invoicing patterns from dollars to euros for traded good transactions.

In short, the euro has been a success within limits at home, but the eurozone economy is not yet strong enough – and is unlikely to be so for some time – to challenge the dollar as a global reserve currency or even to be widely utilized outside its borders. The euro, however, is not judged solely on its own merits, either by markets or by the international community, but rather is judged also in relative terms against developments in the dollar zone and elsewhere.

Euro Zone Crisis 2010

Daniel Gros and Cinzia Alcidi

Abstract

The euro zone crisis is commonly regarded as a sovereign debt crisis. This definition certainly applies to Greece, but the Irish case represents an almost pure specimen of a banking crisis voluntarily transformed into a sovereign crisis. A debt crisis in two small, peripheral economies could become systemic because the financial system of the euro area is overstretched and highly integrated. Had the Greek and Irish crises occurred when euro zone banks were strong and/or not very interconnected, the euro zone crisis would not have happened.

Introduction

The euro zone crisis started in early 2010 when it emerged that the Greek government had for years doctored the official data on its deficits and debt. The figures for the deficit and debt level presented by the new government were so much higher than the previous ones that rating agencies and many market participants downgraded their assessment of Greece's ability to service its debt fully. As a result, the cost of refinancing the Greek debt increased sharply and the government could not secure the resources needed to fund its current deficit and roll over the portion of the debt coming due. By the end of April 2010 it had to be bailed out with a €110 billion programme.

The second stage of the crisis came about six months later when it emerged that the Irish government had been 'misled' about the scale of the losses in its banks. As the Irish government had guaranteed all the liabilities of its banks it was now itself on the brink of insolvency. Moreover (although this was not made public at the time), the ECB had become uncomfortable with the huge exposure it had to Irish banks, which had become totally dependent on central bank financing. The ECB therefore pushed the Irish government to recapitalize its banks, but this could be done only with outside help. The Irish government had thus little choice but to apply for external financial support.

With the Greek and Irish bailouts, the euro zone has shown the world two pure specimens of financial crisis: one originated by the mismanagement of fiscal policy (Greece), the other by mismanagement of a credit bubble and banking supervision (Ireland). The Portuguese crisis, which emerged in early 2011, seems to represent a hybrid specimen: a combination of a fiscal crisis (like Greece) and a private debt crisis (like Ireland).

A Brief Chronology

Although Greece accounts for a small portion (less than 3%) of the euro area GDP (and even less of its banking assets), in early 2010 financial markets reacted strongly to the prospect of a sovereign insolvency. A first consequence of the realization that Greece would not be solvent without external financial support was that investors started to price more widely government solvency in the bond market. As a result, the risk premia on the debt of other countries with weak fundamentals also rose. But more important was a generalized increase in risk aversion, which led to a fall in the prices of all risky assets in a similar vein (but of course a much less severe magnitude) as after the collapse of Lehman Brothers in late 2008.

The European banking sector was particularly affected because it was widely believed that a number of banks would not survive a default by Greece. However, which banks held how much of Greek debt was not known. In an environment of widespread risk aversion and many highly leveraged banks this resulted in a drying up of parts of the interbank market, which performs a vital role in the financial system.

The German government reiterated on several occasions its aversion to a bailout, stressing that this must be only an *ultima ratio* mechanism. But when faced with the spectre of a 'second Lehman crisis' and the prospect of large losses in the weak German banks heavily exposed to Greece and other peripheral countries, it had no choice but agree to a rescue package of about h110 billion. This is an EU/IMF rescue package according to which the IMF provides support under a three-year €30 billion standby arrangement (the IMF's standard lending instrument) while euro area members pledge a total of €80 billion in bilateral loans against the implementation of strict austerity measures monitored by the IMF. The sum agreed is supposed to fully finance Greece's remaining deficits (and rollover obligations) during the following three years. It was assumed then (on the basis of experience with 'normal' IMF programs) that Greece would be able to access private capital markets at reasonable rates towards the end of this period. However, in early 2011 it became clear that the hypothesis was far too optimistic. In March the terms and the conditions of the loans to Greece were reviewed to include an extension of the maturity and lower interest rates.

In the spring of 2010, Europe's leaders also thought that Greece was a unique and special case and that no other country would ever need financial support. However, only a few days after the Greek rescue, financial markets went into such a tailspin (risk premia rose, some markets ceased to function) that a new and much larger financing mechanism had to be hastily created.

During the dramatic weekend of 9 May 2010, two financing mechanisms were set up in order to allow the authorities to react to future financial crises in a more coordinated and organized manner. The headline figure of the total potential funding was €750 billion, to be provided by three different entities: €60 billion, guaranteed by the EU budget, coming through a newly created European Financial Stabilization Mechanism (EFSM); €440 billion, guaranteed on a pro rata basis by euro area member states, coming through the also newly created European Financial Stability Facility (EFSF); and up to €250 billion from the IMF.

Together with the ECB interventions in the euro area public and private debt securities markets (Securities Markets Programme) aiming at ensuring liquidity in those market segments judged to be 'dysfunctional', this package did restore stability in the financial markets for a few weeks.

In early June 2010, since tensions in the interbank market persisted, member states and the European Institutions (Commission and Committee of European Banking Supervisors, CEBS) agreed to make public for the first time the results of ongoing stress tests for major European banks.[1]

The rationale for the tests was to disclose information about the state of the European banking system in order to dissipate doubts about their resilience. The Spanish supervisory authorities were particularly keen on this move because they hoped that by showing that their banks were 'safe and sound', it would be easier for Spanish banks to regain access to the interbank market. More generally, the publication of the stress tests was supposed to prove that the most important banks had sufficient capital to withstand even a so-called 'adverse' scenario. This should have improved confidence in the banking system in general.

Yet the objective of the exercise was achieved only temporarily.[2] During the summer of 2010 risk premia on the government bonds of the four 'fiscally challenged' countries (Portugal, Ireland, Greece and Spain) started to increase again. This accelerated after a Franco-German agreement in Deauville on economic governance and the decision by the European Council of 28 October to establish a permanent crisis mechanism to safeguard the financial stability of the euro area. This decision proved to be a watershed because it suggested a change in the ground rules of peripheral euro area debt markets: on that occasion all 27 Member States agreed on the proposal (then submitted to the European Council and implemented in early 2011) for a limited, technical Treaty amendment to provide a legal basis for establishing a permanent crisis mechanism. In March 2011, the European Council adopted the basic features of the new device: the European Stability Mechanism (ESM). The ESM, which will be operational as of mid-2013, is based on the existing EFSF but, unlike the EFSF, the provision of liquidity is conditional to a debt sustainability assessment (conducted by the European Commission and the IMF, in liaison with the ECB). In the event that the analysis reveals that a member state is insolvent, the country is expected to negotiate a comprehensive plan with its private creditors. Moreover collective action clauses (CACs) will be included in the terms and conditions of all new euro area sovereign bonds, starting in June 2013. These clauses should provide the legal basis for the negotiation process with creditors and enable them to pass by qualified majority a decision agreeing a legally binding change to the terms of payment. This could take different forms (standstill, extension of maturity,

[2] See, among others, Veron (2010) and Blundell-Wignall and Slovik (2010).

interest-rate cut and/or haircut) depending on the specific case, but clearly implies that if losses materialize they will be borne, at least partially, by the private sector.

Financial markets did not welcome this approach, and Ireland became the first victim of deteriorating market conditions. Indeed, market pressures on Ireland had started mounting in October 2010, when the Irish government decided to rescue some of its banks that had published losses that were considerably higher than estimated a few months earlier. The high costs of this bank bailout program resulted in a deficit of 32% of GDP, and the risk premia on Irish government (and bank) bonds shot up. As a consequence the Irish government quickly had to ask for external support. On 28 November, an h85bn financial assistance package was agreed and Ireland committed to a sweeping restructuring of its banking system and even more sweeping budget cuts. According to the rescue plan, the EU provides financial assistance for €45bn, through the European Financial Stability Mechanism and the European Financial Stability Fund, together with bilateral loans from the UK (€3.8bn), Sweden (€0.6bn) and Denmark (€0.4bn). The IMF provides h22.5bn and the Irish sovereign €17.5bn through the Treasury cash buffer and investments of the National Pension Reserve Fund. It was also agreed that more than one third of the total package (35bn) was to be destined to recapitalization measures in support of the banking system.

After some hesitation, the Irish parliament did ratify the bailout agreement, but the government fell, new elections were set for 25 February 2011 and resulted in the victory of the opposition who had promised to renegotiate the agreement.

The Irish bailout (as that of Greece) did not have an immediate impact on risk premia and interest rates did not fall (nor for other countries). If anything, the Irish crisis had two major consequences. First it discredited completely the results of the banks' stress tests, as in July 2010 only six small banks had not passed the test and Allied Irish Bank and Bank of Ireland, the two largest Irish banks, both passed the test (Anglo Irish Bank was not included in the tests). Second, it did not allay concerns about the sustainability of Irish debt because the interest charged (close to 6%) on the EFSF loans is much higher than the growth rate Ireland could hope to achieve.

The brief review of the chronology of the crisis shows that Greece was just a trigger and the euro zone crisis is in fact a complex tangle of sovereign debt and banking crises.

The Irish experience has shown that even a government with a strong fiscal position (budget surplus during boom and low initial debt level) can become insolvent in the attempt to save insolvent banks. The sequence of events in Ireland is archetypal: a property bubble ending with a bust leaves a massive housing overhang. This leads to huge losses in banks which had fuelled the bubble with excessive lending. As often happens, the local regulators pretend that there is no problem; but as the losses mount investors pull the plug and the risk of collapse of the entire system increases. This is what happened during the late summer of 2010: as banks were shut out of the interbank market and depositors started to withdraw their funds, the Irish government decided to stand behind the banks and put the entire nation at risk, transforming a banking crisis into the second sovereign debt crisis in the euro zone. A third case of crisis has emerged in early 2011. Portugal has not experienced a bubble as Ireland, neither its fiscal stance is as bad as the Greek one, but the overall financial position of the country is extremely weak. Both private and public sectors have been accumulating excessive levels of foreign debt, which international investors are not willing to finance at sustainable rates and hence increasing dramatically the probability of another bail-out.

The Sequence of the European Council and Euro Group Statements in Response to the Crisis

- **16 February 2010:** The Council focuses on the situation regarding government deficit and debt in Greece, adopting:

(continued)

  - an opinion on an update by Greece of its stability programme, which sets out plans for reducing its government deficit below 3% of gross domestic product by 2012;
  - a decision giving notice to Greece to correct its excessive deficit by 2012, setting out budgetary consolidation measures according to a specific timetable, including deadlines for reporting on measures taken;
  - a recommendation to Greece to bring its economic policies into line with the EU's broad economic policy guidelines.

  http://www.consilium.europa.eu/uedocs/cms_data/docs/pressdata/en/ecofin/112912.pdf
- **2 May:** Eurozone finance ministers agreed upon a rescue package for Greece amounting to €110 billion: €80 billion in bilateral loans over three years and h30 billion coming from the International Monetary Fund.
- **9/10 May:** The Council and the member states decide on a comprehensive package of measures to preserve financial stability in Europe, including a European Financial Stabilization Mechanism, with a total volume of up to €500 billion from euro area countries and European institutions and the IMF commitment to provide funding up to EUR 250 billion.
  http://www.consilium.europa.eu/uedocs/cms_data/docs/pressdata/en/ecofin/114324.pdf
- **29 October 29:** The European Council endorses the report of the Task Force on economic governance. The report also sets out the guiding principles for a robust framework for crisis management and stronger institutions; this includes the involvement of the private sector in the crisis mechanism.

(continued)

http://www.consilium.europa.eu/uedocs/cms_data/docs/pressdata/en/ec/117496.pdf
- **28/29 October:** The European Council agrees on the need to set up a permanent crisis mechanism to safeguard the financial stability of the euro area as a whole. Eurogroup Ministers agree that the European Stability Mechanism (ESM) will be based on the European Financial Stability Facility, capable of providing financial assistance packages to euro area Member States under strict conditionality functioning according to the rules of the current EFSF. Two further elements are key here:
  - First, support will be available only on the basis of 'a rigorous debt sustainability analysis conducted by the European Commission and the IMF'.
  - Second, 'an ESM loan will enjoy preferred creditor status'.

  http://www.consilium.europa.eu/uedocs/cms_data/docs/pressdata/en/ecofin/118050.pdf
- **28 November: (Euro-group statement on the Irish rescue package)** Ministers unanimously agreed to grant financial assistance in response to the Irish authorities' request on 22 November 2010. Ministers concur with the Commission and the ECB that providing a loan to Ireland is warranted to safeguard financial stability in the euro area and the EU as a whole. The total size of the package is h85 billion, one-third of it coming from the IMF.
  http://www.consilium.europa.eu/uedocs/cms_data/docs/pressdata/en/ecofin/118051.pdf
- **16 December:** The Council agreed on the text of a limited amendment to the Treaty on the establishment of a future permanent mechanism to safeguard the financial stability of the euro area. This

(continued)

amendment should enter into force on 1 January 2013. Heads of state reiterated their commitment to reach agreement on the legislative proposals on economic governance by the end of June 2011, with the aim of strengthening the economic pillar of the EMU.

- **24/25 March:** The Council endorses the features of the EMS decided by the euro area Heads of State or Government and takes necessary steps to ensure that the effective lending capacity of the EMS is of EUR440bn. http://www.consilium.europa.eu/uedocs/cms_data/docs/pressdata/en/ec/120296.pdf

The Root Causes of the Crisis: Leverage and Bubbles

The euro zone crisis is certainly not the result of a single cause but the outcome of a combination of several factors and dynamics of macroeconomic, regulatory and institutional nature. These include irresponsible behaviour by several euro zone governments, the steady deterioration in peripheral EMU Member States of macroeconomic fundamentals to levels inconsistent with long-term EMU participation, failures in financial market regulation at global level, shift in markets' expectations induced by the financial crisis of 2007–08 and finally, also, defects in the institutional organization of the European Monetary Union.

All these factors are likely to have played a role in originating the crisis, but even together they are still insufficient to account for its systemic nature. This feature can only emerge from the vulnerability of the highly integrated European financial system. Had the Greek and Irish crises occurred when euro zone banks were strong and/or not very interconnected, the euro zone crisis would not have happened. But the European financial system was (and still is) fragile because of the high level of leverage accumulated over the credit boom.[3]

Excessive leverage is an essential ingredient in any major financial crisis and this case is no exception. In financial markets, leverage is defined as the ratio of debt to equity financing; when this ratio increases in general the capacity of a firm to absorb losses declines and hence its fragility is boosted. In macroeconomic terms, leverage is better defined as the ratio of debt to GDP and the concept can be applied to all the sectors of the economy. Leverage defined this way increases when credit expands without a consistent adjustment in GDP. Since regular cash flows are proportional to GDP, this implies that many agents have issued promises to pay a certain nominal amount but do not necessarily have the 'expected' regular cash flow to honour these promises (see Minsky (2008) for the classical description of leverage schemes leading systems towards instability). It is not possible to establish an absolute benchmark for leverage, as different financial systems can support quite different ratios of credit to GDP. However, rapid and persistent increases in this ratio constitute alarm signals which have been identified as reliable predictors of financial crisis. These signals were clearly blinking before 2007, but they were ignored. Table 1 shows that over the last decade euro zone private debt relative to GDP increased by about 100 percentage points, more than it did in the USA. In addition, and unlike the USA, the increase took place in the financial system, whose fragility became apparent first in 2008 and then again in May 2010.

The question is why and how this could actually have happened.

[3]We leave aside the question of why the build-up of the credit boom was ignored. Inflation targeting by central banks was probably one key reason. According to Borio and Lowe (2002), a low-inflation environment increases the likelihood that excess demand pressures show up in the form of credit growth and asset prices bubble rather than in goods price inflation. If this is the case, inflation-targeting central banks with a 'myopic behaviour' could contribute to financial instability (de Grauwe 2009; de Grauwe and Gros 2009).

Euro Zone Crisis 2010, Table 1 Leverage: euro zone versus USA (*Source:* Federal Reserve, Flow of Funds Z1 (outstanding debt), Eurostat and authors' calculations)

Euro area	Non-financial corporations	Financial corporations	General government	Households
1999	67	66	74	49
2007	93	111	69	62
2010	102	127	87	65
US				
1999	63	76	51	67
2007	74	113	51	96
2010	75	101	76	92

Note: For the euro area debt is computed as sum of loans and securities other than shares, excluding financial derivatives (only loans in the case of HH). This definition broadly corresponds to the definition of the outstanding debt used in the US flow of funds

Euro Zone Crisis 2010, Table 2 Leverage for euro zone selected countries and sector break-down (*Source*: Eurostat and authors' calculations)

	Financial corporations		Non-financial sector		Households and non-financial corporations	
Debt-to-GDP	2000	2007	2000	2007	2000	2007
Greece	132	162	175	219	55	105
Ireland*	450	1142	181	294	151	210
Spain	164	310	187	255	122	214
Germany	273	293	200	196	139	130

Note: Debt is computed as sum of loans and securities other than shares, excluding financial derivatives, only loans in the case of households and including also deposits in the case of financial corporations
Non financial sector includes households, non financial corporations and government
*Data for 2000 are not available, those shown refer to 2001

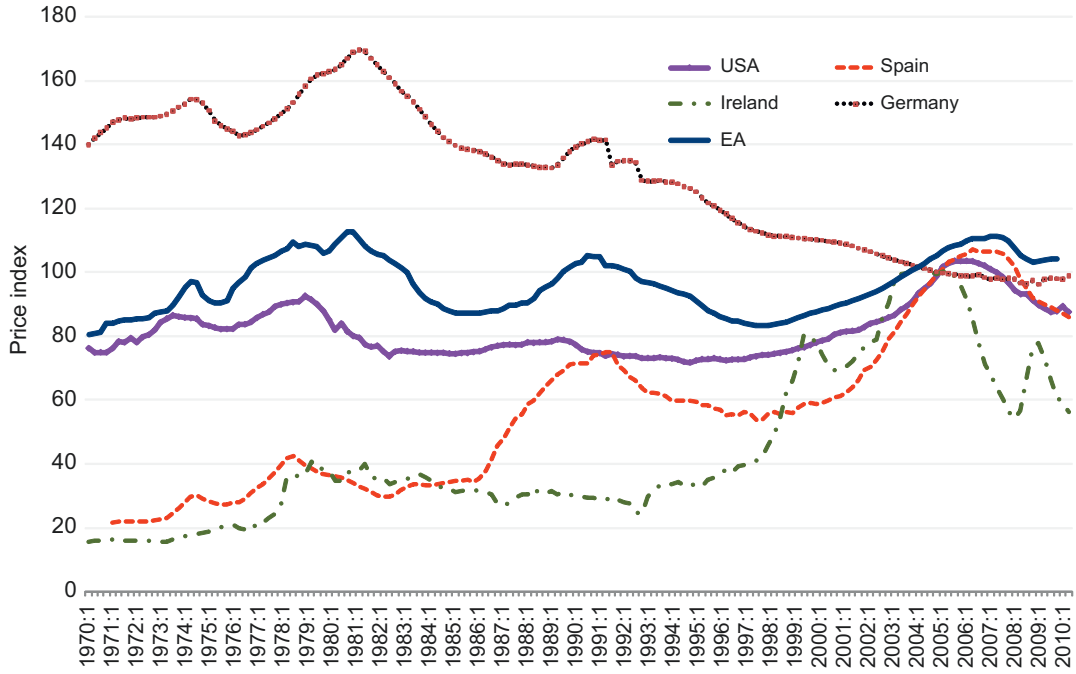
Excess leverage in the banking sector was probably encouraged by scant financial regulation, but it would be too easy to blame car accidents for the absence of speed limits (despite speed limits helping to reduce accidents) or police control. The main driver of growing leverage was of an economic nature and tightly linked to large capital flows flying from core euro zone countries into the periphery after the creation of the euro. The peripheral euro zone economies (Greece, Ireland and Spain) in their catching-up phase appeared to core European Member States with large savings and little domestic investment prospects as a great investment opportunity: they seemed to offer the opportunities of emerging economies, but without the exchange rate risk.

The capital inflows generated their own fundamentals: high growth rates driven by strong demand for consumption and construction investment, supported by easy credit fed from abroad. In all this the financial system, banks in particular, played a crucial role. They made the capital flows possible and magnified the availability of credit through leverage by generating a tight network of intra-sector exposures.

Table 2 shows the level of leverage and the break down by sector in the euro zone countries embedding the most extreme conditions. Data suggest that while leverage barely changed in Germany over the prior decade, in the peripheral euro zone countries, and in particular in Spain and Ireland, the increase was dramatic.

However, it turned out that growth was unsustainable because it was driven by a bubble, and when the bubble burst, banks, not only in the periphery but also in core countries, who were at the origin of the credit flows, found themselves weak (because of high leverage) and very exposed to large potential losses.

The magnitude of the losses was, and still is, potentially very large because some euro zone member countries (notably Ireland and Spain) experienced a real estate price bubble of the magnitude of the USA. Figure 1 provides evidence of



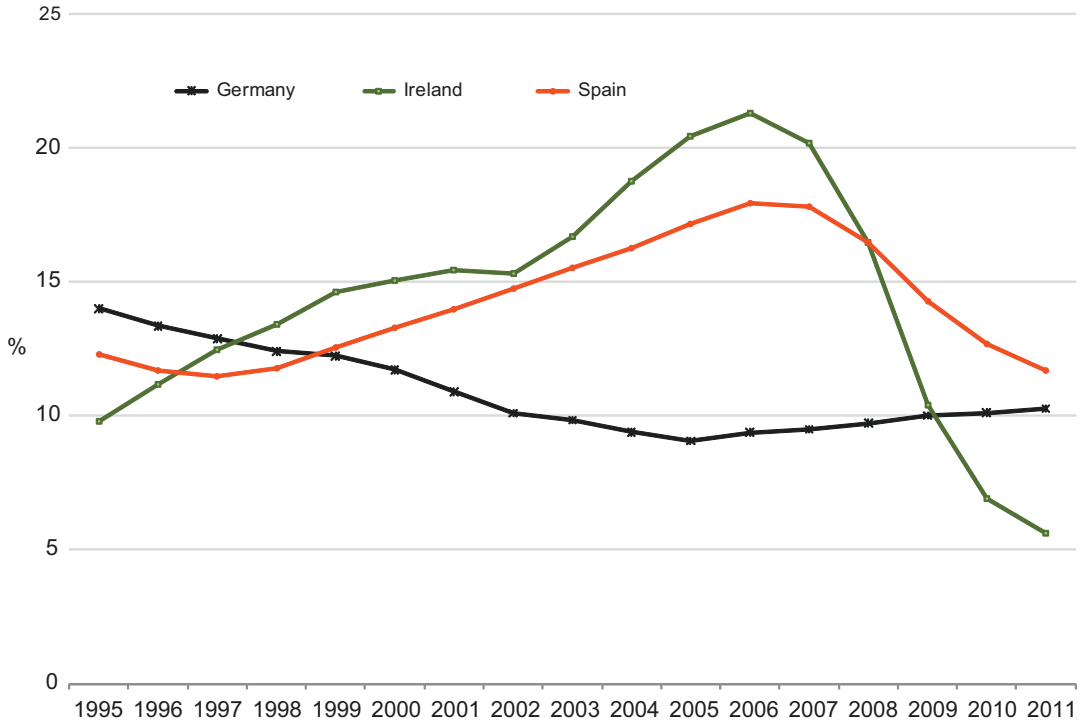
Euro Zone Crisis 2010, Fig. 1 House prices: price-to-rent ratios. *Source*: OECD, March 2011, and author's computations. *Note*: Euro area index is defined as the weighted average (by GDP) of Belgium, Finland, France, Germany, Greece, Ireland, Italy, Netherlands and Spain

this by showing the house price-to-rent ratios. This ratio, similar to the price/earnings ratio for stocks, should be stable over long periods. From the chart it is apparent that since the mid-1990s house prices have increased by almost exactly the same relative amount, reaching an unprecedented level on both sides of the Atlantic. The main difference between the USA and the euro area is that since 2006–07 house prices have declined more in the USA than in the euro zone.

As shown in the Fig. 1, the euro area average hides important differences between countries: Between 1995 and 2006, while house prices have been declining or stable in Germany, they increased by over 80% and more than 140% (more than in the USA) in Spain and Ireland respectively. Furthermore, as shown in Fig. 2, in these two countries the average investment in construction relative to GDP reached 18% and 21% of GDP respectively against an EU average of about 11% (see Fig. 2). This seems to suggest that those countries are destined to suffer for years the consequences of housing and debt overhangs, and dealing with the legacy of national real estate bubbles and busts will remain a challenge for monetary union for some time to come.

This argument is of course related to the so-called 'Walters critique', which holds that a monetary union can amplify shocks because in a country subject to an inflationary pressures the real interest rate will be lower than in the rest of the union. This will fuel domestic demand, which in turn drives inflation even higher, thus lowering real rates even further. This feedback loop is self amplifying and could even be explosive.

However, it seems that in reality the importance of lower real interest rates, defined as nominal interest rates deflated by consumer price inflation, has been overrated. In the case of Spain, consumer price inflation was about 1.6% higher than in Germany over the first 8 years of the euro, but mortgage interest rates were actually over 1% point lower than Germany because they were indexed on short term rates and, even more importantly, house price inflation was 10% points higher than in Germany. This suggests that difference in the characteristics of national financial markets (e.g. the availability of mortgages



Euro Zone Crisis 2010, Fig. 2 Investment in construction % of GDP. *Source*: European Commission Services (Ameco database, Gross fixed capital formation at current prices: construction)

indexed on short-term rates, different loan-to-value ratios etc.) meant that the easing of financial conditions after the creation of the euro had quite differentiated impacts on different member countries (Gros 2009; Baldwin et al. 2010; Calza et al. 2009) with the housing markets playing a key transmission mechanism in Spain and Ireland.

Eurodollar Market

W. P. Hogan

The Eurodollar Market is the term still commonly used to describe international financial activities by intermediaries whereby deposits are accepted and loans made in currencies other than the currency of the country in which the participating intermediary is located. The geographical focus was originally in Europe, especially London, but activities are now located in centres around the world.

The origins of the Eurodollar Market lay in exchange control restrictions on the use of national currencies for capital transactions, including the financing of trade between third parties. Banks and other financial intermediaries having longstanding involvement in the financing of such international trade, sought other means of maintaining their position in this sphere. Funds were canvassed in the one capital market where exchange controls did not apply, namely the United States. Thus dollars were borrowed and used to finance exports and imports between countries other than the country in which the financing intermediary was located. Given this circumstance it was inevitable that the US dollar became the currency of denomination for these transactions. Thus the term Eurodollar Market bears witness to the origins of this international financing arrangement. Nevertheless it remains a fair description as more than 70 per cent of all transactions continue to be denominated in that currency.

London remains the largest centre for Eurodollar activity, followed by New York, Frankfurt and Zurich. Transactions may be determined in these centres. The formal completion of transactions may, however, be registered in 'off-shore' places such as the Cayman Islands and the Bahamas in the Caribbean. By completing transactions in various centres external to the United States, such as those in the Caribbean, US banks avoided restrictions on their portfolios such as the locking up of assets in non-income earning reserve requirements. The US authorities bowed to the realities of this situation when in 1981, they established International Banking Facilities in the United States. Extra-territorial recognition to these activities was given while keeping them on-shore.

With the origins of eurodollar activity in a period of rigorous exchange controls, it might have been expected that the market would stagnate, and possibly wither, when exchange controls were whittled down or abandoned altogether as was the case by the late 1970s in many industrial economies. This was not the case. However, distinctions between the Eurodollar Market and transactions in the national currency of the country in which intermediaries were located, were blurred.

Size and Structure

Estimates of the size of the Eurodollar Market or more correctly the Eurocurrency Market are compiled by the Bank for International Settlement, Morgan Guaranty Trust Company of New York and the International Monetary Fund. The IMF series was not published until 1984 so that most attention has been given to the other two. The series of estimates provided by the Bank for International Settlements (BIS) has been the basis for most analysis. The differences between the BIS series and those provided by Morgan Guaranty are explained largely by timing and coverage.

The BIS series is compiled on gross and net bases, the difference being depositing and lending between participating intermediaries. As is evident from the estimates in Table 1, the growth of lending was spectacular for many years during the 1970s. Only in recent times, with the onset of the debt crisis in 1981/82, has lending slowed.

Eurodollar Market, Table 1 Eurofinance lending, 1972 to 1983 (U.S. $ billions)

Amounts outstanding at the end of year				
	Gross		Net	
Year	Value	%increase	Value	%increase
1972	203.7	–	120.6	–
1973	291.4	43.1	172.1	42.7
1974	363.6	24.8	214.6	24.7
1975	442.4	21.7	254.6	18.6
1976	548.0	23.9	324.6	27.5
1977	671.3	22.5	435.0	34.0
1978	856.4*	28.9	530.0*	21.8
1979	1120.3	30.8	665.0	25.5
1980	1335.4	19.2	810.0	21.8
1981	1550.2*	14.1	945.0*	16.0
1982	1694.5	9.3	1020.0	7.9
1983:I	1757.0	0.4	1085.0	6.4
1983:II	2097.9	–	1240.0	–
1984	2153.9	2.7	1280.0	3.2

Source: Bank for International Settlements, various annual reports and reviews.

Note: *Change in series due to alteration in coverage of countries and transactions. Where the series breaks the estimated rate of growth is based on the old series for that year while the new series is the base for estimating growth in the subsequent year. This is illustrated in 1983 where both series are shown.

The difference between the gross and net series for loans outstanding reflects mainly transactions between intermediaries in the Eurodollar Market, often referred to as 'interbank transactions'. The significance of these transactions lies in the provision of liquidity within the market. Intermediaries, by borrowing and lending amongst themselves, could meet liquidity needs arising from the mismatching of maturities between liabilities and assets. Loss of confidence in the asset quality of intermediaries brought illiquidity from 1982 onwards. Many intermediaries, were not prepared to place funds with other intermediaries, a feature evident in the different rates of growth of gross and net lending.

Estimates of the maturity structure of liabilities and assets are provided by the Bank of England for activities in London. About 40 per cent of liabilities have had a maturity of less than a month with over 20 per cent less than eight days. Assets have a longer maturity, about 32 per cent with maturities of less than a month and more than 22 per cent over one year. Maturity mismatching increased during the 1970s and 1980s.

Vital to any understanding of the impact of this market is the short maturities of these deposit liabilities. The financial intermediaries are constantly seeking new deposits or the rolling-over of existing deposits. Given the size of the Eurodollar Market and the frequency with which new funding is required, foreign exchange transactions have come to be dominated by these capital transactions. A modest estimate would be a turnover of US $150 billions per day and, in all likelihood, closer to double that estimate. The scale of these transactions far outweighs transactions related to trade in goods and services.

Mechanisms

Analyses of the workings of the Eurodollar market remain controversial. Initially the market was treated as an extension of a national monetary system; given the predominance of transactions denominated in US dollars, this was viewed as an adjunct of American banking. This general approach for explaining the growth of the Eurodollar Market was matched by the belief that the function of this market was to 'recycle petrodollars'. What that expression meant was simply the functioning of the Eurodollar Market to take up the balance of payments surpluses of the oil-exporting countries after 1973, and then

again in 1980, to fund the deficits of mainly oil-importing countries.

These interpretations do not stand inspection. The Eurodollar Market is not bound by the actions of any one national supervisory authority. Equally, it is not supported by the activities of any central bank. The participating intermediaries, even though they may be called banks, do not have recourse to lender of last resort facilities. They cannot, as yet, write cheques on themselves; rather they must write cheques on accounts in banks within a national banking system. They accept deposits with a specified term to maturity, often very short, and lend for specified periods with provisions for adjusting interest rates. Lending rates are most frequently quoted as some margin over LIBOR – the London Inter-Bank Offered Rate. The participating intermediaries bid for deposits from business, governments, banks, monetary authorities and wealthy individuals all being resident within national monetary systems, and from other participating intermediaries. They lend amongst themselves and to final users of funds, predominantly governments, banks and business in various countries, most often those with trade and payments deficits.

The Eurodollar Market is not an extension of national banking systems. It is a market in debt, not money. The functions performed by the participating intermediaries are central to an understanding of the impact of that market for not only the substantial debts incurred by many countries but also the balance of payments adjustment and exchange rate relativities.

Issues

The stability of the Euromarket mechanism rested upon the capacity of borrowers to meet their obligations. But in providing a means whereby deficit countries could maintain those deficits and not adjust to worsening balance of payments, the participating intermediaries accumulated an increasing proportion of their assets in the obligations of a relatively few countries. Portfolio risk could not be spread.

Impetus to expansion in the Euromarket was maintained during the late 1970s and early 1980s by the narrowing of margins over the cost of funds to participating intermediaries and slender capital/assets ratios. Although the dangers of such developments were recognised quite early in the 1970s, the Bank for International Settlements was unable to make effective its efforts to get coordination amongst national bank supervisory authorities about activities being pursued in the Euromarket. Efforts by the Bank of England and the Swiss authorities, while valuable within their national boundaries, did not gain that wider recognition which, with hindsight, was all too obviously needed.

An explanation for this failure to gain international coordination is the lack of recognition of problems likely to arise with the system. Attention was focused on individual failure either of a participating intermediary or a borrowing country. Only in the 1980s did the systemic problem become clear. By then modest arrangements for coordination proved inadequate, most obviously with the collapse of Banco Ambrosiano in Italy with repercussions for affiliates in Luxembourg and Switzerland.

The rapid escalation of debt problems for chronic borrowing countries in Eastern Europe, Latin America and Africa brought Euromarket activities to a virtual halt by late 1982. Debt renegotiation strained the capital structure of many participating intermediaries and their parent banks. Most were forced to improve capital ratios and hence liquidity, a not surprising development in view of debt rescheduling stretching the maturity structure of assets.

Direct lending by the participating intermediaries meant that the quality of the borrower was not subject to market tests. That lending activity was opaque, not transparent. By maintaining the flow of funds to chronic deficit countries, adjustment problems for those countries were deferred, but the strains were transferred in part to the participating intermediaries. The inherent weakness of this financing system was revealed when rising interest rates, shifts in exchange rate relativities and weak commodity markets in the early 1980s found the chronic debtor countries unable

to service their borrowings and, in many instances, meet repayments.

One repercussion of the harsh strains on participating intermediaries has been to restore activity in international bond financing. That financing, being directly subject to market tests, is confined to countries not facing chronic debt problems. Moreover, governments and companies from those countries are superior credit risks quite often to many participating intermediaries now bearing the penalties of lending to chronic debtors. Those same intermediaries have been willing to foster new techniques of financing, such as note issuance facilities and revolving credits, to maintain participation in international capital transactions. These new techniques offer possibilities for future strains no less than what emerged through direct lending.

European Banking Union

Corrado Macchiarelli

Abstract

The sovereign crisis that has characterised the eurozone since 2010 has highlighted the potentially vicious circle between banks and sovereigns, adding an extra dimension to the 2007/08 financial crisis. This is why the EU heads of state and government committed to a European banking union in June 2012; a vision that was further developed in the European Commission's blueprint. The aim of the banking union is to ensure that the financial institutions of the – for now – 19 member states will be subject to a single supervision, a single resolution and a common deposit insurance system. This article explains the background to these initiatives and weighs the progress towards their completion.

European Banking Union

European banking union (henceforth banking union or BU) introduces for the first time an integrated approach in supervision and resolution of European banks, representing an important step towards enhancing economic and monetary union. The aim of banking union is to deliver absolute consistency of implementation of new regulatory rules across the euro area (at the time of writing 129 banking groups, representing more than 80% of the euro area banking sector's assets; ECB (2015)), ensuring that the financial institutions of all member states will be subject to a single supervision, a single resolution and a common deposit insurance system. The need for a banking union emerged in response to the 2007/08 global financial crisis and the ensuing sovereign debt crisis in the eurozone. In particular, the sequence of events highlighted the costs of the vicious link between public and private sector debt, and how these can easily overflow national borders and cause systemic risk and failures.

The banking union proposal dates back to June 2012; it covers a preventive stage (regulation and supervision), and a crisis management stage (resolution and safety nets) (European Commission 2012; IMF 2013b).

The first two components of BU, a single European supervisor (the Single Supervisory Mechanism; SSM) and a single resolution authority (the

Single Resolution Mechanism; SRM) have been agreed. The third element of BU, however – a European deposit insurance scheme covering eligible individual deposits in all participating countries – has been stalling, largely because of political opposition from some creditor member states (Germany in particular).

The SSM has been in place since 4 November 2014; this is the date from which the European Central Bank assumed responsibility for bank supervision. The SSM is a key ingredient of the BU, but it is not the only one. In particular, a European approach to the resolution of banks – with the SRM centred on the idea of a Single Resolution Board (SRB) and a Single Resolution Fund (SRF) – needed to follow. The EU adopted a Bank Recovery and Resolution Directive (BRRD) together with an agreement on the SRM from December 2013. This agreement – following on from the SSM already agreed – was significant because it meant that two of the three components of BU have been operational since 2015. Nonetheless, both elements of BU have been somewhat watered down from their original conception. The SSM will *de jure* not be supervising the whole European banking system, with national authorities continuing to supervise smaller financial institutions. Furthermore, unlike the SSM, the SRM will be 'single in name only' (Posen and Véron 2014) as the framework that sets up the resolution mechanism foresees a significant degree of continuing autonomy for national authorities (see the section below on 'Progress Towards Achieving a Banking Union') – particularly on the issue of funding – at least for the next eight years. Progress has been very uneven on the third element of BU as well, with a common approach to deposit insurance having been sidelined during the first stages of the negotiations. Despite a first legislative proposal for a euro-area wide protection for bank deposits that came as late as 24 November 2015, negotiations are currently stalling. The lack of this third element is critical because it means there will ultimately be no European backstop for depositors in the event of a new banking crisis.

If implemented properly, the original vision for BU may be the most far-reaching reform since the inception of the euro (Constâncio 2013). The fact that the BU vision was further developed in the European Commission's blueprint for economic and monetary union (Juncker et al. 2015) reveals the Eurozone's willingness to continue to deepen integration and to put in place a framework making member states' participation in the eurozone 'sustainable' (see also Pisani-Ferry 2012). However, with an established supervisory authority, a resolution mechanism on the way and a delayed agreement on a common deposit insurance scheme, it remains to be asked whether the European banking project can be credible without a fully fledged fiscal backstop.

Background to Financial Supervision in Europe

Financial market regulation under the Basel Accords, as well as the system of EU financial supervision before 2010, were generally characterised by the lack of mutual recognition. The existing Lamfalussy Process envisaged a largely delegated legislation and enforcement system with an explicit legislation in co-decision procedures (see also ECB 2010). The implementation and transposition of detailed rules on supervision and resolution were delegated to three Committees – the so-called 3 Level Lamfalussy (3 L3) Committees: the CESR (Committee of European Securities Regulators), the CEBS (Committee of European Banking Supervisors) and the CEIOPS (Committee of European Insurance and Occupational Pensions Supervisors). Day-to-day supervision was left to national supervisory agencies, with a strict separation of supervision from central banking, both geographically and functionally (see also Masciandaro et al. 2013).

After 2010, such an approach to financial supervision and regulation changed, under the pressure of the systemic nature of the crisis and the de Larosière report. On the legal side, there was a significant tightening of the regulation of banks, with Basel III raising minimum capital ratios and redefining riskiness of assets. Furthermore, the de Larosière Report (de Larosière Group 2009) established a European Systemic

Risk Board (ESRB), chaired by the ECB's President and Vice-President, with the aim of providing macroeconomic supervision of the financial system as a whole. (For a discussion of the governance of the ESRB see Gerba and Macchiarelli (2015).) The ESRB was created at the end of 2010 as a part of a new two-pillar system of financial supervision, the European System of Financial Supervision (ESFS). The report also gave recognition to three European Supervisory Authorities (ESAs) to cover micro-prudential supervision, representing the ESFS second pillar. These three EU-level bodies, being effective as of 1 January 2011, were not created *ex novo*, but they upgraded the existing 3 L3 Committees. In particular,

- the CEBS was upgraded into the European Banking Authority (EBA);
- the CEIOPS was upgraded into the European Insurance and Occupational Pensions Authority (EIOPA); and finally
- the CESR was upgraded into the European Securities and Markets Authority (ESMA).

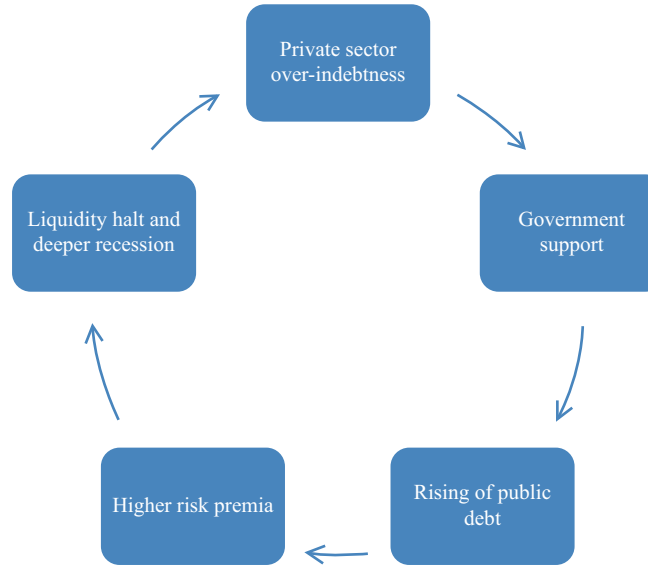
This change in governance structure marked not only the beginning of a greater (than in the rest of the world) involvement of the central bank in Europe, but also the start of a two-pillar strategy ensuring – by means of institutional separation and coordination with national supervisors – a system of checks and balances between macro- and micro-prudential supervision (see also Goodhart and Schoenmaker 1995; Masciandaro et al. 2013; Eijffinger 2013; Goodhart 2014).

The first agreement on banking union came in September 2012. The European Parliament's final 'go-ahead' for the ECB to be fully entrusted with responsibility for the supervision of banks in the framework of the SSM came after extensive negotiations between various stakeholders. This happened one year after the first agreement, on 12 September 2013. The 2012 EU Council agreement appropriately conferred broad investigatory and supervisory powers on the ECB, which – as of November 2014 – is responsible for the effective and consistent functioning of the SSM. National authorities remain responsible for the banks remaining under their direct supervision (the so-called 'less significant financial institutions').

Guidance on the design of an effective supervisory mechanism for Europe was provided in the Basel Core Principles (the so-called 'Core Principles for Effective Banking Supervision'; http://www.bis.org/publ/bcbs30a.htm). According to these principles, a number of preconditions and prerequisites were to be met at the euro area level, including (1) the implementation of coherent and sustainable macroeconomic policies; (2) a clear framework for financial stability policy; (3) an effective crisis management and resolution framework to deal with bank failures and minimise disruptions; (4) an adequate safety net to deal with confidence crisis while minimising distortions; (5) a well-developed public infrastructure; and (6) effective market discipline. On the other hand, as underlined by IMF (2013b), prerequisites to establish a sound basis for the SSM included: (1) its operational independence; (2) clear objectives and mandates; (3) legal protection of supervisors; (4) transparent processes, sound governance and adequate resources; and (5) accountability (see also IMF 2013b; Gerba and Macchiarelli 2015). As we shall discuss in the following sections, after the comprehensive assessment performed by the SSM at the end of 2013, with extensive granular balance-sheet facts being provided and a higher degree of transparency and availability of information to the public, the SSM seems to meet these criteria.

The European 'Doom Loop'

The crisis highlighted the importance of having in place a framework for dealing efficiently and in a timely manner with the resolution of cross-border financial entities (Obstfeld 2013), avoiding the long-term implications on fiscal sustainability of having national governments and banks dangerously tied together (see, *inter alia*, Reinhardt and Rogoff 2013; Gennaioli et al. 2014). These ties essentially intensified during the eurozone's crisis for two reasons. First, banks engaged in *carry-trade* by using 'cheap' central bank liquidity to purchase government bonds (Acharya and Steffen



European Banking Union, Fig. 1 A stylised representation of the European 'doom-loop'

2015). (Central bank liquidity came mainly in the form of three-year long-term refinancing operations (LTRO), with the interest rate fixed at the average rate of the main refinancing operations at the time (1% p.a.) and full allotment of the bids (for further technical details see ECB 2011).) Second, there was a rapid rebalancing of banks' international portfolios towards 'home' assets and bonds (Battistini et al. 2014; Valiante 2015). The latter was possibly the result of risk-shifting (Gennaioli et al. 2014; Farhi and Tirole, 2016; Acharya et al. 2015); discrimination (Broner et al. 2016); and financial repression (Chari et al. 2014; for a general discussion see also Reinhart et al. 2011).

Government guarantees to banks at the expense of higher debt and the inability of regulators to stall the crisis, together with a 'faulty' design of the currency union – centred on a single central bank and multiple Treasuries (see De Grauwe 2016) – are known to be amongst the weighty factors at the root of the private-public European 'doom loop'.

In the euro area, in particular, together with the impossibility of monetising debt (an explicit provision contained in the Lisbon Treaty on the Functioning of the EU – the 'no bailout rule' – art. 125), as of 2010 countries had *de facto* to compete 'internally' over capital flows (Valiante 2015). This was the reflection of an institutional setup built on the idea of 'tying one's hands' – i.e. guarding against government failure by simply agreeing on strict fiscal rules (e.g. the Stability and Growth Pact) and letting markets find their equilibria (Fuest and Peichl 2012). (A key reason for the failure of international capital markets to differentiate sufficiently between countries according to the state of their public finances was that the 'no bailout rule' was just not credible (Fuest and Peichl 2012). In other words, before 2010 financial markets simply did not set incentives to limit government debt in the Eurozone, and very small borrowing premia were to be paid over German *safe-haven* rates.) The sovereign debt crisis that followed confronted almost all non-AAA-rated euro area countries (Greece and Ireland first, followed by others by 2012) with a liquidity dry out, as the result of a flight-to-quality of capital – facilitated indeed by the single currency – towards their 'safer' EMU peers. This translated into higher public borrowing costs, a frailer banking system and overall larger bailout charges *ex post*.

Figure 1 proposes a stylised representation of the aforementioned European doom-loop. This representation does not consider contagion or spillover effects from, or to, other countries, being broadly related to recent literature on doom loops in closed economies (see e.g. Acharya et al. 2015). In this representation, whatever the

entry point is (private sector leverage, unsustainability of public finances, lack of structural reforms) there is a self-reinforcing effect relating to the classical problem of (ir)rational runs in which the market can push an economy into a 'bad' equilibrium (see also De Grauwe and Ji 2013). This amplification within the EMU had to do, firstly, with a collapse of confidence in certain markets and institutions at the same time, and the broader fragility of financial systems, because of increased counterparty risk or asymmetry of information (see also IMF 2013a). Secondly, it was linked to the distressed financial sector inducing government bailouts (or private sector *deleveraging*; see Acharya et al. 2015). The latter, in particular, created a vicious interaction between asset prices (via banks' balance sheets) and borrowing constraints (Borio and Zhu 2012; Brunnermeier and Pedersen 2009; De Grauwe and Macchiarelli 2015), where – simplifying – the fire sale of government bonds in some countries (as the result of confidence loss and excessive debt taking) increased sovereign credit risk, in turn weakening the financial sector, with an ensuing liquidity dry out and freezing of lending to the real economy. Overall this eroded bond holdings and the value of government guarantees, requiring further support, and so on.

Why a Banking Union for Europe?

The governments' last-resort guarantees to their own financial institutions were initially granted in an uncoordinated manner within the EU. Government asset support mainly took two forms (see also Gros and Schoenmaker 2014): asset insurance schemes, which maintained the assets in the banks' balance sheet, and asset removal schemes, which transferred the assets to a separate institution (bad bank). Purchases of impaired assets often occurred after earlier government capital injections. In the case of bank debt guarantees, approximately half of those that received capital injections also received government guarantees for their bank debts. Coordinated support happened only later and was led by the European Commission in the context of its State Aid policy, with the aim of preserving an EU integrated financial market. Before the Commission launched a bank recovery proposal, a number of EU countries, including Austria, Belgium, Denmark, France, Germany, Ireland and the UK had already put in place new rules for the resolution of their distressed banks. Such repeated bailouts not only increased sovereign debt, but also imposed a large encumbrance on taxpayers. The state aid measures that were used, in the form of recapitalisation and asset relief measures between October 2008 and December 2012, amounted to €591.9 billion or 4.6% of EU 2012 GDP, with the highest share belonging (in order) to Ireland, the UK and Germany (European Commission State Aid Scoreboard's (2013) figures. Available at http://ec.europa.eu/competition/state_aid/scoreboard/amounts_used_2008-2012.xls). Including approved aids and guarantees, this figure jumps to over 12% of EU GDP for the period 2008–12 only. In the euro area, 37% of capital injections and 63% of the asset relief measures were granted to the three largest financial institutions (see also Gros and Schoenmaker 2014).

Beyond government upkeep, central banks provided unprecedented liquidity support to illiquid (and insolvent) banks as well. Specifically, the European Central Bank during the first stage of the crisis focused its programme – albeit not exclusively – on direct lending to banks (see the preceding section), reflecting the bank-centric structure of the euro area financial systems (see also Gabor 2014; ECB 2014). This was different from the Federal Reserve and the Bank of England, which expanded their respective monetary bases largely by purchasing bonds in the first place.

Looking at the recent history of bailouts, the advantage of a permanent bank supervision and resolution framework, as compared to the *ad hoc* measures that were employed during the crisis, primarily resides in its transparency regarding the list of eligible institutions and the conditions of access to funding. Second, it introduces a limitation to free-riding derived from unlimited recourse to public money, allowing overall a balanced burden-share between private investors and taxpayers, possibly resulting in lower funding

costs *ex post*. At the same time, the BU proposal recognises the systemic nature of risk facilitated by the single currency, and the potential dangers and domino effect that 'systemically important' financial institutions would have, given their cross-border reach, within the E(M)U (see also Obstfeld 2013; Gros and Schoenmaker 2014; Goodhart 2014). Finally, the proposal acknowledges the issue of the moral hazard of national governments both over time – with a tendency to offload the costs of restructuring the domestic banking sector to future governments – and across countries – particularly, relying on the ECB's and European Stability Mechanism's last resort support. The latter two points relate to the literature analysing the combination of limited commitment on the part of the government *ex ante*, and the possibility of bailouts *ex post* (see, among others, Acharya and Yorulmazer 2007; Chari and Kehoe 2016; Farhi and Tirole 2012). In particular, this literature highlights a mechanism by which government bailouts are provided only when a sufficient number of financial institutions are in trouble *ex post*, so that strategic complementarities in financial risk-taking arise: i.e. individual financial institutions may engage in higher financial risk-taking *ex ante* the higher the collective risk-taking, as this increases the likelihood of a government bailout *ex post*. The existence of such complementarities and systemic risk thus provides a rationale for macro- and European measures. (Broner et al. (2016) put forward another rationale for a BU: a BU is thought to reduce discrimination between domestic and foreign investors.)

Legal Underpinning

The legal foundation of BU is contained in a single rule book made up of three main elements.

1. A set of **rules on capital requirements** (Capital Requirements Directive – CRD IV).

These rules entered into force on 1 January 2014, and replaced the original Capital Requirements Directives (2006/48 and 2006/49), transposed the international Basel III agreement into EU regulation and ensured that banks hold a sufficient buffer to withstand potential losses.

2. The proposal for strengthening the **Deposit Guarantee Schemes Directive** (DGSD) (Revision of Directive 94/19/EC).

The aim of the latter was to harmonise and simplify deposit guarantee rules in the EU and improve the functioning of the existing guarantees across the board, with protection of deposits up to €100,000 (from the existing €20,000 limit). According to the directive, all credit institutions will be required to join the DGS instituted at the national level. The Council has reached a political agreement with the European Parliament on the revised directive, with the Parliament formally adopting this revision in April 2014.

3. **Bank Recovery and Resolution Directive** (BRRD) (Directive 2014/59/EU).

This directive gives powers to authorities across the EU to act effectively to prevent bank crises and to ensure orderly restructuring and resolution in the event of bank failure. The aim is to avoid negative effects on financial stability and to reduce recourse to taxpayers' money, avoiding replicating the scenario seen during the first stage of the crisis. The directive followed a Commission proposal in June 2012. The European Parliament and the member states reached an agreement on 11 December 2013. These new rules, which entered into force on 1 January 2015, established that the costs of bank failure will in the first instance be borne by bank shareholders and creditors, according to a clearly defined hierarchy, and thereafter met from dedicated resolution funds held by each member state.

Progress Towards Achieving A Banking Union

Common Bank Supervision

A European single supervisor (SSM) became operational in November 2014 (see section on 'Background to Financial Supervision in

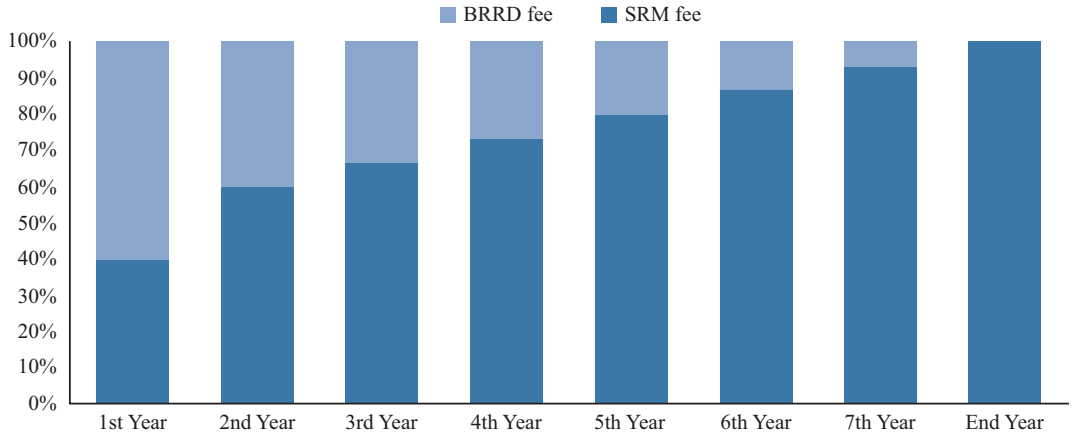
Europe'). Under the SSM, responsibility for bank supervision in the euro area was shifted from national authorities to the European Central Bank. The ECB is in charge of supervising 'systemically important' banks directly (equal to more than 80% of euro-area banking assets, including banks with over €30 billion in assets or 20% of national GDP, or 'if otherwise deemed systemic'). National authorities will continue to supervise smaller financial institutions. (In September 2014, the ECB published the list of significant supervised entities. The latest release (31 May 2016) with change in significance for some banks is published here: https://www.bankingsupervision.europa.eu/ecb/pub/pdf/list_of_supervised_entities_20160331.en.pdf.) The latter arrangement was essentially a political one, championed by some member states – Germany primarily – wanting to keep direct monitoring of 'local' institutions. The federal approach that emerged as a concession to local banks' lobbies highlights how banks' management in some countries cultured a strict affiliation with the political establishment and local electorate (Valiante 2015), largely through 'not-for-profit' credit institutions such as foundations (e.g. the Spanish Cajas and the German Landesbanken). Overall, however, while smaller banks were *de jure* exempted from direct SSM supervision, the €30 billion threshold has *de facto* left the majority of the eurozone banking assets under the SSM's umbrella – including almost all German Landesbanken (Posen and Véron 2014). Furthermore, the ECB will set and monitor supervisory standards and work closely with the national competent authorities for these banks, with the option of expanding its remit and supervising them directly in order to ensure that SSM standards are applied consistently (ECB 2014, 2015).

To conclude, while the design of a common bank supervisor is far from faultless, given the challenge to financial stability that small financial institutions may pose, these challenges in terms of supervision are, for the moment, not large. (It is worth noting that the majority of 'local' banks in the EMU are concentrated in Germany, and, to a lesser extent, Austria and Italy; see Véron's blog entry on Bruegel: 'Europe's Single Supervisory Mechanism: Most small banks are German (and Austrian and Italian)', 22 September 2014.) The current SSM design represents an adequate compromise given the existing trade-off between political feasibility and economic 'first-best' in Europe. In addition, achieving a truly single market in banking services will possibly require more time than a couple of years, with further supervisory initiatives, as well as regulatory and legislative steps, having to be adopted in the future (see also Schoenmaker and Véron 2016).

The Single Resolution Mechanism

The SRM was first proposed by the European Commission in July 2013. This mechanism came to complement the SSM as of 1 January 2015. Countries joining the SSM are to join the SRM too, which means that the SRM applies to banks in the euro area member states under the SSM, plus those EU countries wishing to opt in. The SRM is built on the national resolution authorities established by the BRRD. The SRM aims to ensure that if – despite SSM supervision – a bank faces serious difficulties, its resolution would be managed in a centralised manner, with minimal cost to taxpayers and the real economy; which is one of the focal points of BU.

The SRM consists of a resolution authority (or Single Resolution Board – SRB) and a Single Resolution Fund (SRF). The SRB became operational in January 2015, but it started to work at full capacity one year later, on 1 January 2016, the date when the SRF was also on the schedule. The Finance Ministers of the member states have decided to keep some elements of the functioning of the future SRF in the form of an intergovernmental agreement, which complements the SRM regulation. According to the terms of reference of the agreement, the fund is to be financed by bank levies raised at the national level. As a general rule, banks taking higher risks will pay higher contributions. Contributions, initially consisting of national compartments, which will be progressively mutualised and eventually merged into a single fund administrated by the Board, start with 40% of resources in the first year. National



European Banking Union, Fig. 2 Evolution of phasing-in (−out) of contributions to SRF (from national target levels in accordance to the BRRD) (*Source*: ECB (2015) data)

compartments would cease to exist when the fund reaches the target funding level of 1% of covered deposits in the participating member states or after an eight-year transitional period – i.e. by 2024.

Under the SRM Regulation, the SRB is required to calculate the contribution from each individual bank to the SRF each year. Contributions are determined by applying the method detailed in a Commission delegated act and the specifications provided for in a Council implementing act, adopted respectively on 21 October and 19 December 2014. The establishment of the SRF will thus entail a shift from national to European resolution, which has the implication that each member state's banking sector will progressively contribute more to the European resolution fund with respect to what they will be contributing to the national fund under the BRRD. This is summarised in Fig. 2.

The SRF has an overall target level of €55 billion. While this amount may seem small in principle – given the need to signal to the markets that a reliable backstop exists (see also Macchiarelli 2014; Gros and Schoenmaker 2014) – one should consider that the fund has been given the ability to borrow directly from the market, if decided by the Board (ECB 2015); the terms and conditions of this have not been disclosed yet. Secondly, explicit provisions for bailing-in exist, as detailed by the revised BRRD (SRF website, https://srb.europa.eu/en/content/bail (accessed August 2016)). Bailing-in would apply until at least 8% of banks' total assets had been used. After this threshold, the resolution authority may grant the bank the right to use the resolution fund, up to a maximum of 5% of the bank's total assets. Some have observed how the actual procedures for bailing-in may not only risk cutting credit in already fragile economies, but could also reduce the willingness of lenders to extend new credit, having overall a negative effect on the financial conditions of that country.

Bank contributions to the SRF began in January 2016. However, a plan on bridge financing was put in place in the context of the Five Presidents' Report (Juncker et al. 2015) in order to avoid a situation in which the SRF would run out of monies while bank contributions were being consolidated. The agreement, which was reached by the Council of Ministers in December 2015, introduced public support through the establishing of national credit lines that would provide a loan to the SRF in the case of capital shortfalls before 2024. As well as providing support where needed, the establishment of credit lines is intended to enhance the standing of the SRF. Importantly, a common backstop to the SRF itself should follow before the end of the transitional period, as a last resort measure, in order to ensure the durability of the BU project as a whole, as the Five Presidents' Report also recognises (Juncker et al. 2015). (See also Communication

from the Commission to the European Parliament, the Council, the European Central Bank, the European Economic and Social Committee and the Committee of the Regions, 'Towards the completion of the Banking Union' COM (2015) 587. Available at http://eur-lex.europa.eu/legal-content/EN/TXT/?uri = CELEX:52015DC0587.) This will be difficult to achieve in the short term as it will require a more far-reaching fiscal agreement among the member states (for an extended discussion see the following section).

Banking Union and Fiscal Backstops

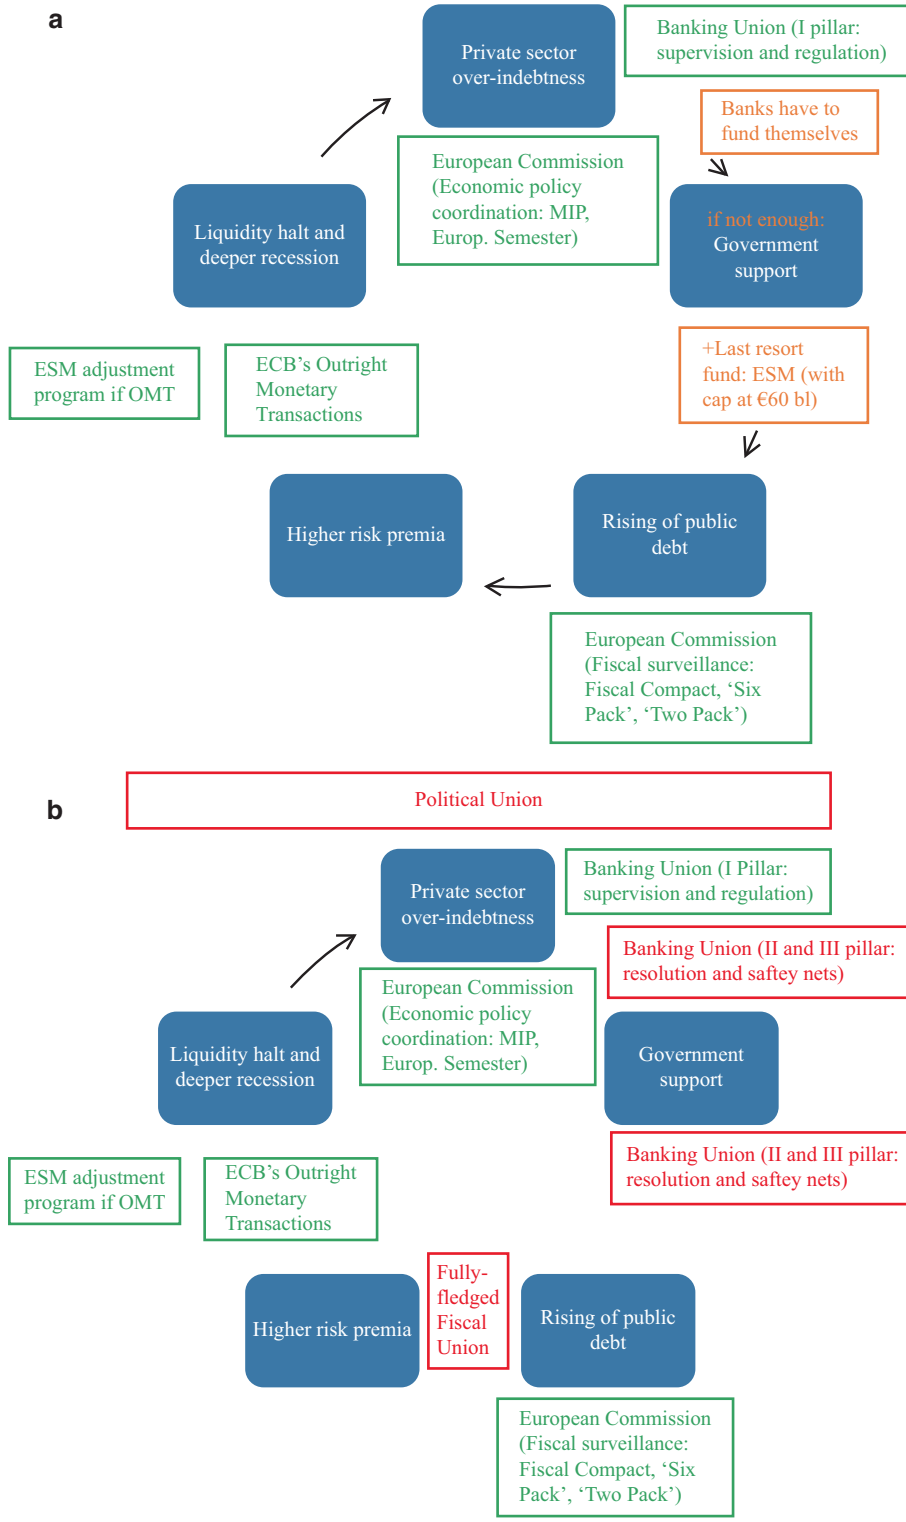
While it is widely recognised that the proposals and compromises reached to deal with deposit insurance and resolution represent an exceptional step forward, many member states underscore that a well-functioning BU will require an unlimited burden-sharing mechanism, where fiscal authorities have to be involved. As highlighted above, the current design of the BU still leaves a role for an intergovernmental agreement, particularly in deciding the role and functioning of the future SRF – as a complement to the SRM regulation – before its final consolidation by 2024. Furthermore, the Commission's deposit insurance mechanism (EDIS) is still on the negotiating table. Hence the stage in the governance framework that is lacking is the fiscal backstop.

The existing national DGSs and resolution funds – before a common backstop is created – may quickly run out of money and need last-resort support from sovereigns. This, however, was the origin of the so-called doom loop, pushing even countries with a sound fiscal record into a wrecking spiral, as the cases of Ireland and Spain show. Should this be the case, the sovereign will then need a backstop itself. In Fig. 3a, b we have used the 'doom loop' representation of Fig. 1 to summarise this discussion. The figure particularly compares (a) the current state of BU with a representation of (b) fully fledged BU in the context of the GEMU.

The current state of BU is an incomplete banking union which could create coordination failures and be costly overall (Posen and Véron 2014). As mentioned above, leaving resolution funding and safety nets predominantly at the national level or, equally, limiting the BU's 'federal' reach and burden-sharing capacity, would mean perpetuating the bank–sovereign doom loop, which is what the BU is intended to break. Alternative arrangements exist, but it remains to be seen whether these are convincing.

Figure 1(a) highlights a role for the European Stability Mechanism (ESM), as a last resort support. The ESM was primarily created with the purpose of providing a fiscal backstop for member countries and (more recently) their banking systems. However, the stability of banking systems can be assured only if investors know that such a backstop is not limited *ex ante*. This is why many commentators have defined the ESM as a 'poor surrogate' for a last-resort lender (De Grauwe 2011). The main reason why the European banking sector needs a common backstop is fundamentally macroeconomic and has to do with the very nature of systemic risk (Gros and Schoenmaker 2014; see also Allen et al. 2011). Once all of the above is in place (SRF plus EDIS), in the great majority of cases no public support will be needed. But in exceptional circumstances, for relatively large shocks, additional resources might be necessary, and clear arrangements on backstops should be made. Thus, the stability of banking systems can be assured only if investors know that such a European backstop exists, and the current ESM capacity can hardly be credible (see also Gros and Schoenmaker 2014).

Secondly, there are agency costs to consider, as the ECB/SSM may itself be trapped in a fiscal dominance game (see also Goodhart and Schoenmaker 1995; European Parliament 2012). The existence of a transition period before the SRM and the EDIS (whose deadlines for full functioning are aligned) makes it possible that, until resources are fully mutualised, the SSM will have an incentive to offload the fiscal cost of any problem to national authorities if it thinks that any given bank is insolvent and needs to be restructured or closed down. The SSM would do this on the basis of its comprehensive assessment of the viability of the bank and any danger it might constitute for financial stability. By contrast,



European Banking Union, Fig. 3 (continued)

national authorities in charge of bank restructuring would have a tendency to minimise their own costs by keeping the bank (even if illiquid) solvent through ECB support. This leaves some grey areas in the crisis management capacity of the BU (ECB 2015), with this type of conflict being prevalent between now and the start of the new system, when mutualisation is low. The endgame would be accelerating the process of consolidation of European deposit insurance and resolution schemes, thus minimising potential costs and avoiding providing the SSM and national authorities with the wrong incentives. (Other inter-agency conflicts and fiscal dominance may arise in the context of keeping two different coffers for European deposit insurance and resolution, respectively (for an extended discussion see Gros and Schoenmaker 2014).)

The nature of fiscal backstops beyond resolution and safety nets will be a crucial issue to define in the coming years.

Safety Nets

Authorities are now equipped with a broad set of tools to ensure that the costs of bank failure will, in the first instance, be allocated to bank shareholders and creditors following a clearly defined hierarchy (bailing-in), and only later involve dedicated resolution funds held at the national level (bailing-out). (Higher coverage will be granted for deposits related to certain transactions (e.g. real estate transactions and payment of insurance benefits). See ECB (2015).) In particular, as far as deposit protection goes:

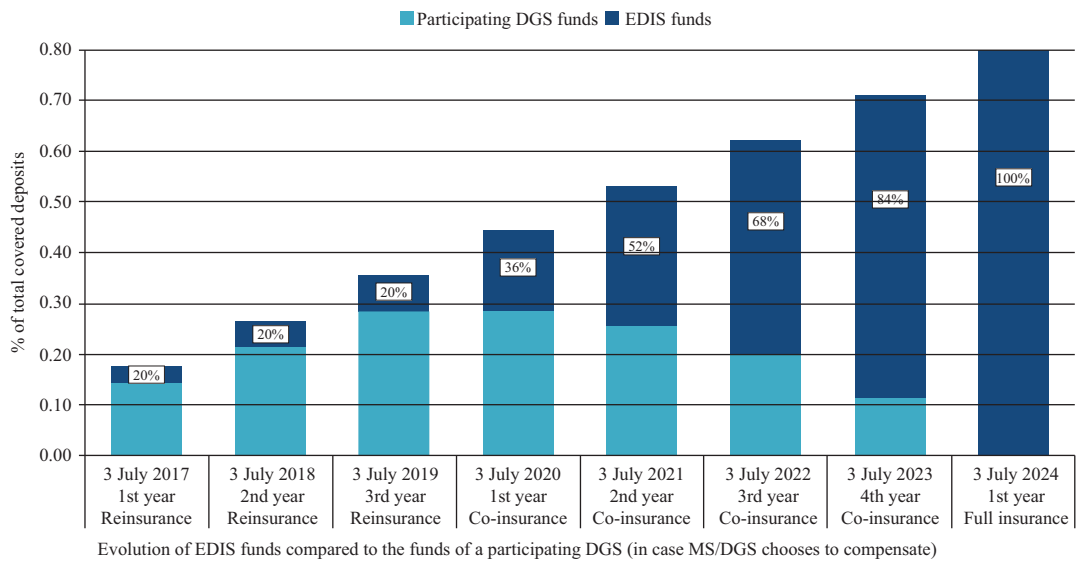
- Citizens' covered deposits up to €100.000, representing about 48.6% (47.3%) of total euro area (EU) deposits, will be exempt from any loss. This number goes up to 70.9% (66%) for the euro area (EU) if the eligible over total deposits ratio is considered (author's computation from Cannas et al. (2014) data).
- Deposits of natural persons and SMEs above €100.000 will benefit from preferential treatment (they will not suffer any losses before other unsecured creditors do).

The Deposit Guarantee Schemes Directive (DGSD), which was transposed by the member states into national law in July 2015, concentrated on harmonising existing national deposit guarantee schemes without any common funding element. While regulators agreed to an increase in the minimum coverage of insured deposits from €20,000 to €100,000 and an increase in the speed of repayment for insured depositors, the most worrying gap is that of the unification of deposit insurance within the banking union.

In November 2015 the Commission put forward a legislative proposal to fill this gap, i.e. a European deposit insurance scheme (EDIS), taking a concrete step towards completing the third leg of BU. This is a very significant proposal, as the absence of a union's deposit guarantee that could credibly back it underscores the dangers of incompleteness. A DGS funded at the European level would, in this case, make a material difference because it would provide an external loss absorption device that would be independent of the fiscal position of that sovereign (Posen and Véron 2014). Yet the EDIS has still to be approved, and it is currently stalling owing to political opposition.

The DGSD stipulates new thresholds for the financing of the national Deposit Guarantee Scheme (DGS), notably by requiring a significant level of *ex ante* funding (0.8% of covered deposits – or, where viable, a target level of 0.5% of covered deposits for highly concentrated banking systems) to be built up by 2024 by each member state. By that date, the Commission's proposal envisages that resources will be mutualised in the EDIS. With the EDIS, the protection of deposits

European Banking Union, Fig. 3 European banking union. (**a**) Current state of European banking union; (**b**) European banking union in the context of the GEMU – in theory (*Note:* The figures include the main reforms of the European economic governance framework already in place (*green*); measures to be adopted during the transition to a BU (*orange*), and measures not yet in place (*red*). They do not consider measures which are temporary in nature such as unconventional monetary policy)



European Banking Union, Fig. 4 Evolution of EDIS and participating DGSs funds in the Commission's proposal (*Source:* European Commission website – European deposit insurance scheme)

would be fully guaranteed at the European level, supported by close cooperation with national DGSs (Fig. 4). Given that national DGSs may remain vulnerable to idiosyncratic shocks, the purpose of EDIS would be to ensure equal protection of deposits in a centralised manner.

In the period elapsing between now and the EDIS, harmonised national deposit guarantee schemes will be necessary, meaning that member states concerned by a particular resolution plan will have to provide bridge financing from national sources (ECB 2015). In particular, if capital shortfalls are identified, the Council clarified on 15 November 2013 the order of the backstops. In the case of insufficient *ex ante* funds, the DGS must collect *ex post* contributions from the banking sector. Exceptional contributions should not exceed 0.5% of covered deposits per year. In the first instance, banks will thus have to raise capital in the market or raise capital from another private source. Should this not be sufficient, public money could be engaged at the national level in line with state aid rules and, if needed, through the provision of public backstops. Here, the DGS may have access to alternative funding arrangements, such as loans from public or private third parties. The DGSD also establishes a voluntary mechanism of mutual borrowing between DGSs from different EU countries (ECB 2015), the viability of which has still to be tested, particularly given the possibly competing interests of debtor and creditor countries.

Should national backstops not be sufficient, instruments at the European level may finally be enabled, including the ESM, consistent with the ESM's agreed procedures. On the latter point, the Eurogroup agreed that the ESM would have the possibility to recapitalise 'systemic and viable' banks directly, with maximum exposure for direct bank recapitalisations capped at €60 billion (equal to 12% of the ESM's maximum lending capacity).

Given the uncertainty about the full viability of the project in the medium to long term, information to markets and depositors should be prepared and coordinated.

Managing 'The Outs'

One issue with the current approach to the European BU is that it minimises the importance of cross-border externalities of bank failures across the EU. Given the skewed design of the BU towards the euro area member states, the problem of funding is likely to be more severe when it

involves guarantees to or resolution of banks which are systemic in both euro area and EU-non-euro area countries. For that reason, some of the 'outs' may make use of their option to opt-in to BU going forward (Gros and Schoenmaker 2014), provided that European resolution and deposit insurance schemes will be available. In this respect, the UK's vote to leave the EU will place both the EU and the UK in uncharted waters, given the large presence of important European banks in London, and in the absence of clear rules on cross-border banking supervision and resolution under BU across EU and non-EU member states.

Final Remarks

A European banking union centred on the idea of single supervision, single resolution and a common deposit insurance system may be the most far-reaching reform to date since the inception of the euro (Constâncio 2013), if successful. Overall, however, the political resistance of creditor countries may restrain the effectiveness of crucial elements of BU, such as resolution and safety nets. A credible banking union would entail moving responsibility for potential financial support from the national to the supranational level, implying transfer of resources and risk, and, henceforth, requiring an explicit agreement on fiscal European support in the longer term. The latter agreement is a necessary step in the broader context of the European governance framework (see ▶ Genuine Economic and Monetary Union), in particular in achieving long-term 'sustainability' (see also Pisani-Ferry 2012; Gros and Schoenmaker 2014; Posen and Véron 2014; Schoenmaker and Véron 2016). For the time being, political resistance mainly focuses on the issue of permanent and unlimited vs. temporary and limited burden-sharing, leading to a 'small steps' approach.

An incomplete banking union can create coordination failures and could be costly overall (Posen and Véron 2014). An incomplete union can be interpreted in two ways. One is that it is a sequence in which much remains to be settled, but with reasonable clarity about the eventual destination. In this interpretation, the principal policy challenges will be how to manage the transition until 2024. The alternative explanation is that political resistance to burden-sharing will mean that only an incomplete banking union can be attained in fact. As mentioned above, leaving resolution funding and safety nets predominantly at the national level – i.e. the current state of BU – or, equally, limiting the BU's 'federal' reach and burden-sharing capacity, would mean perpetuating the bank–sovereign doom loop; which is what the BU is intended to break. The nature of fiscal backstops beyond resolution and safety nets will be a crucial issue to define in the coming years.

Abstract

The establishment of the European Central Bank (ECB) and with it the launch of the euro has arguably been a unique endeavour in economic history, representing an experiment of hitherto unknown magnitude in central banking. This article aims to describe the main aspects of the set-up and the responsibilities, strategy and operations of the ECB. It also aims to summarize some of the main lessons learned from the establishment of the ECB for monetary economics, and to sketch some of the prospects for the ECB and the euro.

The European Central Bank (ECB) was established on 1 June 1998 and since 1 January 1999 has been responsible for the conduct of a single monetary policy for its member countries, namely, Austria, Belgium, Finland, France, Germany, Ireland, Italy, Luxembourg, the Netherlands, Portugal and Spain (with Greece subsequently becoming a member country on 1 January 2001 and Slovenia on 1 January 2007). Among European Union (EU) member countries Bulgaria, Czech Republic, Denmark, Estonia, Cyprus, Latvia, Lithuania, Hungary, Malta, Poland, Romania, Slovakia, Sweden and the United Kingdom are, as of 2007, not member countries of the ECB. These countries for the time being either have opted out of becoming member countries of the ECB (Denmark, Sweden and the United Kingdom) or have – according to the judgement of the EU Council – not yet achieved the necessary degree of economic convergence.

The launch of the ECB was the culmination of a process of monetary and economic integration that dates back at least to the efforts of the French government official Jean Monnet and others in the 1950s and gained decisive momentum with the April 1989 report of a committee headed by the then President of the European Commission, Jacques Delors, which drew up a blueprint for the progressive realization of the European Economic and Monetary Union (EMU). The establishment of the ECB and with it the launch of the euro (the currency of the ECB member countries for which banknotes and coins first went into circulation on 1 January 2002) has arguably been a unique endeavour in economic history, representing an experiment of hitherto unknown magnitude in central banking. In what follows, we shall describe the main aspects of the set-up and the responsibilities, strategy and operations of the ECB, discuss what appear to be the lessons learned from this experiment for monetary economics, and sketch some of the prospects for the ECB and the euro.

Lesson One: How to Converge?

There can be little doubt that the European Council's June 1989 decision to pursue the Delors Committee's blueprint of a feasible path towards monetary union for its member countries was primarily driven by political considerations, viewing monetary union as a building block towards tighter political and economic integration of the member countries of the EU. However, given the broad consensus among economists and policymakers that, ideally, economic similarity rather than political boundaries should define the

geographic area spanned by a common currency, the Delors report put considerable emphasis on realizing economic convergence before the establishment of a single European central bank. Key elements of the three stages to realization of the EMU as envisioned by the Delors Report were

- Stage 1 (1 July 1990): improvement of economic convergence; abolition of restrictions on cross-country flows of capital; increased cooperation between national central banks.
- Stage 2 (1 January 1994): strengthening of economic convergence; establishment of the European Monetary Institute (EMI) as predecessor of the ECB to strengthen cooperation between national central banks and increase coordination of monetary policy.
- Stage 3 (1 January 1999): completion of the necessary economic convergence; irrevocable fixing of currency conversion rates; single monetary policy to be conducted by the European System of Central Banks (ESCB).

It was envisioned in the Delors plan (and enacted in the Maastricht Treaty, which established the EU, as signed in February 1992) that only those countries should become member countries of the EMU that were successful in accomplishing economic convergence. The convergence criteria (Maastricht criteria) were meant to specify a sufficient degree of economic similarity of member countries with respect to price stability, sustainability of fiscal policy, exchange rate stability and the level of long-term interest rates. In particular, with respect to price stability member countries' average rate of inflation in the year preceding completion of the EMU was to fall within a one and a half per cent interval of average inflation in the three member countries displaying the highest degree of price stability. With respect to sustainability of fiscal policy, member countries were supposed not to carry an 'excessive deficit' – which would occur if the actual or planned government deficit to GDP ratio exceeded three per cent or if the ratio of government debt to GDP exceeded 60 per cent. Concerning exchange rate stability, member countries would in the two years preceding completion of the EMU have to keep the fluctuations of the value of their currency within the bands provided for by the European Exchange Rate Mechanism (ERM) and in particular not initiate any devaluation of their currency against that of any other member countries. Finally, with respect to the level of long-term interest rates, member countries' average long-term interest rates (on government bonds or comparable securities) in the year preceding completion of the EMU were to fall within a two per cent interval of average long-term interest rates in the three member countries displaying the highest degree of price stability.

Of course, economic similarities desirable for an optimal currency area do not end with these four criteria, but inter alia also include similarities in the monetary transmission mechanism, the coherence of the shocks and of the propagation mechanisms driving national business cycles as well as similarities in the prospects for trend output growth. These latter criteria were not part of the Maastricht criteria, though it was widely hoped that the economic convergence process prior to or immediately after the formation of the ECB would result in these latter criteria being approximately met as well.

Despite the relatively modest requirements for economic convergence in the Maastricht Treaty, the goal of EMU was jeopardized during the 1992–3 crisis of the ERM when foreign exchange market participants widely viewed the ERM's margins of fluctuation of two and a quarter per cent as not sustainable in the light of at best limited coordination of monetary policy, especially in Germany, with that in several other countries in the EU, specifically that in Italy and in the United Kingdom. The fact that despite the widening of the ERM's margins of fluctuation to 15 per cent in August 1993 the goal of EMU was maintained appears to have been due to the commitment of some of the then political leaders of the EU – perhaps most notably the then German Chancellor Helmut Kohl – who saw their vision of building a united Europe jeopardized. Owing to this political commitment as well as the fact that markets increasingly gave weight to complying with the Maastricht criteria as a signal for sound

monetary and fiscal policy, convergence as outlined by the Maastricht criteria was sufficiently advanced in May 1998 for the heads of state and government of the EU to decide to proceed with Stage 3 of EMU as planned, if only for the 11 initial member countries of the ECB.

While it is a valuable lesson to have observed in the context of the establishment of the ECB that the prospect of a monetary union may itself help to induce partial economic convergence, it appears key to keep in mind that the process of formation of the ECB would probably not have been successful without the strong desire of the member countries' political leadership to see commonalities in cultural heritage also reflected in increasingly cohesive institutional entities, trusting that a common European currency would help the emergence of a single European identity.

Structural economic diversities between euro area member countries continue today (in 2007). Among these diversities perhaps most notable are persistent differences in trend output growth rates. The widely voiced hope expressed at the time of the signing of the Maastricht Treaty – that formation of the ECB would significantly spur convergence of trend output growth rates for euro area member countries through alignment of structural reforms of labour and product markets – has so far proven to be wishful thinking. While some critics of the ECB have argued that this is due to the mandate of the ECB being too narrowly focused on price stability, it may have been exactly this focus that allowed the ECB to successfully establish itself as a credible safeguard of price stability, an issue which we will discuss further below.

Lesson Two: How to Design and Implement a Monetary Policy Strategy

The starting point for any discussion of the ECB's monetary policy strategy has to be the mandate that the ECB was given by the Maastricht Treaty. Article 105 of that treaty specifies: 'The primary objective of the ESCB is to maintain price stability. Without prejudice to the objective of price stability the ECB shall support the general economic policies in the Community with a view to contributing to the achievement of the objectives of the Community as laid down in Article 2.' Article 2 specifies these objectives to be a high level of employment as well as sustainable and noninflationary growth. (The Maastricht Treaty refers to the ESCB rather than the ECB since it envisioned that all member countries of the European Union would eventually adopt the euro and that even before this was to happen all national central banks of member countries not part of the euro area would be bound by the same objectives.)

While the Maastricht Treaty does not specify a precise quantitative definition of price stability, the ECB, particularly on the basis of the argument that such quantification would strengthen its commitment to its primary objective as well as strengthen its accountability, in October 1998 defined price stability as a year-onyear increase in the Harmonized Index of Consumer Prices (HICP) for the euro area of below two per cent over the medium run. While this definition of price stability does exclude deflation as being consistent with price stability and leaves the ECB with no degree of freedom to potentially remove more volatile and/or temporary components of overall consumer prices in order to declare price stability, the definition does leave the ECB some flexibility in that a time horizon as to what would constitute the medium run was not established.

In its pursuit of price stability, the ECB decided to base its monetary policy framework on two pillars: 'monetary analysis' and 'economic analysis'. In declaring monetary aggregates as providing information valuable to the objective of price stability that should be separated from other economic and financial variables, the ECB has so far maintained that monetary aggregates do not just offer incremental information relative to such other variables for purposes of projecting inflation, but that at longer horizons (stretching beyond those typically adopted by central banks for the computation of their inflation projections but still essential for medium-run price stability) monetary aggregates provide information qualitatively different from that which other economic variables can provide. The ECB in this context has so far also

maintained that money demand (as measured by the monetary aggregate M3) for the euro area has been stable at least over longer horizons, with some short-run instabilities being due to an exceptionally prolonged (but still temporary) period of high asset price volatility. Finally, the ECB has so far maintained that conventional macroeconomic analysis is not sufficiently advanced to combine the analysis of real economic phenomena with monetary trends within a single pillar framework. Driven by these considerations, the ECB therefore initially decided to announce annual reference values for the growth rate of M3 as a benchmark for keeping monetary growth in line with the objective of price stability.

The 'economic analysis' pillar of the ECB's monetary policy framework aims at identifying and quantifying short- to medium-term non-monetary risks to price stability. Variables entering this analysis include (*a*) gap measures of the discrepancy between actual output as well as its factors of production on the one hand and their medium- to long-run equilibrium values on the other hand; (*b*) labour cost measures; (*c*) exchange rates for the euro and international prices; and (*d*) asset prices other than exchange rates, particularly yield curve measures. Reflecting the sizeable degree of persistence of consumer price inflation in the euro area, considerable weight in the economic analysis is also given to recent consumer price dynamics.

The ECB's two-pillar strategy has been heavily criticized and remains controversial. Critics argue that monetary aggregates such as M3 – specifically due to the lack of sufficient stability of money demand – lack the degree of reliability needed to separate information in such monetary aggregates from other economic and financial variables. These critics inter alia also argue that, if the transparency and accountability of the ECB's decisions were to be improved, this would be helped most by the publication of inflation forecasts by the ECB as well as the publication of the minutes of the meetings of the ECB's Governing Council (for more on the latter, see below). The two-pillar strategy was reaffirmed in a broad internal assessment by the ECB in 2003, but two clarifications were provided. First, the Governing Council noted that it aims to maintain inflation rates below, but close to, two per cent over the medium run. A number of arguments in favour of tolerating a low rate of inflation – and not aiming at zero inflation – were acknowledged, among which the most important are the need for a safety margin against potential risks of deflation and the 'zero bound' on nominal interest rates. While this 'zero bound' renders central bank interest-rate management less effective at low rates of inflation, ECB studies argued that inflation rates below, but close to, two per cent would provide a sufficient safeguard against these risks. Second, the Governing Council emphasized that the 'monetary analysis' pillar was meant to serve mainly as a means of cross-checking, from a medium- to long-term perspective, the short- to mediumterm indications provided by the 'economic analysis' pillar. To underscore the longer-term nature of the reference value for monetary growth, the practice of an annual review of the latter was discontinued.

It will be interesting to observe whether eventually the monetary pillar comes to be viewed as having been of importance only in the early years of operation of the ECB when the ECB had to establish its credibility by being as committed to price stability as the Deutsche Bundesbank (the German central bank) had been prior to 1999 and when the ECB was confronted with sizeable problems regarding the measurement of harmonized euro area-wide real economic aggregates, or whether ECB-style cross-checking by means of monetary analysis will become a common practice of central banks around the globe.

The operational framework used by the ECB to implement its monetary policy strategy is less controversial than the strategy itself and includes three main instruments: open market operations, standing facilities and reserve requirements. Among the open market operations of primary importance are the 'main refinancing options' that provide the bulk of refinancing to the financial sector and, through signalling the ECB's monetary policy stance, are supposed to steer market interest rates. The 'main refinancing options' are executed by the national central banks of the euro area member countries on a weekly basis through

a tender procedure spanning three working days. 'Standing facilities' aim at providing and absorbing overnight liquidity, and 'minimum reserve requirements' (the ECB imposes minimum reserves on all credit institutions in the proportion of two per cent of the reserve base) aim at stabilizing market interest rates.

By way of evaluating the overall success of the ECB in terms of it being able to adhere to its price stability objective, we may observe that inflation rates in the euro area since 1999 have on an annual basis on average been slightly above two per cent (in the range of up to 30 basis points above two per cent). Also, given that surveys of average long-term inflation expectations in the euro area have consistently measured such expectations as below, but close to, two per cent, its track record has quite firmly established the ECB's credibility with regard to safeguarding price stability.

Lesson Three: One Central Bank for Many Countries: How to Organize Decision-Making

The most important decision-making body of the ECB is its Governing Council, which is made up of the Executive Board of the ECB (which in turn is made up of its president, vice-president and four other members) as well as the governors of all the national central banks of euro area member countries. It is the responsibility of the Governing Council to formulate monetary policy for the euro area, including decisions about intermediate objectives and key interest rates. The Executive Board is in charge of implementing the monetary policy decisions taken by the Governing Council, and to this purpose cooperates with the national central banks through open market activities. Each member of the Governing Council has one vote. Given that at present slightly more than two-thirds of the votes in the Governing Council, therefore, belong to national central banks, the latter have a strong influence on the ECB's monetary policy decisions.

This organizational structure implies an asymmetry between the economic size of euro area member countries and their influence on decisions arrived at by the Governing Council. Indeed, more than half the euro area member countries at present have an economic weight (as measured by the ratio of their national GDP to euro area GDP) that is smaller than their voting weight within the Governing Council. This is quite different from the structure of, say, the US. Federal Reserve, which is significantly more centralized. While decentralization of the implementation of the ECB's monetary policy arguably is useful, particularly as long as there are important differences among national financial markets and institutions in the euro area, the decentralized institutional set-up of the ECB has risks, particularly during episodes of real divergence. It will be interesting to see whether the 'one person, one vote' principle for the Governing Council will be maintained after possible enlargement of the euro area to incorporate (some of) the EU member countries not presently member countries of the ECB. Even if the 'one person, one vote' principle is to be maintained, there appears to be considerable scope for future revision of the organizational system of the ECB, such as requiring approval of nominations of new central bank presidents by the Executive Board of the ECB.

Lesson Four: Common Currency and Monetary Policy: Gains and Losses

In general, the principal advantages of a common currency are widely held to include the reduction of transaction and information costs implied by the use of a common medium of exchange as well as the stimulus the common currency provides for the convergence of organizational principles used in business, in turn stimulating trade in goods and services and of cross-country flows of capital. The principal disadvantages of a common currency for multiple countries are widely held to include the loss of shock-absorber properties of flexible exchange rates and of independent national monetary policies. Furthermore, if a single monetary policy is accompanied by a diverse set of national fiscal policies, inappropriate fiscal policy in one country will – through its effect on interest rates – directly spread to other countries in the

monetary union. Thus macroeconomic stability could be affected for the worse.

How has the euro area so far fared on these counts? Trade within the euro area increased from approximately 26.5 per cent of (euro area) GDP in 1998 to approximately 31 per cent of GDP in 2005; one and a half per cent of this increase was due to trade in services. Taking into account the limited time span, it is difficult to assess, however, to what extent this increase in trade was indeed driven by the creation of a single currency and to what extent it may instead have been driven by the process of economic globalization. We do know, in fact, that trade with trading partners outside the euro area over this same time period rose by a slightly larger margin than intra-euro area trade, from approximately 24 per cent of GDP in 1998 to approximately 30 per cent of GDP in 2005.

Regarding financial markets, for which the volume of transactions is probably still more sensitive to even small costs and risks associated with the use of multiple currencies, by a variety of measures deeper, broader and more liquid markets have emerged for the euro area member countries since establishment of the ECB. On the money market, issues of their interpretation aside, cross-country standard deviations for average overnight lending rates fell from 130 basis points in January 1998 to three basis points one year later, and since then have decreased to approximately one basis point. Cross-country standard deviations for rates at longer maturities (one and 12 months) for unsecured money market instruments have fallen to less than one basis point also, with the spreads still somewhat larger in the collateralized repurchase agreement (repo) market (due to continued differences in legal structures across euro area countries). In the interest rate derivatives market, the euro interest rate swap market at a daily volume of 250 billion euro was in 2006 one and a half times as large as the corresponding US dollar market. In the government bond market also, spreads have fallen to low levels, suggesting – in the likely absence of major changes in default risks – a significant fall of liquidity risk. The holdings of euro-denominated debt securities overall since 1999 have increased by well over ten per cent to approximately one-third of the global market (through holdings tend to be concentrated in countries neighbouring the euro area).

In the equity and retail banking markets integration has progressed more slowly. For example, despite a decrease in the number of credit institutions in the euro area member countries by almost 50 per cent between 1997 and 2006, less than one-third of the mergers and acquisitions driving this consolidation process have been crossborder. Also, the cross-country standard deviation of interest rates on consumer credit from 2004 to 2006 has still been close to one per cent.

While, just as for trade, it is difficult to disentangle the euro's contribution to the process of financial integration in euro area member countries from the global trend towards financial integration, the euro surely has greatly facilitated the task of bringing the European financial system closer to US standards in terms of market depth and liquidity. Further improvements in this direction, including the creation of a single payment system for the euro area member countries, are likely to intensify the debate about the potential role of the euro as a complement or competitor to the US dollar as an international reserve currency.

Finally, to turn to macroeconomic stability and the potential cost of losing flexible exchange rates and independent national monetary policies as shock absorbers, some such costs clearly have been observed since 1999. While the cross- country standard deviation of consumer price changes has fallen from approximately six per cent in the late 1990s to one per cent with the launch of the euro, and has been rather stable at this level in the following eight years, there have been persistent deviations from euro area average inflation rates for some countries, implying sizeable (and potentially destabilizing) differences in real interest rates. For example, for a sizeable part of the time period since 1999, real interest rates have been significantly lower in a booming Irish economy than in a German economy experiencing weak growth. When it comes to assessing the implications of the establishment of the ECB for macroeconomic stability, these costs have to be subtracted from benefits owed to factors such as

the elimination of intra-euro area exchange rate crises and the fact that inflation rates for some euro area member countries have been falling sizeably in the eight years since 1999. However, a stronger degree of real convergence through aligned policies aimed at removing structural deficiencies in European product and labour markets would have helped to render the benefits yet larger.

Conclusion

While this article has suggested that on various counts (such as the monetary policy strategy and the organizational set-up) there is as of 2007 no consensus as to whether the ECB adheres to best international practice in central banking, it would appear rather questionable to label the establishment of the ECB and with it the introduction of the euro as anything but an enormous success. The ECB has successfully mastered the technical challenges of establishing a new common currency across a set of countries comprising one of the largest economic regions in the world, has in a short period of time established a strong track record of success in preserving price stability, and has on many counts, particularly in the area of financial markets, helped lead the way to a stronger integration of European markets. While it is undisputable that this integration of markets along with structural reforms needs to proceed much further, the key decisions that could facilitate such integration and structural reforms fall outside the core domain of responsibility of the ECB and, for that matter, should probably remain so for any central bank primarily entrusted with maintaining price stability.

European Central Bank and Monetary Policy in the Euro Area

Vítor Gaspar and Otmar Issing

Abstract

Since 1 January 1999 the European Central Bank (ECB) has had sole responsibility for monetary policy in the euro area. Its main aim is to maintain price stability over the medium term. It is completely independent. The ECB has been successful in maintaining price stability and well-anchored inflation expectations. The euro is now a well-established international currency and a symbol of European integration. The financial and economic crises of 2007–2011 made the tension between the single monetary policy and national responsibilities for economic policies and financial stability visible. This is the main challenge going forward.

A single monetary policy covering all the sovereign states participating in the euro area replaced the separate national policies on 1 January 1999. The date is also a milestone in the history of international monetary integration. For the first time a group of advanced countries has chosen to entrust the exclusive competence for the conduct of their monetary policy to an independent and supra-national monetary authority: the European Central Bank (article 3 and article 127 of the Treaty on the Functioning of the European Union – EU). The euro area started with the participation of 11 EU Member States: Austria, Belgium, Finland, France, Germany, Ireland, Italy, Luxembourg, the Netherlands, Portugal and Spain. Since then, it has expanded to include 17 countries with the participation of Greece (2001); Slovenia (2007), Cyprus and Malta (2008), Slovakia (2009) and Estonia (2011). Euro banknotes and coin became a physical, day-to-day reality on 1 January 2002.

At the time of writing (2011), the euro is the currency of almost 330 million people in 17 different European countries. Most of the remaining EU Member States intend to adopt the euro in the future and, with the exception of the UK and Denmark, have a treaty obligation to do so. The euro is the second most important currency in the global economy (after the US dollar) and the euro area is the monetary area with the second largest economy (after the USA). In contrast with the economies of the participating countries, which can mostly be characterized as small open economies, the euro area is a large and relatively closed economy. Aggregate differences, in the structure of production by sector, relative to the USA are relatively small. For the conduct of monetary policy, an important difference relative to the USA is that in the euro area the financial system is dominated by banking. This contrasts with the predominance of market financing in the USA. For more information on the global role of the euro, the economic weight of the euro area and further references see, for example, EMI (1997c), ECB (1999), Issing et al. (2001) and Buti et al. (2010).

The transfer of powers from the participating Member States was limited to monetary policy. Their competences in economic policy, in general, and budgetary policy, in particular, remained unchanged. The combination of an independent and supranational monetary authority, with Member States largely responsible for the conduct of economic policies, implies an original tension that remains unsolved. Many observers were sceptical about the outcome. After a few years the pendulum swung the other way and most observers started taking the success of the euro for granted, forgetting how difficult it had been to prepare the launch of the new currency, to establish the credibility of the ECB and to put in place a new monetary policy strategy and operational framework. The degree of uncertainty associated with the transition to the single monetary policy was enormous. Issing (1999b) writes:

> As a central banker directly involved in monetary policy making, I have been dealing with uncertainty and its consequences for a large part of my professional life. From my experience as a member of the Board of the Bundesbank, I have vivid memories of challenges posed by German reunification and the turbulence surrounding ERM crises. But never have I felt the impact of uncertainty as acutely as in the weeks that preceded and followed the introduction of the euro and the birth of the single monetary policy.

According to the Treaty on the Functioning of the European Union the primary objective of the European System of Central Banks (ESCB) is to maintain price stability (article 127.1 and 282.2, and also article 2 of the Statute of the European System of Central Banks and of the European Central Bank). The ESCB is governed by the decision-making bodies of the ECB (article 129.1 and 282.2 of the Treaty and 9.3 of the Statute): the Governing Council and the Executive Board. The independence of the ECB and of the ESCB is protected by the Treaty and the Statute (respectively by article 130 and by article 7). Without prejudice to the objective of price stability, the ESCB shall support the general economic policies in the Union with a view to achieving their objectives, as specified in article 3 of the Treaty on European Union. These include:

- balanced growth;
- a highly competitive social market economy, aiming at full employment and social progress;

- the promotion of scientific and technological advance;
- equality between women and men;
- solidarity between generations;
- the protection of the rights of the child;
- economic, social and territorial cohesion; and
- solidarity among Member States.

The ESCB is composed of the ECB and the national central banks of the Member States of the European Union. The Eurosystem is made up of the ECB and the national central banks of the Member States that have adopted the euro as their currency. These definitions are provided in article 1 of the Statute.

Most of the preparatory technical work was carried out by the European Monetary Institute (EMI) and the participant national central banks during the second stage of Economic and Monetary Union (1994–1998). During this period the foundations for the proper functioning of the single currency were conceived. These included a basic set of analytical tools; statistical information; internal organization rules for the new central bank; a new pan-European interbank payment mechanism; and the operational framework for implementation of the single monetary policy. The technical work was already mature when the ECB was established (on 1 June 1998) and the final six months of the preparatory period started (see, for example, EMI 1997a, b, 1998).

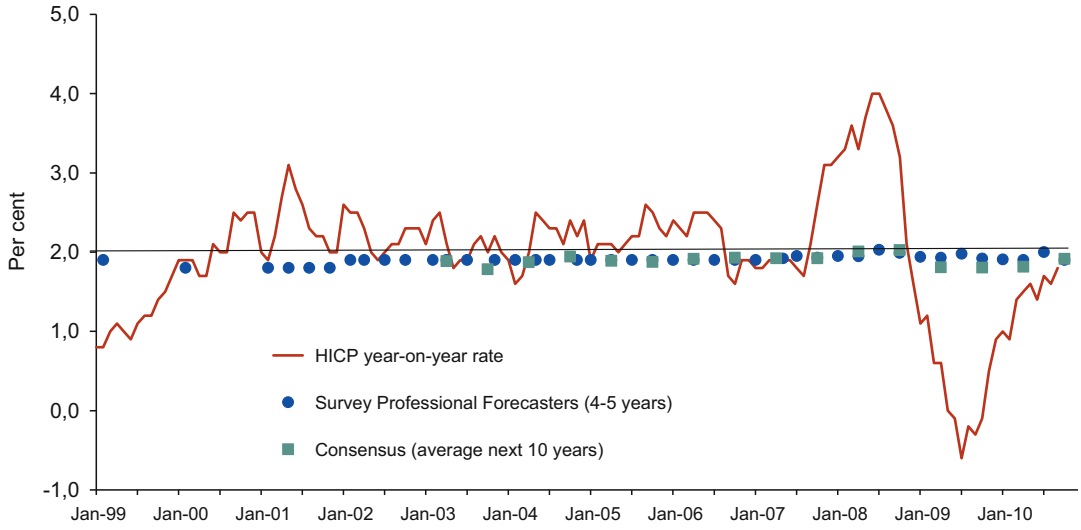
The institutional provisions described in the previous paragraphs underline the importance of price stability as a central element in the economic constitution of monetary union in Europe. However, all institutional guarantees notwithstanding the most basic questions at the beginning were: would the ECB deliver price stability? Would the ECB be credible in fostering well-anchored inflation expectations? How could the ECB be credible in the absence of a track record? How could the ECB deal with the uncertainties associated with monetary unification and financial integration?

The importance of credibility for the conduct of monetary policy is a common feature of virtually all models that emphasize the endogenous character of private sector expectations. Expectations management is strongly emphasized in the academic literature, starting with Kydland and Prescott (1977) and Barro and Gordon (1983). This important issue has been revisited recently, in the context of the standard new Keynesian model, by, for example, Clarida et al. (1999), Woodford (2003), Galí (2008) and Walsh (2010). This literature stresses that an independent central bank, with a clear mandate, should be able to maintain low and stable inflation and to anchor inflation expectations. Credible policy relies on a well-understood strategy, implying a systematic and predictable pattern of response to the current state and prospects for the economy.

Figure 1 shows inflation in the euro area, measured in accordance with the 12 month change in the Harmonized Index of Consumer Prices (HICP) and long-term inflation expectations following the Consensus forecasts and the ECB's own Survey of Professional Forecasters (SPF). In the period from January 1999 to December 2010, average inflation was 1.97%, which is below (but close) to 2% and therefore in line with the ECB's definition of price stability. Importantly, the same applies to the long-run inflation forecasts according to the Consensus forecasts and the SPF. For example, according to the latter average, long-term inflation expectations have always remained well-anchored within a narrow range from 1.8% to 2.0%.

Figure 1 also makes it clear that year-on-year inflation has been above 2% most of the time. In June and July 2008 it peaked briefly at 4% (twice the upper limit in the ECB's definition of price stability). Equally, for most of the period, average annual inflation has been close to but not below 2%. Only recently, in the context of the Global Financial Crisis and the associated Great Recession, have very low – or even, for a brief period, negative – inflation rates pushed average inflation below the 2% limit.

In Buti et al. (2010), Geraats, Neumann and Smets look back at the performance of the ECB during the first decade of the euro. They emphasize the behaviour of inflation expectations and credibility. For example, Smets (2010) looks at the first decade of the euro. He excludes the first year (1999) on the ground that given transmission lags the outcome cannot be attributed to the ECB. Hence, for the period available to him, HICP



Sources: Consensus Economics, ECB and Eurostat.

European Central Bank and Monetary Policy in the Euro Area, Fig. 1 Euro area – inflation (HICP) and long-term inflation expectations

inflation, for the euro area, averaged 2.2%. Smets argues that the deviation is mostly due to unforeseen and large oil and other commodity prices disturbances. In fact, excluding energy and unprocessed food prices, the average inflation rate was 1.8% in the same period. But mostly he stresses, as already mentioned above, that while headline inflation has fluctuated significantly long-term inflation expectations remained anchored, in line with the ECB's definition of price stability.

European monetary unification has been debated since the establishment of the so-called Werner Group (1969). The discussion intensified after the publication of the Delors Report in 1989. In the academic world, the vast majority of commentators have been highly sceptical and critical (see Issing (2008) and Jonung and Drea (2010) for reviews and references). Even before the start of the single monetary policy several groups of economists organized ECB watching activities. The title of the first of these reports, CEPR's 'ECB: safe at any speed?', published in 1998, is representative of the prevailing tone at the time. Since 1999 the ECB has been meeting annually with academics and professionals from the financial sectors at 'ECB and Its Watchers Conferences'. Thee meetings are organized by the Center for Financial Studies (CFS) at Frankfurt University. These conferences, unique in the world of central banking, provide a very full picture of the ongoing debate between the ECB and its critics (the programme of the first 12 editions of the conference and a wealth of additional information can be obtained from the CFS website: http://www.ifk-cfs.de/index.php?id=1164). Whereas the monetary policy decisions were mostly welcomed, the initial criticism concentrated on the ECB's monetary policy strategy. However, the critical tone lessened somewhat over time. In the context of the financial crisis, even early critics have seen the ECB less critically than other major central banks (see, for example, Buiter (2009)).

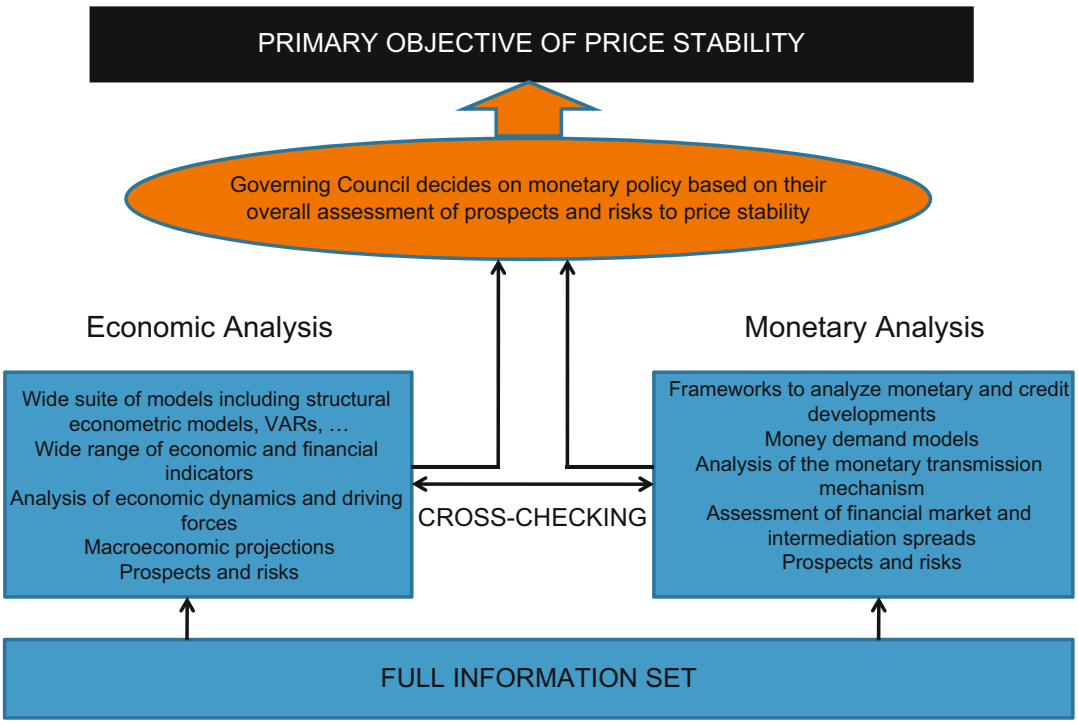
The Stability-Oriented Monetary Policy Strategy of the ECB

The environment relevant for the conduct of monetary policy is characterized by pervasive uncertainty. As argued above, this general point was of particular relevance for the ECB at the time of the launch of the euro. Moving from national currencies and monetary policies to a common currency and a single monetary policy implied a deep

regime shift with a huge potential for structural breaks (Lucas 1976). However, knowledge about the structure and the functioning of the economy and of the financial system is always imperfect. The structure and functioning themselves are constantly changing, which limits the usefulness of past data. Therefore it is the case that the monetary transmission mechanism is always uncertain. Moreover, economic data are contaminated by measurement error. In this environment it is crucial that monetary policy does not itself become an additional source of uncertainty. A monetary policy strategy helps to dispel such uncertainty, first by structuring a well-ordered internal decision-making process; second, by providing a consistent and coherent framework for communication; and third, by contributing to the credibility and predictability of the single monetary policy.

The stability-oriented monetary policy strategy of the ECB was disclosed immediately after a decision by the Governing Council, on 13 October 1998 (ECB 1998). The strategy comprises three elements: (1) a quantitative definition of price stability: (2) economic analysis and (3) monetary analysis. The latter two are used to organize an all-encompassing assessment of price prospects and risks to price stability. The two perspectives are systematically used for cross-checking (see Fig. 2). Versions of Fig. 2, differing in some details, have been used over time by the ECB to convey a schematic representation of the monetary policy strategy. It was presented for the first time in an *ECB Monthly Bulletin* article in 2000 (ECB 2000).

It is important to clarify the status of the definition of price stability within the monetary policy strategy. In fact, as already referred to above, price stability is set as the primary goal of the ECB in the Treaty on the Functioning of the European Union itself and the ECB does not, as some critics have suggested, have independence in setting its goal. Rather, price stability as the overriding goal of monetary policy is taken as given by the ECB (Issing 2000). Instead, the ECB's decision was to



European Central Bank and Monetary Policy in the Euro Area, Fig. 2 The stability-oriented monetary policy strategy of the ECB

announce a precise and operational definition of price stability based on a specific statistical indicator. Such an announcement is, in itself, an important form of commitment and a key for the communication of the central bank with the general public (Issing et al. 2001, Chapter 4).

In October 1998, the Governing Council decided that 'Price stability shall be defined as a year-on-year increase in the HICP, for the euro area, of less than 2 per cent. Price stability is to be maintained over the medium term'. About five years later, on 8 May 2003, when announcing the results of its evaluation of the monetary policy strategy, the Governing Council confirmed the definition, but clarified that it aimed to maintain inflation below (but close) to 2% over the medium term. The clarification was justified by the benefits of making explicit a safety margin against the risk of deflation. The Governing Council spelled out that it regards low and stable inflation as compatible with price stability. Inflationary and deflationary departures from the benchmark are both undesirable departures from price stability. Therefore the definition is clearly symmetrical.

The definition of price stability provides a benchmark against which to evaluate the performance of the ECB. It provides an anchor for inflation expectations and therefore serves to reduce uncertainty about price developments over the longer term.

Pervasive uncertainty also recommends a focus on robustness. Seeking robustness involves a willingness to consider different 'views of the world'. In the ECB's stability-oriented monetary policy strategy such diversity is symbolized by 'two pillars', supporting decision-making by the Governing Council: economic analysis and monetary analysis (Fig. 2).

Economic analysis spans a wide range of indicators which are relevant for risks to price stability over the short to medium term. This includes overall output, demand and labour market conditions, fiscal policy, and exchange rate developments, as well as financial market indicators and asset prices. Economic projections are an important element of economic analysis as they synthesize a very rich information set. They do not, however, constitute a sufficient statistic. The projections are produced by staff, as an input to Governing Council deliberations, at a quarterly frequency. Twice a year they stem from a broad exercise involving not only the ECB but also the national central banks of the Eurosystem. Twice a year they are conducted under the sole responsibility of ECB staff. Economic analysis focuses, to a large extent, on the interaction between aggregate supply and aggregate expenditure and the role of factor costs on pricing behaviour. Economic analysis uses a vast array of structural econometric models, including new Keynesian Dynamic Stochastic General Equilibrium Models. The ECB has been pioneer in this area of research through the work of Smets and Wouters (2002). At the time of writing the new area-wide model (NAWM), developed by the Econometric Modeling Division, to be used in the broad macroeconomic projection exercises and policy simulations, constitutes an important element in the ECB's modelling toolbox. It is a micro-founded, open-economy model for the euro area. It relies on a neo-classical core and incorporates a number of important frictions including wage and price rigidities; habit persistence in consumption behaviour; and adjustment costs in investment. It incorporates some open economy extensions of these frictions, including domestic currency pricing and costs associated with the adjustment of trade flows (Christoffel et al. 2008). The NWAM follows the area-wide model (AWM) that was developed and made available in the early years of the ECB (Fagan et al. 2001).

Monetary analysis starts from the fundamental insight that inflation is ultimately a monetary phenomenon (according to Milton Friedman). Inflation, that is persistent increases in the price level, is ultimately determined by monetary trends. Although many factors may affect price behaviour in the short to medium term, only monetary trends can account for lasting inflation (see, for example, Romer 2006, p. 407). The money–price relationship is confirmed by a wide variety of empirical studies using times series, cross-country and pooled data, spanning different monetary regimes and definitions of monetary aggregates. A central bank with the mandate to maintain price stability cannot ignore its responsibility for monetary developments. By giving 'money' a prominent

role, in its monetary policy strategy, the ECB has recognized this role and, at the same time, avoided some of the shortcomings of inflation targeting. Therefore monetary analysis contributes to cross-checking economic analysis from a long-term perspective. Monetary analysis may also be relevant at shorter horizons through, for example, the monitoring of credit developments, financial spreads and the monetary transmission mechanism. More generally, cross-checking the results from economic and monetary analysis provides the foundation for monetary policy decisions, which take into account all relevant information, seen from two different angles (see Fig. 2).

Beck and Wieland (2008) show that, when the central bank misperceives the output gap, supplementing interest rate prescriptions, derived from Keynesian or new Keynesian models, with estimates of trend inflation derived from monetary analysis, substantially improves inflation outcomes.

From the beginning monetary analysis was not restricted to broad definitions of money such as M3 and its relation to the reference value, but took into account 'developments of a wide range of monetary indicators, including M3 and its components and counterparts, notably credit and various measures of excess liquidity'(ECB 2003a). Over time, monetary analysis was broadened and deepened (Issing 2005a).

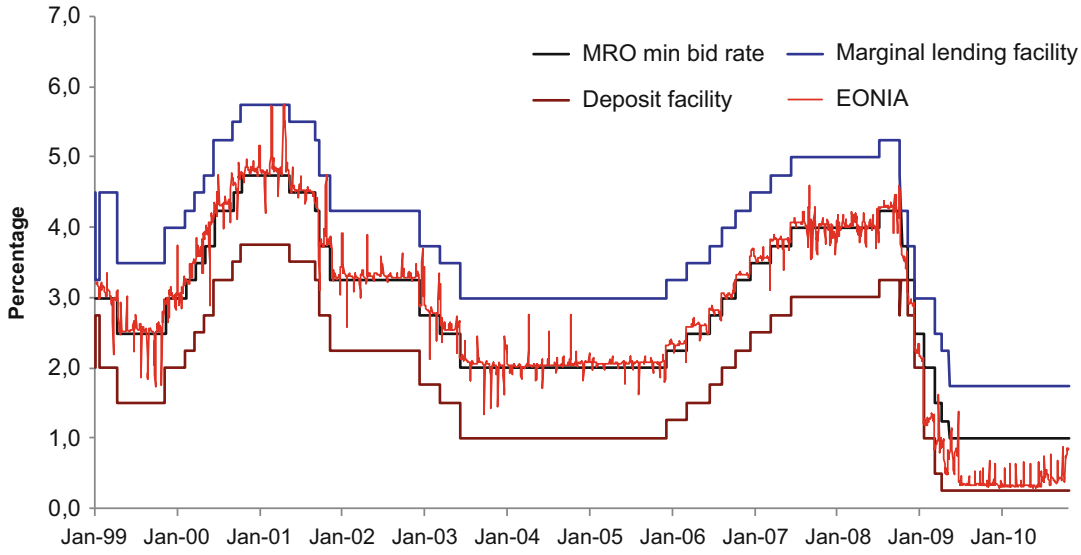
In the context of the Global Financial Crisis, starting in 2007, links between liquidity and asset price dynamics have become evident, stressing the relevance of monetary analysis also for identifying risks to financial stability. There is much ongoing research at the ECB and elsewhere. Recently Beyer (2009) has estimated an empirically stable, small macroeconomic model for the euro area. It considers the broad monetary aggregate, M3, of real GDP, annual inflation, the nominal growth of housing wealth and interest rate measures (specifically the annualized three-month interest rate and the annualized own return on M3). The model is able to track closely trend velocity since the late 1990s. While the money demand model identifies the influence of wealth variables on money demand another strand of research, building on insights from Hyman Minsky (see, for example, Minsky 1975), looks at the reverse link. Money and, in particular, credit growth in excess of what is needed for sustainable growth begets asset price bubbles and financial instability. Therefore they are associated with boom and bust and, from a medium-to long-term perspective, with price instability. Alessi and Detken (2009) have found that the global private credit gap is a leading indicator of asset price booms that will be followed by costly episodes of macroeconomic instability and ultimately price instability.

A volume recently published by the ECB (Papademos and Stark 2010) presents studies on various aspects confirming the importance of a thorough monetary analysis while providing subjects for further research (summaries are provided in ECB (2010) and Amisano et al. (2010)).

The monetary policy strategy of the ECB was designed in a way that, notwithstanding basic principles, is open to new insights from research and actively seeks to identify structural changes in the financial system as well as in the real economy. This approach is confirmed by this statement (Papademos and Stark 2010, p. 11): 'Developing a better understanding of the behaviour of monetary and credit aggregates and their influence on the economy has given rise to new questions and challenges which will influence our future work on both monetary analysis and other approaches. Reciprocally, improvements in other approaches will again need to be considered from the perspective of monetary analysis. Both to crosscheck their results and to maintain the encompassing nature of a robust monetary policy strategy. Such is the nature of progress. Such is also the nature of science. And such should be the nature of a robust monetary policy strategy if it is to ensure effectiveness, accountability and transparency'.

The Operational Framework for Monetary Policy Implementation

The Eurosystem implements monetary policy through financial markets. The operational framework is the set of instruments and procedures through which the Eurosystem intervenes in markets with a view to determining the monetary



Source: Thomson Reuters

European Central Bank and Monetary Policy in the Euro Area, Fig. 3 ECB policy rates and EONIA

policy stance, in accordance with decisions made by the Governing Council. The Treaty and the Statute contain relatively few provisions about the instruments of monetary policy. Furthermore, those provisions are of a general nature. For example, article 127.1 of the Treaty on the Functioning of the European Union (article 2 of the Statute) prescribes that the Eurosystem 'shall act in accordance with the principle of an open market economy with free competition favoring an efficient allocation of resources'. The operations of the Eurosystem are specified in chapter IV of the Statute (articles 17–24). For example, the Eurosystem may operate in financial markets (article 18), and impose minimum reserves on credit institution, including penalties for non-compliance (article 19). Importantly, article 20 states: 'The Governing Council may, by a majority of two thirds of the votes cast, decide upon the use of such other operational methods of monetary control as it sees fit. . .'. Therefore, the Treaty and the Statute provides the ECB with ample room to adapt its instruments as required by unforeseen circumstances. Naturally, discretion in this area is, as in all other areas, constrained by the primary goal of maintaining price stability, as prescribed by article 2.

Under normal circumstances, the first step in the monetary transmission mechanism is the control, by the central bank, of an overnight interest rate. The ECB does so through a 'corridor system' (see Fig. 3). In a 'corridor system', reserve requirements operate as a device to create a structural demand for central bank money and a buffer to smooth demand for reserves and reduce the volatility of interest rates. Overnight interest rates (in Fig. 3 represented by the Euro Overnight Index Average (EONIA)) are bound by two standing facilities provided by the central bank: a deposit facility and a lending facility. Banks can deposit excess funds at a predetermined interest rate. Banks can also have recourse to a credit facility, accessing funds at a predetermined interest rate, securing the operation through the pledging of eligible collateral (see 'Marginal lending facility' in Fig. 3). Within the corridor, the Main Refinancing Operation (MRO) minimum bid rate is the most important policy rate, as it serves as the reference for overnight market interest rates (for details see Bindseil (2004) and ECB (2008)). Issing (2008) offers an overview of the process of development of monetary policy instruments by the Eurosystem).

ECB Policy in Action: Simple Rules as Benchmarks

In the models used by monetary policy researchers, the rules summarizing the systematic response of interest rates to the state of the economy are central. In forward-looking models under perfect foresight or rational expectations, the model cannot be solved in the absence of such rules. Focus on systematic (rule-like) behaviour is not, however, the most common way of discussing the practice of monetary policy. Many people fail to distinguish between actions taken in the context of a systematic practice and the characterization of the features of the practice itself. Nevertheless, it is a fundamental distinction. The stability-oriented monetary policy strategy of the ECB induces systematic, rules-like behaviour on the part of the ECB. It is therefore interesting to assess how closely simple rules are able to account for the past behaviour of the ECB. Close tracking is direct evidence of systematic behaviour. Significant departures are episodes that demand explanation and clarification on the basis of the strategy itself.

In normal times, the Eurosystem conducts monetary policy through control over money market interest rates. Therefore the most straightforward example of a simple policy instrument rule is to express the interest rate as a function of a small set of relevant variables. Review reveals relatively little evidence that hosting the Games produces significant economic benefits for the host cityTaylor rule (Taylor 1993) that expresses the interest rate as:

$$i = r^* + \pi + \theta_\pi + (\pi - \pi^*) + \theta_y(y - y^*)$$

where the interest rate is i; r^* is the natural rate of interest; π is the rate of inflation; π^* is the inflation rate deemed compatible with price stability and y^* is the level of potential output (in logs). Taylor originally proposed $r^* = 2.0$ and $\theta_\pi = \theta_y = 0.5$.

In empirical studies it is common to consider also a term with the lagged interest rate on the right-hand side so as to reflect interest rate smoothing. Another simple rule has been proposed by Orphanides (2003, 2006, 2010). It has the form:

$$\Delta i = \theta[(\pi - \pi^*) + (\Delta y - \Delta y^*)]$$

The Orphanides rule departs from the Taylor rule in that, by using first-differences, it eliminates the dependence of the rule on the unobserved level of the natural interest rate, r^*, and also on the level of potential output, y^*. Following in Taylor's footsteps, Orphanides proposes $\theta = 0.5$. Smets estimates the rule and finds that the estimated coefficients on inflation and output growth deviations are not significantly different from 0.5. The coefficient on lagged interest rate is close to 1 (but the estimated coefficient is 0.89 and the difference from 1 is statistically significant).

The Orphanides rule may be derived from a quantity theory of money framework (Orphanides 2003). Indeed, the ECB derives the reference value for money growth from the equation of exchange:

$$\Delta m^* = \pi^* + \Delta y^* + \Delta v^*$$

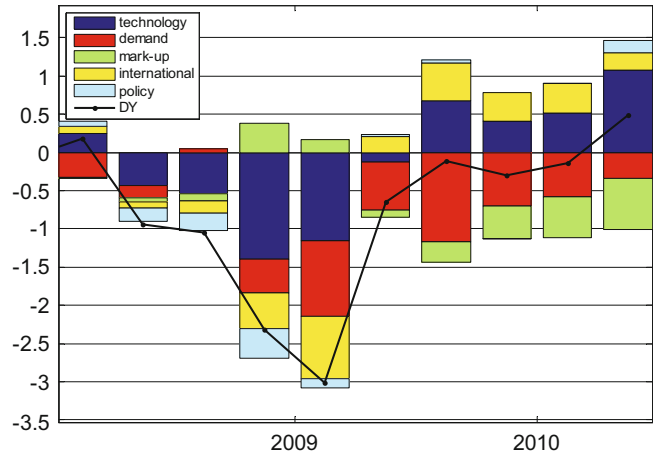
as explained in Issing (2008). In order to derive the interest rate rule it suffices to use the simplest money demand equation – which relates deviations of velocity from long run trends to the relevant interest rate and transitory departures from trend – and to ignore temporary disturbances.

The NAWM includes a Taylor-type monetary policy reaction function that includes interest-rate smoothing, the deviation of aggregate output from the trend implied by permanent technology shocks as the measure of the output gap and an inflation objective that may temporarily deviate from its long run value.

Issing et al. (2001, p. 42) state:

> Simple rules, in particular of the Taylor type, appear to provide *ex post* a good description of policies actually followed by central banks in the eighties and the nineties (though with notable exceptions such as the period of ERM crisis in Europe).... In spite of these good descriptive properties, simple rules are rarely advocated as *prescriptive* policy tools, even by their proponents. A total commitment to a simple rule could lead to sub-optimal policies since, by assumption, they do not take into account all potential sorts of information that can, from time to time, be relevant for monetary policy (for example, financial crisis or asset market bubbles).

E



European Central Bank and Monetary Policy in the Euro Area, Fig. 4 Decomposition of output growth into the shocks (*Source*: Christoffel et al. (2008), updated by courtesy of the authors of the NAWM)

The simple difference rule, proposed by Orphanides, and the Taylor rule used in the NAWM are two examples (among many possible) of rules that track well ECB monetary policy decisions made in the period 1999–2010. Nevertheless, both identify episodes of significant deviations. Most interestingly the relevant periods include the Global Financial and Economic Crises.

In the NAWM deviations of actual policy rates (captured in the model by the Euro Interbank Offered Rate (EURIBOR)) from the levels implied by the rule were positive during 2008 and the beginning of 2009. In other words, policy rates were higher than implied by the rule. It can be seen from Fig. 4, which decomposes the contributions of various shocks to growth, that from 2008:2 to 2009:1 there is a negative contribution of deviations of monetary policy from benchmark to GDP growth. However, during this period, the three-month EURIBOR reflected a substantial risk premium, while the EONIA became substantially lower than the MRO rate during the period (see Fig. 3). Time-varying risk premia and financial intermediation spreads explain departures from the stylized transmission mechanism that obtains in models with a single interest rate. Those departures are particularly important in times of financial stress. Moreover, the monetary policy rule captures only monetary policy stance as far as it is reflected in interest rates. During this period the ECB introduced non-standard measures aiming at compensating for the malfunctioning of some aspects of the monetary transmission mechanism and the zero bound on nominal interest rates (see 'Monetary policy measures during the Global Financial Crisis', below). Orphanides (2010) comments on the same episode on the basis of the similar indications obtained from the simple first-difference rule.

The discussion makes clear that a variety of simple rules do help to convey the systematic character of monetary policy making. They do account *ex post* for a substantial part of monetary policy decisions taken. Nevertheless, it is important to avoid the mistake of thinking that they can substitute for the monetary policy strategy itself. As the above quote makes clear, the relevant considerations in a particular situation cannot be known in advance. No simple rule can come close to summarizing the full set of relevant considerations. The stability-oriented monetary policy strategy of the ECB strives to include the full set of relevant information filtered through a diversity of analytical perspectives.

Communication, Accountability and Transparency

Communication, accountability and transparency are today of crucial importance for central banking. This is the case for two basic reasons. First, in a democratic society independence goes together with accountability. In the euro area, the ECB has full independence in the pursuit of price stability. At the same time it is made accountable for the results achieved through a number of statutory

requirements (in article 284.3 of the Treaty on the Functioning of the European Union and article 15 of the Statute). These include the obligation publish an annual report on monetary policy and other activities of the system. The report is presented, by the President of the ECB, to the European Parliament and to the Economic and Financial Affairs Council (ECOFIN). The ECB must also prepare quarterly reports and weekly consolidated financial statements for the ESCB. Second, the transmission of monetary policy to prices and economic activity depends on private sector expectations. A central bank controls only very short-term interest rates. However, what matters most for the transmission of monetary policy impulses to the economy are longer-term interest rates that are determined by financial markets. Those longer-term rates and financial prices reflect market expectations of future short-term interest rates and premiums for uncertainty. In an uncertain and complex environment, monetary policy decisions do not necessarily convey the central bank's overall assessment of the current state of, and future prospects for, the economy. Hence monetary policy actions can only be properly understood within the broader context of the monetary policy strategy. Such requirement implies a constant effort of communication on how individual decisions and the monetary policy stance contribute to the achievement of the mandatory goals. By stabilizing market expectations good communication and transparency help to reduce uncertainty and volatility in financial markets. This reduces risk premia in real interest rates to the benefit of overall economic welfare.

The ECB went much beyond the statutory accountability requirements and communication constitutes a central element of ECB monetary policy-making. As an important example we have already emphasized above the ECB's decision to inform the public comprehensively before the start about its monetary policy strategy including a quantitative definition of price stability, based on a specific statistical indicator (HICP for the euro area).

Monetary policy decisions are communicated in real time. The key elements of the ECB's communication policy are the press conference held by the President and the Vice-President after the first Governing Council meeting of each month and the *Monthly Bulletin*. The introductory statement read out by the president provides a summary of the policy-relevant assessment of economic developments in line with the ECB's monetary policy strategy. This assessment is agreed by the Governing Council and contains the core message for communication with the markets, the media and the public. This assessment is typically reflected in numerous statements and speeches by Council members. The introductory statement is immediately followed by questions and answers. A transcript of the statement is published in all EU languages within a few hours. A week later the ECB publishes its *Monthly Bulletin*, which includes a thorough analysis of developments in the euro area and the global environment. It contains also all relevant statistical data.

The ECB also publishes economic projections regularly (see above). Detailed information on the models used in the projection exercises and in policy analysis is also released and made available through the ECB's web site.

An early and constant critique of the ECB's communication policy refers to the fact that voting records are not published (Buiter (1999); for a rejoinder see Issing (1999b), which also includes a survey of practices of major central banks). As a matter of fact, monetary policy decisions of the Governing Council are taken by consensus. This underlines the collective responsibility of the decision-making body. Any attempt to make individual policymakers personally accountable entails the risk that the public may attach more importance to individual opinions than to the relevant economic arguments. Particularly in a monetary union constituted of many countries, the behaviour of national central bank governors might be interpreted from a 'national' perspective (Issing 2005b).

Blinder et al. (2008) show that there is no consensus on best practices in central banking communication. Ehrmann and Fratzscher (2007) focused on the specific experience of the ECB, with press conferences as vehicles for explanation of monetary policy decisions. They looked at evidence from financial markets. They found

that press conferences provided substantial additional information to financial markets and with relatively low effects on volatility.

Monetary Policy Measures During the Global Financial Crisis

The global nature of the crisis made its first appearance on Thursday 9 August 2007. In the morning, traded volumes fell sharply in money markets, while interest rates suffered a sudden and significant increase to elevated levels, well above the ECB's minimum bid rate. In this context, the ECB was the first central bank to take action: it immediately provided liquidity through a fine-tuning operation. The ECB distinguishes the **monetary policy stance** from **monetary policy implementation**. The former, in normal circumstances, can be gauged on the basis of a money market interest rate. Monetary policy implementation, in contrast, is performed in the context of the operational framework, and is used, for example, to maintain orderly money market conditions and adequate provision of liquidity to banks.

On 3 July 2008, the ECB announced that it had decided to increase its key interest rates by 25 basis points. The decision was based on the ECB's assessment of the prospects for price developments and risks to price stability. The exchange of views between Petra Geraats and Frank Smets (Geraats 2010; Smets 2010) highlights the importance of private sector inflation expectations in this context.

However, the situation and prospects changed rapidly over the summer. Clear signals of a sharp economic slowdown in the USA and elsewhere became apparent. More dramatically, from September 2008, a perverse feedback spiral between economic and financial developments threatened to take hold. The failure of Lehman Brothers on 15 September 2008 became the emblematic event, marking the transition to the acute stage of the Global Crisis.

Again the ECB reacted rapidly and forcefully.

It is possible to summarize all measures taken by the ECB under five points:

1. Adjustment in key interest rates: interest rates were lowered 325 basis points from October 2008. For example, the minimum bid rate was lowered from 4.25% to 1%.
2. Liquidity support mechanisms; adjustments in the operational framework:
   a. Extended use of fine-tuning operations;
   b. Conduct of fixed rate tenders with full allotment;
   c. Expansion of the list of eligible collateral;
   d. Temporary narrowing of the interest rate corridor;
   e. Lengthening of maturity for Long-Term Refinancing Operations.
3. Acquisition of selected assets: purchase of euro-denominated covered bonds (under the Covered Bond Purchase Programme (CBPP)) and interventions in euro area public and private debt markets (under the Securities Markets Programme (SMP)).
4. Joint action with other central banks on October 2008 to announce a reduction in interest rates.
5. Cooperation with other central banks in the management of liquidity in foreign currencies.

This episode suggests that the Eurosystem made use of the ample flexibility afforded by the operational framework to meet the special challenges associated with the crisis.

Challenges Going Forward

In this article we have argued that the conduct of monetary policy has been effective in the first years of the euro area. Nevertheless the ongoing crisis has brought into sharp focus a number of fundamental questions that will mark developments going forward. These include (for a longer list see Gaspar (2010)):

- Will the ECB manage successfully the exit from its current exceptional stance and continue its impressive record in maintaining price stability over the medium term?
- Will the framework for financial supervision and regulation prove effective? Will the new

European Financial Stability Risk Board and the European System of Financial Supervision work well? How will the ECB, in particular, and central banks, in general, adapt to the new systemic risk management framework?
- Will the single currency continue to be an important driver of deeper integration in the single market?
- Can rules and procedures, aiming at fiscal discipline in the euro area, effectively mitigate the deficit bias in government finance and ensure sound public finances in view of the ongoing demographic transition and of the need to provide for fiscal space?
- How to protect financial stability, of the euro area as a whole, in the face of turmoil in sovereign debt markets?

In more general terms, the challenge derives from the combination of a single market and a single currency with national responsibilities in the areas of economic policy and financial stability.

European Cohesion Policy

Willem Molle

Abstract

One of the main objectives of the EU is cohesion, namely a decrease in the disparity of wealth between its constituent parts. A considerable part of the EU budget is earmarked for this policy. The policy should also support the EU 2020 strategy, which focuses on smart, inclusive and sustainable growth. Over the past decades the EU has been able to realize to some extent its ambitions. Effectiveness can be further stepped up by making improvements in the delivery system.

Why EU Involvement?

The European Union has to contend with enormous disparities in wealth between the Member States. Successive enlargements have considerably increased this inequality due to the accession of low income new Member States. These disparities lead to social and political problems that endanger the internal cohesion of the EU. Moreover, the very dynamics of the integrated economy of the EU may lead to further agglomeration and hence increase cohesion problems. Hence a policy is needed to change the situation and bend the autonomous development processes in such a way that they lead to less disparity and more cohesion. In principle the national governments of the Member States are the first in line to cope with these problems.

However, there are two sound reasons (related to the subsidiarity principle) why the EU should also step in. One important consideration is the economies of scale applied to finances: the EU can mobilize and provide greater funds under far better conditions than poor Member States. Moreover, it can offer long-term predictability about the availability of resources to all beneficiaries. This means that investors will be more inclined to invest and growth is therefore likely to be enhanced. The second important factor is regulation: the EU sets rules to limit internal competition between Member States which offer state aid. Moreover, the EU determines the architecture and operation of the delivery system while leaving Member States to oversee the application of the eligibility criteria and the selection of projects within the EU priorities. (For an elaborate systematic analysis of all stages of the policy and for detailed references to the relevant literature, see Molle (2007)).

Definition and Measurement of Cohesion

Cohesion is a concept that has been introduced into EU policy without a precise definition. Over time a practical definition has been developed. Cohesion has increasingly become understood as the degree to which disparities in social and

economic welfare between the different regions or groups within the European Union are politically and socially tolerable. Whether cohesion is achieved is largely a political question.

Cohesion is measured by the change in disparity from one period to another. A decrease in disparity (convergence) means improved cohesion, whereas an increase in disparity (divergence) means less cohesion. In general one uses simple indicators to measure disparity; the most common one is regional Gross Domestic Product per head. Another common indicator is (un-) employment. Moreover, a series of other indicators are used, such as the risk of poverty, health, and access to broadband Internet.

Objectives of the Policy

The EU has set a number of objectives for its cohesion policy. The fundamentals have remained fairly constant over time, although the specifics have constantly been adapted to new challenges (Begg 2010). The main ones are:

1. To improve cohesion (that is convergence of wealth levels) on three dimensions:
   - economic – i.e. the conditions for economic growth such as innovation
   - social – i.e. employment and social exclusion (e.g. poverty)
   - territorial – i.e. specific types of regions (such as urban), elements directly related to spatial planning (e.g. infrastructure) and the environment (Duehr et al. 2010).
2. To contribute to other EU objectives, for instance:
   - facilitating major advances in economic integration, such as enlargement or the passing on to higher stages of integration (e.g. Economic and Monetary Union)
   - contributing to major policy targets such as the increase in competitiveness, the decrease of social exclusion or the stimulation of environmental sustainability. (The latter has notably come to the fore with the so called Lisbon strategy, launched in 2000, and the new Europe 2020 strategy (EC 2010a).)

The objective discussed under 1 is generally referred to as the *convergence* objective. The regions that fall under this objective have a GDP/P level below 75% of the EU average. They are the main beneficiaries of the policy. The EU has decided to let all other regions also benefit from cohesion policy; the main objectives here are the improvement of competitiveness and social inclusion (these regions are therefore generally called *competitiveness* regions). (Up till the present programming period the former type regions were formally called objective 1 regions and the second type objective 2.)

Instruments

The main instruments by which the cohesion policy is put into effect are:

1. The provision of financial means (see the following section). The EU does this by allocating funds to the disadvantaged regions to improve their economic structure and to social groups to improve their employability and to avoid their social exclusion. Both should lead to increases in competitiveness.
2. The setting of rules and the coordination of actions (see 'Regulation and coordination', below). As cohesion is a matter of shared responsibilities between the Union and national authorities, such coordination is vital for effectiveness. This applies equally to national cohesion policies and to other EU and national policies, such as environment.

Financial Support

The main instrument of cohesion policy is financial support paid by the EU budget. As a first step, a share of the budget (some 40%) is earmarked for cohesion. In the next step, funds are allocated to the different Funds (see next paragraph). In the third step the former are allocated to the various cohesion objectives. Convergence regions (defined as those with an average wealth level of less than 75% of the EU mean) get the lion's share

(three quarters). They are mostly located in the new Member States and in the Mediterranean South. The rest is for regions anywhere else in the EU to improve their competitiveness and for territorial cooperation. This step also defines the allocation of resources over countries. In the fourth step a selection is made of the programmes and projects that are eligible for support.

Spending on cohesion operates mainly through two types of fund:

- The European Regional Development Fund (ERDF) and the European Social Fund (ESF). These funds are called 'structural' because they support measures that aim at the improvement of the structural aspects of the regional economy. There is a certain specialization between the two funds: the ERDF concentrates on economic cohesion and finances mainly infrastructure and innovation; the ESF concentrates on social cohesion and finances mainly training and education.
- The Cohesion Fund (CF). Beneficiaries are the member countries with below EU average (actually 90%) GDP per head figures, with a programme of economic convergence to EMU conditions. The Cohesion Fund finances environmental and transport projects in a framework that is different from the Structural Funds; it delivers national, not regional funding and the programming is simplified compared to the ERDF and the ESF.

Note that these funds provide only financial support to projects and programmes. The principle of additionality prescribes that major contributions to the financing have to be made by the national and or regional governments too. The lower the wealth level of the region, the higher, in percentage terms, is the EU contribution.

Main Actors

The EU is not the only body responsible for cohesion. Member States also play an important role. Moreover, according to the partnership principle the policy involves local governments and representatives of the third and private sector. This multi-level governance of the EU cohesion policy is meant to increase participation and coordination and hence consistency and effectiveness. The competences of the three main actors, and hence the power balance between them, changes in the course of the policy cycle (see Table 1).

A whole administrative and institutional system has been set up to deliver the policy. This consists first of Management Authorities, which are responsible for the programming and execution of the various projects, such as the building of roads and the training of people. They also guide the work of the Monitoring Committees, which are the responsibility of the Member States. They are the highest decision-making bodies of each Operational Programme. They are charged with surveillance of the progress of the work; reporting to the European Commission and making proposals for adjustments. The financial disbursements are done by so-called Certifying Authorities, while control on spending is done by Auditing Authorities.

European Cohesion Policy, Table 1 Changing roles of the major actors during the policy cycle (adapted from Molle (2007), p. 127)

Stage in the policy cycle	European Commission	National governments (Council)	Regional authorities
Basic design	strong	dominant	weak
Financial packages Definition of objectives and of eligibility criteria	modest	dominant	weak
Institutional framework and delivery system	strong	strong	modest
Implementation	weak	variable	strong
Evaluation	strong	variable	variable

Regulation and Coordination

The EU cohesion policy also uses the instrument of regulation to set uniform rules that govern the use of financial instruments (the Structural Funds; see Instruments, above) and to set the framework for the coordination among partners (see previous section) to realize mutual consistency of objectives, priorities and concrete projects.

Moreover, the instrument of regulation is used where one can assume that the coordination instrument is insufficiently effective at controlling certain negative effects of independent national and regional policy making. This applies notably to state aid. The main principle of EU competition policy sets a complete ban on state aid. However, this ban can be lifted in the case of regional structural weaknesses. The degree to which this is possible has been made dependent on the level of development of the Member States: restricted in the case of rich Member States and somewhat more lenient in that of poor Member States. This rule serves the purpose of effectiveness; subsidy wars would always be won by the richer Member States, as they have the resources to outbid the poorer Member States, which would render ineffective the EU support given to the latter.

Consistency with Other EU Policies

The EU pursues a large number of policies, some of which can have a significant influence on the distribution of economic activity, which in turn can have an adverse effect on cohesion. To avoid such problems the design and implementation of major EU policies have to be coordinated. This is notably the case for policies with a strong spatial or territorial dimension, such as transport and environment, but also for policies dealing with research and the information society. Indeed, innovation being one of the main determinants of competitiveness and hence growth, EU-wide policies and national and regional policies in this domain have to be dovetailed to achieve maximum effect (Molle 2009). It is to be noted here that the policies of the EU that are fundamental for the functioning of the internal market (such as freedom of movement) and Monetary Union (such as the Stability and Growth Pact) are spatially blind; their potential negative effects on cohesion have to be compensated for by an increased focus on cohesion policy in the affected areas.

Integrated and Territorial Approach

The coordination of sectoral policies in a multilevel government framework is particularly difficult (Meijers and Staed 2004). Indeed, the search for compromises at the EU level on cross-cutting issues tends to lead to vertical inconsistencies at the national and regional levels, and other compromises between sectoral policies may have been worked out. Vertical policy integration by sector may complicate the solution of intersectoral conflicts on the EU, national or local levels. As part of a solution to these simultaneous problems the EU has decided to make Impact Assessments of its policy proposals and put some accent on territorial impact assessments. Moreover, it has opted for integration of its policies at the regional and local levels, as at this level things move from the abstract into the concrete; indeed general objectives have to be translated into concrete projects on the basis of priorities that are selected with a view to their local potential (Barca 2009; EC 2010b).

Evaluation of Effectiveness

The performance of the EU cohesion policy (that is realization of its objectives) is difficult to evaluate due to methodological and practical insufficiencies. Over the past decades much effort has been made both by academics, consultants and policy makers to improve the situation (Basle 2006; Mairate 2006; Martin and Tyler 2006). However, these have not resulted in a consensus as to its effectiveness. On the contrary one sees two almost opposite views.

The *dominant view is positive*. Those who hold this view have found that in the past the EU cohesion policy has been effective in decreasing the wealth gap between its member countries and regions (Bornschier et al. 2004; Ederveen et al. 2003; Martin and Saenz 2003; Tselios 2009). Moreover, due to the interrelations between different member countries the net payers have benefited also because their industries have been the main suppliers of investment goods to the projects executed under the cohesion policy. Next, they indicate the contribution to a series of side objectives, such as the environment (ENEA 2006). Finally they stress that the EU has increased effectiveness by setting up a better intervention and delivery system than the national ones (Lion et al. 2004; Gualini 2004), geared to local needs and capacities (Leonardi 2005). These results are embraced by the Commission (EC 2010c).

There are also (*highly*) *critical views*. Some find that cohesion policy is not appropriate: a good set of other policies producing the conditions for healthy growth would also lead to convergence of wealth levels. Others find that cohesion policy is not effective; they observe that during the years that the EU cohesion policy was still very limited, disparities decreased, while they have increased since the huge increases in EU cohesion spending (Boldrin and Canova 2003; Dall'Erba and Gallo 2008). Others find that the policy is inefficient; the actual management of the policy takes up too large a share of resources.

Conclusions and Future Developments

Although there is no clear-cut conclusion from empirical research as to the performance of the policy, there is much evidence to support the view that over the past decades the EU cohesion policy has been conducive to the attainment of major EU policy objectives. This applies in particular to the convergence objective and some side objectives, such as the internal market and the EMU. All is not rosy however; in the course of time certain weak points have become apparent that need adaptation. We may mention the dependency on aid of the convergence countries, the welfare loss incurred in transferring money from rich member states back to their regions via the 'competitiveness' route, the rigidity of pre-fixed quota and priorities, the high delivery cost for atomized projects notably of the European Social Fund, etc.

To remedy such problems many proposals have been made for a renewed structure of the EU cohesion policy. Some of them are not new; indeed, the inadequacies of the basic architecture of the policy have been apparent for some time (Bachtler and Mendez 2007). The most far-reaching proposals include the abolition of the 'competitiveness' objective or at least the redirection of these funds to the respective budget headings (implied in the subsidiarity tests as given in, for example, Begg (2008) and ECORYS (2008)). Another proposal is the abolition of the quota system of the competitiveness objective and its replacement by a system of competitive bidding for EU priority projects (Ederveen et al. 2003; Tarschys 2003). Finally, proposals have been made to remedy the potential negative effects on aid dependency by much stricter conditionality in matters of administrative capacity (Molle 2011).

Much like in the previous round of reforms of the cohesion policy the European Commission has maintained as an essential feature of the policy that all regions may benefit. The reasons are of a political nature. First, the regions of rich Member States are not inclined to give up access to EU funds. Second, the Commission is not inclined to give up its influence in all regions of the EU, the less so because it considers that the EU 2020 strategy justifies continuation of the competitiveness objective – this notwithstanding the general view that the use of the cohesion policy instruments for such purposes is a rather distorted way of matching objectives with instruments.

So, the proposals of the Commission for adaptation of the policy in the period 2013–2020 focus on delivery aspects such as the strategic programming (see also Barca 2009). They follow certain of the proposals mentioned earlier by critics, such as thematic concentration, conditionality of

support, evaluation of impact, the use of new financial instruments (not only grants but also loans), streamlining of the financial management and control systems and finally strengthening of the institutional capacity of the recipients (EC 2010d).

European Employment Policy

Robert Strauss
European Commission, Brussels, Belgium

Abstract

The European Employment Strategy (EES) was included in the 1997 Treaty of Amsterdam to accompany the newly completed Single Market and the advanced preparations for the European Monetary Union. It constitutes the core of European employment policy. The entry examines how and why the EES came into being and the employment policy challenges it has focused on since its inception until today. It looks at some of the labour economics underpinning it and at what the EES but also other employment policies have been able to achieve in the EU, especially since the economic and financial crisis of 2008.

Definition

European employment policy is the set of actions taken at the level of the European Union to enhance the quantity and quality of jobs in all the Member States.

Introduction

Employment has been a key concern and indeed an objective of the European integration process since the Treaty of Rome establishing the European Economic Community was signed in 1957. In its preamble its signatories declared that they are "resolved to ensure the economic and social progress of their countries. . .. affirming as the essential objective of their efforts the constant improvement of living and working conditions. . .." The European Social Fund providing financial support for improving workers' mobility and employment opportunities in the common market was also established (EEC 1957). But it was only at the Paris Summit of 1972 that it was decided to use the European Social Fund to support "the carrying out a co-ordinated policy for employment and vocational training, . . . improving working conditions and conditions of life, . . . closely involving workers in the progress of firms" (European Communities 1972). A European employment policy was emerging containing three pillars: a legislated rights pillar comprised of European employment legislation; "law via collective agreement" based on social partners' agreements; and thirdly, coordination of national employment policies (Rhodes 2005). Employment policy coordination became the basis for the European Employment Strategy, provided for in the Amsterdam Treaty (TEU 1997).

Included in the revised Treaty, to accompany the newly completed Single Market and the advanced preparations for the European Monetary Union (EMU), the European Employment Strategy (EES) constituted the crux of what is understood to be a, or the, European employment policy. It is buttressed by the legislative side, the first two pillars mentioned above, and the financial support provided by the European Social Fund. This entry will focus on how and why the EES came into being and the employment policy challenges it has focused on since its inception. In doing so, it will attempt to discuss some of the labour market economics underpinnings of the evolution of the EES. It will also look briefly at what it and other employment policies have or have not been able to achieve in the EU, especially since the economic and financial crisis of 2008.

The European Employment Strategy

The Delors White Paper and the Essen Process

The content of the Amsterdam Treaty establishing the European Employment Strategy did not come out of the blue. It was the result of the Delors White Paper on Growth, Competitiveness and Employment (Delors 1993) and the Essen European Summit of December 1994. And these two milestones had been preceded by several actions in the 1970s and 1980s with both legislative and Social Dialogue aspects to the fore

(Goetschy 1999). The Delors White Paper sought to offset the potentially deflationary convergence criteria of maximum shares of GDP of 60% for public debt and 3% for the fiscal deficit for the EMU enshrined in the Maastricht Treaty. In the employment field it pushed for greater use of active labour market policies (ALMPs) to complement increased labour market flexibility. ALMPs could be financed (unlike passive measures including unemployment benefits) from the Social Fund and the academic world was increasingly underlining their benefits (see e.g., Layard et al. 1991).

In Europe the employment situation had been deteriorating sharply. Between 1990 and 1994 the soon-to-become EU 15 saw six million net jobs lost. The unemployment rate rose from a cyclical low of 7.7–11.1%. Unemployment was at the top of the political agenda in many countries. The Essen summit of December 1994 certainly did not only focus on labour market issues, the accession process for Central and Eastern European countries was the key topic, but it did lay the groundwork for the EES. It agreed to set up a multilateral employment monitoring procedure closely modelled as the economic monitoring procedure contained in the Maastricht Treaty. Member States were recommended to take measures at national level in five areas:

- Improving employment opportunities by promoting investment in vocational training (especially for the young) and encouraging lifelong learning
- Increasing the employment intensity of growth, particularly through a more flexible organisation of work and working time, wage restraint, job creation in local environmental and social services
- Reducing non-wage labour costs to encourage employers to hire low-skilled workers
- Developing active labour market policies through the reform of employment services, encouraging occupational and geographical labour mobility and developing incentives for the unemployed to return to work
- Targeting measures to help groups particularly affected by long-term unemployment

Member States were urged to translate these recommendations into a long-term programme in the light of their specific economic and social circumstances and were required to submit an annual progress report. The Commission, in conjunction with the Economics and Financial Affairs Council (ECOFIN) and the Labour and Social Affairs Council, was to synthesise these national reports into an annual assessment submitted to the December European Council. On this basis, the European summit would review the employment guidelines, issue further recommendations to Member States and decide new initiatives at Community level.

"This procedure was intended to have a threefold effect. First, the annual report would help improve the efficiency of national employment policies by exposing these to public examination and facilitating explicit comparison of the performance of each Member State. Second, the prescribed cooperation between ECOFIN and the Social Affairs Council in drafting the annual report might facilitate greater integration of economic and employment policy, [essentially at a European level]. Third, it was hoped that multilateral employment monitoring would encourage greater convergence of employment policies in the Member States along the lines of the Essen recommendations" (Goetschy 1999, pp. 121–122).

The Amsterdam Treaty

The Amsterdam Treaty revising that of Maastricht made "full employment" an explicit priority of the EU and "a question of common concern." There was a realisation that the good or bad employment situation of one Member State affected or had spill-overs on another. The Community acquired new powers to develop "a coordinated strategy for employment" which should in particular promote "a skilled, trained and adaptable workforce and labour markets responsive to economic change."

The employment chapter of the Treaty covered: first, the integration of employment in the formulation and implementation of other Community policies; second, the establishment of mechanisms for coordinating employment policies at Community level. These mechanisms

reflected practices already in operation as part of the Essen monitoring procedure, but also borrow extensively from the economic policy coordination model setup by entry 103 of the Treaty of Maastricht. The main difference, and it is significant, is that recommendations issued on employment matters lack any binding effect.

In four significant respects, however, the Amsterdam Treaty involved an advance on the Essen process. First, the "annual guidelines for employment" were established as the driving force and the key component of coordination. Second, the Council carries out an annual examination of measures taken by Member States to implement the guidelines. The Council's evaluation is based on the annual report that each Member State must submit to the Council and the Commission, and on the opinion of the Employment Committee. The requirement to submit an annual programme was thus "hard" law and ultimately if not done could lead to fines being levied by the European Court. The quality of such programmes was not however specified. If necessary, in the light of this examination, the Council "acting by a qualified majority on a recommendation from the Commission, may, if it considers this to be appropriate, make recommendations to Member States." Such recommendations to individual states deemed not to have followed the guidelines would have no legally enforceable effect but are symbolically powerful. This implied a strengthening of influence at Community level.

Third, the Treaty establishes an Employment Committee with advisory status, formally ratifying an initiative taken by the Council in December 1996. The Member States and the Commission each appoint two members of the Committee. It has a dual purpose: to monitor the employment situation and employment policies in the Member States and the EU, and to formulate opinions (at the request of the Commission, the Council or on its own initiative) and to prepare the Council's work. In fulfilling its mandate it is required to consult the social partners.

Finally entry 5 of the Treaty allows the Council to adopt, by a qualified majority and after consulting the Economic and Social Committee and the Committee of the Regions, "incentive measures designed to encourage cooperation between Member States and to support their action in the field of employment." Such measures can involve the dissemination of best practice, the evaluation of experiences and the launch of pilot projects. The provisions of the Amsterdam Treaty came into force in May 1999, cementing practices known in Brussels circles as the Luxembourg process. Furthermore, the employment and labour ministers at the OECD in the 1997 ministerial meeting had endorsed "the need to shift public spending on labour market policies from passive to active measures" (OECD 1997).

The Luxembourg Process, the European Employment Strategy and the Lisbon Strategy

In November 1997, as unemployment remained high, an extraordinary ministerial Jobs Summit was held in Luxembourg. It launched the European Employment Strategy (EES) as set out in the Treaty, complemented by features which made it into the first open method of coordination (OMC) – the Luxembourg process. This process was the basis or model for similar soft law instruments in other social areas such as social protection, social inclusion and certain aspects of education and training. The key features of the EES were an annual coordination and monitoring of national employment policies based on Member States' commitments to establish a set of common objectives and targets. To its supporters, the EES ensured that the objective of a high level of employment saw the same political importance as the (other) macroeconomic objectives of growth and economic stability.

The EES added a dimension. The existing legislative pillar was about minimum standards, the EES was about policy directions, from stimulating employability to considering labour taxation. Employment coordination at the EU level meant – for the first time – a structured and systematic debate about labour markets at the EU level, and working towards and arriving at agreement about a common agenda and policy directions. This is a prerequisite if one is to set common goals such as the employment guidelines and arrive at a more integrated social-economic

agenda. It specifically saw three components: building of, and agreement on a common set of indicators to track progress/problems; understanding different systems, e.g., the role of social dialogue; and, understanding different policy outcomes and the possibilities/limits of the transfer of good practices.

As the EES was becoming more and more embedded in European and national employment policy-making, the Commission launched an ambitious, wide-ranging programme to make the EU "the most competitive and dynamic knowledge-based economy in the world, capable of sustainable economic growth with more and better jobs and greater social cohesion." This programme was agreed at the Lisbon European Council in March 2000 giving rise to the Lisbon Strategy (Lisbon European Council 2000). With its commitment to "more and better jobs," European employment policies and in particular the EES were to be a key part. The employment guidelines, discussed with and adopted by Member States each year, contained detailed guidance as to how they would obtain more and better jobs. The employment guidelines for 2001 saw 18 separate detailed aspects of how to do this including some quantitative targets – key aspects of the Lisbon Strategy – such as an employment rate of 70% overall including at least 60% for women and 50% for older workers by 2010 (European Communities 2001).

The Kok Report "Jobs, Jobs, Jobs" Begats Flexicurity

Though subject to annual revisions, Member States displayed increasing dissatisfaction with the way the EES was being run. It was seen as too bureaucratic not sufficiently focused on the key challenges and not always coherent with the Broad Economic Policy Guidelines (BEPGs). In March 2003 the European Council invited the Commission to establish a European Employment Taskforce to be headed by former Dutch Prime Minister Wim Kok. It was charged with carrying out an independent in-depth examination of key employment-related challenges and to identify practical reform measures. It reported in November 2003 (Kok 2003) and its key findings were that increased efforts needed to be made to boost productivity and employment in Europe. Four priority actions were needed: increasing adaptability of workers and entrepreneurs; attracting more people to the labour market; investing more and more effectively in human capital; and, ensuring effective implementation of reforms through better governance. The first three actions stemmed from a hard-headed analysis of the economic workings of Europe's labour markets. It provided the analytical and political underpinnings of the major policy priority of the EES – enhancing flexicurity. This, with ups and downs linked with the economic and financial crisis, has remained a core element of European employment policies until today. Similarly, the employment guidelines became and have remained much more integrated with the BEPGs with finance ministers in recent years often the major champions of flexicurity.

Getting Member States to agree on the principles of flexicurity was not easy. The trade unions were suspicious and fearful believing most of the labour market reforms would increase flexibility with reduced employment protection legislation (EPL) and little in the way of increasing employment security. One reason for such doubts was that flexibilisation usually cost the public purse nothing while investing in ALMPs, more comprehensive training or better social protection was expensive at least in the short term for public budgets and finance ministries (that in any case often seemed to believe the less EPL the better).While the Commission was trying to convince Member States of the benefits of flexicurity, the European Trade Union Institute noted, in early 2007, "the permanent place flexicurity is acquiring in the Commission's employment policy. . .. There has been little attention paid to the broader EES which now seems to stand in the shadow of the more confused flexicurity approach" (Keune and Jepsen 2007).

Employment ministers agreed the principles of flexicurity in late 2007 (Council 2007). It did dominate the EES until the crisis, but the aspects of lifelong learning and skills saw a particular emphasis in 2008/9. This manifested itself as a determination to equip workers displaced by changing technology and globalisation with the light (new) skills for the new jobs the EU would need to create. Human capital investment had

long been seen as a vital component of more and better jobs. Workers were more productive but also more adaptable with a good skills basis. Getting new skills for new jobs was also something both employers and trade unions could agree on, one aspect of flexicurity that saw relatively non-conflictual social dialogue. The Commission's Communication highlighting the importance of and means to achieve new skills for new jobs (European Commission 2008a) was published in late 2008 as it was becoming clear that the EU was not seeing a normal economic downturn but a major recession, originating and largely imported from the USA but now global in nature.

The Crisis and Stressing Short Time Working

The financial and economic crisis saw output fall quite dramatically in most European countries as banking systems imploded and export markets collapsed. Unemployment, with the usual lag, started to increase after 6 or 7 years of sustained falls across the EU. Most policy-makers thought a large part of this decline was due to good employment policies being implemented, sometime with politically difficult struggles. Germany, with its hard-won Hartz reforms, was seen as the leading example of what had needed to be done. The key features included *inter alia* more active support including vocational training for the unemployed, "mini-jobs" with much lower social security contributions and less generous unemployment benefits. These increased the adaptability of labour markets by increasing flexibility of jobs but also security for employment As the crisis deepened, it was tackled by most Member States with conventional Keynesian increased fiscal spending under the Commission's European Economic Recovery Plan. It proposed a coordinated economic stimulus of 11/2% of EU GDP with budgetary spending supposed to be timely, targeted and temporary (European Commission 2008b). Nevertheless, EU unemployment rose steadily although less fast than in the USA. Nearly all Member States saw a rise but some much more than others and such rises were often uncorrelated to the amount that output had fallen. Germany saw a big fall in GDP as exports crashed but little rise in unemployment. Spain, with a similar GDP decline and caused first and foremost by its construction bubble bursting, saw a much steeper increase in joblessness. This divergent response of labour markets to the crisis continued into aftermath and suggested that although macroeconomic conditions were very determinant for the levels of unemployment, labour markets and employment policies that affected their working could also play a major role.

During the crisis the EES had focused on braking the rise in unemployment through the use of short time working schemes in which the state paid part of the income of workers put on shorter hours. Germany was a major user of such schemes and Belgium, France, the Netherlands and Italy also used them significantly. Not only did it ensure better incomes and thus more aggregate demand in the economy (and political support) compared with more workers simply being put on the dole, but keeping workers at work and providing training in some of the hours they were not working would reduce the risk of permanent loss of skills and hysteresis. The German "Kurzarbeit" scheme was seen as a useful complement to the Hartz reforms and fully in line with the flexicurity paradigm. (Short time working was a form of internal flexicurity.) The OECD and Commission worked together on identifying the best employment policies to confront what many were already calling the Great Recession (see European Commission 2010).

Prolonged Crisis, the Europe 2020 Strategy and a Focus on Youth and the Long-Term Unemployed

The crisis and a new Commission wanting to make its own mark rendered the Lisbon Strategy obsolete in its final months. It was superseded by a more focused programme, the Europe 2020 Strategy to achieve smart, sustainable and inclusive growth with European and national targets in five domains: research and development expenditure; environmental improvement; employment; educational attainment; and poverty reduction. The last three areas found themselves in the four employment guidelines the Council adopted in October 2010; they also contained the EU targets for 2020: an employment rate of 75% for men and

women aged 20–64; reducing early school leavers to 10% and raising the share of 30–34 years with tertiary or equivalent level education to 40%; and reducing by 20 million the number of people at risk of poverty. The annual cycle of reporting, guidelines and recommendations in the EES, already merged with that of the BEPGs in the Lisbon Strategy, was subsumed into the European Semester process that the Europe 2020 Strategy gave rise to. The Joint Employment Report became an annex of the Annual Growth Survey the Commission published each Autumn to launch it.

Unemployment continued rising and then plateaued in late 2010. The crisis appeared to be over as output recovered. Germany and others phased out their short time working arrangements. Interest rates were increased by the ECB in 2011 as unemployment was just beginning to decline. But financial markets did not believe all of Europe's economy was back as the road to prosperity. Greece and other EMU countries on the geographic periphery of Europe saw a growing reluctance to be lent money through government bonds. Output fell once again and the EU entered its double dip crisis. The renewed recession in 2011 threatened to undo the Europe 2020 Strategy almost before it had started. Employment rates fell rather than rose and the number of people at risk of poverty increased rather than decreased. As unemployment again began to rise in the EU, and especially in the EMU periphery, it was the labour market group that had suffered most which began to become the new policy priority – young people. Youth unemployment, usually defined as the unemployment rate of those aged 15–24, had been higher than adult unemployment for several decades. But as the crisis had first unfolded rates in the EU had risen from 15% in 2008 to 23% in 2010 and were now going higher particularly in Greece, Portugal, Spain, Ireland and Italy.

As it had done with flexicurity, the Commission used devices or instruments outside the employment guidelines (even if these came to reflect the main political thrust contained in them) to prioritise action for the EES. Policy guidance was issued in the form of packages. In April 2012 the Employment Package focused substantially on the demand side of job creation just as fiscal consolidation was having an opposite effect. The policy prescriptions included reducing taxes on labour and supply business start-ups. It also underlined the need for greater involvement of the social partners in setting EU priorities. In December 2012 the Commission sought to address the persistent, and in some Member States still rising, youth unemployment. It proposed a European Youth Guarantee, which was adopted as a Council Recommendation in April 2013, in which all young people under the age of 25 would receive a good quality offer of employment, continued education or an apprenticeship of traineeship within 4 months of them leaving formal education or becoming unemployed (European Commission 2012). And, exceptionally, extra funding was found to the tune of six billion Euros to be used via the European Social Fund to help the most affected Member States finance such measures.

Unemployment in the EU, both overall and for young people, actually peeked in 2014. The crisis appeared to be over but in September 2015 a third package was prepared by the Commission to deal with one potentially long lasting or even permanent consequence; the high numbers of unemployed people who remained unemployed more than 1 year – the long-term unemployed (European Commission 2015). It varied widely across the EU but was as high as 19.5% of the active population in Greece. Inspired by the Youth Guarantee, the key element was to ensure all those who had been unemployed for at least 18 months were registered with national employment services, received an individual in-depth assessment of their employability including skills needs and signed up into a job integration agreement. Member States agreed to the package in February 2016 even though there was no additional funding proposed to help them facilitate the re-entry of the long-term unemployment into employment. Perhaps the recovering European economies were supposed to do this without significant extra investment in ALMPs for the long-term unemployed. But those Member States with the highest long-term employment rates tended to be those under the most pressure to continue fiscal consolidation and thus had least resources to finance additional ALMPs themselves.

What Have European Employment Policies Achieved?

In early 2017 EU unemployment is just above 8% while the employment rate is around 70% for 20–64 year olds: the former is a little higher than the best figures just before the crisis while the latter is fractionally better than that in 2008. These averages hide large variations among the Member States with some still seeing very high levels of overall unemployment, youth unemployment and long-term unemployment. As the 2017 Joint Employment Report notes: "unemployment, youth unemployment and poverty levels remain far too high in many parts of Europe; labour market and social outcomes vary by gender, age and education; income inequality remains high in many EU countries with negative implications for economic output and inclusive and sustainable growth" (JER 2017).

In many ways the challenges confronting employment policy in Europe and the recommended measures to address them are not very different from those facing policy-makers when the EES was first launched 20 years ago. One clear difference is the greater emphasis put on poverty, social protection and inequality, issues largely absent for the first employment guidelines. These concerns have been an increasing part of the EES within the Europe 2020 strategy and its explicit poverty target of reducing those at risk of poverty by 20 million. They also reflect the legacy of the crisis which saw number of those at risk of poverty rise sharply rather than fall. Though new to the EES, these concerns had been evident in the social OMCs but these were far from fully integrated into the Europe 2020 strategy.

With the figures for employment and unemployment in the EU on average at best little better than 10 years before, and the challenges identified remaining quite similar, it seems difficult to say 20 years of the EES was a resounding success. Nevertheless, many would say it is unfair to measure its achievements looking at these data; they would say that it was the crisis and macro policy responses to it, especially the fiscal consolidation programmes, which overwhelmed the supply side changes employment policies could have brought about. Others would point to the apparent success stories of individual countries which weathered the crisis reasonably well, either by implementing EES-advocated reforms before it such as Germany or already had policies and institutions in place from the beginning along the lines of the flexicurity paradigm such as Sweden, Denmark, Austria and the Netherlands. There is some independent evidence that up until 2008, the EES led to convergence and improved employment outcomes over and above long-term or international trends (Van Rie 2012).

Poland, the Czech Republic and the Baltic States also have well-performing labour markets today at least when looked at with data for employment and unemployment rates. They are doing much better than they were in the late 1990s and it could be claimed that it was preparing for EU and thus EES membership, and as of 2004 being full members, that has played a significant role in their success stories. The critics of the EES would retort that it had little or nothing to do with this and all to do with their integration into German-led industrial supply chains and sound macroeconomic policies. The debates about the desired flexibility of labour markets continue to be similar to those when the EES was set up. It would be fair to say that the jury is still out on how effective the EES or employment policies in Europe have been. Similarly, there is no agreement on what difference the EES itself has made or whether the apparent successes in labour market performance in individual Member States because of policy reforms would have happened in any case through national pressures to raise economic performance. How much of the Hartz reforms was inspired by what the EES guidelines were advocating or did the EES take up Germany's reform model? Were the reforms in Spain and Italy in the wake of the crisis largely inspired by or even done through European guidance and examples from other countries or largely internally driven and designed? To end on a more positive note, there are very few people who say that employment policy coordination, including Council adopted Recommendations, at a European level is bad and that it should be left entirely to Member States. Even the UK which is

leaving the EU to "regain control" did not object most of the time to being in the EES, stressed the usefulness of learning from others and nearly always played a full part in developing it.

Workers' mobility was and is one of the four fundamental freedoms, together with goods, services and capital, underpinning the original common market. European employment policies have sought to promote it to enhance productivity and employment across the EU. During the crisis it was seen as a significant means to reduce divergence; the unemployed from countries with high unemployment were actively encouraged to seek work in countries with much lower rates. But recent times have seen growing concern that this puts undue pressures on host countries. Combined with a surge of refugees, both political and economic, concentrated in just a few Member States, and growing support for nationalist political parties, enhanced labour mobility is little seen and less talked about as a priority for the EES. The same Joint Employment Report for 2017 identifies four priorities for the EES to promote the creation of quality jobs: removing barriers to labour market participation, tackling labour market segmentation and undeclared work, ensuring that social protection systems provide adequate income support and ensuring all people had access to enabling services while transactions into employment and making work pay are encouraged. These can be considered its work programme for the next few years.

European Labour Markets

Giuseppe Bertola

Abstract

Labour taxes and subsidies, collective wage bargaining, and employment protection

legislation affect labour market outcomes in European countries more strongly than in other advanced countries. This article outlines theoretical approaches to their motivation and consequences and reviews empirical insights from comparative crosscountry studies of how employment, unemployment, and wage dynamics are shaped by the interaction between institutions, macroeconomic developments, and structural features.

European labour markets, especially those of Continental countries, are characterized by more unionized wage setting and more stringent regulation of employment relationships than those of other OECD countries. Within that group of advanced countries, their unemployment rates used to be relatively low, and became very high. Around 1970, the unemployment rate was approximately 3.1 per cent in the OECD aggregate and five per cent in the United States, but the unemployment rate hardly exceeded four per cent in any European country. In the aggregate of 11 core European Union countries that later adopted the euro at its inception, unemployment stood at only 2.2 per cent in 1970. It then rose rapidly, exceeding ten per cent in 1984 and hovering around 12 per cent in the second half of the 1990s, while both the United States and the OECD aggregate unemployment rates fluctuated between four per cent and nine per cent.

The wide variety of labour market developments over the last quarter of the 20th century has motivated extensive modelling efforts and comparative empirical studies of institutional features' motivation and effects. This article reviews the roles of institutions, shocks, and structural change in shaping aggregate and disaggregate labour market outcomes.

Labour Market Policies

To illustrate the spirit of more general approaches to the relevant issues, it is useful to focus initially on the simplest models and the best understood labour market institutions (Prescott 2004). Consider inverse demand and supply functions

$$w^d = a(l), \quad w^s = s(l), \tag{1}$$

where l denotes log employment and w^s and w^d denote log wage rates. The wage w^* and employment l^* that equate supply and demand satisfy the condition

$$s(l^*) = a(l^*) = w^* \tag{2}$$

in static competitive equilibrium. As the simplest example of how institutions can change this outcome, consider a labour income tax that, inserting a wedge τ between employers' labour costs and workers' take home pay, changes the equilibrium condition to

$$s(\underline{l}) = a(\underline{l}) - \tau \tag{3}$$

and lowers employment by about

$$\underline{l} - l^* \approx -\tau/(\eta + \varepsilon) \tag{4}$$

where $s'(l) = \varepsilon \geq 0$ and $a'(l) = -\eta$, $0 < \eta < 1$. It is also simple to characterize formally the effects of binding legal or contractual minimum wage levels. If the wage is $\underline{w} > w^*$, the employment levels corresponding to $\underline{w}$ on the supply and demand curves are defined by $s(L) = \underline{w}$ and $a(\underline{l}) = \underline{w}$, and differ by the number

$$L - \underline{l} \approx (\underline{w} - w^*)(\varepsilon + \eta)/\varepsilon\eta \tag{5}$$

of unemployed workers, who would be willing to work at the going wage but cannot obtain employment.

From this simple perspective it is obvious that differences in taxation and wage floors may explain cross-country differences in employment and unemployment. Qualitatively similar insights can be derived in the context of more complex and realistic models of unemployment, and can be applied to other institutions. When unemployment is due to matching frictions, efficiency wages and other imperfect allocation mechanisms, taxes and wage rigidities can affect search efforts and equilibrium employment and unemployment, which are affected in turn by the market's structure (such as the extent of mismatch between workers' qualifications and vacancies) and by other institutional features (such as the scope and efficiency of employment agencies). In both competitive and frictional models of the labour market, benefits paid to out-of-work individuals can affect labour supply and search effort, and there can be similar effects from less visible policy aspects, such as the availability of public-sector employment opportunities at favourable wage–effort ratios (Algan et al. 2002).

At the same time as it offers obvious explanations for labour market outcomes, institutional variation raises the less obvious issues of why institutions should be as different across countries as they are observed to be, and of how their configuration and impact may depend on structural labour market features.

The relevance of distributional issues and of market imperfections can explain some of the labour market institutions' heterogeneity. The equilibrium condition (1) efficiently equates employed labour's marginal productivity with its non-employment opportunity cost, and distorting this outcome reduces the welfare of a perfectly competitive economy's representative individual. If workers disregard non-labour income, however, their total surplus can be increased by trading lower employment against higher pay along downward-sloping labour demand curves such as (2). It is maximized when the wage exceeds the marginal opportunity cost of employment by a monopolistic markup factor, and employment is set at a level $\underline{l}$ such that

$$a(\underline{l}) - s(\underline{l}) = \log[1/(1-\eta)] \approx \eta. \qquad (6)$$

All workers' welfare can be increased if the higher wages earned by those who are employed more than compensate for the labour income lost by those who would be employed at the competitive wage. Such compensation may take place within families, or over individual lifetimes, and can also be explicit if the revenue raised by employment taxes is spent subsidizing non-employed individuals.

Institutions that decrease employment and increase labour costs can be rationalized recognizing that they affect not only the amount of production but also its distribution across heterogeneous individuals, and that markets (especially financial markets) are not perfect in real-life economies. Higher wages and lower employment can benefit workers who have negligible non-labour income, and households' limited access to formal financial markets can rationalize collectively administered risk-sharing schemes (Agell 2002). In European countries, legislation meant to endow workers with some bargaining power and to insure them against health, unemployment and old-age hazards was introduced at times of actual or feared social unrest, in Bismarck's industrializing Germany or in Lord Beveridge's post-war United Kingdom. In principle, it can be efficient to try to provide insurance through mandatory government schemes when information and legal enforcement problems make it difficult for private markets to do so. But public schemes are not immune from such problems, and tend to reduce employment as, for example, recipients of unemployment subsidies reduce work effort. Such efficiency losses are more easily affordable by richer societies, and Europe's fast and stable post-war growth was unsurprisingly accompanied by development of increasingly extensive legislation and co-decision powers by unions. By the early 1970s, the institutional structure of labour markets was distinctively different not only across the United States and Europe as a whole, but also across countries

within Europe, where labour market policies play different roles in different welfare state models (Bertola et al. 2001). In Nordic countries, a tradition of full employment and universal welfare is based on generous unemployment benefits and a very important role for active labour market policies (including job creation in the public sector). The Bismarckian model of Continental countries such as France and Germany features centralized wage determination and stringent employment protection legislation, and contributory pension, health, and unemployment insurance programmes. The Beveridgian model of the United Kingdom and other Anglo-Saxon countries features social assistance safety financed by general taxation and comparatively light regulation of wage determination and employment relationships.

The Dynamics of European Labour Market Outcomes

Even though relief from the need to work should in general reduce employment, until the 1970s, and even in the aftermath of the late 1960s period of worker unrest, increasingly generous pro-worker institutions coexisted in Europe with low unemployment rates; much lower, in fact, than in the comparatively unregulated United States. The first oil shock and the following decades of slower growth saw the inception and persistence of high unemployment in most European countries, and increasing attention to the effect of institutions on labour market performance. If wages are preset, shocks can cause employment and unemployment fluctuations, the size and persistence of which depends on the extent of *ex post* wage flexibility and on the character of wage bargaining. Nominal shocks are a more relevant source of real wage misalignments and unemployment in labour markets with more pervasive and longer-term collective wage contracts. Conversely, real wages react more promptly to productivity shocks or growth slowdowns if bargaining parties are in a better position to take into account their employment implications. Reactions to country-wide shocks are quicker, and the unemployment consequences of such shocks less severe, when wage bargaining is more centralized and better coordinated across industries (Calmfors and Driffill 1988).

This can explain why unemployment began to increase, more or less sharply, when in the 1970s European countries were hit by oil shocks and other macroeconomic developments that reduced the amount of labour demanded at any given wage. Inflation and output dynamics subsequently appear to drive European unemployment fluctuations around a natural level that, after having raised sharply until the early 1980s, has remained essentially flat since the mid-1980s (Blanchard 2006). The prolonged upward trend and the resilience of high unemployment levels naturally draw attention to non-cyclical, structural aspects of labour market dynamics. Wage floors can prevent underbidding by the unemployed of Eq. (5), but it is difficult for that static relationship to explain why, in the absence of institutional changes that would further increase unions' wage-setting power, unemployment remained high in the aftermath of the 1970s crises.

A more suitable dynamic perspective is offered by models where labour demand shocks can permanently affect the link between wages and outside options, for example because job losers no longer have a say in wage determination, or because replacement of employed workers would entail large turnover costs (Lindbeck and Snower 1988). The persistence of employment and unemployment dynamics, however, is in fact influenced not only by limited wage-setting flexibility but also by regulatory constraints on hiring and firing. In European countries, employment protection legislation (EPL) typically requires that the reasons for individual dismissals be stated by employers and subject to court appeal, and that collective dismissals be conditional on administrative procedures involving formal negotiations with workers' organizations and with local or national authorities.

Such provisions do have the intended effect of 'protecting' jobs at times of declining labour demand, when firing costs smooth out job losses and reduce downward wage pressure. Just because such a situation is costly for employers,

however, it is optimal for them to refrain from hiring in upturns, so as to reduce the desirability of labour shedding in downturns. In terms of simple demand-and-supply relationships such as those introduced above, the marginal productivity of labour should be lower than the wage when employment is declining and firing a marginal worker entails firing costs as well as wage-cost savings, but it should symmetrically be higher than the wage when employment is increasing, and the marginal worker's costs include expected future firing costs as well as the current wage. Thus, the implications of EPL are similar to those of labour taxes for expanding firms, and to those of employment subsidies for downsizing firms. If employment fluctuations are efficient in laissez-faire, EPL obviously reduces production and profits. Unlike labour taxes, however, it does do not do so by reducing employment on average (Bentolila and Bertola 1990), because its contrasting effects on employers' propensity to hire and fire reduce employment volatility but affect its average level ambiguously. Empirically, in fact, there is no convincing evidence of any relationship between EPL and the employment or unemployment level. As discussed in some detail below, correlations have to be treated with caution in this context, but more stringent EPL is associated with more stable aggregate employment paths and with longer unemployment durations within the pool of unemployed workers (Bertola 1999). There is also some evidence that EPL affects the demographic composition of employment and unemployment – as it should in theory, since it reduces job finding rates for young job market entrants and female workers with intermittent labour force participation at the same time as it reduces job-loss rates for mature workers.

Another important related difference across labour markets pertains to the extent and character of wage inequality. Earnings are typically less dispersed in Europe than in other advanced countries. The extent of underlying heterogeneity in workers' characteristics is an important determinant of earnings dispersion, but institutional wage-setting constraints also appear very relevant, both theoretically and empirically. While centralized bargaining may be better able to coordinate reactions to aggregate shocks, it tends to result in less detailed, more homogenous wage structures across firms, sectors, regions and individuals. Similar wages for heterogeneous workers imply divergence of employment outcomes, for example across demographic groups (Kahn 2000) and across regions in Italy, Germany and Spain, where the uniformity of centrally bargained wages (and of other national institutions) tends to lower employment where labour is less productive. Empirically, relative wage variation appears to be heavily constrained in the same countries where EPL is most stringent (Bertola and Rogerson 1997). This is unsurprising, because quantitative firing restrictions could hardly be binding if, in the face of negative labour demand shocks, wages could fall so as to make stable employment profitable, or to induce voluntary quits. Across countries, the combination of wage and quantity rigidities indeed appears to protect employed workers from labour income volatility, as individuals enjoy more stable wages and longer tenures.

At the aggregate level, the role of institutions in shaping heterogeneous dynamics across labour markets is not as immediately apparent. Institutions vary widely across countries but, within each country, they are much more stable than unemployment, wage inequality and other labour market outcome variables. As discussed above, however, wage-setting institutions can shape an economy's reaction to aggregate shocks. More generally, the same dynamic developments can produce very different employment and wage outcomes in countries with different (albeit stable) institutions. This can explain why, in the 1970s and 1980s, countries with more extensively regulated labour markets experienced more pronounced unemployment increases in the aftermath of similar productivity, inflation and wage shocks (Blanchard and Wolfers 2000). Empirically, in fact, the forces that interact with labour market institutions in driving dynamic trajectories can be almost equally well represented by period-specific dummy variables as by observable macroeconomic variables, which tend to behave rather similarly over time across industrialized countries. Thus, the evidence can be consistent with a role for common structural trends rather than for country-specific shocks.

For example, the relationship between country-specific labour market institutions and unemployment and wage dispersion dynamics can be interpreted in the light of skill-biased technological progress trends, or of increasing opportunities for advanced countries to import unskilled labour-intensive goods and export skillintensive ones. Over the last three decades of the 20th century unemployment displayed a trend increase in Continental European countries but remained trendless in the United States and other Anglo-Saxon countries, while earnings inequality remained stable (or even declined) in the former group of countries but trended upward in the latter. If technological progress or international trade increase laissez-faire wage inequality, they also increase the relevance of wage floors: if in European countries low wages cannot decline, employment of unskilled workers must decline (Krugman 1994). Similar insights into the changing implications of unchanging institutions can be gained by considering other structural aspects. More intense product market competition, as implied by Europe's economic integration process and by more general globalization trends, increases the elasticity of labour demand.

In the context of the simple example above, a smaller η implies larger employment losses from any given tax wedge in Eq. (4), and higher unemployment from any given wage floor in Eq. (5). In more complex dynamic models, if reallocation towards higher-paying jobs is costly, then institutions that tend to prevent wage inequality and restrict mobility have sharper implications for employment and unemployment when more volatile shocks affect labour demand (Ljungqvist and Sargent 1998).

Structural change can magnify the unemployment and employment effects of institutions meant to redistribute income and remedy financial market imperfection, or it can make them redundant (for example, because financial market development makes labour income fluctuations less problematic). Then, institutions should be reformed. In the simple formal framework above, the same smaller η that amplifies the negative employment implications of given institutions also calls for a smaller markup in Eq. (6). And, in reality, policy frameworks introduced in the 1990s, such as those recommended by the OECD Jobs Study (OECD 1994) and by the European Union's Lisbon Strategy (Council of the European Union 2000), de-emphasize income support for job seekers and job losers in favour of job creation spurred by wage and employment flexibility, and the role of training and other active labour market policies aimed at bringing workers' productivity in line with wage aspirations.

Reforms are at least partly motivated by better theoretical and empirical understanding of the effects of labour market institutions. But while it is in principle obvious that institutional interference can be responsible for high unemployment and low employment, just because such effects depend on potentially heterogeneous structural parameters, that it is hard to assess their impact in data where many relevant confounding factors cannot be controlled. Simple correlation can be very misleading. For example, a negative cross-country correlation between EPL and employment rates is fully accounted for by low female employment–population ratios in southern Europe (Nickell 1997), while effects on prime-age male employment rates tend to be positive. Both policies and outcomes can jointly respond to underlying cultural differences in this and other cases, and it is difficult to obtain reliable estimates from cross-sectional relationships between institutions and outcomes (Baker et al. 2005). More articulate and robust insights may be obtained from specifications where time-series variation and interactions play important roles (Bassanini and Duval 2006). As the time dimension of available data increases, however, it will be increasingly important when interpreting time-series evidence to focus on the economics and politics of reform processes rather than on institutions at each point in time (Saint-Paul 2000), and to be aware of plausible channels of institutional endogeneity. If shocks or structural changes make job loss more or less likely or trigger painful changes in the generosity of unemployment insurance or in the stringency of employment protection legislation, for example, the correlation between such institutions and employment performances may be largely spurious. The wide and changing

variety of labour market policies across countries offers opportunities to try to disentangle their effects in increasingly available disaggregated data, at the same time as it makes it necessary to take into account the many important and related respects, besides labour market structure, in which countries differ.

European Monetary Integration

David G. Mayes

Abstract

This article explores the development of Economic and Monetary Union in Europe from the Second World War through to the end of 2010. It concentrates primarily on the earlier part of the process and contrasts what has been implemented since 1999 with its antecedents and with the prescriptions suggested by economic theory. It covers the work of the Werner Committee, the European Monetary System (including its Exchange Rate Mechanism), the

provisions of the Maastricht Treaty, the Stability and Growth Pact and their implementation.

It is easy with the benefit of hindsight to treat the path to the present euro area as if it was an inevitable and carefully planned process. In practice it has been a series of decisions taken in the light of the broad goal of closer integration on the one hand and the more immediate needs and concerns on the other. If this had not been the case then it is unlikely that the EU would have reached the difficulties at the time of writing (2011), where Greece, Ireland and Portugal have been forced into an emergency support programme from the EU and the IMF because markets regard their debt financing programmes as unsustainable within the euro area. Monetary union is not a topic which can somehow be treated separately from the rest of economic integration. Indeed, it is important to recall in the EU context that EMU stands for Economic and Monetary Union and not European Monetary Union. All the work on optimum currency areas makes it very clear that integration in product and labour markets as well as the existence of complementary structures and policy frameworks are essential if a monetary union is to work well. The process is clearly incomplete in the European environment. In many respects the process of closer integration in Europe has been opportunistic in the sense that integration has progressed in those dimensions that appeared tractable at the time.

In this article, therefore, I map the progress towards monetary union in Europe since the Second World War against the criteria which are required for a successful monetary union, so that the balance between the political decision-making and the economic requirements can be clear. The article is in four parts: monetary integration in the immediate post war period; the Werner Plan and the creation of the EMS (European Monetary System); the road to the euro area; and the development of monetary union. In that final section I relate the structure of the existing system to the problems encountered in 2010 and the real threats to the continuation of European monetary union in the form currently envisaged. These four phases cover the periods: 1944–1970; 1971–1992; 1992–2001; and 2002 onwards.

Monetary Integration in the Immediate Post-war Period

The European input to the design of the post-war international monetary system was largely undertaken by the UK, but the final form of the system agreed at Bretton Woods in 1944 was mainly US inspired and was centred on the USA. The monetary system in Eastern Europe was imposed by the Soviet Union. The Bretton Woods system itself was a reaction to the interwar experience and the problems of adjustment after the First World War. The immediate post-war experience had not been a happy one. Germany had dissolved into hyperinflation and for most other countries the intention had been to return to the stability of the gold standard. But the attempts to return at parities that were too high had imposed strains and a decade later the system in the largest economy, the USA, itself collapsed, resulting in the Great Depression. Countries looked to protect themselves on the one hand and tried to obtain competitive exchange rates on the other.

The Bretton Woods system offered stability by comparison. Exchange rates were to be fixed but adjustable should parities become unsustainable. Fixity was not total, but a fluctuation of $\pm 1\%$ was permitted. While fluctuations of that size offer arbitrage opportunities, they are small enough to be neglected by commercial businesses in setting prices. Although there were some initial realignments, by and large the system worked rather well for 20 years and was the basis of the post-war recovery. The Bretton Woods agreement also led

to the setting up of the International Monetary Fund (IMF) which could use deposits from all of the member countries to provide temporary assistance to a country that was having balance of payments difficulties. This reflected the inherent asymmetry of the system. A country that is running surpluses has little problem maintaining its exchange rate at fixed parity. One which is running a deficit, on the other hand, will eventually run out of reserves. While other routes to restoring surpluses may be possible, the obvious route is to devalue. However, devaluations do not produce immediate surpluses; in fact they do the opposite in the short run as existing contracts are honoured before expenditure is switched towards domestic goods and exports in response to the change in relative prices – hence the need for temporary assistance by the IMF conditional on moving towards a new and sustainable long-term position at the new parity.

Thus by the mid-1960s, when strains began to emerge, the system of fixed but adjustable exchange rates was the peacetime system that European countries were accustomed to. The strains in the main came not from European countries but from the USA itself, which was the anchor of the system. All parities were expressed with respect to the US dollar, which was itself convertible into gold at $35/ounce giving a basis reminiscent of the gold standard. The US problems, to quite some extent, stemmed from the costs of financing the Vietnam war, and, once inflation began to take hold, a different anchor was needed.

No other country was in a position to take on the anchor role and hence the result was a drift into floating exchange rates, something only the Canadians had had any substantial experience of in the post-war period. What the countries of the European Community sought (as this was the Community of the Six up until 1971) was a route back to stability at least with respect to each other. The route chosen by the time of the Hague summit in December 1969 was to try to create a form of economic and monetary union in which exchange rates among the members would be fixed. The process was to be progressive, and a committee was set up under Pierre Werner, then Prime Minister of Luxembourg, to map out a plausible way forward. The Commission document on which the Hague resolution was largely based already incorporated the main ideas of the Werner Committee's ultimate proposals for an economic and monetary union by stages. It also drew on the Barre Report, issued in February 1969, which called for coordination to achieve medium term economic objectives.

The Werner Plan and the Creation of the EMS

The Werner Committee worked quickly, producing an interim report in May 1970 and a final report in October the same year. The proposals were adopted by the European Council in February 1971. The plan envisaged economic and monetary union being achieved in three phases over the course of the ensuing decade, so it would be completed in 1980. Such an economic and monetary union would include the four freedoms of movement of goods, services, labour and capital laid down in the Treaty of Rome as well as having 'a single monetary entity… characterized by the total and irreversible convertibility of currencies; the elimination of fluctuation margins of exchange rates… [and] the irrevocable fixing of parities' (Commission of the European Communities 1970, p. 10). While a single currency was not viewed as essential to this scheme, it was thought the best option. While it recognized the need for a single monetary policy at the Community level and agreement on medium-term economic objectives and coordination of shorter run economic policy, it expected the union to be relatively decentralized and for there to be no large Community budget or fiscal resources.

It was quite explicit about the form of the institutions for monetary policy 'The constitution of the Community system for the central banks could be based on organisms of the type of the Federal Reserve System' in the USA (Commission of the European Communities 1970, p. 13). The Community institution would take the interest rate and other monetary decisions and manage the Community's foreign exchange reserves. It is also clear that an organ of 'economic

government' was envisaged: 'While safeguarding the responsibilities proper to each it will be necessary to guarantee that the Community organ competent for economic policy and that dealing with monetary problems are aiming at the same objectives'. This approach to increasing coordination of economic and monetary policies had been signalled by the Commission as early as 1962 and the Committee of central bank governors had been set up in 1964 to assist the process.

The bold characteristics of the plan are summarized as (Commission of the European Communities 1970, p. 26):

> 'Economic and monetary union is an objective realizable in the course of the present decade provided only that the political will of the Member States to realize this objective. . . is present'
>
> 'Economic and monetary union means that the principal decisions of economic policy will be taken at Community level and therefore that the necessary powers will be transferred from the national plane to the Community plane. . .. The economic and monetary union thus appears as a leaven for the development of political union which in the long run it will be unable to do without.' (p. 26).

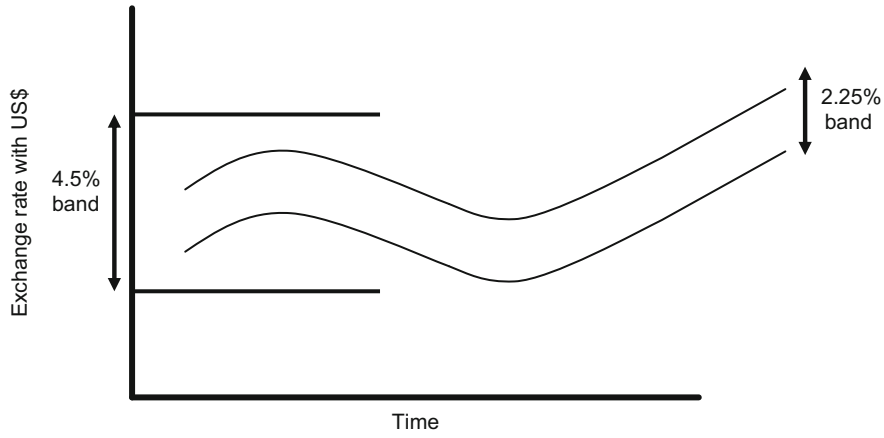
The requirements of the first stage were sweeping, going beyond what has been achieved in economic policy cooperation in the ensuing forty years, with a three-stage coordination of fiscal policy each year and a harmonization of tax instruments, organized in the first instance through the Council of economic and finance ministers. For monetary policy, 'From the start of the first stage, by way of experiment, the central banks acting in concert will limit de facto the fluctuations in the rates of exchange between their currencies to narrower margins than those resulting from the application of the margins in force for the dollar at the time of the adoption of the system. This objective will be achieved by concerted action in relation to the dollar'. The Committee of central bank governors would be required to make twice yearly reports on progress in developing the joint tools.

The progression would involve complete liberalization of capital movements and integration of financial markets. The final stage would however require a treaty revision in order to create the new institutions to replace coordinated national 'instruments' with 'community instruments' (Commission of the European Communities 1970, p. 24). These new institutions would include a European Fund for Monetary Cooperation under the control of the Governors of the central banks (Commission of the European Communities 1970, p. 25). Only the first stage had a timetable, three years.

The proposals did not really get off the ground as the dollar was effectively floated during 1971 and the best the countries could attempt was a joint float against the US dollar with limited fluctuation of each EC currency with respect to the others, as agreed by the central bank governors in April 1972. This mechanism was known as 'the snake' as illustrated in Fig. 1, where the shape of the joint movement over time might look somewhat like a snake. Under the snake the member states were required to keep their currencies within 2.25% of each other. In August 1971 the USA ended convertibility with gold and in December the Group of 10 largest countries made the Smithsonian Agreement, whereby the other countries appreciated with respect to the dollar and tried to keep their exchange rates within 62% of the new parity.

This proved difficult for many countries and the arrangements were abandoned in March 1973, when the system moved to floating exchange rates. By that time also the Community had been enlarged by the addition of Denmark, Ireland and the UK, the latter two having already started floating against the US dollar. This early period is known as the 'snake in the tunnel' as the Smithsonian Agreement permitted fluctuation of $\pm 4.5\%$, the edges of that band constituting the 'tunnel'. France, Ireland, Italy and the UK found remaining in the snake difficult and exited quite early with the impact of the first oil crisis. The system continued with Belgium, Luxembourg, Denmark, West Germany and the Netherlands until 1979 (the first two countries already having a common currency with parities fixed in 1944).

By 1978 the pressure to achieve more comprehensive exchange rate stability in the Community had risen to the point that the French President Valéry Giscard d'Estaing and the German Chancellor Helmut Schmidt proposed the creation of a



European Monetary Integration, Fig. 1 The snake

European Monetary System (EMS), following the suggestions of the then President of the European Commission, Roy Jenkins, the year before. The principle was agreed at the Bremen Council in the spring and the details agreed at the Brussels European Council in December. The arrangement came into force on 13 March 1979.

The key difference from the snake was that instead of being a dollar-based system it reflected purely intra-Community exchange rate fluctuations. At the heart of the system was the European Currency Unit (ECU) which was a weighted sum of the nine component currencies. (This followed on directly from European Unit of Account (EUA), a similarly weighted synthetic currency unit, which had been used internally in the Community in budgetary calculations.) The same $\pm 2.25\%$ bands were maintained, although for Italy a band of $\pm 6\%$ was instituted initially and the UK decided not to join in the exchange rate mechanism (ERM) part of the system. This last broke the link between the Irish punt and sterling. A European Monetary Cooperation Fund was also set up to ease ECU payments, with each country contributing 20% of its gold and foreign exchange reserves. Country weights in the ECU were recomputed at five year intervals, and Greece and then Portugal and Spain were included in the weights at the first opportunity after they joined the Community.

In the early years, fairly frequent alterations in parities were required, the first as early as September 1979 and then again in October 1981 and April 1982. By the time of the main problems with the EMS in 1992 there had been 12 realignments and none in the previous six years. The idea was that any country having difficulty maintaining its parity within the bands should start to intervene to keep within the limits when it had diverged by 75% of the permitted range. When it reached the edge of the range, intervention was supposed to be symmetric. However, in practice the burden of adjustment was placed largely on depreciating currency countries. Increasingly the system resembled a Deutschmark area, with West Germany setting interest rates for domestic purposes and the other countries having to follow suit in order to maintain their parities. As a result the EMS arrangements were amended by the Basle–Nyborg agreement of September 1987, which sought to encourage coordinated foreign exchange intervention and interest rate changes when a country approached the permitted limits of its parity. One important feature of the ERM was that changes in parities were intended to be decided by common consent and not by the country in difficulty unilaterally deciding where it would try to repeg its exchange rate. If that had been permitted there would have been a danger of competitive exchange rate changes and the system would not have been characterized by increasing stability.

Possibly the most significant feature of the EMS period was the development of the 'private' ECU, the issuing of ECU bonds and related

instruments. Large corporates and indeed governments found it cheaper and more efficient to issue ECU-denominated bonds rather than to issue bonds in a number of the component countries. It was not necessary to be a member of the system to do so. One of the larger issuers for example was the UK government, even though it was not participating in the ERM. Similarly the international financial institutions also had ECU offerings. It was thus clear that there was a demand for such a currency. Hence, while the system was designed in immediate terms to try to achieve greater exchange rate stability among the members, it acted as an important step towards a European financial market.

The apparent stability of the ERM in the period from 1986 to 1992 in fact covered up some of the underlying tensions in the system. Exchange rate stability is only possible if the countries involved are subject to common shocks, to which they react in a reasonably similar manner. By the end of the 1980s this was no longer the case, particularly with the collapse of the former Soviet Union and the unification of East and West Germany. Much as the collapse of the Bretton Woods system was led by problems in the base country, the USA, so the collapse of the ERM was to quite a large extent driven by problems that were specific to Germany. Unification resulted in a major fiscal challenge, which resulted in the need to raise interest rates. In countries that did not share this need, the appropriate strategy would have been to devalue, but with the ERM commitment this was not welcome. Strains therefore built up and the system began to fall apart as markets speculated against each of the most exposed countries in turn, thereby forcing the devaluations.

It is ironic that, as discussed in the next section, the EU was simultaneously trying to put in place the next steps towards monetary union, with the negotiation and ratification of the Maastricht Treaty. The rejection of the treaty in a referendum in Denmark in July 1992 made the continuance of the present set of parities seem rather less likely. The initial problems occurred in September 1992, when Finland and Sweden faced problems as a result of their financial crises, which had erupted a year earlier. Although not members of the EU, they had both pegged their currencies to the ECU under the same terms as the member states, although of course without any commitment to reciprocal intervention. Finland floated, allowing a devaluation, but Sweden fought off the challenge by applying exceptionally high interest rates (the respite was only temporary and Sweden too floated after a second attack in November). Attention then turned to Italy, which was forced to devalue its parity. However, within a few days that new parity also looked unsustainable and the attacks were extended to the UK and Spain. On Black Wednesday, 16 September, the losses proved too great and the UK left the ERM, followed by Italy, but Spain, although devaluing, continued in the ERM. On 20 September France narrowly voted in favour of ratifying the Maastricht Treaty in a referendum. Speculation beforehand that the result might be rejection is likely to have contributed to the exchange rate pressures. But although France was itself subject to pressure it survived. Ireland, Portugal and Spain introduced exchange controls.

The exchange rate speculation continued and in mid-November Sweden gave up the struggle and floated. Spain and Portugal devalued three days later. Ireland devalued in January 1993, Spain and Portugal devalued again in May. However, it was clear that the pressure on all the remaining currencies except the guilder was likely to force further devaluations, and on 1 August the permitted bands of fluctuation were extended from $\pm 2.25\%$ to $\pm 15\%$, which was sufficient to cope with the misalignment and more importantly allowed exchange rates to move far enough to choke off market pressure. (The Netherlands was able to continue with the narrower band.) While technically the ERM had survived, in practice floating had been required to survive the crisis. Fixing of exchange rates only came back as the member states moved to monetary union itself under the terms of the Maastricht Treaty.

The Road to the Euro Area

The increasing success of the EMS in the 1980s brought the ideas of moving towards monetary union onto the agenda again. At the beginning of

his first Presidency of the Commission, Jacques Delors had canvassed a number of ideas for greater progress on European integration. The idea of completing the internal (or single) market came first, but monetary union was second. However, closer integration of product markets, which included financial services and labour markets as part of the single market programme, which was incorporated into the Single European Act in 1987, itself helped pave the way for monetary integration. The closer integration increased the extent to which the member states were likely to move together in economic fluctuations and increased the ability to respond to shocks through increased flexibility. The decision to try to move forward was made at the Hanover Council in June 1988. As in 1970 this also took the form of a Committee, to be chaired by Jacques Delors. However, the composition of the committee was completely different. It was composed of the central bank governors from each of the member states and two experts. This meant that it was dominated by the practical considerations of how to move to a single currency from the monetary perspective.

The resulting proposals had significant differences from their 1970 counterparts. In particular, they focused on creating the appropriate EU level institutions to implement such a currency. However, the framework was still one of economic and monetary integration, although the economic side did not involve matching EU level institutions. It was also to be achieved in three stages, echoing the Werner Report. The first stage was to concentrate on fiscal consolidation, greater convergence of macroeconomic policy and performance through closer coordination, completion of the single market, greater financial integration and coordination of monetary policies. The second stage, which would require a treaty change, would set up a European System of Central Banks (ESCB) and involve national monetary policies being executed with EC-level objectives in mind and harmonization of the tools of monetary policy. In the third stage, exchange rates would be irrevocably fixed and the ESCB would assume responsibility for monetary and exchange rate policy, with a pooling of reserves.

It was agreed to proceed with these ideas at the Madrid summit in June 1989 and commence Stage 1 on 1 July 1990 after the details had been sorted out by an intergovernmental conference. This conference produced the Treaty on European Union, which was approved at the Maastricht Council in December 1991.

The Treaty clarified two main issues: first it announced the creation of the European Monetary Institute, which was to come into being at the start of the second stage to prepare all the instruments and procedures for the single monetary policy to be followed by the European Central Bank as the EC level institution to implement policy in Stage 3; second it set out the timetable and a set of criteria for joining Stage 3. Stage 2 was to start in 1994 and Stage in 1997 if seven or more of the member states met the convergence criteria, or failing that in 1999 with as many states as met the criteria.

There were five criteria

- *Price stability*: 'a price performance that is sustainable and an average rate of inflation, observed over a period of one year before the examination that does not exceed by more than 1.5 percentage points that of, at most, the three best performing member states'.
- *Interest rates*: 'over a period of one year before the examination. . . an average nominal long-term interest rate that does not exceed by more than two percentage points that of, at most, the three best performing member states in terms of price stability'.
- *Budget deficits*: the member state must not have an 'excessive deficit', which a protocol attached to the treaty defines as 3% of GDP but Council can override this if 'either the ratio has declined substantially and continuously and reached a level that comes close to the reference value; or. . . the excess over the reference value is only exceptional and temporary'.
- *Public debt*: the ratio of government debt should not exceed 60% of GDP 'unless the ratio is sufficiently diminishing and approaching the reference value at a satisfactory pace'. The proviso was to be decided by the Council (using qualified majority voting).

(It was also noted that the Council should take a medium term view, so just passing the reference value on the assessment date might not be enough.)

- *Currency stability*: 'respected the normal fluctuation margin provided for by the exchange rate mechanism... without severe tension for at least two years before the examination'.

These constitute a rather narrow 'monetary' view of what constitutes adequate convergence to be able to join a monetary union. This is clearly distinct from an 'economic' view, which would require real convergence in a number of key respects and the ability to respond flexibly to future shocks (described as asymmetric or idiosyncratic shocks that would affect that member state but not the EU as a whole) without the ability to use monetary policy. The real convergence would imply economic structures, policies and income levels. If these three were too different then a common policy would impose undue strains on the member state from common shocks that affected the whole monetary union. This focus on the monetary characteristics no doubt reflects the composition of the Delors Committee, but it also helps explain subsequent difficulties with the union.

Even within the monetary framework, there is no direct explanation of the fiscal criteria. A 60% debt to GDP ratio was around the average prevailing in the EU at the time and, with a 3% growth rate, a deficit of 3% a year would not worsen the position (after making a fairly sweeping assumption about the relationship between inflation rates and interest rates). Hence setting this as a minimum requirement would tend to imply an improving debt position. Furthermore, by restricting convergence to inflation rather than the price level left open the problem that, as countries move closer to a genuine single market, price levels can be expected to converge, which entails that subsequent inflation rates will be different until that process is complete.

The process of negotiating and ratifying the treaty was not straightforward. The UK insisted on an opt-out from the requirement to join monetary union, and a similar opt-out was accorded to Denmark after the rejection of the treaty in a referendum (a second referendum narrowly approved the revised proposals in May 1993). Thus although the treaty was agreed in December 1991 in Maastricht and signed in February 1992 in Limburg, it did not ultimately come into force until November 1993.

The process of convergence proved difficult, and at the first date of assessment in June 1996, for commencement in 1997, only Luxembourg qualified so there was no attempt at a formal examination. The EU had in the meantime increased its membership by three in 1995 with the accession of Austria, Finland and Sweden. By June 1998 the picture was very different. Finland, France and Luxembourg met all the criteria on a strict interpretation and Austria, Germany, Ireland, the Netherlands, Portugal and Spain were close to meeting the fiscal criteria. Belgium and Italy, with debt ratios of 122.2% and 121.6% respectively, were nowhere near, but nevertheless were admitted.

Greece had inflation 1.5% above the convergence criterion (and a debt ratio of 108.7% and a deficit of 4%), Denmark and the UK exercised their opt-outs (although both could have converged) and Sweden, having had membership of EMU rejected in a referendum, remained outside the ERM, thereby technically failing to qualify.

The Maastricht Treaty concentrated on the monetary side of EMU. Unlike the Werner recommendations, it did not agree for there to be an organization for the coordination or management of fiscal or other macroeconomic policies nor their interrelationship with monetary policy. Instead, it set out a general requirement for coordination of economic policy: 'Member States shall regard their economic policies as a matter of common concern and shall co-ordinate them within the Council'. Over the ensuing years the process of macroeconomic coordination was slowly developed into a comprehensive scheme by a series of 'processes' whose individual names reflect the location of the Council meetings at which they were agreed: the Luxembourg process coordinating employment policies (1997); the Cardiff process coordinating structural policies (1998); and the Cologne process (1999) coordinating macroeconomic policies. These all operate under the

framework of the Broad Economic Policy Guidelines, which were originally discussed annually but have subsequently had a three-year horizon. The important feature of these processes is that they do not compel action but draw up common objectives, areas of focus and principles for action, in what is known as the Open Method of Coordination. The Commission then monitors progress against the targets.

While the member states could manage to 'coordinate' their fiscal policies with the single monetary policy if the latter had clear objectives and a transparent and clearly articulated strategy for implementation, it was not felt possible to proceed simply through the coordination process, as countries might otherwise run profligate fiscal policies that would damage the creditworthiness of EMU as a whole. At the same time as the idea of the processes was launched at the Dublin Council in 1996, it was agreed to seek an approach to fiscal stability which in effect would ensure that the fiscal criteria laid down for entry to Stage 3 of EMU were perpetuated during its operation. This latter approach was agreed as the Stability and Growth Pact in 1997. The Pact had two elements to it, which have been labelled 'preventative and corrective'. The preventative part involves the setting of longer term objectives for prudent fiscal policy and an annual process of surveillance by the Commission on progress, including the shorter term progress across the cycle. Thus the longer term aim is to keep the debt position steadily improving by ensuring that budgets are 'close to balance or in surplus' across the economic cycle and in the shorter term ensuring that at no stage does the budget deficit fall below 3% unless the country concerned is under substantial economic pressure.

The corrective part of the Pact involves the rules for avoiding and correcting any such 'excessive deficits' and is therefore labelled the Excessive Deficit Procedure. In the annual cycle of surveillance the Commission can opine that a country is likely to encounter an excessive deficit and then the Council of Economic and Finance Ministers (ECOFIN) can recommend that remedial action should be taken. If that action is not taken or is insufficiently applied, ECOFIN can in theory require an interest-free deposit of up to 0.5% of GDP and could convert this into a fine. This, however, has never been applied in practice and the lenient treatment of France and Germany when they got into difficulty in 2003 and the subsequent revision of the Pact in 2005 to make the criteria for excessive deficits softer could be taken to suggest that such sanctions are unlikely in future.

The Development of Monetary Union

An analysis of how Stage 3 of EMU has evolved since its inception at the beginning of 1999 lies beyond the scope of this article, but the experience of the period up to 2011 provides some insights into the structure and development of EMU up to that point. Three items stand out. The first is that in technical terms the design of the monetary side of EMU has been shown to be exemplary. There were no technical slip-ups or instability in financial markets and both the single monetary policy and the currency came into operation exactly as planned. Thus the framework set out by the committee of central bankers and the staged implementation through the EMI provided a workable template that others could build on. Having the institutional arrangement at the EU level was essential. The second issue that stands out is that the economic side of EMU has not proven particularly successful. There is no matching institution, as envisaged in the Werner framework. While fiscal behaviour since the mid-1990s has been a great improvement on that before, Greece and (to a lesser extent) Portugal have been unable to impose the fiscal stability desired and an emergency lending programme has been required in concert with the IMF to enable them to meet their debt obligations. (Ireland has also had debt problems, but to a major extent these are due to bad banking supervision and crisis management and only partly to an optimistic fiscal policy relying on continuing rapid growth.)

The third insight is that a focus on a narrow view of monetary convergence as a precondition for a successful economic and monetary union rather than a focus on the economic optimum currency area criteria has provided difficulties.

Countries faced by different shocks in the global financial crisis have had difficulty adjusting as they no longer have the exchange rate as an adjustment mechanism. Countries joining with lower than average real income per head and lower price levels have found that while they experience faster growth, they also face faster inflation, as monetary policy focuses only on the rate of inflation for the EU as a whole. Since the MacDougall Report in 1977, the EU has shown little enthusiasm for fiscal equalization across countries and has not pursued anything like the scale of fiscal transfers observed in other large diverse countries with a monetary union, such as Australia, Canada, the USA and even Germany. Thus this route to adjustment, widely used elsewhere, has also not been available. The criteria for membership and their interpretation in 1998 reflected the political pressure for monetary union rather than simply an economic assessment. The changes to the proposed process of economic and monetary integration after the Werner Committee report in 1970 reflected the wish by the member states for more economic policy autonomy while pursuing tight exchange rate stability.

However, no satisfactory test of the success of EMU is possible, as it requires the ability to simulate a credible alternative, which would be a purely hypothetical exercise. Thus one can neither estimate with any reliability how the chosen form of EMU has fared by comparison with a Werner-style arrangement, perhaps with harsher criteria and hence fewer members or with a slower process that required a reasonable degree of real convergence and adherence to the optimum currency criteria. While the Werner vision may have taken three decades, and not one, to implement, EMU has been able to progress far faster and further than would have been thought likely in say 1985.

European Monetary Union

Paul De Grauwe

Abstract

The introduction of the euro in 1999 is without any doubt one of the great achievements in the European integration process. In one bold stroke, national monetary sovereignty was abolished and transferred to a new European institution, the European Central Bank, that from then on became the guardian of the new currency.

Until the eruption of the sovereign debt crisis there was a general perception that the euro zone was a great success. In 2008 the European Commission issued a report (euro@10; European Commission. *Europe@10. Successes and challenges after ten years of economic and monetary unions*. Brussels, 2008) that was unqualified in its praise about the achievements of the euro zone. Then came the sovereign debt crisis that has led many observers to reevaluate European Monetary Union (EMU). This article discusses its successes and failures, analyzes the fragility of EMU, and identifies two sources of this fragility. Finally, it discusses governance issues and the nature of the political institutions that will be necessary to sustain the European Monetary Union.

Successes of EMU

The very fact that European countries managed to move into a monetary union using a peaceful process can be seen as an important historical achievement. Most of the monetary unions in history came about as a result of military conquest or forceful political unification. This was not the case in Europe during the 1990s when monetary integration process was set in motion. A massive transfer of monetary sovereignty was successfully organized, leading to the establishment of the European Central Bank, which was given the task to manage a common currency: the euro.

Up until the eruption of the sovereign debt crisis, the successes appeared overwhelmingly strong. The benefits of a common currency, which were analyzed in the theory of optimal currency areas, could not easily be disputed. The use of one currency in the euro zone eliminated the transaction costs that existed prior to union and that arose from the fact that in order to make trade possible between two member countries one national currency had to be exchanged for another. The EC Commission (1990) estimated that the elimination of these transaction costs amounted to approximately half a per cent of GDP.

There can be equally little doubt that the elimination of exchange risk within the euro zone helped to boost internal trade and capital mobility. A lot of research has been done to measure the effect of a monetary union on trade between the members of the union. Following Andy Rose's ground-breaking research (Rose 2000), which demonstrated strong positive effects of monetary unions on trade flows, subsequent econometric research has confirmed that monetary unions in general, and EMU in particular, indeed lead to significant increases in trade. However, the Rose's spectacular results were not replicated in subsequent work (see Baldwin 2006; Berger and Nitsch 2008). The consensus today seems to be that EMU may have added approximately 20 per cent of extra trade within the union; a significant increase that certainly should be added to the successes of the Union.

The institutional setup of the euro zone also contributed to the successes of EMU. By giving the ECB a strong mandate to maintain price stability, and by enshrining the political independence of the ECB in the EU Treaties, the ECB quickly gained credibility as a tough inflation fighter. There can be little doubt that the ECB was very

successful in keeping inflation low. From 1999 to 2010 the average inflation rate in the euro zone was 2.2 per cent – not much above the target of 2 per cent that the ECB had set itself as an objective, and certainly lower than the rate of inflation its members experienced during the post-war period until the start of the euro zone. As a result, the euro zone became a centre of price stability.

Behind this apparent success, however, there are deep structural weaknesses that have appeared with full force since the eruption of the sovereign debt crisis. These are discussed in the next section.

Failures of EMU

Two structural weaknesses lie at the heart of the sovereign debt crisis that began in 2009. The first one arises from asymmetric shocks and the absence of flexible adjustment mechanisms. This is the feature that has been stressed by the Optimal Currency Area (OCA) theory as generating costs of a monetary union (well-known contributions to this theory are Mundell (1961) and McKinnon (1963). For surveys see Ishiyama (1975), De Grauwe (1992) and Baldwin and Wyplosz (2006). See Eichengreen (1990) and Bayoumi and Eichengreen (1996) for empirical implementations). The second structural weakness arises from the fact that the euro is a currency without a country.

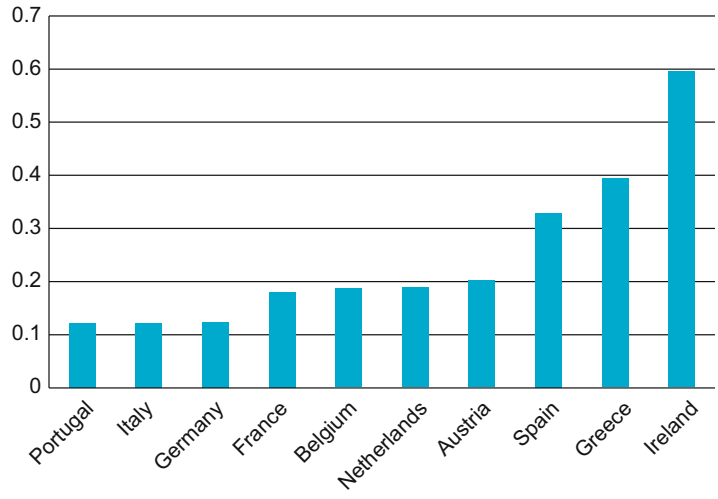
Failing Adjustment to Asymmetric Shocks

In EMU, monetary policies are centralized, and therefore cease to be a source of asymmetric shocks. The member countries of EMU, however, continue to exercise considerable sovereignty in several economic areas. The most important one is in the budgetary field. The spending and taxing powers in EMU continue to be vested in the hands of national authorities. Today, in most euro zone countries, spending and taxation by the national authorities amount to close to 50 per cent of GDP. The spending and taxing powers of the European authorities represent barely 1 per cent of GDP. This situation has not changed since the start of monetary union in 1999. By changing taxes and spending, the authorities of an individual country can create large asymmetric shocks. By their very nature these shocks are well contained within national borders. For example, when the authorities of a country increase taxes on wage income, this only affects labour in that country and will influence spending and wage levels in that country. As a result, asymmetric shocks are created that lead to necessary adjustments later.

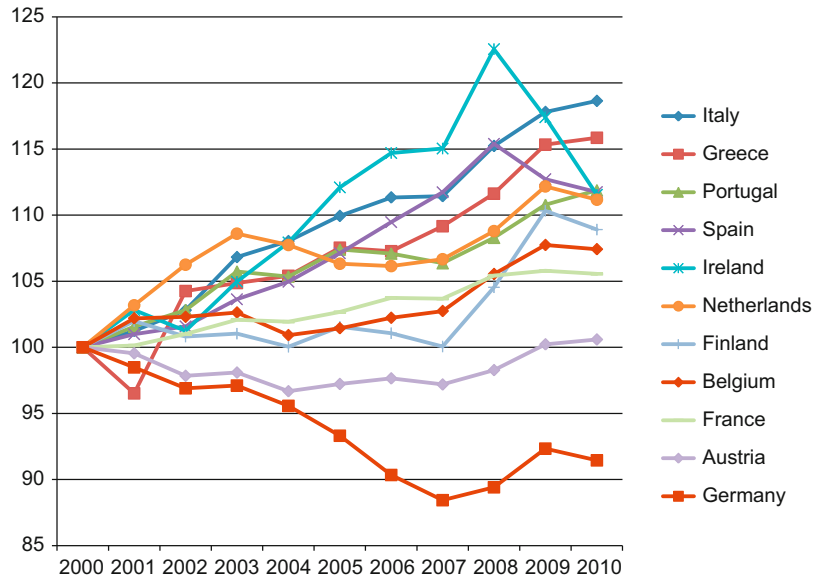
There are other aspects of the existence of nation states that can be a source of asymmetric disturbances. Many economic institutions are national. Wage bargaining systems, for example, differ widely between countries, creating the possibility of asymmetric disturbances. In addition, differences in legal systems and customs generate significant differences in the workings of financial markets. For example, regulations about the conditions under which mortgages are granted by banks differ from one country to the other in the euro zone. These differences can lead to very divergent movements of housing prices in member countries. There are many more such examples of these asymmetric disturbances.

The effect of these national idiosyncrasies can be that countries experience very different economic conditions. This is illustrated in Fig. 1, which shows the cumulative growth rates of GDP prior to the financial crisis in the euro zone. We observe that indeed the differences in national growth rates in the euro zone were substantial. Some countries experienced booming economic conditions during 1999–2007 (Spain, Greece, Ireland); others experienced very slow growth (Portugal, Italy, Germany). There can be little doubt that part of these differences is attributable to the different national economic policies and institutions.

These diverging trends in economic activity can contribute to another important phenomenon: the emergence of large divergences in competitive positions of members of a monetary union. This is exactly what happened in the euro zone. Figure 2 illustrates this by presenting the trends in the relative unit labour costs in the euro zone during 2000–2010. The relative unit labour cost is defined as the unit labour cost of one country (say Germany) relative to the average unit labour



European Monetary Union, Fig. 1 Cumulative growth of GDP 1999–2007 (Source: European Commission; AMECO databank)



European Monetary Union, Fig. 2 Relative unit labour costs for euro zone countries (2000 = 100). (Source: European Commission, AMECO databank)

costs in the other member countries of the euro zone. When the relative unit labour cost declines, as in the case of Germany, one can say that Germany has improved its competitive position during the period 2000–2010. Conversely when the relative unit labour costs increase, as in the cases of Ireland, Italy, and Greece, among others, these countries lost competitiveness during 2000–2010.

Note that the unit labour costs are defined as the labour costs corrected for labour productivity. The unit labour cost is defined as: ULC = $W/(Q/L)$, where W is the wage rate, Q is the value of output and L is the amount of labour used in production. Q/L is the average labour productivity. Note that the formula can also be rewritten as follows: ULC = WL/Q. This expression makes clear what unit labour costs means: it is the wage cost embedded in one euro (dollar) of output. It follows that unit labour costs can increase for two reasons. They increase when wages increase or when labour productivity declines (or, in relative terms fails to keep pace with competitors). Thus it appears that countries like Italy, Spain, Portugal and Ireland have lost significant competitiveness

since 2000 because wages in these countries increased faster than labour productivity. This leads to serious adjustment problems. These countries have to reduce their wage levels relative to the other countries of the euro zone (if they cannot raise productivity). This is likely to be a slow and painful process, mainly because other adjustment mechanisms such as labour mobility and wage flexibility function poorly in most of these countries (see Krugman (1993) and De Grauwe and Vanhaverbeke (1990)). In the past, when these countries were not in a monetary union, they would have been able to devalue their currencies, thereby making it possible to restore their competitiveness in a single stroke, albeit only by risking higher inflation.

The Euro: A Currency Without a Country

The second major structural weakness of EMU is that it created a currency without a country, i.e. without a government with the full powers of a government to back up the value of the currency. This feature has sometimes been hailed as revolutionary. It turns out, however, that it is a profound structural weakness that creates great fragility in the euro zone and lies at the heart of the sovereign debt crisis. Let us analyze why this is so.

When entering monetary union, member countries lose their capacity to issue debt in a currency over which they have full control. As a result, a loss of confidence of investors can, in a self-fulfilling way, drive the country into default (Kopf 2011). The reason for this can be described as follows. Suppose that investors fear a default by, let's say, the Spanish government. They sell Spanish government bonds, thereby raising the interest rate. The investors who have acquired euros are likely to decide to invest these euros elsewhere, perhaps in German government bonds. As a result, the euros leave the Spanish banking system. Thus the total amount of liquidity (money supply) in Spain shrinks. The Spanish government experiences a liquidity crisis, i.e. it cannot obtain funds to roll over its debt at reasonable interest rates. In addition, the Spanish government cannot force the Bank of Spain to buy government debt. The ECB can provide all the liquidity in the world, but the Spanish government does not control that institution.

This is not the case for countries capable of issuing debt in their own currency. Let's trace what would happen if investors were to fear that the UK government might be defaulting on its debt. In that case, they would sell their UK government bonds, driving up the interest rate. After selling these bonds, these investors would have pounds that they would most probably want to get rid of by selling them in the foreign exchange market. The price of sterling would drop until somebody else would be willing to buy them. The effect of this mechanism is that the pounds would remain bottled up in the UK money market to be invested in UK assets. Put differently, the UK money stock would remain unchanged. Part of that stock of money would probably be reinvested in UK government securities. But even if that were not the case, and the UK government was unable to find the funds to roll over its debt at reasonable interest rates, it would certainly force the Bank of England to buy up the government securities. Thus the UK government is assured of the liquidity needed to fund its debt. This means that investors cannot precipitate a liquidity crisis in the UK that could, ultimately, push the UK government into default. There is a superior force of last resort, namely the Bank of England.

This different mechanism explains why the Spanish government has been obliged to pay up to 200 basis points more on its ten-year bonds than the UK government since 2010, despite the fact that its government debt and deficit were significantly lower than the UK ones.

Because of the liquidity flows triggered by changing market sentiments, member countries of a monetary union become vulnerable to these market sentiments. These can lead to 'sudden stops' in the funding of government debt (Calvo 1988), setting in motion a devilish interaction between liquidity and solvency crises. This is because the liquidity crisis raises the interest rate, which in turn leads to a solvency crisis. This problem is not unique to members of a monetary union. It has been found to be very important in emerging economies that cannot issue debt in their own currencies

(see Eichengreen et al. (2005), in which these problems are analyzed in great detail).

There are further important implications of the increased vulnerability of member countries of a monetary union. In De Grauwe (2011) these implications are developed in greater detail; see also Wolf 2011). One of these implications is that member countries of a monetary union lose much of their capacity to apply countercyclical budgetary policies. When, during a recession, budget deficits increase, this risks creating a loss of confidence of investors in the capacity of the sovereign to service the debt. This has the effect of raising the interest rate, making the recession worse and leading to even higher budget deficits. As a result, countries in a monetary union can be forced into a bad equilibrium, characterized by deflation, high interest rates, high budget deficits and a banking crisis (see De Grauwe (2011) for a more formal analysis).

What Kind of Governance?

The previous discussion points towards the existence of a coordination failure in EMU. Financial markets can drive member countries into a bad equilibrium that is the result of a self-fulfilling mechanism. This coordination failure can in principle be solved by collective action aimed at steering countries towards a good equilibrium, but as the difficulties in dealing with the Greek crises of 2010 and 2011 showed, taking collective action is always politically difficult.

In addition to this coordination failure, there is another important feature of the euro zone that requires collective action. This is that the euro zone creates externalities, especially through contagion. When one country is pushed into a bad equilibrium, this affects all the other countries, mainly because of the intense degree of financial integration. As a result, a default risk in one country can lead to a default risk of sovereigns and banks in other countries. As with all externalities, government action must be resolute in internalizing these.

Collective action and internalization can be pursued at two levels. One is at the level of the central banks; the other at the level of government budgets.

Liquidity crises are avoided in standalone countries that issue debt in their own currencies, mainly because the central bank can be forced to provide all the necessary liquidity to the sovereign. This outcome can also be achieved in a monetary union if the common central bank is willing to buy the different sovereigns' debt. In fact, this is what happened in the euro zone during the debt crisis. The ECB bought government bonds of distressed member countries, either directly or indirectly by the fact that it accepted these bonds as collateral in its support of the banks from the same distressed countries. In doing so, the ECB rechannelled liquidity to countries hit by a liquidity crisis, and prevented the centrifugal forces created by financial markets from breaking up the euro zone. It was the right policy for a central bank whose *raison d'être* it is to preserve the monetary union. Yet the ECB has been severely criticized for saving the euro zone this way. The main reason for this criticism is that these liquidity provisions have potential fiscal policy consequences. For example, when the ECB buys Greek and Portuguese government bonds in order to rechannel liquidity to Greece and Portugal, it exposes itself to the risk of future losses. In doing so it commits euro zone taxpayers to foot the bill in the future, without having asked their permission. This criticism has been powerful enough to convince the ECB that it should not be involved in such liquidity operations, and that liquidity support must instead be done by other institutions, in particular a European Monetary Fund.

An important step was taken in May 2010 when the European Financial Stability Facility (EFSF) was instituted. The latter will be transformed into a permanent fund, the European Stabilization Mechanism (ESM), which will obtain funding from the participating countries and will provide loans to countries in need of liquidity assistance. This makes it possible to make the fiscal commitments of each country explicit. Thus a European Monetary Fund will be in existence, as was first proposed by Gros and Mayer (2010).

Although an important step forward, the EFSF, as well as the future ESM, suffer from problems

that undermine their effectiveness. The most important one is that neither will be an autonomous institution in the way that the IMF is. Each country keeps its veto power for every new financial assistance program. This feature risks making these institutions less than fully effective. As a result, the credibility of the institution will be undermined, as nobody knows whether and under what conditions the EFSF (ESM) will be willing to provide credit. The only way to solve this problem is to transform the EFSF (ESM) into a true monetary fund in which decisions are taken by qualified majority, as is the case in other European institutions (e.g. the Council of Ministers). This, of course, implies that there will be a willingness to transfer sovereignty to the monetary fund.

Collective action and internalization can also be taken at the budgetary level. Ideally, a budgetary union is the instrument of collective action and internalization. By consolidating (centralizing) national government budgets into one central budget a mechanism of automatic transfers can be organized. Such a mechanism works as an insurance mechanism transferring resources to the country hit by a negative economic shock. In addition, such a consolidation creates a common fiscal authority that can issue debt in a currency under the control of that authority. In so doing, it protects the member states from being forced into default by financial markets. It also protects the monetary union from the centrifugal forces that financial markets can exert on the union. The need to create a budgetary union together with a monetary union has long been recognized by economists (McDougall Report, 1977; Sachs and Sala-i-Martin 1989; Mélitz and Vori 1993; Von Hagen 1996). However, monetary union was started in Europe without such a budgetary union, creating the fragility discussed earlier.

While a full budgetary union is not a realistic prospect in the euro zone in the foreseeable future, smaller steps could be taken, signalling a desire to move towards budgetary union in the future. One such step consists in the joint issue of Eurobonds. By jointly issuing Eurobonds, the participating countries become jointly liable for the debt they have issued together. This is a very visible and constraining commitment that may help to convince financial markets that member countries are serious about the future of the euro (Verhofstadt 2009; Juncker and Tremonti 2010). In addition, by pooling the issue of government bonds, the member countries protect themselves against the destabilizing liquidity crises that arise from their inability to control the currency in which their debt is issued. A common bond issue does not suffer from this problem. Several concrete proposals have been formulated by Bruegel (Delpla and von Weizsäcker 2010; De Grauwe and Moesen 2009). These also discuss the inevitable moral hazard issues that arise with the implementation of the common Eurobond issues (see also Issing (2009) and Gros (2011).

It should be noted that if successful, such a common Eurobond issue would create a large new government bond market with a lot of liquidity. This in turn would attract outside investors, making the euro a reserve currency. It has been estimated that the combined liquidity and reserve currency premium enjoyed by the US dollar amounts to approximately 50 basis points (Gourinchas and Rey 2007). A similar premium could be enjoyed by the euro. This would make it possible for the eurozone countries to lower the average cost of borrowing, very much like the USA has been able to do.

Another important step in the process towards political union is to set some constraints on the national economic policies of the member states of the euro zone. As argued earlier, the fact that, while monetary policy is fully centralized, the other instruments of economic policies have remained firmly in the hands of national governments is a serious design failure of the euro zone. Ideally, countries should hand over sovereignty over the use of these instruments to European institutions. However, the willingness to take such a drastic step towards political union is completely absent. Here also small steps should be taken.

Some progress has been achieved in setting up new rules of economic governance in the euro zone. A so-called 'six pack' of measures strengthening control on budgetary policies and coordinating macroeconomic policies is very likely to be adopted. These measures include a tightening of the Stability and Growth Pact, including a

stronger sanctioning procedure; the 'European Semester', which requires national governments to present their annual budgets to the European Commission prior to their approval in national parliaments; and the monitoring of a number of macroeconomic variables (current account balances, competitiveness measures, house prices and bank credit) aimed at detecting and redressing national macroeconomic imbalances. Failure to take action to eliminate these imbalances could trigger a sanctioning mechanism very much in the spirit of the sanctioning mechanism of the Stability and Growth Pact.

The proposals for reforming the governance or the euro zone that have been discussed in this section all require a far-reaching degree of political union. Economists have stressed that such a political union will be necessary to sustain the monetary union in the long run (EC Commission 1977; De Grauwe 1992). It is clear, however, that there is little willingness in Europe today to increase the degree of political union substantially, although the decisions taken by the heads of state and government of the euro area at their meeting on 21 July 2011 represented a shift in this direction. This unwillingness to go significantly further in the direction of more political union will continue to make the euro zone a fragile construction.

Conclusion

Any monetary union creates benefits and costs. This is also the case in the European Monetary Union. The benefits that were created in the euro zone are significant. They arise from the fact that the elimination of national currencies reduces transaction costs and eliminates the uncertainty produced by exchange rate volatility.

The costs, however, are also substantial. They arise from the fact that member countries of a monetary union lose an instrument of economic policy that can help countries to adjust to asymmetric shocks. In addition, countries that join a monetary union lose their capacity to issue debt in a currency over which they have full control. As a result, a loss of confidence of investors can, in a self-fulfilling way, drive the country towards default. This is not so for countries capable of issuing debt in their own currency. In these countries the central bank can always provide liquidity to the sovereign to avoid default. This may lead to future inflation, but it shields the sovereign from a default forced by the market.

Thus member countries of a monetary union become very vulnerable to changing market sentiments. The latter can lead to 'sudden stops' in the funding of the government debt, setting in motion a devilish interaction between liquidity and solvency crises. This feature of a monetary union creates great fragility in sovereign debt markets in a monetary union. This fragility can only be overcome by collective action.

A monetary union can only function if there is a collective mechanism of mutual support and control. Such a collective mechanism exists in a political union. In the absence of a political union, the member countries of the euro zone are condemned to fill in the necessary pieces of such a collective mechanism. The debt crisis has made it possible to fill in a few of these pieces. What has been achieved, however, is still far from sufficient to guarantee the survival of the euro zone.

European Unemployment Insurance

Sebastian Dullien

Abstract

'European unemployment insurance' is one of many proposals that aim to create a countercyclical automatic fiscal stabiliser for the euro area. References to such systems were made in the 1970s when the idea of a European monetary union was first developed. During the first decade following the introduction of the euro in 1999, discussions about such transfer systems were all but dead, but it has experienced a revival after the onset of the euro crisis in 2010. This article explains the background and the evolution of the idea.

Keywords

Automatic stabilisers; European Monetary Union; Optimum currency area theory; Unemployment insurance

The idea of a fiscal transfer system for the euro area is almost as old as the first proposals for monetary integration of Europe. A number of early reports on the feasibility and preconditions of a common currency in Europe, such as the Marjolin (1975) or MacDougall (1977) reports, include references to and recommendations for fiscal transfer mechanisms between participating countries. Standard textbooks on monetary integration, such as de Grauwe (2014), have also discussed the basic logic of fiscal transfers in currency unions from their first editions onwards.

The Traditional Economic Argument

The basic argument is that with joining a monetary union, a member state gives up some of its key macroeconomic policy instruments, i.e. control over short-term interest rates and the ability to let the domestic currency appreciate or depreciate against other currencies. Compared to flexible exchange rates, this leads to a diminished ability to shelter the domestic economy against external shocks.

As a consequence, the need for alternative adjustment mechanisms arises. One option for such an alternative adjustment mechanism is to increase labour mobility, as explained in Robert Mundell's (1961) seminal work on optimum currency areas. Workers from a country hit by a negative asymmetric demand shock would then migrate to countries which have not been hit by such a shock, rendering devaluations unnecessary.

Another alternative is to deal with asymmetric shocks by using fiscal policies. If a country is hit by a negative asymmetric shock, its government can increase public spending or cut taxes in order to boost domestic demand. However, sometimes a country's government might not have the necessary funds for such a stabilisation policy, especially if shocks are large.

Proposals for fiscal transfer mechanisms between countries (often also dubbed 'insurance against asymmetric shocks') are linked to this argument: if a transfer mechanism is designed in a way that funds are moved from countries being hit by a positive asymmetric demand shock to countries which experience negative shocks, both groups of economies can be stabilised. In the country that experiences the negative shocks, transfers could be used to prop up domestic demand; in the country hit by the positive demand shock, funds available for both private and domestic expenditure would be reduced, thus preventing an overheating of the economy.

Early Proposals

The first detailed mentioning of fiscal transfer mechanisms in the debate on a European monetary union was made in the Marjolin report in 1975. In the annex to this report, the authors discuss the possible institutional details of a 'Community Unemployment Benefit Scheme', proposing to introduce a European fund which pays a certain lump sum to the unemployed, financed by a community contribution on wages. Building on this, for a later point of time, the authors envision the transformation of this insurance with lump sum transfers into an unemployment insurance system more in line with existing national schemes, with benefits based on past earnings.

MacDougall (1977) expands the ideas of the Marjolin report, discussing both a transfer system from a common fund to national unemployment systems dependent on the current cyclical situation as well as a scheme under which only member states in exceptionally dire economic conditions would receive transfers from the rest of the union. Overall, the MacDougall report concludes that for a meaningful macroeconomic stabilisation function, the European budget should be increased to 5–7% of GDP. While this would still have been far below the volume of the federal budget in the USA (which is often taken as a point of reference for the fiscal capacity of the European Monetary Union), it would have been way above what has been reached in Europe even by 2015 (when the EU budget amounted to slightly more than 1% of GDP).

The contributions to this debate further proliferated, with the project of a European monetary union becoming more concrete in the early 1990s. Two main arguments were made during this time.

On the one hand, Asdrubali et al. (1996) and von Hagen (1992) argued that transfer systems in US unemployment did less to bolster state-specific shocks than previously thought (Asdrubali et al. came to the conclusion that US unemployment insurance only stabilised less than 2% of these shocks). On the other hand, the estimates of funds needed for meaningful stabilisation were greatly reduced relative to the volumes referred to in the MacDougall report. Specifically, Italianer and Vanheukelen (1993) demonstrated that a macroeconomic stabilisation comparable to that in the USA could actually be achieved with as little as 0.2% of GDP if intra-regional transfers were linked to the changes of national unemployment rates relative to changes in EU-wide unemployment rates, and hence would be well targeted on the goal of macroeconomic stabilisation.

The Maastricht framework Without Fiscal Transfers

Despite this in-depth debate on fiscal transfer systems, the final framework agreed in the Maastricht Treaty in 1992 did not include any mentioning of such mechanisms. Instead, the Maastricht framework was explicitly built on the idea that each country would be responsible to deal with its own (idiosyncratic) macroeconomic problems. Monetary policy was unified and transferred to the European Central Bank and was sheltered from policy interference both by defining 'price stability' as the ECB's primary goal and by prohibiting monetary financing of government deficits. Fiscal policy was left at the national level. A 'no bail-out clause' actually even prohibited one country or the European Union as a whole from taking over another country's liabilities. In order to prevent spill-overs from unsustainable fiscal policy at the national level to the common monetary policy, the Stability and Growth Pact limited national government deficits to 3% of GDP, except in cases of deep recession.

This reluctance to include automatic stabilisers in the Maastricht framework was likely due to two reasons: one political and one based on changing perceptions of the academic community.

Politically, in the early 1990s there was little appetite to introduce a transnational transfer system with large financial volumes. In particular, the West German electorate had just been burdened with the transfers for rebuilding the East German economy and would not have accepted new transfers to economically weaker euro zone countries.

From an economic (academic) point of view (at that time), new theoretical economic models had led a number of economists to rethink their belief in the need for fiscal transfer systems in order to stabilise national business cycles in a monetary union. First, the advent of New Classical macroeconomic models with rational expectation elements (especially in their real business cycle variety) had led to the conclusion that fiscal policy was all but ineffective for stabilisation of the business cycle. According to these models, macroeconomic fluctuations were created either by exogenous technology shocks or by the reaction of rationally thinking agents to disturbances created by monetary or fiscal policies. As in these models, agents were always in a situation that was optimal given the underlying economic fundamentals; they would react to any anticipated change in fiscal policy and try to counteract its effect, greatly reducing its effectiveness.

In contrast, economists more closely aligned with Keynesian thinking believed that stabilisation through fiscal policy could still be conducted effectively, but transfers would not be a precondition for such policies. Instead, it was assumed that countries with open financial markets could always borrow the resources needed in international markets.

Finally, a number of economists believed that a growing integration of product and factor markets would reduce the need for automatic fiscal stabilisers (von Hagen 1992; see also Bertola and Boeri 2002; Blanchard and Giavazzi 2003). According to these arguments, first, the integration of goods markets would make asymmetric shocks less likely, as shocks would quickly be transmitted to the whole euro area through trade linkages, making them symmetric. Second, with the growing integration of labour markets, increased factor mobility would work as a shock absorber. Third, as Mélitz and Zumer (1999)

pointed out, EMU itself would lead to a closer integration of financial markets and hence provide risk sharing through credit and insurance markets.

Recent Poposals

After the introduction of the euro as a virtual currency in 1999 and in the form of notes and coins in 2002, the discussion of European transfer systems was all but dead. It only re-emerged after the onset of the euro crisis in 2010. As the specifics of the Maastricht Treaty were a result of the specific economic experience of the early 1990s and of the specific economic thinking of the time, the revival of ideas for fiscal stabilisers also can best be explained against the background of change in (mainstream) academic thinking and empirical experiences with the existing institutional setup.

First, theoretically, fiscal policy made a comeback as a stabilisation tool during the 2000s. Extending standard macroeconomic models with frictions such as wage and price stickiness (Galí et al. 2007) or with the assumption of underdeveloped financial markets (Aghion and Howitt 2006) led to the conclusion that the costs of macroeconomic fluctuations were much bigger than previously thought and that fiscal policy was indeed able to reduce volatility and hence increase welfare substantially.

Second, more recent econometric studies have hinted that the US unemployment insurance might have contributed more to macroeconomic stabilisation than previously thought. For example, Chimerine et al. (1999) put the stabilisation effect of US insurance in selected recessions to 15–20% of the initial drop of GDP. Vroman (2010) comes up with a stabilisation effect of almost 30% in the Great Recession of 2008/09. According to Dullien (2014), one reason for the huge differences in these works and the earlier works by Asdrubali et al. or von Hagen et al. are that the earlier research often did not take into account all payment flows in US unemployment insurance and neglected the extended benefits and emergency benefits which are enacted in recessions. Another reason is a difference in the measured concept of stabilisation. While the Asdrubali et al. contribution looks at fluctuations over the whole business cycle, literature in line with Vroman's approach focuses on recessions and compares the actual GDP path to a counterfactual simulation without unemployment benefits. As unemployment only increases strongly in a recession and recessions are rather rare events, stabilisation in a recession is larger than that measured on average over the cycle.

Third, the run-up to and the eruption of the euro crisis have exposed a number of weaknesses of the monetary union's macroeconomic framework. Already, in the years prior to the crisis, large economic divergences within the euro area had been observed (Dullien and Fritsche 2009), which were subsequently linked to the absence of effective macroeconomic stabilisation at the national level. It was argued that housing price bubbles in Ireland and Spain might not have become so large had a transnational transfer system drained purchasing power earlier.

In addition, the euro crisis has cast some countries into extremely deep recessions. These recessions demonstrated that even countries which had a sound budgetary position prior to the crisis might experience problems financing their budget deficits in a downturn. Spain and Ireland were the most obvious examples of this possibility: both countries had actually run budget surpluses prior to the crisis and both countries fought against the fear of insolvency and for continued capital market access during the crisis. This experience cast doubt on the premise that countries could just stabilise the business cycle on their own during a downturn by borrowing in financial markets and spending the funds on tax cuts and public expenditure.

As a consequence, when institutional reform of the euro area was discussed in the wake of the crisis, the topic of a fiscal transfer mechanism re-emerged. Both the European Commission's (2012) 'Blueprint for a Genuine European Monetary Union' and the Four Presidents' Report (drafted by the President of the European Council, the President of the European Commission, the President of the Eurogroup and the President of the European Central Bank) mentioned explicitly the long-term goal of transnational fiscal transfers.

According to the latter, European policymakers should build 'a well-defined and limited fiscal capacity to improve the absorption of country-specific economic shocks, through an insurance system set up at the central level' (van Rompuy 2012, p. 5). While the four presidents remained relatively vague on the details of the desired fiscal capacity, they explicitly discussed, as possible options, both a cross-country insurance system with transfers between national budgets and a European unemployment insurance with individual claims to benefits. In a related paper, the European Commission (2013) later outlined a vision for the 'Strengthening of the Social Dimension of Economic and Monetary Union' in which a European unemployment insurance was discussed in detail. However, the discussion in the so-called 'Five Presidents' Report' of 2015 (a follow-up report to the Four Presidents' Report published under a new Commission and with the inclusion also of the president of the European Parliament) on this topic was subsequently toned down (Juncker et al. 2015). While still asking for a 'euro area stabilization function' through fiscal transfers, the five authors avoided providing any clear direction in the debate and only defined some required characteristics of such a system – among others that it must not create permanent transfers and not distort incentives for national policy makers for sound fiscal policymaking or structural reforms.

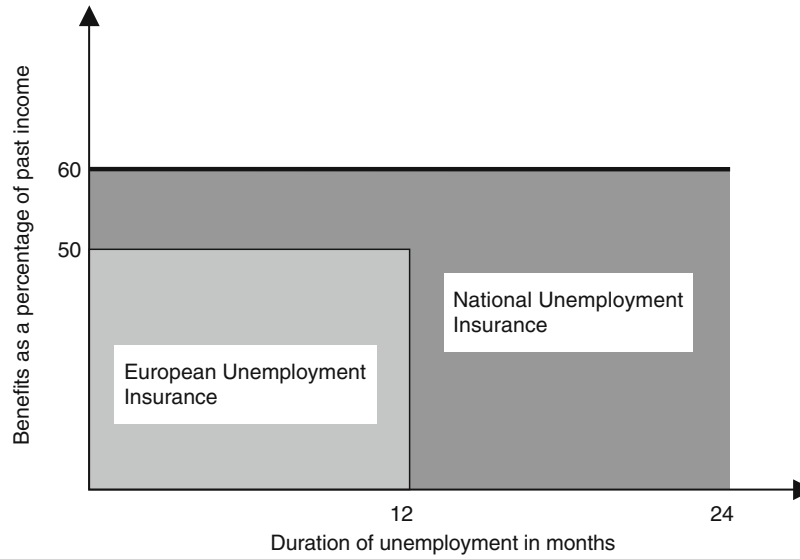
From the academic side, this discussion was supported by a number of more or less elaborate proposals for the design of automatic stabilisers for the euro area. These new contributions can be grouped into three categories: (1) proposals for a genuine unemployment insurance system that directly provides some kind of transfers to the unemployed; (2) proposals for reinsurance schemes which transfer money into national unemployment insurances in case of financial strain; and (3) proposals for transfer systems between national budgets.

Proposals for Genuine Unemployment Insurance Systems

The most prominently discussed proposal for genuine unemployment insurance is the one originally presented in Dullien (2007, 2008), although Deinzer (2004) had presented a similar proposal slightly earlier. According to Dullien's proposal, all employees in the euro area would pay a small payroll tax on their wages up to a certain threshold into a European unemployment insurance. After a certain number of months of insured employment (e.g. 20 out of the past 24 months), an individual would have the right to receive unemployment benefits in the event of job loss for a limited period of time. The benefits would be set as a share of past earnings.

The benefit duration and replacement rates from the European system would be defined roughly in line with the lowest common denominator for existing systems in euro area countries. In addition, each country would be allowed to top up the European system with national means, with regard to its duration, replacement rate and duration of unemployment benefits, to reach levels similar to those before the introduction of a European unemployment insurance. The aim of this setup would be to leave individual incentives to look for a new job unaltered by the introduction of this European unemployment insurance and allow for different levels of social protection between the euro area member states, depending on national preferences. Figure 1 illustrates this principle: prior to the introduction of a European unemployment insurance, all of the replacement payments are paid by the national unemployment insurance. From the individual unemployed's perspective, the solid black line represents the replacement payments. After the introduction of a European unemployment insurance, this transnational system pays 50% of past earnings for one year, while the national system would top up this payment for the first 12 months and cover the whole payment afterwards. In the figure the light grey area is paid by the European system and the dark grey area by the national system. From the individual unemployed's perspective, the solid black line would represent the replacement payments.

It is important to note that in contrast to national unemployment schemes, which were mostly introduced with social objectives in mind (see e.g. for the US case Blaustein 1993), the motivation for a European unemployment



European Unemployment Insurance, Fig. 1 Principle of a top-up unemployment insurance

insurance is mostly macroeconomic. Almost all euro area countries already have unemployment insurance systems in place which are actually more generous than the proposed European scheme, and hence no overall improvement in replacement rates for the unemployment would be expected from the introduction of such a scheme. Only the flow of funds would change: after the introduction of the European unemployment insurance a significant share of replacement payments would run through the European system instead of through national unemployment systems and national budgets. As national public budgets in the euro area are constrained through various fiscal rules (and sometimes by markets cutting off countries from the possibility to borrow at acceptable rate), this would give national governments more fiscal breathing space in recessions and hence hopefully lead to more countercyclical fiscal policies.

Proposals for Reinsurance Systems

In contrast to these genuine unemployment insurance systems, reinsurance systems such as the one proposed by the Brussels-based Centre for Economic Policy Studies (Beblavý and Maselli 2014) only transfer money to countries which experience a deep recession. Moreover, instead of insuring individuals (as in the genuine unemployment systems), here the insured entity would be the existing national unemployment insurances.

Specifically, the CEPS economists propose that each country pays 0.1% of its GDP annually into a European buffer fund until the fund's reserves reach 0.5% of euro area GDP. If, now, unemployment in one member state increases by more than two percentage points above its equilibrium unemployment rate, the country's unemployment insurance receives resources from the fund. It is further envisioned that countries that have drawn an excessive amount from the system would see their contribution rate increased to 0.2% of GDP.

The logic of this system is based on the reasoning of insurance economics: small damages (low to medium rates of unemployment) are assumed to be manageable by member states alone, while for large damages reinsurance payments are considered necessary. The contribution here is seen as an 'insurance premium' which is adjusted according to the risks insured, with high-unemployment countries paying a higher premium.

Proposals for Transfer Systems Between National Budgets

The third group of proposals, recommending rule-based direct transfers between national governments' budgets, is best represented by Enderlein

et al.'s (2013) idea of a 'cyclical shock insurance'. According to this proposal, euro area countries would pay into a transfer system and receive funds from this system depending on their position in the economic cycle relative to other euro area members. To measure the position in the business cycle, Enderlein et al. propose using the output gap (defined as the deviation between potential and current output), as this variable is already used in other euro area policy contexts (e.g. in the evaluation of excessive budget deficits).

According to this proposal, if a country's output gap is more negative (or less positive) than the euro area's average (or current output further below or less above potential output), it receives funds from the common pool. If a country's output gap is less negative (or more positive) than the currency union's average (or current output further above or less below potential), it would pay into the common pool. According to the Enderlein et al. proposal, the system's finances would be balanced each year, even though one could envision a system with direct transfers between national budgets without this specific feature.

Stabilisation Impact of Different Schemes

While the systems look rather similar at first sight, they have very different stabilisation properties. Firstly, some of the systems can help in stabilising the national and the overall business cycle *over time*. This is the case if the system is allowed to receive more funds in good times than it pays out, and pays out more in bad times than it receives – in other words it is allowed to accumulate reserves and go into deficit. Such a property would lead to a transfer of aggregate demand from boom times to recessions and the overall business cycle would be dampened.

In contrast, some of the systems might *only stabilise across space*. This is the case when the system's finances have to be balanced each year. Here, funds are transferred only between countries that do relatively better than others towards those that do relatively worse. While this kind of system might help to bring the euro area's business cycles closer together (and hence make a single monetary policy more appropriate for each single member state), it might actually *destabilise* the national business cycle. For example, in the deep recession in the global financial and economic crisis of 2008/09, all euro area countries saw output falling. Yet GDP in some countries contracted by more than in others. Systems which only stabilise between countries would have taken funds from countries with only a small decrease in GDP (but still in recession) and transferred them to the countries more severely hit, further decreasing GDP (and hence deepening the recession) in the former, but increasing GDP (and alleviating the recession) in the latter. This feature of these systems is an unavoidable consequence if they are not allowed to go into deficit or accumulate reserves. For the supporters of these schemes, this is usually seen as a secondary problem as they (implicitly or explicitly) rely on the European Central Bank to stabilise the overall business cycle and hence see the aim of the fiscal stabilisation scheme only as increasing convergence of the national business cycles.

A third question is in how far the systems work symmetrically: that is, whether they also stabilise the business cycle in a boom. If a system relies on fixed contributions, but pay out only in bad times, it will not significantly dampen an economic boom. In contrast, if contributions and/or payouts vary proportionally over the whole business cycle, booms are also dampened. The question of symmetric stabilisation is important if one believes that one of the reasons for recent deep recessions in some euro area member states was a prior overheating of national economies, as is often argued in relationship with the construction boom in Spain prior to the crisis of 2008/09.

Table 1 summarises the three dimensions of stabilisation for three representative proposals mentioned above. Looking at stabilisation over time and over space, genuine unemployment insurance stabilises in both dimensions: firstly, it stabilises both the overall euro area business cycle and national business cycle, as payouts are higher in a recession than in a boom and contributions are higher in a boom than in a recession. This holds

European Unemployment Insurance, Table 1 Stabilisation properties of different proposals for fiscal transfer systems

	Stabilisation of the overall (also national) business cycle	Stabilisation between countries (narrows the deviation of output gaps among euro area member states)	Symmetric stabilisation – dampens (relative) booms as well as (relative) busts
Genuine unemployment insurance	++	+	+
Reinsurance for national unemployment insurance systems	++	+	0
Cyclical shock insurance	–	++	++

+ some stabilisation; + + strong stabilisation; 0 no stabilisation; – potential destabilisation (Source: Author's elaboration)

both at a European level for the overall business cycle and at the national level for the national business cycle. Secondly, it also stabilises between countries, as countries that do relatively better pay in more (or receive less) than countries doing less well. Thirdly, the genuine unemployment insurance works symmetrically in a boom and a bust. In a boom, growing wages and employment rates lead to higher contributions and hence less disposable income in the country in question. In a bust, a country receives more unemployment benefits.

For the reinsurance model, similar arguments apply when it comes to the question of whether the overall business cycle is stabilised and whether cross-country differences in the business cycle are reduced: as the system provides assistance in a downturn and does so to all countries that have unemployment rising above the threshold, it stabilises a country's (and the euro area's) overall business cycle. As countries that are harder hit receive larger payments, it also moves the cyclical position of countries closer together. Yet it does so only when it is activated (in recessions). Reinsurance also differs in the question of symmetry of stabilisation: as payouts are only made in a crisis and contributions are fixed over the cycle, it does not stabilise in a boom, but only in a recession.

In contrast, the cyclical shock insurance does not stabilise a country's overall business cycle and it might even deepen recessions or magnify booms in single member states when the whole euro area is in recession or in a boom, as it only redistributes between countries but is not designed to accumulate or run down reserves. This potential destabilisation in a recession is not only an economic issue, but also a political economy problem: it is very likely that a system which forces a country already in recession (but in a less deep recession than the euro area as a whole) to further cut expenditure and transfer the funds to the European system (thus deepening the national recession) would quickly become the target of public criticism in the country concerned.

On the positive side, the cyclical shock insurance has the strongest effect for cross-country stabilisation and also provides the strongest symmetric stabilisation among the proposals: by its construction, it takes as many funds from booming economies as it pays out to weak economies.

Other Advantages and Disadvantages of the Proposed Schemes

Beyond the stabilisation impact, there are a number of other advantages and disadvantages of the current proposals which have been discussed.

For genuine unemployment insurance, the potentially complicated implementation, given the interaction with different, already complex existing national unemployment insurance systems, is often mentioned. In addition,

administering the database of contribution history of all of the insured in participating countries would require the creation of a significant central infrastructure, which would be more expensive than the rather sleek administrations necessary for just calculating transfers between national unemployment insurances or national budgets based on macroeconomic indicators.

Moreover, given limitations of data availability on the individual employment and earning histories of the unemployed, it is not currently possible to simulate the exact payment flows that such a scheme would create. Thus there is a risk that the system would create permanent transfers. An attempt to simulate a basic European unemployment insurance with the EUROMOD model came to the conclusion that, for the period from 2000 to 2013, some countries would have become permanent net payers or net recipients (Dolls et al. 2014). As Bargain et al. (2013) show for the case of the introduction of a common tax and benefit system for Europe, these transfers might have surprising directions (in their simulation, Germany becomes a net recipients of transfers). While, in principle, such a risk could be mitigated by allowing contribution rates to vary between countries if single member states draw too much from the system, such a variation in contribution rates also carries the risk of lowering the stabilisation impact of the scheme.

A related issue is the question of how far the introduction of European unemployment insurance creates a moral hazard for national governments. One issue here is in how far such a system might alter the incentives for national governments to conduct structural reforms. Occasionally, it is argued that the introduction of such a system would reduce national governments' willingness to liberalise their labour markets, as some of the costs of unemployment are moved to the European level. Yet this argument is not entirely convincing. Firstly, by its construction, the genuine unemployment insurance only covers short-term unemployment (as the unemployed only receive benefits after a substantial period of insured employment and only for a very limited time). Labour market reforms usually aim at reducing structural unemployment, which by its nature is long-term employment. Secondly, many structural reforms discussed for European labour markets (e.g. the loosening of dismissal rules) would initially lead to more short-term unemployment, not less. Thus, if part of these costs were borne at the European level, the incentives of national governments for such structural reforms might actually increase.

A further moral hazard issue is the question of how far national governments or administrations could minimise national net payments into the system. As has been observed in other federal systems, lower levels of the administration might reduce their efforts to put the unemployed to work if higher levels are responsible for paying the related unemployment benefits. Thus, it would be possible that national unemployment administrations might focus more strongly on putting those unemployed who receive benefits exclusively from the national system (e.g. because the minimum requirements for receiving European benefits have not been met) into new jobs and neglect those who are mostly financed by the European insurance. It is unclear, however, how big a problem this really would be as, empirically, most short-term unemployed who find a new job do so on their own and not through the unemployment administrations' efforts.

On the positive side, a clear advantage of genuine unemployment insurance would be that the concept of European unemployment insurance could be easily communicated to the general public, as most countries already have a similar national system of unemployment insurance in place. It has also been claimed that European unemployment insurance could provide a 'human face' for the European integration project (Fattibene 2015).

When it comes to the reinsurance system, one potential problem is the binary character of the potential triggers. As payments are only made if unemployment rises above a certain threshold, but then payments might be large, there might be an incentive for national governments to push unemployment beyond this threshold if it is already close. However, this criticism could be mitigated if payouts were phased in above a certain threshold instead of being allowed to kick in fully after the threshold is reached.

Another issue is the question of how far the unemployment rate is an appropriate indicator for determining transfers. Only part of the unemployment observed in Europe is of a cyclical nature, while in many countries the larger part of unemployment is considered to be structural. This is why the CEPS authors propose linking payments to deviations of the national unemployment rate from the structural unemployment rate (technically, the non-accelerating wage rate of unemployment: NAWRU). Yet, as discussed in Blanchard and Katz (1997) and other contributions to the winter 1997 issue of the *Journal of Economic Perspectives*, all real-time empirical estimations of the natural rate of unemployment are subject to a large degree of uncertainty, so it is possible that under reinsurance proposals payments are linked to questionable underlying data. However, one should keep in mind that, due to the specific construction of the payments to a trigger value, this problem is mitigated: even if the estimate of the underlying natural unemployment rate is off by one percentage point, countries meeting the trigger value of their actual unemployment rate having risen by two percentage points above the estimated national rate are clearly in a recession and would benefit from the stabilisation.

A third question – which applies equally to cyclical shock insurance – is how to make sure that the funds disbursed to national unemployment insurance systems or national budgets are also spent in a timely manner, which is a precondition for effective business cycle stabilisation. The problem is that, given the trigger issue, national governments faced with a moderate recession would initially have to plan their budgets without revenues from the central system if they do not want to risk excessive deficits. If, during the year, unemployment worsens and payouts are made from the reinsurance, it might be difficult to spend the extra funds quickly in a meaningful way.

In addition to the problem that the cyclical shock insurance might exacerbate national recessions under certain conditions (as discussed above), it is also often criticised for its reliance on the output gap for the calculation of transfers. While the output gap is a straightforward theoretical concept (defined as the difference between potential and current output), its empirical measurement is fraught with difficulties. Usually, econometric filter techniques such as the Hodrick–Prescott filter are used to estimate potential output. The problem is that the end point (i.e. the latest estimate in a time series) is susceptible to large changes if future output turns out differently than assumed. As a consequence, estimates of potential output are often very strongly revised *ex post* and, as a consequence, estimates for the output gap are revised even more strongly. Especially in times of crisis, these revisions tend not only to be large, but also to change the sign of the estimated output gap (Kempkes 2012). These revisions might result in payments which actually amplify the business cycle, rather than stabilising it. The European Commission's estimates for the Spanish output gap during the late 2000s are a case in point. In spring 2007, the Commission put the Spanish output gap for 2006 at minus 1.1% of GDP, meaning that current output was 1.1% below potential. Without large revisions of the underlying GDP data, but just because of new knowledge about GDP in the years 2007 and after, the Commission's estimate for the output gap 2006 from Autumn 2012 stood at *plus* 1.8%, meaning now that current output in that year was seen as being 1.8% in excess of potential output. Had one made transfers according to the real-time estimates, Spain would have received extra stimulus at a time when (at least with hindsight) the economy was already overheating.

Similar to the question of a potential destabilisation of the national business cycle, this is not purely an economic problem, but also a political economy one: it is difficult to imagine that a system under which a handful of econometricians in Brussels calculate large transfers between national budgets on a questionable methodological basis will be accepted by the taxpayers (and voters) of potential net payers.

For both the reinsurance system and the cyclical shock insurance, the low number of staff needed to administer the scheme is often mentioned as an advantage: only aggregate national data need to be analysed, so there is no need for a large central administration.

Political Considerations

In addition to these economic considerations, there are a number of political obstacles to overcome before (if ever) European unemployment insurance or one of the other fiscal stabilisation systems can be implemented. While it is disputed which of the proposals would require a treaty change (and hence unanimity), it is clear that the introduction of any fiscal stabilisation scheme would only be possible if there were a broad consensus among euro member states for the proposed scheme. At the time of writing, such a consensus is not in sight.

Predictably, all of these proposals are challenged by those who prefer limiting the EU's reach into national sovereignty. In addition, the single proposals each face political challenges of their own.

The genuine unemployment insurance faces the largest political resistance for a number of reasons. Firstly, the common European fund would be allowed to go into deficit in a deep recession (especially if a recession were to hit right after the fund's introduction); it might be seen by some as the introduction of 'euro bonds through the back door' and hence is faced with opposition from opponents of joint liabilities. Moreover, as this proposal carries the largest risk of creating permanent transfers (as exact payments are difficult to simulate *ex ante* with currently available data), it is opposed by many of the countries which saw their unemployment increase only a little in the crisis of 2008/09 and the subsequent euro crisis (and which hence would have been net payers during this time), such as Germany or the Netherlands. Thirdly, some countries have long opposed increasing EU competencies for social policies and hence fear that the introduction of genuine unemployment insurance at the European level might be used by EU institutions to limit national discretion for social protection. Finally, as the unemployment insurance systems in many euro area countries are managed under the strong influence of social partners, the national unions and national employers' federations fear the loss of influence if a significant part of the funds were in future funnelled through a European system.

The cyclical shock insurance faces the problem of shaky methodological foundations of the estimates of the output gap. While some authors have put some hope into improving the estimation methods for the output gap (Carnot et al. 2015), the underlying methodological problem – notably that it is difficult to estimate a trend in real time when the future is uncertain – will not go away. While there are not many interest groups which feel directly threatened by cyclical shock insurance, the technical issues will make it difficult to communicate the idea to the broader public and hence gain backing by national voters for the proposal.

The reinsurance system seems to be confronted with the least political resistance: it remains relatively easy to explain and yet it does not threaten directly specific interest groups. Yet so far very few politicians on the national level have put their weight behind the proposal.

In conclusion, one can see that, even though the number of supporters for some kind of fiscal transfer system for the euro area in order to stabilise the business cycle of the currency union has been growing, and there is a certain consensus about the desirability of additional macroeconomic stabilisation, none of the stabilisation mechanisms proposed is perfect and ready to be implemented. Even if political consensus about the introduction of such a scheme could be reached among member states (which seems to be difficult enough at the moment), a lot of work would have to be put into the technical details of these proposals before they truly could become operational.

European Union (EU) Research and Experimental Development (R&D) Policy

Henri Delanghe

Abstract

The European Union (EU)'s research and experimental development (R&D) policy pursues a range of objectives stated explicitly in the Treaty. Over time, EU R&D policy has gained in importance compared with other EU policies (as a result of the EU Lisbon, revised Lisbon and Europe 2020 strategies) and compared to Member State policies (as a result of a better recognition of the added value of action at EU level). EU R&D policy has so far consisted mainly of supply side-oriented direct financial support in the form of ever larger and more complex multi-annual 'Framework Programmes' supporting cross-border research programme coordination, frontier and cross-border collaborative research projects, international researcher mobility, research infrastructure access etc. Large-scale 'additional' impacts have been achieved by these Framework Programmes. In recent years, indirect support in the form of policy advocacy has gained in importance.

The General Framework of R&D and Technological Innovation Policy

The basic framework for R&D policy has already been described elsewhere (see 'R&D and technological innovation policy'). R&D, when appropriately valorised, leads to technological innovation in the form of new products and processes, which contribute to growth, competitiveness and job creation, and which produce other societal benefits. Because of market failures, the private sector, left to its own devices, invests in R&D in sectors not always fully aligned with, and at levels below, the socially desirable, and is unable to fully valorise its research output, which justifies public intervention. The latter needs to be thought through carefully, based on *ex ante* impact assessment informed by credible *ex post* evaluation.

The Stated Objectives of EU R&D Policy

The stated objectives of the EU's R&D policy fully recognise the potential societal impacts of R&D. As revised most recently under the Lisbon Treaty, they read as follows: 'The Union shall have the objective of strengthening its scientific and technological bases by achieving a European research area in which researchers, scientific knowledge and technology circulate freely, and encouraging it to become more competitive, including in its industry, while promoting all the research activities deemed necessary by virtue of other Chapters of the Treaties' (for the consolidated versions of the Treaty on European Union and the Treaty on the Functioning of the European Union and the Charter of Fundamental Rights of the European Union, please refer to the website: http://register.consilium.europa.eu/pdf/en/08/st06/st06655-re07.en08.pdf).

The Increasing Importance of R&D Policy Compared to other EU Policies: The Lisbon, Revised Lisbon and Europe 2020 Strategies

Over time, the EU's R&D policy, i.e. the policy put in place to achieve the aforementioned Treaty

objectives, has gained in importance. This trend has accelerated over the past 10–15 years, mainly as a result of two factors. The first is the move of R&D policy to the heart of the EU policy agenda (just as R&D policy has also gained a central place in national policy agendas over the same period). The Founding Treaties had already provided the Community with a responsibility in the field of research, yet research policy remained mainly a national affair until at least the late 1970s. European research policy was of an *ad hoc* nature, tied to particular sectors (agriculture, coal, nuclear energy, steel etc.) and fragmented. The inclusion of a separate chapter on R&D in the Single European Act (1986) heralded the shift towards a legally solidly grounded integrated European research policy focusing on the competitiveness of European industry and the quality of life of European citizens. Yet it was only as a result of the knowledge-based so-called 'Lisbon' (2000) and 'revised Lisbon' (2005) strategies that R&D policy moved to the heart of EU policy.

The purpose of the 'Lisbon Strategy' was 'to become the most competitive and dynamic knowledge-based economy in the world, capable of sustainable economic growth with more and better jobs and greater social cohesion' (Presidency Conclusions, Lisbon European Council, 23 and 24 March 2000). An important supporting objective in the field of R&D was the so-called 'three per cent' objective. In 2002, the Barcelona European Council agreed that 'overall spending on R&D and innovation in the Union should be increased with the aim of approaching 3 per cent of GDP by 2010. Two thirds of this new investment should come from the private sector' (Presidency Conclusions, Barcelona European Council, 15 and 16 March 2002). Because of the perceived lack of success of the 'Lisbon Strategy', a 'revised Lisbon Strategy' was defined which focused more on growth and jobs and identified the following areas for priority action: (1) investing more in knowledge and innovation; (2) unlocking business potential, especially for SMEs; (3) increasing employment opportunities for priority categories; and (4) climate change and energy policy for Europe (Spring European Council 25–26 March 2005). The successor to the Lisbon Strategies, i.e. the 'Europe 2020' strategy (2010) currently being implemented, continues in this vein with its basic goal of smart, sustainable and inclusive growth.

The Increasing Importance of EU R&D Policy Compared to Member State R&D Policies: The Concept of european Added Value

The second factor driving the increasing importance of EU R&D policy is the more explicit consideration and recognition by the Member States of the added value that can be produced at European level. The concept of European added value relates to one of the key principles underpinning the EU Treaty, the subsidiarity principle, which states that in areas of shared competence, like R&D, the EU shall act only if and in so far as it adds value, i.e. can achieve proposed objectives better than the Member States. In this respect, Article 5 of the consolidated version of the Treaty on European Union states that 'the use of Union competences is governed by the principles of subsidiarity and proportionality' and that 'under the principle of subsidiarity, in areas which do not fall within its exclusive competence, the Union shall act only if and in so far as the objectives of the proposed action cannot be sufficiently achieved by the Member States, either at central level or at regional and local level, but can rather, by reason of the scale or effects of the proposed action, be better achieved at Union level' (see the consolidated versions of the Treaty on European Union and the Treaty on the Functioning of the European Union and the Charter of Fundamental Rights of the European Union).

Because of its key role in the Treaty and its increasing political visibility, the added value of action at EU level cannot be automatically assumed and needs to be demonstrated explicitly. This requirement is set out formally in the Treaty Protocol on the Application of the Principles of Subsidiarity and Proportionality, which states that 'the reasons for concluding that a Union objective can be better achieved at Union level shall be substantiated by qualitative and, wherever

possible, quantitative indicators' (see the consolidated versions of the Treaty on European Union and the Treaty on the Functioning of the European Union and the Charter of Fundamental Rights of the European Union). This obligation is also included in the European Commission's guidelines on *ex ante* impact assessment (for an overview of EU IA, please refer to the website: ec.europa.eu/governance/impact). *Ex ante* impact assessment is obligatory for all major new EU initiatives and consists of assessing the applicability of the subsidiarity principle, in addition to assessing the future economic, social and environmental impacts. The former is accomplished by answering the following set of questions:

- Why can the objectives of the proposed action not be achieved sufficiently by Member States (necessity test)?
- As a result of this, can objectives be better achieved by action by the Community (test of EU Value Added)?
- Does the issue being addressed have transnational aspects which cannot be dealt with satisfactorily by action by Member States? (e.g. reduction of CO_2 emissions in the atmosphere)
- Would actions by Member States alone, or the lack of Community action, conflict with the requirements of the Treaty? (e.g. discriminatory treatment of a stakeholder group)
- Would actions by Member States alone, or the lack of Community action, significantly damage the interests of Member States? (e.g. action restricting the free circulation of goods)
- Would action at Community level produce clear benefits compared with action at the level of Member States by reason of its scale?
- Would action at Community level produce clear benefits compared with action at the level of Member States by reason of its effectiveness?

In the field of research, the issue of European added value arose at a relatively early stage. In 1973, the then European Commissioner for Research, Science and Education, Ralf Dahrendorf, asked the following set of targeted questions, all of them still relevant and not fully answered today:

> Are there points at which competition between national science policies – in itself a healthy phenomenon – makes no sense or has not got the desired effect? Are there subjects of scientific inquiry which require, because of their order of magnitude or for other reasons, a co-operative European effort? Are there needs for co-operation across borders due to the specific nature of given problems? Are there efforts of science for which the competitive space is worldwide, with Europe as one competitor rather than European with internal competition? Should co-operation take the form of co-ordination or of a common research effort? Since all this may sound rather abstract, can we afford to have several publicly financed research programmes for the development of telecommunications? Should there be a European computer programme? Can we pool our resources to conduct research into pollution and methods to fight it? Are there experiences in research in occupational medicine which should be shared? It is not difficult to prolong this list of subjects which require public support and have relevance beyond the borders of any single country: methods of enriching uranium, fighting epidemics, urban planning, identifying regional policy needs, producing software for computers, providing European programmes of management training, etc. Thus I should like to be able to take it for granted that there is a place for a European science policy (Dahrendorf 1973).

This explains why, compared with other policy areas, exploration of the issue is relatively advanced in this field. Since 1987 there have been successive multi-annual EU Framework Programmes for Research, Technological Development and Demonstration, the design of which necessarily involves identifying areas and means of EU intervention that would deliver European added value. Since the 1990s, there have been a number of large-scale *ex post* evaluations of these Framework Programmes. While these have acknowledged the evolving nature of the concept of European added value, they have stressed the need for clear *ex ante* definitions, i.e. the robust *ex ante* identification of instances in where the EU can add value. Good examples of such early calls are the so-called 'Five-Year Assessment 1995–1999' (Majó et al. 2000), which concluded that 'there is a need for a better understanding of European Added Value and for a more precise and

operationally useful definition of this concept', and the 'Five-Year Assessment 1999–2003' (European Commission 2005), which concluded that 'a simple and robust definition of European Added Value is needed for the design and implementation of future Framework Programmes'.

In response, Framework Programme evaluators and the European Commission have attempted to compile *ex ante* lists of instances of European added value. The 'Five-Year Assessment 1992–1997' (European Commission 1997) made a start by concluding that 'evidence of European added value is demonstrated by: the existence of important large-scale facilities which no individual Member State would develop and sustain; the promotion of internationally competitive R&D communities in new interdisciplinary areas such as information technology and biotechnology; the creation of strong European industrial platforms based on common technical standards able to compete or cooperate at a global level e.g. mobile telecommunications; the development of pan-European norms and standards for commercial applications'. Stampfer thought European added value was clearer in the case of, for instance, big infrastructures, 'single issue instruments', and European Research Area coordination instruments like ERA-NETs (Stampfer 2008). The most recent attempt to define in an *ex ante* manner instances of European added value in the field of research was made in the *ex ante* impact assessment of Horizon 2020, the new (2014–2020) Framework Programme for Research and Innovation (see "Appendix"; European Commission 2013, Box 4 and Annex 2).

The Evolution of the Framework Programmes

The main policy tool for implementing the EU's R&D policy so far has been direct financial support disbursed through the aforementioned multi-annual Framework Programme. There have been seven Framework Programmes so far (FP1: 1984–1987; FP2: 1987–1991; FP3: 1990–1994; FP4: 1994–1998; FP5: 1998–2002; FP6: 2002–2006; FP7: 2007–2013) and the eighth (2014–2020), called Horizon 2020, has just started (for detailed bibliographical references for the remainder of this section, please refer to Muldur et al. (2006, Chapter 4) and European Commission (2013, Annex 1)).

In accordance with the aforementioned increasing importance of the EU's R&D policy, the FPs have experienced large-scale budget increases over time, from about h5 billion for FP1 to about €70 billion for Horizon 2020. Because of these increases, the EU R&D policy budget has increased in importance not only compared to other EU policy budgets but also to Member State R&D policy budgets, in particular the competitively allocated parts of those. FP5, for instance, which preceded the much larger programmes FP6, FP7 and Horizon 2020, already accounted for a quarter of total funding for publicly financed research projects in the EU.

Most FPs so far have focused on the supply side through subsidies for, for instance, cross-border research programme coordination, frontier and cross-border collaborative research projects, international researcher mobility, research infrastructure access, etc. Horizon 2020 is the first FP to consider the demand side as well, through support for public procurement, for instance. Most of the FPs so far have also focused on research at the expense of innovation. FP6 was the first FP to include innovation support measures. FP7 no longer included such measures, however. Learning the lessons from the past, Horizon 2020 will once more bring research and innovation into a single programme.

In accordance with the expanding range of activities understood to be marked by European added value, the scope of the FP has expanded over time and its structure has become more and more complex: from one FP to another, new activities have been added on, such as public–public partnerships under FP6, and the European Research Council, public–private partnerships and the so-called Risk-sharing Finance Facility under FP7.

Public–public partnerships promote the coordination of public research funding at Member State level. These initiatives were developed based on a double observation: that, on the one hand, apart from the (supranational) FP and a number of inter-governmental initiatives, most

(i.e. well over 80% of) public funding for research in Europe remains uncoordinated and that, on the other hand, coordination can generate benefits in the form of improved programme scope and programme depth, greater scientific excellence because of increased competition between applicants, common solutions for common challenges, improved horizontal policy coordination, reduced programme management costs etc. Public–public partnerships usually involve the EU making available a suitable legal framework (based on Article 185 of the Treaty) as well as 'seed money' that should incentivise Member States to put together their research funding into a common pot.

The European Research Council awards research grants to individual researchers for excellent frontier research. It was developed based on the observation that Europe is lagging behind in terms of research excellence, as reflected in *inter alia* highly cited publications. The European Research Council constitutes an entirely new kind of FP initiative in the sense that its rationale is based not on the usual cross-border collaboration and coordination arguments traditionally underpinning FP actions, but on an entirely new type of European added value argument: the EU produces added value by letting researchers compete at the pan-European level rather than at the Member State level, thereby raising the intensity of competition, which raises the quality of research proposals and projects and contributes to European excellence in research.

Public–private partnerships promote the development and execution of longerterm strategic research agendas in areas that are critical for Europe's competitiveness, growth and jobs, but which suffer from large-scale market and systemic failures due to the scale of investment needed, the degree of coordination between stakeholders required, the market risk involved etc. These initiatives were developed based on the observation that in areas perceived as critical for Europe's industrial future (e.g. pharmaceuticals, aeronautics, energy) Europe was starting to lag behind in terms of research, innovation and deployment.

The Risk-sharing Finance Facility (RSFF), involving in addition to the European Commission the European Investment Bank, is a facility to finance higher risk research, technological development, demonstration and innovation investments. The rationale for the RSFF is that one of the key factors constraining the implementation of research and innovation activities is the insufficient availability of financing, at acceptable terms, to promoters of investments involving complex products and technologies, unproven markets and intangible assets. In order to overcome these difficulties, the RSFF improves access to debt financing for private companies or public institutions promoting research and innovation activities.

The thematic coverage of the FP has also expanded. While the FPs initially focused on energy and ICT, currently the whole range of scientific and technological fields is covered. The same applies to the range of instruments.

In accordance with the expansion in terms of budget, scope, thematic overage and instruments, the level of participation in the FP has increased over time. In the cross-border collaborative research projects, for instance, the number of participants has increased from 13,000 under FP2 to 40,000 under FP6.

Over time, the FP has become more academic in nature, as industrial participants, initially accounting for the majority of the aforementioned participations, lost out compared to academic institutions. As of FP6, this trend of declining industrial participation has stabilised, however, and even been reversed somewhat. This is due in no small part to the focused attention paid in recent FPs to facilitating the participation by SMEs.

Driving the Evolution of the Framework Programmes: Evaluation and 'Lessons Learned'

The evolution of the Framework Programmes described above has been driven by the lessons learned from numerous interim and *ex post* evaluations. Each FP has been the subject of interim and *ex post* evaluations, which each time have identified weaknesses that subsequent FPs have tried to address. During the preparations of the

most recent FP (Horizon 2020), for instance, it was noted that research, innovation and education should be addressed in a more coordinated manner and coherently with other policies, and that research results should be better disseminated and valorised into new products, processes and services. The intervention logic of EU support programmes should be developed in a more focused, concrete, detailed and transparent manner. Programme access should be improved and start-up, SME, industrial, EU-12 and extra-EU participation increased. Monitoring and evaluation should be strengthened.

A number of FP *ex post* evaluations have noted that the coordination between, on the one hand, the FP and other EU policies, and, on the other hand, the FP and Member State research activities, could be improved. With regard to horizontal policy coordination in the narrow sense, the FP7 interim evaluation (Annerberg et al. 2010) noted that a strategic shift is needed to establish stronger and better connections between research, innovation and education (the so-called knowledge triangle). As for broader horizontal policy coordination, the FP6 ex-post evaluation (Rietschel et al. 2009, pp. 58–59) called for a clearer division of labour between the FP and the cohesion funds. It also stated that other EU policies, such as transportation and energy, would benefit from a more coordinated interface between FP research activities and regulatory and demand-side policies.

With regard to vertical policy coordination, the FP6 *ex post* evaluation noted that, given its small size compared to Member State expenditure, the FP should not try to substitute for Member State R&D policies but should use its added value in a more strategic way and set an attractive and accepted European agenda. In the same vein, European research policy expert Erik Arnold (Arnold 2009, p. 28) concluded that the division of labour between the EU and national levels should be further refined and more explicitly defined, in particular in view of the introduction of the likes of the European Research Council and the Joint Technology Initiatives.

A number of FP *ex-post* evaluations (Rietschel et al. 2009; European Court of Auditors 2007, paragraph IV) have noted that the programme's design could be improved. The view held is that the FP lacks a transparent, clear and robust intervention logic: the programme has too many objectives, and higher-level objectives are insufficiently translated into lower-level objectives. With regard to the FP's objectives, the FP6 *ex post* evaluation (Rietschel et al. 2009, p. vii) as well as expert evidence (Arnold 2005, p. 29) noted that there were too many – addressing almost all science and technology (S&T) and socioeconomic challenges – and that they were too abstract and vague and therefore untestable, complicating *ex post* evaluation. A recent European Parliament ITRE Committee report (ITRE Committee Report 2011, paragraph 9) noted in the same vein that 'an ever-growing number of objectives and themes covered and diversification of instruments has widened the scope of FP7 and reduced its capacity to serve a specific European objective'. In addition, no explicit links are made between higher-level objectives and lower-level concrete technical goals (European Commission 2005, p. 19; Arnold 2009, p. 2). Meanwhile, instruments are not designed explicitly to achieve particular objectives: challenges are defined so as to match existing instruments, not the other way around (Stampfer 2008, p. 13). The result is 'catch all' instruments trying to tackle all problems and to satisfy all types of stakeholders. That is why the European Court of Auditors has called for a system which addresses a single objective in each instrument (European Court of Auditors 2009, paragraph 57.).

All FP *ex post* evaluations – see, for example, the chapters on participation in the FP6 *ex post* (Rietschel et al. 2009) and FP7 interim evaluations (Annerberg et al. 2010) – are unanimous in their view that FP application, contract negotiation and project management procedures are too complex and burdensome, and that this results in high barriers to FP application and participation in general, but for firsttime, start-up, SMEs and EU-12 applicants in particular.

Participants' main reasons for getting involved in the FP relate to networking and the creation of new knowledge (Arnold 2009, p. 2). FP research is also more of a long-term, exploratory, technologically complex nature (Polt et al. 2008). The FP

should not, therefore, be expected to produce new, immediately commercialisable products and processes. Nevertheless, FP evaluations conclude that more attention should be paid to the production of project outputs and to their dissemination and economic valorisation, in particular since the FP is supposed to support Europe's competitiveness. What is highlighted is the absence in the FP of valorisation channels that enable the exploitation of research results and the linking of knowledge created through the FP with socially beneficial uses (Rietschel et al. 2009, pp. 26 and 37; Annerberg et al. 2010, pp. 62 ff). In the same vein, the FP7 interim evaluation observes a lack of clarity on how the FP incorporates innovation (as opposed to 'pure' research).

The main problem affecting the FP monitoring and evaluation system relates to the aforementioned lack of focused objectives and a robust intervention logic. The evaluation process aims to link evidence emerging from project implementation with the strategic and specific objectives set for the programme. As the European Court of Auditors (2007) observed, if this connection is difficult to make, an assessment exercise becomes extremely complicated.

The Impacts of the Framework Programmes

Throughout their existence, the FP have been thoroughly evaluated and they have been demonstrated to have achieved large-scale impacts. Thus it has been shown that the FP have involved large numbers of top (A-team) EU and extra-EU researchers in thousands of first rate, mixed (firms, universities, research institutes), cross-border projects carrying out excellent, often interdisciplinary, collaborative research on a very wide range of topics. For instance, based *inter alia* on an FP-wide bibliometric study that demonstrated that the publication and citation performance of FP project 'lead scientists' is better than that of their non-FP peers (EPEC 2009), the FP6 *ex post* evaluation (Rietschel et al. 2009) concluded that FP6 involved top-quality researchers in first-rate projects performing high-quality research. Observing *inter alia* that 'the list of organisations that have obtained the largest amounts of funding from FP7 can be read as a Who's Who of European research quality', the FP7 interim evaluation (Annerberg et al. 2010) concluded that 'there can be little doubt that FP7 attracts the top EU researchers from universities and RTOs'. According to a Dutch FP impact study (Technopolis 2009), 'bibliometric research and over 100 interviews held in the Netherlands, confirmed that the European research programmes produce high-quality research and attract the best European researchers'.

The FP has facilitated the training and pan-European/extra-European mobility of researchers, enhanced the quality of doctoral training (including through industrial doctorates), added to the research capabilities of participating institutions, and formalised and oriented the R&D and innovation processes of, in particular, small organisations (e.g. SMEs), young organisations (e.g. start-ups) and organisations from new Member States and candidate countries. For instance, the FP6 *ex post* evaluation (Rietschel et al. 2009) noted that FP6 human resources and mobility schemes involved 8,000 organisations and supported some 12,500 fellows. The FP7 interim evaluation (Annerberg et al. 2010) noted that the specific programme 'People' was making a valuable contribution to the development of researcher human capital and that 'the Marie Curie Actions, through their bottom-up approach, have promoted excellence and have had a pronounced structuring effect on the research landscape'. According to an Irish evaluation of FP6, each project produced, on average, 2.3 newly trained/qualified personnel (Forfás 2009). A study of the impact of FP6 in new Member States (COWI 2009) found that FP6 'had an important impact on research organisations' interests and capacity in networking and . . . inspired a networking approach to the management and implementation of research projects with more focus on cooperation, formation of consortia, multidisciplinarity, communication and management skills'. It also produced 'an increase in skills and research capabilities of its key research staff' and resulted in the 'development of administrative capacity/competence to handle international project management processes'.

The FP has produced new knowledge embodied in large numbers of influential (because highly cited) (co-)publications and enhanced the development of new products and processes; the development and use of new tools and techniques; the design and testing of models and simulations; the production of prototypes, demonstrators and pilots; and other forms of technological development. For instance, according to Forfás (2009) each project produced, on average, 12.7 publications (of which 5.3 were in refereed journals and books) and 5.2 conferences, seminars and workshops.

The FP has generated large numbers of patents and enabled participants to increase their turnover and profitability, raise their productivity, increase their market share, obtain access to new markets, reorient their commercial strategy, improve their competitive position, enhance their reputation and image, and reduce commercial risk. For instance, according to an FP6-wide survey (IDEA Consult 2009), industrial organisations clearly expected commercial returns. Almost half of them (47%) stated that these were 'likely' to 'very likely', and 60% of this group expected these returns within 2 years (90% within 5 years). According to the FP5 and FP6 Innovation impact study (Polt et al. 2008), the great majority of FP participants reported at least one form of commercialisable output (new or improved processes, products, services, standards) stemming from their FP project and a large number even recorded more than one such output; an econometric analysis showed that the FP produces output additionality – a positive impact on the innovative sales of firms participating in the FP; and small and medium-sized enterprises indicated the most positive results in terms of innovation in FP projects. According to a German evaluation of FP6 (Federal Ministry of Education and Research 2009), scientific personnel participating in FP6 stated that a substantial part of their patent applications was due to their participation in the FP. According to a UK evaluation of the FP (Technopolis 2010), a majority of UK business participants stated that their involvement in the FP had yielded important commercial benefits; in terms of immediate project outputs, a significant proportion of business respondents reported having made or gained access to new or significantly improved tools or methodologies, and in a large minority of cases firms reported the creation of formal elements of intellectual property; beyond these immediate project results, around 20% of businesses stated that their participation had made significant contributions to the development of new products and processes and in around 10% of cases organisations reported increased income and market share. Lastly, company interviews suggested that FP participation had made a significant contribution to the competitiveness of leading players in several niche technology markets, from inkjets to photonics.

In addition, the results of FP direct and indirect actions have supported EU-level policy formulation. For instance, according to an EC-commissioned evaluation of FP6 environmental research (EPEC 2008), at the international level EU research related to climate change contributed to the International Panel on Climate Change (IPCC), either directly, through individual researchers involved in the IPCC review, or through references to EU-funded projects in IPCC reports.

The FP's positive impacts on innovation have translated, down the line, into large-scale positive macroeconomic, social and environmental impacts. For instance, according to econometric analyses underpinning the Horizon 2020 *ex ante* impact assessment, Horizon 2020 will help to boost industrial productivity, with every €1 invested generating an average of €13 in increased added value of the business sector. Investing €11.5 billion per year on average under Horizon 2020 (and sustaining this investment in the years thereafter) will, by 2030, generate €115 billion per year of extra GDP. This means that by 2030 each euro invested annually in research and innovation under Horizon 2020 will generate around 10 euros of extra GDP. In addition, Horizon 2020 will create about 830,000 durable jobs by 2030 or one job per 100,000 euros disbursed under Horizon 2020.

The FP has produced so-called structuring effects: durable changes in the EU research and innovation landscape. If it were not for the FP, the European Research Council, promoting excellence across Europe, would not have been created; the EU would then have been left with a landscape of compartmentalised national research councils, but

would have had no funding mechanism to promote EU-wide competition for funds and to encourage higher scientific quality in frontier research. As a result of the Marie Curie Actions, the EU has created the right framework for researchers' careers and the free movement of knowledge. The EU leads in the creation and use of research infrastructures of pan-European importance: as a result of EU leadership, for the first time, a pan-European strategy on research infrastructures (the so-called ESFRI roadmap) has been developed and is now being implemented. Collaborative research projects, international cooperation actions, mobility actions, and research infrastructure actions have generated durable, cross-sectoral, interdisciplinary research and innovation networks across Europe as well as with the world's most dynamic and fastest growing research nations that have survived after the end of EU funding. European Technology Platforms and ERA-NETs have served as useful focusing devices that have helped stakeholders identify and explain their R&D needs jointly, easing the process of developing mutually supportive policies at EU and Member State levels. Joint technology initiatives have focused and aligned key actors in their respective areas, serving as a support to develop coherent sectorial strategies. Article 185 and joint programming initiatives have achieved a better coordination of R&D in Europe and supported a more coherent use of resources.

It is important to emphasise that the evaluation literature has convincingly demonstrated that, in the absence of EU funding, these projects would not have been carried out, or would have been postponed or scaled down in financial terms, in terms of scope and ambition, or in terms of the number of partners involved. In other words, the FPs achieve large-scale additionality effects.

The Increasing Importance of Policy Advocacy

While the main policy tool for implementing the EU's R&D policy so far has been direct financial support disbursed through the aforementioned multi-annual Framework Programme, policy advocacy has gained in importance over the past 10–15 years. This started with encouraging the Member States to invest 3% of their GDP in R&D within the context of the Lisbon Strategy. This still continues with the 'soft' approach being taken towards the achievement of a European Research Area, which is defined as 'a unified research area open to the world based on the Internal Market, in which researchers, scientific knowledge and technology circulate freely'. And this has taken on a larger scale still with the so-called 'Innovation Union' flagship initiative of 'Europe 2020', which is the European Union strategy to create an innovation-friendly environment that makes it easier for ideas to be turned into products and services that will bring the economy growth and jobs and which pursues improved access to finance, innovation-friendly rules and regulations, accelerated standard-setting, cheaper patenting, innovation supported by the public sector, innovation partnerships to give EU businesses a competitive edge, facilitated access to EU research and innovation programmes.

Appendix: European Added Value – Why Fund Research at EU Level?

EU support to research is provided only when it can be more effective than national funding. It does this through measures to coordinate national funding, and through implementing collaborative research and mobility actions.

Coordinated Funding and Agenda-Setting

EU initiatives help to coordinate funding across national borders and to restructure the R&D and innovation landscape in Europe:

- The EU has created the European Research Council. Without it, the EU would have a landscape of compartmentalised national research councils, but no mechanism to promote EU-wide competition for funds and to encourage higher scientific quality.
- Thanks to EU leadership, for the first time, a pan-European strategy on research infrastructures is now being implemented.
- The EU helps private companies come together and implement joint strategic research agendas through tailored instruments, such as European Technology Platforms and Joint Technology Initiatives.
- The EU joins up compartmentalised national research funding using instruments such as ERA-NETs and Article 185 initiatives, which set common agendas and achieve the funding scale required for tackling important societal challenges.
- Through its Marie Curie actions, the EU set standards for innovative research training and career development and put in place a framework for the free movement of knowledge.

Coordinated funding reduces duplication and increases efficiency. EU support is vital – none of the above measures would have seen the light of day without an EU initiative.

Collaborative Research Projects and Mobility Actions

When it comes to implementing research and innovation projects, EU actions add value by stimulating transnational collaboration and mobility. These actions generate a series of benefits that could not be achieved by Member States acting alone:

- Support for collaboration helps to achieve the critical mass required for breakthroughs when research activities are of such a scale and complexity that no single Member State can provide the necessary resources.
- The EU supports research which addresses pan-European policy challenges (e.g. environment, health, food safety, climate change, security), and facilitates the establishment of a common scientific base and of harmonized laws in these areas.
- Working in trans-national consortia helps firms to lower research risks, enabling certain research to take place. Involving key EU industry players and end users reduces commercial risks by aiding the development of standards and interoperable solutions, and by defragmenting existing markets.
- Collaborative research projects involving end users enable the rapid and wide dissemination of results leading to better exploitation and a larger impact than would be possible only at Member State level.
- SME involvement in research and innovation at EU level improves their partnerships with other companies and labs across Europe, and enables them to tap into Europe's creative and innovative skills potential, to develop new products and services, and to enter new national, EU or international markets.
- Companies can collaborate with foreign partners and end users at a scale not possible at national level, in projects tested for excellence and market impact, which induces them to invest more of their own funds than they would under national schemes.
- Cross-border mobility and training actions are of critical importance for providing access to complementary knowledge, attracting young people into research, encouraging top researchers to come to Europe, ensuring excellent skills for future generations of scientists, and improving career prospects for researchers in both public and private sectors.

European Union (EU) Trade Policy

Stephen Woolcock

Abstract

The European Union's (EU) role in international trade has evolved from a defensive position during the 1960s and 1970s, to being a firm supporter of a rule-based multilateral trading system as a member of the Quad (US, EU, Japan and Canada) in the 1980s and to a role in which it aspires to leadership. Shifts in relative market power with the rise of emerging markets has, however, undermined the EU's ability to shape outcomes. Thanks to a well-developed internal *acquis*, the EU has developed common policies on all trade and trade-related topics, but the normative power this provides has had little discernable impact on multilateral trade outcomes. The decision-making procedures of the EU have functioned tolerably well up to now thanks to Member States having confidence and trust in the way decisions are made and the way the Commission, as agent, is controlled. The need to integrate the European Parliament (EP) into

decision-making procedures following the Lisbon (TFEU) Treaty is, however, likely to result in a period of uncertainty.

Introduction

This contribution provides an overview of the evolution of EU policy, a summary of the EU's positions on key issues in international trade and a summary of the decision-making procedures in EU external trade policy after the adoption of the Lisbon Treaty. The article therefore provides an introduction to the topic as well as sufficient references to enable readers to follow up the various aspects of the topic.

The Evolution of EU Trade Policy

The Treaty of Rome granted the European Economic Community (EEC) exclusive competence for Common Commercial Policy (CCP). (The term 'EU trade policy' will be used as it is the current usage. In actual fact, Common Commercial Policy, the term used in the original Treaty of Rome, more accurately reflects EU policy, which today extends well beyond what has been traditionally considered to be trade policy.) The creation of a customs union required the adoption of a common external tariff and thus a single EEC position on tariffs. The customs union also created a collective market power that exceeded that of the individual Member States. As a result the EEC was able to achieve some important offensive interests during the Kennedy Round (1963–1966) of the General Agreement on Tariffs and Trade (GATT), notably a reduction in US tariffs (Duer 2008). A desire to show solidarity in building Europe and a decision-making process that enabled Member States to veto trade concessions also enabled the EEC to hold its defensive positions. These were to retain the preference margin for EEC producers that the customs union would create and to protect the fledgling Common Agricultural Policy (CAP).

In the 1970s the USA again led the charge in GATT. Facing a deteriorating balance of trade and what it saw as 'unfair' trade practices of the Japanese and Europeans in supporting their national industries, the USA pushed for multilateral controls for subsidies, an opening of government procurement markets and disciplines covering technical regulations and standards. The USA had no active industrial policy, and had decentralized public purchasing and standards setting, so it viewed the coordination of such instruments to favour national companies in other countries as unfair. But European Community (EC) Member States pursued explicit (France and Britain) or implicit (Federal Republic of Germany) national champion strategies. The implications for EC trade policy were, however, the same: namely the defence of the policy space to enable these national policies to be continued.

There was some debate on EC-level industrial policy, but Member States' interests were too divergent for such an active policy. The only EC level intervention was in the form of coordinated adjustment or restructuring (in the face of competition from Japanese and Asian Newly Industrializing Countries) (Turner et al. 1982). Towards the end of the 1970s there was some support for what was called pre-competitive cooperation between producers in different Member States in more advanced technology sectors (McGuire 2006). This was not significant except that it heralded a shift in private sector opinion away from reliance on national markets and towards greater market integration within Europe in order to compete with Japan and the USA.

The EC also entered the 1980s with a defensive position on international trade and resisted new initiatives on non-tariff barriers, services, investment and intellectual property rights (IPRs). But a paradigm shift within the EC towards more

liberal, rule-based policies facilitated both the Single European Market (SEM) initiative and thus support for a more proactive EC position on international trade (Young and Peterson 2006). The SEM embodied a compromise between French dirigisme and rigorous reciprocity in trade negotiations and Anglo-Saxon liberalism. In fact, the outcome was closer to a form of EC 'Ordungspolitik': in other words a policy based on competition within the market and within an agreed framework of regulations guaranteeing key non-economic objectives and competition (Hodges et al. 1991). The SEM and associated introduction of qualified majority voting with the Single European Act (SEA) resulted in common EC approaches to almost all the issues under discussion in the GATT Uruguay Round between 1986 and 1994. There were effective EC level controls of subsidies, a comprehensive regime established for government procurement covering all forms of contract and levels of government. Technical regulations were addressed by the 'New Approach', a combination of harmonization of minimum essential requirements and mutual recognition. The SEM also liberalized some key service sectors, including financial services and telecommunications, two sectors which were seen as priorities for multilateral liberalization.

The deepening and widening of the SEM enhanced EU market power (Holmes 2006). The strengthened *acquis communautaire* gave the EU 'normative power', as did consensus on the balance between market and regulation. Acceptance of a liberal, rules-based regime within the EU meant that the EU was ready to support an equivalent regime at multilateral level provided it was consistent with the EU rules. Taken together, these factors enabled the EU to play an active role in the Uruguay Round, and the EU together with the USA (and other members of the Quad) shaped the agenda and very largely the outcome of trade negotiations. On more traditional trade issues the EU further reduced its bound tariffs on manufactures to an average of about 4 per cent. On agriculture the EU fought a rearguard action against liberalization and in the end accepted the reestablishment of multilateral rules for agriculture, but little in terms of actual liberalization.

From the mid-1990s the EU became the main proponent of a new multilateral round of trade negotiations. With the USA reluctant to engage in further multilateral liberalization due to domestic opposition and developing countries largely opposed to a comprehensive round, the EU assumed a kind of leadership role. The EU approach was shaped by the European Commission, which favoured a new comprehensive multilateral round ahead of preferential trade agreements (Lamy 2004). For the EU a comprehensive round meant coverage of the issues already covered by the GATT/WTO, such as tariffs, non-tariff barriers, services and agriculture, as well as issues for which there were as yet no established multilateral rules, such as investment, competition policy, government procurement and trade facilitation. These four issues became known as the 'Singapore issues' because the EU ensured they were placed on the WTO work programme at the WTO ministerial meeting in Singapore in 1996. Trade and labour standards and trade and the environment, or 'sustainable trade' as the coverage of these two topics have come to be known in the EU, were also discussed at the Singapore ministerial. The EU did not push hard for these topics to be added to the WTO work programme, because opinion within the EU was divided between Member States such as France and some socially minded northern Member States that favoured the inclusion of labour standards, and others, such as Britain and Germany, that opposed discussing labour standards in the WTO. With developing country members of the WTO firmly opposed to including environment and labour standards in talks, the European Commission did not press the issue.

By the time a multilateral round, in the shape of the Doha Development Agenda (DDA), was launched, some sources of EU relative strength had been weakened (Young and Peterson 2006). The Lisbon agenda, a more intergovernmental follow up to the SEM, proved largely unsuccessful. As the 2000s progressed, growth in relatively high tariff and otherwise protected markets such as China, India and Brazil burgeoned, eroding the EU's relative market power.

The negotiating leverage gained from holding out the prospect of concessions on agriculture in

order to pursue offensive interests in non-agricultural market access (NAMA), services and the Singapore issues proved insufficient, and at the WTO Ministerial meeting in Cancun in 2003 the EU was obliged to drop investment, competition and government procurement from the agenda. At the Hong Kong WTO Ministerial meeting in 2005 the EU made further concessions, such as agreeing to phase out export subsidies in agriculture, in order to keep the round alive. But with little support from the USA, and opposition from developing countries, the aim of an ambitious comprehensive round was lost and the DDA reverted to a modest conventional market access trade round focused on agriculture and NAMA. By 2006 the EU recognized the that success at the multilateral level was unlikely and switched to bilateral negotiations with major potential markets, especially in Asia, as well as complete existing negotiations with African Caribbean and Pacific (ACP) states (Elsig 2007; Heydon and Woolcock 2009; Bartels 2007). This policy was codified in the October 2006 Global Europe Strategy (European Commission 2006; Evenett 2007) and has been subsequently confirmed by the November 2010 policy statement on Trade, Growth and World Affairs (European Commission 2010). The 2010 policy statement also suggests a less liberal approach to reciprocity by hinting at the potential withdrawal of access to procurement markets for trading partners that do not offer reciprocal access.

A Summary of EU Policy Positions

In addition to the kind of developments in European integration and the international trading system discussed above, EU trade policy is shaped by sector interests. Indeed, the general structure of EU preferences can be traced to the balance between offensive and defensive interests of sectors of the Member State economies. Such sector interests are of course aggregated in EU level policies, so that the *acquis* itself reflects the balance of sector preferences.

The EU has generally favoured a formula approach to tariff reductions because the creation of the common external tariff (CET) appears to have smoothed the EU's tariff profile so that it has had rather higher average tariffs but fewer tariff peaks than, for example, the USA. Consecutive multilateral rounds have reduced the average MFN tariff for manufactured goods to 3.9 per cent with 100 per cent tariff binding. The EU therefore has less to offer in NAMA compared to the large emerging markets such as China, Brazil and India (9 per cent, 12 per cent and 16 per cent applied rates respectively) with higher bound rates in some cases. (The bound rate is the rate bound under GATT commitments. A higher bound rate than an applied rate means that a WTO member can increase tariffs up to the bound rate without infringing GATT rules and thus facing retaliation from other WTO members.) The EU policy position favours significant reductions in bound rates for major emerging markets. Such reductions in bound rates will not result in any significant reductions of applied rates, so what the EU seeks is discipline to prevent the emerging markets increasing rates on EU exports thanks to 'water' in their tariffs or relatively high bound rates. For least developed countries the EU has offered tariff free quota free access to the EU market and urges other major WTO members to do the same (Faber and Orbie 2007). The EU also supports sector negotiations, there are such negotiations in 14 sectors, and seeks some commitment from the large emerging markets to this process.

The average EU tariff is 15 per cent in agriculture, compared to 10 per cent in Brazil and China and 38 per cent in India, but the EU of course provides significant agricultural subsidies. Since the initial limited McSharry reforms of 1992, the EU further reduced price support levels and 'decoupled' agricultural support from trade in the Agenda 2000 reform and especially the mid term review of the CAP in July 2003 (Daugbjerg and Swinbank 2009). These provided some scope for the EU to make concessions so that it has accepted tiered tariff and subsidy reductions in the chair's text of December 2008 in the DDA. (The tiers as set out in the Chair's text of December 2008 are tariffs of more than 75 per cent (70 per cent reduction), 50–75 per cent (64 per cent reduction), 20–50 per cent (57 per cent) and

less than 20 per cent (54 per cent reduction).) If finally agreed, these could lead to further market opening by the EU, but much depends on the detail, including in particular what percentage of product lines are defined as sensitive and therefore excluded from tariff reductions. Anything more than 4 per cent would limit liberalization considerably. On subsidies the Chair's text would result in an 80 per cent reduction in of the Overall Trade Distorting Support (OTDS) for EU agricultural, with some safeguards against shifting of subsidies between activities. This represents further liberalization, although it is of course dependent on an agreed outcome of the DDA round as a whole. As part of a strategy of diversification out of commodity crops and into higher value-added agricultural products, the EU is seeking greater protection for geographic indications, such as Parma ham and champagne.

The EU has pushed for the Singapore issues. On public procurement, the EU, having adopted a comprehensive EU regime internally, would like other major economies that have not signed the WTO's Government Purchasing Agreement (GPA) to at least adopt measures on transparency. The EU policy also believes that greater transparency is beneficial for all countries because it promotes competition and more efficient use of public finance, and fights corruption in the allocation of public contracts.

The EU supported negotiating investment in the WTO, in part to include investment in the rules-based regime of the WTO and in part because the main restrictions on investment were in developing countries. The USA favoured the plurilateral OECD because it wanted higher standards than could be expected in any WTO agreement. The collapse of the plurilateral 'Multilateral' Agreement on Investment (MAI) in 1998 also effectively ended prospects for agreement within the WTO. The recent extension of the EU's exclusive competence to foreign direct investment with the Lisbon Treaty can be expected, in time, to result in a more common approach to investment by the EU (European Parliament 2010). In the past the EU's policy has been hampered by the fact that competence for foreign direct investment was shared between the European Union and the Member States, with the Member States leading in negotiating investment protection in bilateral investment treaties (BITs). Exclusive competence implies the need to define a comprehensive, common EU position on investment. Given the importance of the EU for foreign direct investment a redefined, 'modern' approach to investment agreements by the EU could breathe some life into the prospects of a genuine international agreement.

The rationale for EU support for the inclusion of competition as one of the Singapore issues was that there was a need to ensure that private restraints to trade do not replace public constraints following liberalization. This was the same rationale used for EU-wide competition policy. Despite difficulties gathering information, there is evidence of damaging international cartel activity. The European Commission led in pushing for the inclusion of competition because it has exclusive powers in this policy area (Damro 2006). But there was little support except among consumer groups within the EU. Internationally there was strong opposition from the USA, where the Department of Justice opposed any substantive international rules on competition, and resistance from developing countries, which argued that they did not have the capacity for such policies.

In services the EU retains an offensive position given its comparative advantage in many service sectors, such as financial services and business services. Since the financial crisis of 2008 the mood has swung against further liberalization of financial services. In the field of intellectual property rights the EU favours more effective enforcement of existing international conventions. Finally, with regard to technical regulations and sanitary and phytosanitary measures the EU appears to have shifted from a policy of seeking mutual recognition agreements, because of the complexities involved in these, and now favours the promotion of full use of existing international standards.

The Policy Process

EU policy-making in trade functions reasonably well, despite the need to reconcile the positions of 27 Member States, when there is a strong internal

consensus as with the SEM and when there is a well-established decision making regime in which the major stakeholders have confidence (De Bievre and Duerr 2007). The decision-making regime for external trade has been established over a period of 50 years since the Treaty of Rome and has provided the model for all external EU policy-making used in the Treaty of Lisbon (Art 218 TFEU). In this regime the Commission provides the strategic orientation of policy thanks to its right of initiative on negotiating mandates. The EU's negotiating aims or mandate are adopted by the Member States in the Foreign Affairs Council after work in the Trade Policy Committee (ex Art 133 Committee) that brings together Member State and Commission senior trade officials (Art 207(3) and 218(2) TFEU). The TFEU confirmed that the consent of the EP, by a simple majority, is needed for all trade and investment agreement negotiated by the Commission. The EP would also like more say in setting EU objectives, because making its consent to any trade agreements conditional upon certain targets being met would strengthen the credibility of the veto power. The TFEU does not provide for this.

During negotiations, whether at multilateral or bilateral levels, at a technical or political level, the European Commission is the sole voice of the EU (Young 2006). This greatly facilitates coordination compared to other policy areas, where there are different negotiators at the technical and political levels, such as in the case of international environmental policy. There remain of course coordination problems both within the Commission between Directorates General and between the Commission and the Member States (Kerremans 2006; Meunier and Nicolaidis 2006). The well-established regime of decision-making in which the Member States, through the TPC, assist the Commission during negotiations has generally promoted trust between Commission and Council. Such close supervision of the Commission's approach to negotiations provides the assurance needed by the Member State governments to allow the Commission to negotiate. The Council can also give the Commission directions during negotiations.

The adoption of the TFEU now requires the European Parliament must now be included in decision-making including during negotiations. The EP (International Trade Committee (INTA)) now receives the same information on the progress of negotiations as the TPC. The Commission has for some time been working more closely with the EP in anticipation of the treaty changes and has already provided a great deal of information (Woolcock 2010). The Council and Member States have a less easy relationship with the EP on trade policy and it will take some time before a *modus vivendi* can be developed between the two. Both Commission and Council, as well of course as interest groups and lobbies, will have to pay more attention to the EP, which has power to grant consent to all trade agreements. The EP also shares powers with the Council on trade legislation, such as the adoption of EU legislation implementing trade agreements or so-called autonomous trade measures, such as the Generalized System of Preferences for developing countries. Prior to the TFEU the Council used to adopt legislation according to the coordination procedure in which the EP played virtually no role. After the TFEU the Ordinary Legislative Procedure (OLP) (formerly co-decision making) is to be used. This will be much slower than the previous arrangements, so it is likely that the Commission will be granted implementing powers to deal with the numerous detailed adjustments needed to trade agreements and schedules, with OLP used only for the relatively few major pieces of trade legislation.

Conclusions

EU trade policy has gone through various stages, some more defensive than others. During the 1980s and 1990s the EU moved to become more supportive of a liberal rules-based multilateral trading order. EU efforts to lead a comprehensive WTO round, in the shape of the DDA during the 2000s, has not had much success. As a result the EU has reverted to pursuing bilateral free trade agreements in order to pursue its aims.

The EU policy stance remains generally liberal, with the exception of agriculture, where

reform has been steady but slow, and there is unlikely to be support among a qualified majority of Member States for any move towards the more aggressive use of reciprocity by threatening to close the EU market. But the EU lacks much leverage in negotiations, especially multilateral negotiations, due to the fact that it has an open market in most sectors, again with the exception of agriculture. The negotiation coinage that could be offered by way of opening the EU agricultural market did not prove sufficient to make progress on the EU's offensive interests in the DDA.

The decision-making procedures of the EU have functioned tolerably well up to now thanks to Member States having confidence and trust in the way decisions are made and the way the Commission, as agent, is controlled. The need to integrate the EP into the decision-making procedures following the Lisbon (TFEU) Treaty is, however, likely to result in a period of uncertainty.

European Union Budget

Mojmir Mrak

Abstract

The EU budget is a tool through which money is collected and allocated for EU policies and objectives as well as for the tasks transferred to it from the national level. This article starts by presenting the concept and evolution of the EU budget. It then discusses the principles and procedures governing its adoption and implementation, presenting the key features of the expenditure and revenue sides of the EU budget. The main deficiencies of the EU budget are addressed, including the problems of correction mechanisms and net balances. Finally, the challenges faced by the EU at the outset of the negotiations about the post-2013 EU budget are outlined.

Introduction

The process of European integration requires financial resources for its activities, and the EU budget is a tool through which money is collected and allocated for EU policies and objectives as well as for the tasks transferred to it from the national level.

The EU budget is modest in size. As agreed by the Member States, in the Own Resources Decision (ORD), the maximum ceiling of the EU budget financing is set at 1.24 per cent of the EU GNI (or 1.27 per cent of EU GNP). In practice, however, the EU budget has always remained well below that ceiling. As public finances of the EU Member states are typically between 40 and 45 per cent of their respective GNI, the EU budget is equivalent to just over 2 per cent of the total public finances of the Member States. The EU budget does not represent a significant factor in almost any consolidated national public finance category. Three key segments of public finance expenditures in practically any country – defence, security and public order expenditure – as well as healthcare, are not even included in the EU budget, while the presence of certain other expenditure items, such as education and housing, is minimal. There is another fundamental characteristic which distinguishes the EU budget from national public finances. In contrast to national public finances, which can run deficits, the EU budget is legally required to be in balance each year.

Even though the EU budget is small in size, it is of a tremendous political importance for the overall EU integration process. This can be illustrated by the highly complex procedure that is required for the adoption and implementation of the annual budget, which involves practically all important EU institutions, as well as by the strongly politicized multi-annual financial framework (MAFF) negotiations that set the ceiling costs on major expenditure items of the EU budget over a five to seven year period.

Evolution of the EU Budget

The evolution of the EU budget can be roughly classified into two periods: the first, between 1951 and 1987, was characterised by a move towards the unification of budgetary instruments and the crisis of Community finances in the 1980s; the second, from 1988 until today, has been characterised by features introduced by the 1988 EU budgetary reform.

1951–1987

The public finance system of the EC began to develop in the early 1950s, when in 1951 the

European Coal and Steel Community (ECSC) Treaty was signed. It was followed by the 1957 European Atomic Energy Community (EURATOM) and European Economic Community (EEC) Treaties. Each of these treaties envisaged different budgets for a particular Community, which led to the co-existence of budgets. The ECSC Treaty provided for two budgets – an administrative and an operating budget. The EURATOM Treaty also set up two budgets: an administrative budget and a research and investment budget. The EEC Treaty, on the other hand, established only one, a so-called 'single budget'.

The 1965 merger treaty incorporated the ECSC and EURATOM administrative budgets into the EEC budget, and five years later, in 1970, the Luxembourg Treaty incorporated the EURATOM research and investment budget into the general budget. The outcome of these developments was the formation of two budgets – the general budget and the ECSC operating budget – and the system was in place until 2002. The ECSC Treaty expired in 2002 and therefore the ECSC operating budget ceased to exist. Since then the EU has operated with a single EU budget.

During the first 20 years of the Community's financial system, there were two important developments for the integration of budgetary instruments. The first was the development of common policies. The most notable events, with considerable financial consequences, were probably the creation of the European Agricultural Guidance and Guarantee Fund (EAGGF) in 1962 as an instrument for implementation of the common agricultural policy (CAP), as well as the establishment of two funds for implementation of the cohesion policy: the European Social Fund (ESF) in 1971 and the European Regional Development Fund (ERDF) in 1975. These two policies still constitute about 80 per cent of current EU budget expenditures. The second development was that the initial system, through which the budgets of all the three Communities were financed through a special system of contributions by the Member States, soon proved to be insufficient and unsatisfactory. The need for a better and more efficient system, which would provide sufficient resources, gradually led to a reform of budget financing. Through the 1970 Luxembourg Treaty, a system of so-called 'own resources' was introduced.

The processes of unification of the budgetary instruments, development of common policies and progress towards financial autonomy were inevitably connected with difficult negotiations. The majority of disagreements had been associated with responsibilities and powers that each of the institutions had in budgetary matters. Although decisions in budgetary matters were in theory primarily the exclusive prerogative of the Council, in practice other institutions were involved at various stages of the budgetary procedure. The 1970 Luxembourg Treaty partly formalised such a practice by giving more power to the Parliament. Since the 1975 Brussels Treaty, powers on budgetary matters have been shared between the Council and the Parliament.

The legal, political and institutional structure for governing the Community's finances established in the early 1970s soon proved to be unsustainable over a longer period of time. Relations between Member States, as well as among the European institutions involved in the budgetary adoption procedure, gradually worsened and finally turned into open conflict. An increasing number of incidents made adoption and management of a budget almost impossible. Between 1980 and 1988, approval of four annual budgets was delayed long enough that provisional arrangements in the form of so-called 'twelfths' had to be applied for several months.

Since 1988

The 1986 enlargement to include Spain and Portugal and the conclusion of the Single Act injected new optimism into the Community and provided a sound political base for a thorough reform of the Community's financial system. In 1987, the Commission presented comprehensive reform proposals and in the following year the European Council adopted the broad lines of these proposals. The main political orientation and operational features of each of these orientations were as follows:

The Community should be given sufficient resources to enable it to operate properly. In operational terms, this meant a revision of the ORD whereby a new (fourth) resource was introduced based on Member States' GNP. From that period on, GNP and later on GNI source, represents the balancing item, i.e. it provides the necessary funding for the Community and, from 1992, for the EU budget.

Strict supervision of the expenditures financed by these additional resources should be exercised. This orientation, aimed at making an effective brake on rising agricultural expenditures, was operationalized through an inter-institutional arrangement for budgetary discipline in procedures, of which a multi-annual financial framework instrument was an integral part.

The political orientation of linking the budget contributions of Member States more closely to their levels of relative prosperity was operationalised through a significant reform of the cohesion policy and especially the instrument for its implementation.

Since 1988, the Community/EU budgetary system has remained more or less unchanged in terms of its size expressed as percentage of EU GNP/GNI as well as in terms of the magnitude of its expenditure and its distribution, with agriculture and cohesion spending consuming the majority of the GNI source.

The EU budgetary system continues to be based on two major elements. *First*, the strategic course of the EU public finances and financial framework for the medium-term period is determined in a multi-annual financial perspective (MAFF). The MAFF is basically an agreement among the institutions on budgetary priorities facilitating the budgetary procedure and the management of various programmes. The MAFF allows financial predictability in the development of EU expenditure. Within the framework of the MAFF, the maximum volume and the composition of the foreseeable EU expenditure are indicated. The MAFF fixes the ceilings for particular expenditure headings as well as for the budget as a whole; the cap on spending levels must be set below the own resources ceiling. The MAFF is a product of an inter-institutional agreement between the Commission, Council and Parliament. Although it is not a multi-annual budget, and the annual budgetary procedure remains necessary to decide the next year's budget, the MAFF is not just indicative, as it sets the maximum ceilings for each year and each category of expenditure (heading). Until now, Community/EU institutions have adopted four MAFFs. The first, called 'Delors I', had duration of five years (1988–1992) while all three of the subsequent ones covered seven-year periods: 'Delors II' (1993–1999), 'Agenda 2000' (2000–2006) and the current MAFF (2007–2013). *Second*, the implementation and operational details of the EU budgetary system are elaborated in the annual budget, which must be consistent with the MAFF.

Principles and Procedures for the Annual Budget and for the MAFF Principles

The EU budget is regulated by six principles that are enshrined either in the Treaty or in the secondary financial legislation.

The *principle of unity* states that all expenditures and revenues of the EU must be included in the EU budget. The European development fund (international development aid) and the financial activities of the European Investment Bank constitute exceptions to this principle.

The *principle of universality* says that revenues cannot be appropriated for specific spending purposes.

The *principle of annuality* requires that budgetary appropriations must refer to a specific year. Due to the multi-annual nature of some programs, two categories of appropriation are entered into the EU budget: appropriations for commitments, i.e. the expenditure committed by the EU in a given year with respect to operations that can be carried out over a longer period of time, and appropriations for payments, i.e. the expenditure effectively incurred by the EU in a given year in meeting the commitments of that and/or of previous years.

The *principle of equilibrium* provides that the EU budget cannot be in deficit or surplus.

Practical enforcement of the principle is through automatic adjustment of the GNI revenue source to expenditures.

The *principle of specification* states that no commitment can be entered in the EU budget without a definite scope and purpose. The only exception is the budgetary reserve.

Finally, the *principle of the unit of account* states that the EU budget is expressed in EUR.

Procedure for the Annual Budget Adoption and Implementation

The procedures are comparable in many respects to procedures at the national level. The EU budgetary procedure consists of five main phases. Preparation of the budget for the year *N* starts with the *proposal of the Commission* submitted by the end of April of year $N - 1$. In the second phase, *Council and Parliament discuss the proposal and adopt the budget* with the required majority by the end of December of year $N - 1$. The next stage consists of the *Commission's execution of the budget* throughout year *N*. *Technical control of the budgetary execution*, which is in the hands of the European Court of Auditors, represents the fourth stage of the EU budgetary procedure and is usually completed around November of year $N + 1$ for the budget of year *N*. The fifth phase – *political clearance* – is given by the Parliament usually in March of year $N + 2$ for year *N*.

Procedures for the MAFF Adoption

The boundaries for the annual budget are set by the MAFF on the expenditure side and by the ORD on the revenue side, with both of them required to be adopted unanimously in the Council. This prerequisite of unanimity is one of the main reasons why MAFF negotiations usually turn into one of the most complex negotiations among the EU Member States, even at the European Council level, where political clearance has to be achieved. On the other hand, the unanimity rule of the Council *de facto* transfers the decision-making power to this institution. The negotiations about the MAFF 2007–2013 clearly confirm this fact, as the Council agreement was significantly changed by the Commission's proposal, and the Parliament's role in the decision-making process was rather symbolic. With the Lisbon Treaty in place, the importance of the Parliament in the MAFF decision-making process has strengthened substantially.

Structure of Expenditures

In the early decades of the Community, CAP absolutely dominated EU expenditure. More recently, due to several enlargements of the Community/EU and through the introduction of the MAFF instrument, CAP expenditures have been capped, allowing funding for some other items, especially cohesion policy expenditures. As shown in Fig. 1, approximately 80 per cent of all EU budget funds was earmarked for these two policies over the last two decades. The remaining share of the budget was allocated for external EU activities and internal policies aimed at boosting competitiveness and the implementation of other objectives.

In the MAFF 2007–2013, the total volume of finally agreed expenditures will amount to h864 bn in commitment appropriations and h821 bn in payment appropriations. As shown in Table 1, these amounts are significantly lower than the comparable figures proposed by the Commission.

The MAFF 2007–2013 classifies expenditures under six headings:

1. *Sustainable growth*, subdivided into competitiveness for growth and employment (research and innovation, education and training, trans-European networks, social policy, economic integration and accompanying policies) and cohesion for growth and employment (convergence of the least developed EU countries and regions, EU strategy for sustainable development outside the least prosperous regions, inter-regional cooperation);
2. *Preservation and management of natural resources* (common agricultural policy,

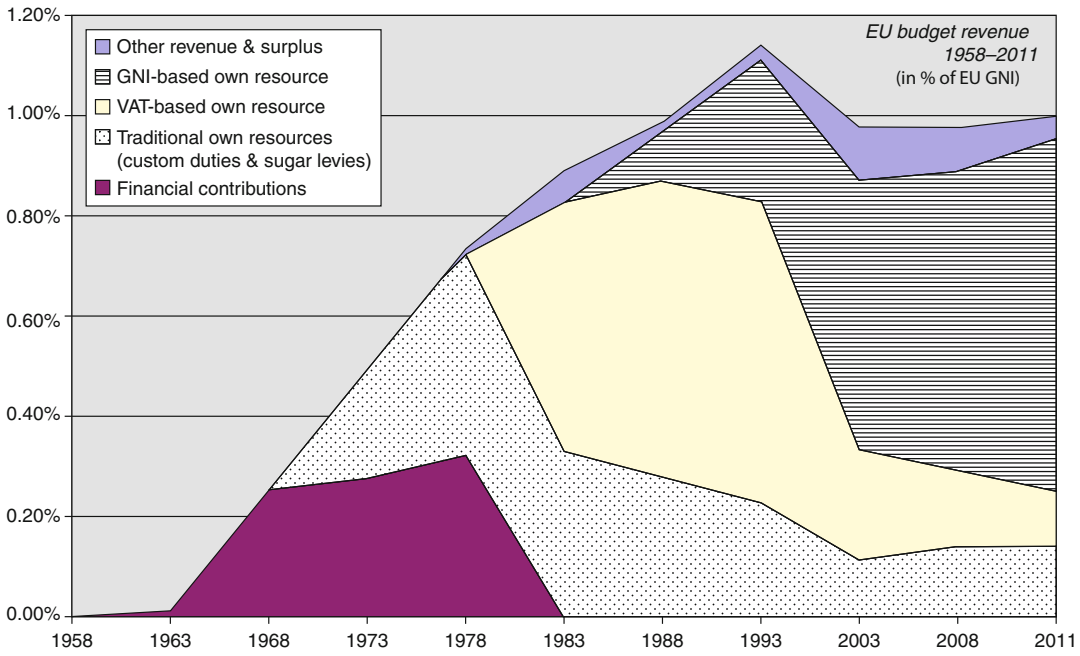
common fisheries policy, rural development and environmental measures);
3. *Citizenship, freedom, security and justice*, subdivided into freedom, security and justice (justice and home affairs, border protection, immigration and asylum policy) and citizenship (public health, consumer protection, culture, youth, information and dialogue with citizens);
4. *EU as global player* (covers all external actions by the EU);
5. *Administration* (covers the administrative expenditure of all the European institutions); and
6. *Compensations* (includes compensatory payments relating to the latest expansion of the EU).

Structure of Revenues

The evolution of the revenue side of the EU budget has been driven by the continuous attempt to strike a compromise between the financial autonomy of the EU budget and sufficiency of resources for its financing. The budget of the ECSC in the early 1950s was financed through a tax-based 'own' resource (a levy on steel production) while, in contrast, the Rome Treaty stipulated that the EEC budget was financed in a totally intergovernmental way, i.e. through direct contributions from Member States. At that time, the EEC budget had no 'own resources' and thus had no financial autonomy from its Member States.

It was in 1970, with the Luxembourg Treaty, that the EEC budget started to move towards an own resources model. At that time, own resources included traditional own resources, i.e. customs duties and agricultural levies, and VAT-based revenues from Member States. This structure remained unchanged until 1984, when the Fontainebleau Council introduced the UK correction, which in fact means a reduction of the UK contribution to the Community budget. The last major change to the EU budget revenue side occurred in 1988 with the Delors I package, which introduced the fourth resource, known today as the GNP/GNI resource. Figure 2 provides a historical overview



European Union Budget, Fig. 2 Evolution of EU budget expenditures, 1958–2011 (as percentage of EU GNI) (*Source*: European Commission 2011)

of how the EU budget has been financed since 1958.

Since its last major reform in 1988 and thus also in the MAFF 2007–2013, EU budget revenue has been made up of four major resources:

1. *Traditional own resources (TOR)*, which include customs duties and agriculture levies. In the 2011 EU budget, this source contributes around 14 per cent of total EU budget needs and is on a downward path.
2. *Funds levied on the basis of value-added tax (VAT-based resource)*, defined on the basis of a statistically adjusted VAT base of the Member States. Its share of the EU budget is also small and accounts for around 11 per cent in 2011.
3. Funds levied on the basis of the Gross National Income of the Member States (the GNI-based resource), i.e. funds earmarked for balancing the budget measured in proportion to the GNI of every Member State. In 2011, this funding source participates with around 70 per cent in total funding needs of the EU budget.
4. The UK correction, as formally the fourth EU budget own resource but in substance terms a zero sum mechanism. It amounts to an annual level of around h3.8 bn in the years 2010 and 2011.

In addition to the four own resources described above, there are some other revenues that may also finance the EU budget. It should be underlined that they are small in size and of a non-foreseeable character. In the 2011 budget, the major source of these other revenues is a budgetary surplus from the previous year. An existence of other revenues reduces the volume of GNI contributions to be provided by Member States.

Correction Mechanisms and Net Balances Issue

An integral part of the own resources system is formally also the 'UK correction' as well as a set of 'corrections on this correction'. Introduction of this instrument dates back into early 1970s when the UK joined the EEC. At that time the UK was among the poorest Member States, but due to the EU budget expenditure bias toward the CAP the country had a negative net financial balance towards the EU budget. As this was considered unfair by the UK authorities, after intense negotiations with other Member States the issue was resolved at the 1984 Fontainebleau European Council through the so-called 'UK correction' arrangement, whereby the UK became entitled to a refund financed by all other Member States. The economic logic of the arrangement was that the UK position *vis-à-vis* the EU budget was excessively negative in relation to its level of development, and that the country is eligible for a rebate on its contribution to the EU budget.

Even though the UK position in terms of its economic development has improved substantially since 1984, eliminating (or at least substantially reducing) the justification for the 'UK correction', the system remains in place with only minor changes. This can be explained by the fact that the 'UK correction' is an integral part of the ORD, which requires unanimity for changes. The correction mechanism system in place in the MAFF 2007–2013 contains, in addition to the 'UK correction' corrections to four other large net payers to the EU budget, whereby Germany, Austria, the Netherlands and Sweden pay only 25 per cent of their normal 'UK correction' funding share.

There are also three other 'corrections on corrections'. First, Germany, the Netherlands, Sweden and Austria have an arrangement whereby their share in financing the 'UK correction' has been reduced via a reduction in the call rates for the VAT-based own resource.

Second, the Netherlands and Sweden receive a fixed lump sum reduction of their annual GNI contributions.

Third, Member States retain a fixed percentage of all traditional own resources collected. Since 2000 this percentage has been set at 25 per cent.

The Main Deficiencies of the EU Budget

The EU budget is dominated by a small number of highly redistributive policies, with CAP providing

funds for European farmers and cohesion policy redistributing funds towards less wealthy regions. Poor representation of broader EU-wide policies on the expenditure side of the EU budget associated with the domination of national contributions on the revenue side have resulted in a system particularly prone to bargaining and supporting the obsession of Member States to demand *juste retour* for their contributions to the EU budget. The two most recent MAFF negotiations have confirmed this pork barrel mentality, where achieving an acceptable net balance position has *de facto* become a more important objective than agreeing the size and structure of the spending.

Despite significant changes within and around the EU over the last two decades, the structural characteristics of the EU budget have remained largely unchanged since 1988. In addition to its strong pro-status quo bias, the EU budget has become less and less transparent. The 2007–2013 MAFF negotiations are a clear confirmation of these problems. In order to achieve acceptable net balances Member States were ready to sacrifice Lisbon-type expenditures as one of the top EU policy priorities at that time, and they also insisted on the continuation of the current corrections and rebates as well as the introduction of new ones.

Structural rigidities in the EU budget reflect the current institutional set-up of the EU and its decision-making system. The MAFF adoption procedure combines elements of an intergovernmental and a supranational approach. According to the Lisbon Treaty, an agreement on a proposal prepared by the European Commission has to be reached in the European Council by consensus, and in the European Parliament by majority. The two institutions have different incentives in these negotiations. While the European Council aims to reduce EU budget expenditures in order to reduce the Member States' contributions from their national budgets, the European Parliament has an incentive to increase the expenditures as the required funds will be provided automatically by the Member States up to the ceiling determined by the ORD.

There have been several attempts to address the net balances problem and the highly complex and non-transparent system of EU budget corrections, but to date none have been successful. The most serious attempt was the 2004 Commission's proposal for a generalized correction mechanism that would be open to all Member States and would replace the 'UK correction'. There have been other ideas to address this subject: One was to modify the calculation of net balances so as to take into account a broader concept of costs and benefits apart from pure budget. There are proposals from academic circles (see, for example, De la Fuente and Domenech 2001; Heinemann 2007; Rant and Mrak 2010) proposing that EU budget negotiations would be divided into two stages. In the first one, net budgetary positions should be fixed followed by the negotiations on the content of the EU budget in the second stage.

Before the 2014–2020 MAFF Negotiations

EU budget has remained conceptually unchanged since the 1988 reform in spite of the fact that the EU has undergone significant changes, including its enlargement from 12 to 27 Member States, completion of the internal market and introduction of new priorities in the areas of internal and external policies. Under the dominant influence of the *juste retour* logic, the main victim of the 2007–2013 MAFF negotiations was the Lisbon strategy itself, even though all Member States had explicitly supported international competitiveness as the top substantive priority of the EU in the forthcoming period. Being aware that the MAFF deal struck under these negotiations was not only unsuitable in its substance but also highly non-transparent in its financial terms, the December 2005 European Council authorized the Commission to prepare a thorough review of the EU budget and report back in 2008 or 2009.

Due to numerous political considerations, including complications with the Lisbon Treaty ratification process and the 2009 European Parliament elections followed by the appointment of the new Commission, the review was published only in late 2010. This delay has in fact prevented the review from serving its original purpose, i.e. to

provide a basis for a thorough discussion about the possible reform of the EU budget. In fact, the review, which was published less than a year before the onset of the negotiations about the 2014–2020 MAFF, has turned into nothing more than a good issue paper for the forthcoming negotiations. Unfortunately, a prime opportunity for a thorough reform of the EU budget has been lost and the negotiations seem to be burdened again with the *juste retour* logic and the dominance of net national budgetary positions.

During the 2014–2020 MAFF negotiations, the Member States and the EU institutions will have to address numerous challenges, including the relatively weak international competitiveness of the European economy, negative consequences of the ongoing financial and economic crisis, incompleteness of the internal market, continued social and economic disparities, import energy dependence and climate change. On the institutional side, this will be the first MAFF to be negotiated under the Lisbon Treaty, with a formally substantially stronger role of the Parliament in the process.

The official proposal of the Commission for the 2014–2020 MAFF negotiations issued in June 2011 has the following main characteristics:

1. The size of the EU budget is to be kept at a similar level as before, i.e. at a level of around 1.05 per cent of EU GNI in payment appropriations.
2. CAP and cohesion policy remain the two largest spending items in the EU budget, although the former will have a significantly reduced share in total expenditure compared with the 2007–2013 MAFF period.
3. On the revenue side, VAT-based resource is proposed to be abandoned while two new EU taxes – a financial transactions tax and a VAT tax – are proposed to be introduced as of 2018.
4. The existing 'UK correction' and 'corrections on corrections' mechanism is proposed to be simplified and exchanged by lump sum gross reduction of GNI payments for four large net payers into the EU budget, namely the UK, Germany, the Netherlands and Sweden.

European Union Single Market: Design and Development

Jacques Pelkmans

Abstract

What precisely is a Single Market, how it has been designed in the case of the European Union (e.g. in the treaty) and how it has

developed over 5 decades, are the three questions answered in this contribution. It is first shown that the design of a Single Market matters: it is not just about goods markets (despite the enormous emphasis in the literature on this aspect) but also about services, labour, capital and codified technology. In order to have a Single Market function properly, it is indispensable to combine negative integration (removal of barriers) with a considerable ambition in positive integration (common regulation, selected common policies, common market institutions where appropriate and endowed with proportionate but sometimes overriding powers). The treaty contained a unique design which has been 'upgraded' with the increasing ambitions of 'deepening' and 'widening' of scope of markets and policies in the EU. The development of the EU Single Market is stylized in four accomplished stages after the mid-1980s, when the 'customs-union-plus' was overcome for a much 'deeper' internal market, until today.

The Roots of the Single Market

The European Union, which began as the European Economic Community in 1958, was based on the new idea of a 'common market'. Strictly, the Rome treaty did not define what the 'common market' was. However, most analysts at the time saw it as the combination of five 'economic freedoms' (four instances of 'free movement' (namely, for goods, services, capital and 'persons', probably including workers) and the right (of companies or individuals) to establish in any other EEC country, various forms of common policy-making (trade, competition, agriculture and transport) indispensable for a common market, common regulation, officially called 'harmonisation', and some coordination or lighter cooperation. All these aspects were specified to some degree in the Rome treaty. Later, with the first revision of the treaty in 1985, the notion of the 'internal market' was introduced in the text. The proposed treaty revision coincided with the famous EC1992 programme of 7½ years aiming for the 'completion of the internal market' (from mid-1985 to late 1992). The term 'completion' as well as the sheer ambition of the EC1992 programme quickly led many people to speak colloquially about the EU 'Single Market' ever since. The treaty has been revised four times since 1985, yet the term 'Single Market' is nowhere to be found. The present contribution will focus on the concept and treaty design of the Single EU Market, and will subsequently show how the EU internal market developed over time.

What Is a Single Market?

More Than the Law of One Price

The benchmark of a single market, which is suggested to every student of economics, is the law of one price. This textbook idea is a useful and simple summary indicator of the result that market integration will yield. Taking it literally would be misleading: even a local market in a small village does not exhibit complete price equality and whether price differentiation is a function of product differentiation on that local market is not easy to verify for consumers, and certainly not for incidental visitors without repeat purchases. Nevertheless, the benchmark is useful because it is expected that, in a single market, price divergences are held in check by actual and potential competition in that market and spatial competition from nearby markets in other locations. The assumptions behind such price convergence include good and timely information and actual and potential mobility of suppliers as well as consumers. Nevertheless, it reflects a very narrow perspective of market integration and its utility is more questionable in markets other than goods, such as all areas of services, in goods and services of network industries, in labour markets across

countries and in knowledge markets (regulated or not by intellectual property rights). Nevertheless, there is much more to a Single Market than a tendency towards price convergence. A Single Market is also about (quality and other) differentiation in goods, services, capital and labour – hence, the gains of variety – and about the stimulus to come up with innovative ways of engaging in competition, be it via goods or services or process innovation, or in distribution or marketing. Companies long used to being a major player might be challenged by different 'business models' more appealing to the same or new consumers or customers. In some sectors, initial national prices may be a bad predictor of later prices in the Single Market due to scale economies (perhaps even amplified by 'learning curves') which can only be reaped with much larger volumes of turnover (see Pelkmans (2011) for a brief survey of the economic impact of the EU Single Market). For all these reasons, price convergence is a helpful but insufficient indicator of market integration for economists. For a proper economic understanding of a single market, one should appreciate the driving forces behind the eventual economic gains of a Single Market: competition in static and dynamic forms driving not only price convergence but also cost minimization and greater variety in goods and services, innovation and choice.

There is also the crucial issue of single market design. Does price convergence and a rich view of competition answer the query 'what' an internal market is? In fact, it does not; it merely tells economists whether a prominent economic test of the 'working' of that market is satisfied. If European integration has taught one lesson, it is that the building of such a Single Market is an extremely complex, highly intrusive and staggered undertaking. And this matters a lot for the economic study of the Single Market. The large 'distance' between one basic economic criterion to assess a Single Market and the many stages of its complex development has inevitably generated a literature which mainly focuses on general and 'aggregated' outcomes. Typically, it fails to give much economic guidance on the what and how of (deep) market integration.

Therefore, when going from the general concept of the internal market to a practical design which can be used for a treaty, the question of what a Single Market is usually answered by a 'stages theory of economic integration'. What does it take, in terms of measures of the EU and market institutions, to get a well-performing Single Market? The traditional institutional approach was initiated by Balassa (1961) and was much refined and adapted later in the light of the EU experience (see Pelkmans 1982, 1985; see also Lloyd 2005). The five Balassa stages are: free trade area, customs union, common market, economic union and total economic integration. Whereas the first two were taken from GATT, art. 24, the other three are new concepts. With the latter three, there are serious problems of design logic.

Single Market: Stages Beyond a Customs Union

The 'common market' – beyond the free circulation of goods in the customs union with common tariffs – is defined by Balassa as the free movement of factors of production (capital, labour, and nowadays also codified knowledge, as in patents etc.). His common market has no institutional features other than a legal duty to liberalise cross-border flows of these factors. Clearly, this is a fantasy world: cross-border free movement of factors would at the very least assume common regulation for labour (not to speak of the profound implications for the welfare states) and for codified technology or knowledge but almost certainly it would also require common institutions enabling more detailed decision-making (especially for harmonisation and EU regulation). In the early 1960s most European countries still had fixed exchange rates and exchange controls; hence cross-border freedoms in capital movements would have had major macro-economic implications. In other words, 'negative' market integration (only removal of barriers) in a common market is unthinkable without ambitious 'positive integration' (common regulation, or lighter harmonisation, plus coordination and

some common decision-making in common institutions) (see also Tinbergen 1954). If countries are wary of this degree of centralisation or commonness, positive integration will be insufficient, and without it 'negative' integration in factor markets will become impossible: it will simply not happen. Another gap in Balassa's third stage is the neglect of services. Again, since many services are regulated and several are tightly supervised, a single market for services cannot come about without common regulation (overcoming market failures, ideally) and some central or coordinating supervisory agencies. As services cover a huge set of economic activities, the scope of centralization would increase considerably. But even in goods, a common market is far more than just free circulation behind common tariff walls. Nowadays, it is well understood that there is a broad range of other barriers or trade cost-raising elements in goods markets which have to be addressed if there is to be any chance of obtaining a 'single' market. But this simple fact changes radically the nature and ambition of that single market. The EU led the way in addressing such barriers, after having dealt with the customs union aspects without any remaining exceptions in less than the required 12 years. But the various 'non-tariff barriers' appeared to be much more difficult to tackle and eventually prompted innovative ways to overcome the frustrating stalemates in Council. At the same time, this process also led to degrees of regulation (and co-regulation, for example in overcoming technical barriers) and selective centralisation which had not been expected by the founding fathers.

The fourth stage of Balassa is called 'economic union'. In Pelkmans (1991), a literature survey since the late 1940s shows that economists have not been disciplined in utilizing a single definition: no fewer than seven definitions, with very different meanings, can be found. Balassa's definition brings in the common institutions and 'positive integration' only at this stage (rather than already for the common market), yet remains vague about what exactly the economic purpose and scope of this 'union' should be. If indeed the disparities in national policies would lead to discrimination (of market players or their goods, services etc.), it would have to be dealt with at the common market stage. As we shall see later, this kind of 'economic union' cannot serve an eventual monetary union either. This simple point underscores that the treaty design of deeper economic integration ought not to be taken lightly by economists.

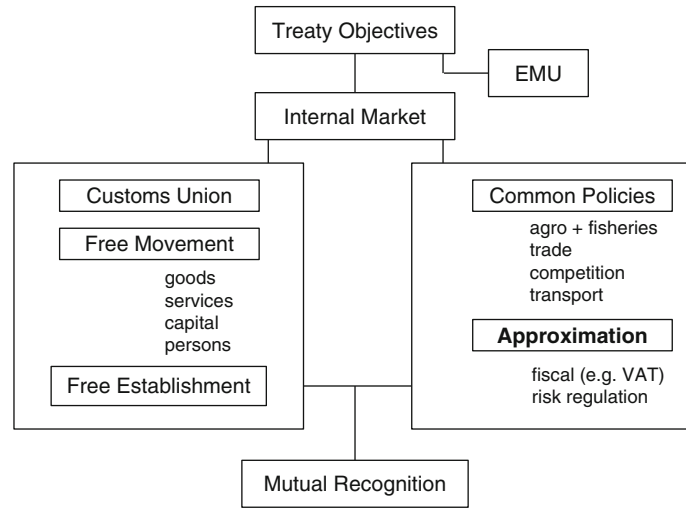
The fifth Balassa stage is called 'total economic integration'. It has two key elements: the 'unification of monetary, fiscal, social and countercyclical policies' and the 'setting up of a supranational authority where decisions are binding for the Member States'. The latter element is several stages 'too late' since substantial positive integration will be required already for genuinely free movement of goods (beyond free circulation in the customs union), and the more so for services, labour, capital and codified technology in the common market. The former element (unification) is not only a huge jump from a vague 'economic union' but there is no obvious justification for so much centralisation. A 'subsidiarity test' (Pelkmans 2005) boils down to a cost–benefit analysis of (de)centralisation of public economic functions such as monetary, fiscal and social policies given an already realised single market. With centralisation criteria like scale and cross-border externalities, besides decentralisation criteria such as diversity of preferences among regions or countries and the (*ceteris paribus*) greater ability of local politicians to 'read' such preferences and act accordingly at the local level, a subsidiarity test will yield a much more nuanced view than Balassa's fifth stage. It would show that social policy is highly unlikely to be a candidate for centralisation, and fiscal policy is suitable only in some respects (e.g. debt caps, but no or only modest union taxes). For present purposes, one can also ask the fundamental design question of whether a 'deep' single market can perform well over time without monetary union or without at least a credible mechanism for maintaining stable exchange rates.

Altogether, a Single Market is a highly ambitious 'means' for the pursuit of higher economic (and possibly non-economic) aims.

The EU's Single Market Design in the Treaty

Today, the relevant treaty for the EU Single Market is the Treaty on the Functioning of the EU (TFEU), in force since 2010. It is one of the two Lisbon treaties (the other is the EU treaty). The basic idea of the internal or common market (the treaties have never used the term 'Single Market') has not changed much over time. What has happened is that both decision-making and 'deepening' have been facilitated several times. This has turned out to be critical. Figure 1 stylizes the EU internal market idea found in TFEU and case-law of the EU Court (CJEU). Figure 1 expresses the notion that the internal market is a 'means' – indeed, the principal means – for the pursuit of EU treaty objectives. Ever since the Rome treaty, these objectives prominently feature economic growth (in various formulations and under conditions, e.g. sustainability). Recurrent treaty revisions have overloaded the EU with new objectives, but how crucial these are and what priority they have is unclear. In any event, every time the Single Market moves (back) to the top of the EU's agenda, the main motivation was and remains economic growth and/or productivity hikes. Figure 1 has a symmetric set-up: on the left side one finds 'negative market integration' (customs union, the four free movements and the right of establishment) and on the right hand side 'positive integration' consisting of the most important common policies as well as two prominent forms of 'approximation' or harmonisation (risk regulation, comprising a very large part of EU regulation and related to health, safety, environment, consumer and saver/investor protection; indirect tax regulation on e.g. VAT). In addition, Fig. 1 depicts 'mutual recognition' hanging in between the two.

Of course, with initial veto-based decision-making and the greatest hesitation on the part of the EU Member States to radically pursue cross-border intra-EU liberalization in goods, services, labour, capital and codified technology, as well as to apply free establishment to all sectors, or to engage in far-reaching and often intrusive risk regulation in many areas and submarkets as a condition of free movement, one can understand that the institutional state of EU market integration has only gradually moved towards the ideal picture of Fig. 1 over a period of five decades. This also goes for the common policies: initially, when a common agricultural policy (as the basis for an internal market in agro-goods) was created, there was no equivalent in fisheries; the common transport policy in the six modes only came about in earnest during the second half of the 1980s; EU competition policy operated almost 30 years without merger control, which is now the most



European Union Single Market: Design and Development, Fig. 1 EU internal market in the treaties

important aspect; and EU trade policy in goods was only complete once third-country quotas at the national level had been outlawed (in 1992), whilst in services and investment full EU-level power was only granted in the Lisbon treaty. All such difficulties are good illustrations of why a proper understanding of the EU Single Market and its actual or potential economic impact is so demanding. Indeed, while Fig. 1 serves as a guide for the overall concept, a proper understanding necessitates the zooming in on some of the more important details and how these EU accomplishments have accumulated over time.

Deepening, Widening and Enlargement of the EU Single Market Over Time

Given the incredibly broad range of negative and positive integration the Single Market entails, we shall stylise the progressive accomplishments of the Single Market in four steps: one on the state of achievements after 25 years of EEC; one on the EC1992 programme; one on the accomplishments between 1993 and 2010; and one on the 2011 Single Market Act. It provides powerful and concrete evidence of the rising ambition of the EU's Single Market. The increasing importance of the Single Market is the result of 'deepening' (firmer application of existing commitments, with fewer exceptions), 'widening' (of scope, that is, more domains are brought under the internal market) and 'enlargement' (more EU countries, hence a larger market size).

The EEC Common Market After 25 Years

Table 1 reflects what the EEC's 'common market' looked like in 1982. It is best described as a 'customs-union-plus'. The main items in the first word column are taken from Fig. 1. The table largely speaks for itself. The drafters of the EEC treaty and subsequently the Member States (and to a lesser extent, even the Commission) simply had no well-informed idea of what a common market, as specified in the Rome treaty, really requires.

Deepening and Widening Under EC-1992

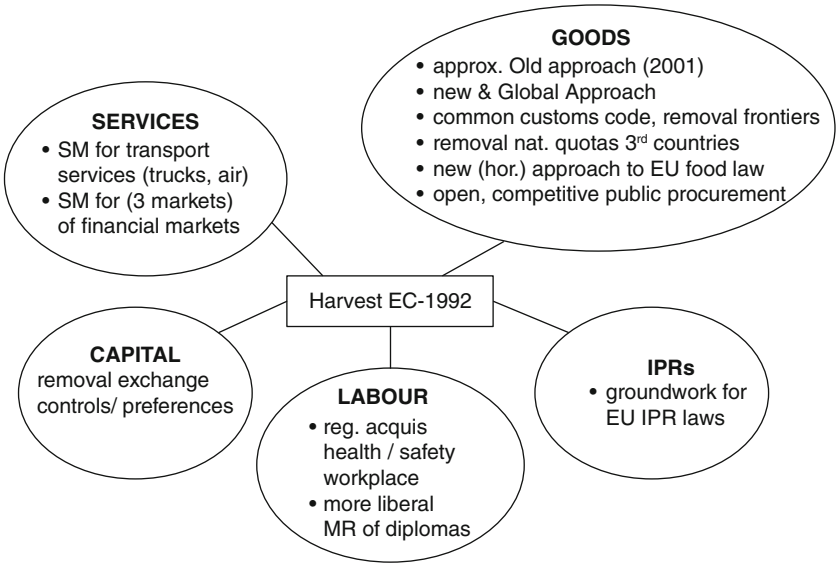
Table 1 allows one to appreciate how radical EC1992 was. The striking difference between Table 1 and Fig. 2 (see above) is that measures and new accomplishments are observed in all five areas of free movement. Besides a range of initiatives in goods markets, two big services sectors (transport and financial services) are tackled and exchange restrictions are abolished. In addition, some horizontal aspects were improved, such as merger control, the gradual inclusion of network industries and more emphasis on mutual recognition. The list for goods markets is impressive: the very detailed customs code is realised, inner frontiers and physical customs are abolished, a huge number of highly technical directives and regulations in risk regulation are adopted (Old and New Approach etc.) including conformity assessment (Global Approach); in addition, food law is remodelled based on mutual recognition, extensive SPS-type harmonisation in no less than 160 directives and the avoidance of food-specific directives (but horizontal food directives instead, with far lower costs while maintaining the great variety that national traditions cherish); finally, public procurement was addressed so as to become competitive and open EU-wide. This is no longer a customs-union-plus: it implies far-reaching free movement in goods and selectively in some important services, such as several modes of transport as well as free movement in and EU regulation of financial services. It also comprises free movement in (financial) capital (albeit that equity in stock exchanges is still subject to problems of clearing and settlement) and at least some minimum rules (e.g. in occupational health and safety) in labour markets. It does not yet add up to a common market, since services are only selectively addressed, network industries still have to be brought in and IPRs have not yet been resolved, for example. Moreover, the regulation and cross-border liberalisation of financial services (banking, insurance and investment services) was incomplete, with serious gaps and omissions due to the reticence of Member States,

European Union Single Market: Design and Development, Table 1 EU common market after 25 years

		Acquis	Gaps/omissions
1	Customs union	• CET	• No common customs code
		• No intra-EU quotas	
2	Free movement		
	2.1 Goods	• Case law on mutual recognition	• Very limited progress on technical barriers
			• No EU regime for national public procurement
			• Network industries excluded from common market
			• Very limited progress on regulatory barriers
			• Customs controls remain
	2.2 Services	• Minimal recognition of services free movement	• Almost no EU regulation in services
	2.3 Workers	• 1968 free movement decision; only 'residual' mobility	• Host of barriers to immigration (health, insurance, housing, taxes, pensions)
			• Many difficulties for frontier workers
			• Host country control removes incentives for migration
	2.4 Capital		• Six out of 10 EU countries maintain exchange controls
			• 1982 court case, allowing restrictions on capital flows
3	Right of establishment	• 1962 liberalisation of FDI	• (restrictive) licensing and authorisation in some (services) sectors
		• National treatment	
4	Common policies		
	4.1 CAP	• CAP well-established but highly distortive	• No fisheries policy
			• 'Green' exchange rates
			• No risk regulation (and controls) in SPS-type aspects of agriculture
	4.2 Trade	• Common policy, for goods only	• Some EU countries maintain selective quotas *vis à vis* specific third countries (e.g. Japan)
			• Nothing on services, IPRs, investment
	4.3 Competition	• (Narrow) anti-trust in place	• No merger control
		• For goods only	• *De facto,* no cases in services
			• Weak and inconsistent control of state aids
			• *De facto,* no cases in network industries
	4.4 Transport	• Some harmonisation (e.g. technical)	• Trucking subject to selected quotas
			• No cross-border liberalisation in air, rail, buses, maritime
			• Rigid restrictive regime in river transport
5	Approximation		
	5.1 Fiscal	• VAT base, regime and bands of VAT rates	• 'Trade' costs at frontiers still high
		• Excise duties on only three types (others illegal)	
		• Case law on alcohol taxes	
	5.2 Risk regulation	• Some selected results in regulation of high-risk goods (Old Approach)	• Vast areas of risk regulation of goods still national and disparate
			• No European standards, except (some) electrical
			• No EU rules for conformity assessment
			• No risk regulation for services or labour/hence no EU supervision

NO EU IPRs or harmonisation

Note: 'Acquis' is a term used in the EU for the accomplishments at EU level



NOTES: (1) CJEU case law promoted M.R.; (2) preventing new barriers in SM via 83/189; (3) merger control '89; (4) network industries not in White Paper (exc. broadcasting); began early 1990s.

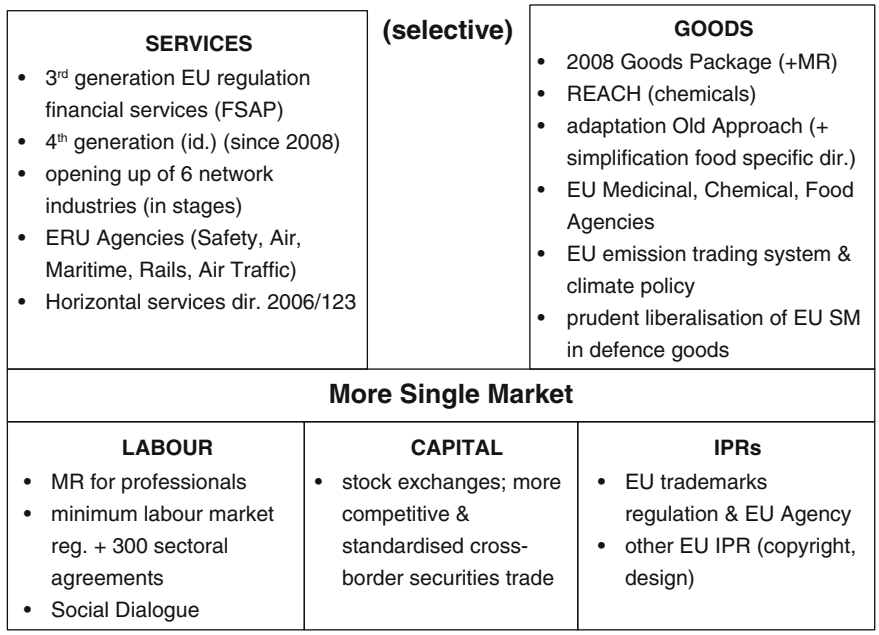
European Union Single Market: Design and Development, Fig. 2 What EC-1992 accomplished

whilst supervision was kept at national level, based on fairly general EU regulatory principles.

Incremental Deepening After 1992

Some further progress as well as refinement of the internal market acquis has been accomplished since 1992. It is summarized in Fig. 3.

The main elements of deepening consist in IPRs at EU level (except the EU patent) and a major assault on barriers in services markets, in a number of ways. The horizontal services directive marks a U-turn in that all services markets should benefit from free movement, unless already regulated by EU rules (or exempted in a few instances). The other significant progress is liberalisation in six network industries (telecoms, electricity, gas, rail, air and postal). Also, a third generation of financial services regulation was built up, after the rules for establishment of financial institutions in the 1970s and those for free movement and mutual recognition of national supervision during the EC1992 process. The third generation (2000–2006) made EU financial services regulation more complete and technically more refined, in particular for investment services. However, it was insufficiently realised that the quality of EU regulation suffered from the undue emphasis of 'light touch' by the London City and the eagerness of many banks and others to exploit financial innovation. The EU regime did not guarantee that market failures were fully overcome and delivered insufficient guarantees for the proper assessment, management and pricing of risks in financial markets, especially at the wholesale level. In the event of major mistakes by large financial players, supervised or not, bank failures would become a real possibility, in extreme cases leading to contagion and systemic risks, hence endangering EU financial stability. Contagion was no longer a theoretical possibility, since the interconnectedness of banks in the deepened EU financial markets was increasing very rapidly. Furthermore, although national supervisors became embedded in EU supervisory networks, the latter remained cooperative and had neither the authority to act directly at EU level nor precautionary plans and/or funds to address cross-border contagion and systemic risks. Actual market



NOTES: (1) modernisation of EU competition policy; (2) RIAs (since 2003) and Better Regulation; (3) better inter-MS horizontal / adm.cooperation; (4) public procurement, 2nd generation.

European Union Single Market: Design and Development, Fig. 3 Deepening and widening the EU internal market: 1993–2010

integration began to run much too far ahead of the EU regulatory regime.

Once the financial crisis broke out in the autumn of 2008, the EU changed course: a fourth generation of EU financial regulation has been built up under duress (2008–2011). One may characterise this fourth generation by three key words: 'better quality' of regulation in overcoming market failures (e.g. in banking) by means of higher capital requirements or otherwise and doing away with 'light touch'; regulating 'all' financial activities or actors, thereby including credit rating agencies, hedge and other investment funds and derivatives; and shifting to 'more centralization' in supervision, via EU Agencies, and in closely monitoring systemic risks and financial stability in a special EU Board. In addition, bank resolution rules have been tightened, with explicit shareholder risks and minimising risks for deposit holders, in combination with proposed EU funds which can immediately address cross-border bank failures if necessary.

In goods markets, the only widening of scope is in defence goods, where restrictions led to absurd practices and trade costs. All other initiatives amount to refinements, either by protecting better free movement and EU rules (e.g. the 2008 goods package), or by improving the benefit/cost ratio of existing EU regulation (e.g. REACH; a more flexible Old Approach) or by joint technical expertise in EU Agencies. Regulation related to climate strategies is new and rightly allocated (given cross-border externalities) at EU level. Mutual recognition of diplomas – a difficult issue even in federations – has been attended to, but this thorny question will require a much more thorough EU approach before it will effectively alter conduct in markets. Moreover, the benefit/cost ratio has also improved for EU competition policy (via modernisation) and for the quality of (proposed) EU regulation (via regulatory impact assessment = RIAs). Going by the list in Table 1, the EU has meanwhile shifted a lot closer to an advanced form of an internal market: how 'single'

it is or not is crucial for the appreciation of further deepening and widening. One obvious gap is the lack of a European labour market, something a federation will enjoy but which would be possible in the EU, if and only if potential mobilities across intra-EU borders could be much larger. Only then would one be able to make an economic case for assigning labour market regulation and (at least part of) social transfers to the EU level. However, that unlikely outcome would, in turn, necessitate EU social charges or taxes, for which the treaty provides no legal basis. It is also possible to identify many 'hidden' obstacles, for a truly 'single' market to emerge in areas other than labour. This even includes a typical taboo so far in European integration, namely EU infrastructure. Certain network markets (electricity, gas, rail) cannot function properly on an EU scale without modern infrastructure designed with the single market in mind, not national or local priorities.

The Single Market Act

The fourth phase, initiated with the Single Market Act [COM (2011) 206 of 13 April 2011, Single Market Act] is yet another attempt to further deepen the internal market, in two steps, the first of which has been specified in some detail with 12 'levers'. The plan comprises initiatives to remove barriers – some of them deep-seated – as well as facilitation and cost-reducing measures which render the use of the Single Market more attractive. Given the high hurdles for smaller companies to actively participate in the internal market (see e.g. Mayer and Ottaviano 2007) these measures may well induce a higher degree of market integration. Amongst the measures removing obstacles, it is worth mentioning the EU common patent (and laws and a Court for common EU patent litigation) where the pure cost reduction of a patent would be as high as 80% and, perhaps even more importantly, the stimulus for innovation would be considerable (Guellec and van Pottelsberghe 2007) and permanent. Other measures proposed include greater investment in (mostly cross-border) energy and transport infrastructures, the removal of complicated obstacles to the Digital Single Market (often linked to private – e.g. contract – law and divergences in consumer protection, which typically tend to have remained largely national) and removal of (e.g. tax) barriers to a Europeanisation of venture capital. A full accomplishment of the Digital Single Market is expected to yield an increment to EU GDP of up to 4% (Copenhagen Economics 2010).

Conclusion

Altogether, the EU Single Market has steadily deepened and widened (in scope) over time. It has also become much larger, from 6 to 27 participating countries. Starting with a uniquely strong treaty, still one of a kind in the world, it has nevertheless taken some five decades, several critical treaty upgrades, and a host of programmes and special initiatives in order to arrive at a 'deep' but nonetheless incomplete Single Market. It has become an impressive edifice which, in some respects, is equivalent to internal markets in federal countries (Anderson 2011) and in other respects exhibits significant shortcomings. What is lacking in particular is a common labour market and the prospects for that are dim. Labour migration inside the EU will remain dominated by east–west flows (but only in a few professions, mostly low skilled) as long as wage divergences remain significant, and otherwise will continue to be 'residual'. The other weak element – a common market for services – has been tackled recently with greater drive and intensity, but it would not be surprising to expect another one or more programmes to arrive at deeper services market integration in the coming decade or so. Nowadays, many services markets are still fragmented in the EU despite the 2006 horizontal services directive, and their contestability is often weak as well. Enforcement by the Commission, new business models in some submarkets and consolidation, as well as new entry, will inevitably take time. Also, services which fall outside this horizontal approach, such as network services, professional services and retail finance (mortgages or consumer credit for example), and also employment agencies and freight rail, are

still encountering numerous problems when Europeanising their business strategies. Financial wholesale markets are rather well integrated. The remaining problems of the fourth generation include queries about (insufficient?) centralisation of supervision and crisis management, besides a few lingering doubts about EU regulation (e.g. should risks of banks arising from large exposure to large private parties not be extended to public securities as well?). A final weak spot in the Single Market is public procurement, a giant market in the EU (some 16% of GDP), where recorded cross-border contracts remain disappointingly low, despite several revisions of directives and reduced red tape.

European Union Single Market: Economic Impact

Jacques Pelkmans

Abstract

This compact literature survey covers the economic impact of the old EEC customs union and, more extensively, of the Single Market as it has emerged since the mid-1980s. The emphasis is on micro-economic studies of the effects on trade in goods (initially trade creation and diversion) and degrees of market integration measured in various ways, such as 'home bias'. Aspects discussed also include trends of price convergence, effects on competition, and induced impact on static and dynamic efficiency (e.g. innovation) as well as variety and higher productivity at the firm level. Economic research on the internal market in services has barely begun in earnest. A very brief discussion of methods highlights some of the problems. Finally, the principal work on macro-economic effects is summarised; that is, on overall productivity,

economic growth or one-off effects of specific internal market initiatives.

Introduction

The EU has built up an ever more ambitious internal market, colloquially called the Single Market, over a period of almost 45 years. For a good understanding of economic impact studies, it is essential to know what the state of the internal market was in the relevant period. For a stylised overview distinguishing stages and some details, see Pelkmans (2011). The following micro-economic effects of the Single Market can be considered: the degree of market integration, including variety, price convergence trends, effects on competition, efficiency effects including dynamic efficiencies such as innovation and higher productivity at the firm or sector level. Of course, the EU has become a very open economy (except for some temporate-zone agro-goods) also in services, and hence the global dimension renders Single Market effects and their attribution (to the Single Market or other factors including globalisation nowadays) more difficult. The literature has also been interested in macro-economic effects such as economic growth or growth of productivity, or one-off effects of specific internal market initiatives on GNP. The final section draws the main conclusions.

Economic Impact of the EEC Customs Union

The initial EEC-6 period was dominated by the effects of the EEC customs union, via extremely simple simulation (e.g. Johnson 1958) or *ex post* empirical quantification (e.g. Verdoorn and Schwartz 1972; Prewo 1974). Scholars were only interested in trade flows and welfare gains, starting from basic partial equilibrium customs union theory. Given this theory, little or no attention was paid to competition, price convergence, technical efficiency improvements (despite Scitovsky's (1958) profound qualitative analysis of the deep inefficiencies in the EEC) or effects on FDI (despite Scaperlanda (1967)). The effects on trade flows attracted most attention, with trade creation and trade diversion being separated out by many authors. Surveys include Mayes (1978) and Winters (1987). The thrust of this impact literature was that trade creation in manufactures was estimated to be much larger than trade diversion, but not in agriculture, where diversion was considerable. The induced intra-EEC trade varied, but findings could go as a high as 50% (of 1958 trade) or more when controlled for growth and other factors. The methods employed relied on *ex ante* and *ex post* approaches, those with residual imputation (using an anti-monde of the same relations but without the EEC) and a range of distinct techniques. The welfare gains were computed as modest at best: the range was between 0.15% of GDP and 1% of GDP. Given that tariffs were still relatively high in the 1960s, such gains are disappointingly small. In part, this is due to overly simple models. And also to the fact that several, presumably significant, gains were omitted. Amongst these one may include (a) the reduction of X- (or technical) inefficiencies due to competitive pressures induced by the EEC; (b) scale economies (which require a sectoral approach); (c) gains from greater variety under intra-industry trade; and (d) terms-of-trade effects (which Petith (1977) estimates at 1% of GDP). Of these, technical efficiency improvements are likely to be the largest, but they risk being amalgamated in overall productivity studies with a range of determinants other than the EEC directly. In some sectors, scale economies led to spectacular welfare gains (e.g. washing machines and refrigerators; see Mueller 1981) as well as an upheaval of prior industrial structures.

Richer Economic Impact Studies of the Single Market

When the internal market – rather than the mere customs union – became a prominent issue, empirical studies and simulations moved away from the simple customs union framework. This was also true for the impact studies of some of the earlier EU enlargements (Viaene 1982, on Spain; Miller and Spencer 1977, a general equilibrium model on the UK; Gasiorek et al. 2002, also a general equilibrium approach, with simulation, on the UK accession; all of these focus on goods only) as well as for the Eastern enlargement (see Baldwin et al. 1997; Breuss 2002, using CGE simulations; and Breuss 2009 for a survey). Following the launch of EC1992, which was about 'deepening', many attempts were published to estimate the economic impact. Although EC1992 is complex and its follow-up even more so, the crucial additions consisted in major services sectors (all transport and financial markets) and, in goods, the removal of a huge number of technical or regulatory barriers and an opening up of public procurement. There have been two large-scale studies commissioned by the European Commission. The *ex ante* Cecchini report (Emerson et al. 1988; European Commission 1988) and the *ex post* Monti report (European Commission 1996, 1997. The Cecchini report made a breakthrough for three reasons: (1) for the first time, it attempted to use a (partial equilibrium) scale and imperfect competition approach and, in doing so, studying the 'pro-competitive' effects of the EC1992 approach, removing many regulatory and technical barriers; the Cecchini Group exploited ample funding for detailed and extensive fieldwork yielding data in areas which had never been addressed empirically (like public procurement in thousands of contracts) as well as for sectoral work, including selected services; and (3) it also attempted a macro impact simulation. With respect to the latter, when aggregating all the micro-effects into four categories and inserting them as 'shocks' (e.g. price reductions mainly) into two macro-econometric models of the European economy, the effects on GDP (a one-off increment), on employment after adjustment and on the price level could be generated. Based on the assumption of an exhaustive implementation of the 1985 programme, it found a 4.5% addition to GDP, an eventual 1.8 million extra jobs and a modest reduction in the price level.

We shall highlight two issues. First, what does exhaustive implementation mean? The Monti report finds lower empirical results than Cecchini and one of the reasons might well be the long-drawn-out and complex implementation issues. Indeed, the seven-year programme led to considerable implementation delays, partly due to slow action by Member States, but partly, too, because major areas required massive follow-up work after EC directives had been legislated. An example is found in the reliance on European standards. The New Approach (see Pelkmans 2011, Figure 2) sets essential safety (etc.) objectives in directives to overcome market failures, and refers to European standards written by independent European standardisation bodies but instructed (in EU mandates) to incorporate these objectives. Thus, the 1989 machinery directive is expected to require up to 1200 European standards and the completion of this huge and complex programme may well take 15 or more years. It goes without saying that, in the early 1990s, for which the data were used for the Monti report, only a few machine standards were in place, even though the one (!) item in the 1992 programme (a machines directive) had been properly dealt with. On this account, for Monti et al. to come to grips with the effects of these New Approach directives and their standards, the work should have taken place at least a decade later. Another reason for lower results by Monti is that the effectiveness of some initiatives (e.g. public procurement) left much to be desired.

Second, the Cecchini report deals with the pro-competitive effects of a deeper internal market in two stages: one is that the reduction of 'trade costs' increases import competition in the Single Market, reducing price-cost margins, and, given scale estimates, these will prompt larger output per firm, hence lowering average costs (although doubts about the empirical validity and relevance of scale were expressed by e.g. Geroski 1989); the other, more controversial, step in Emerson

et al. (1988) is that still 'deeper' integration is reflected by the assumption that prices converge; that is, full exposure to EU competition yielding output effects of up to 5% in concentrated industries. Subsequently, the latter effects were inserted as a shock into the model for the European economy. For many, this implies an upward bias in the report. On the other hand, the Cecchini report missed out on a range of 1992 issues which may have caused an opposing bias, including the abolition of exchange controls, the impact of creating EU IPRs (such as trademarks and copyright) and the removal of national VERs and quotas for some third party countries in, for example, cars and clothing. The most important underpinning of the Monti report is the study by Allen et al. (1998), which uses both CGE and econometric methods, but might nevertheless be somewhat problematic when focusing on the long term (e.g. Sorensen 1998). They also find selected sectors with significant extra output and a clear sharpening of intra-Single Market competition, measured by price–cost margins. The further assault on barriers preventing the EU Single Market in services from being realised began in earnest only with the 2006 horizontal services directive, and reliable empirical estimates are still awaited (but see De Bruijn et al. 2008).

The merits of newer empirical approaches such as CGE simulations and gravity have been called into doubt. Panagariya (2000) is particularly critical of CGE approaches, with and without the Armington assumption and given the utility functions employed. The *ex post* approaches increasingly rely on gravity equations with unclear and somewhat arbitrary links with economic integration theory, mainly because the alternatives are too demanding. Typically, in gravity approaches, detailed internal market effects are not specified but dummies for EU membership are used instead. One consequence is that gradual steps in the long-term economic integration process (such as the EC1992 programme) can no longer be empirically distinguished. A rare exception is Egger and Larch (2011), who arrive at empirical estimates of the economic impact of the Europe Agreements for Central European countries with the EU-15, before EU membership (the mid-1990s). They find that these Agreements generated some 5% extra GNP for the Central European countries and some 30% extra trade with the EU. They also show a strong redirection of intra-Central European trade, at first still influenced by defunct Comecon structures, towards bilateral exchange with the EU of no less than 50%! The authors rely on a structural model of bilateral trade inspired by Anderson and van Wincoop (2003) and utilising a Poisson pseudo-maximum likelihood estimation – thereby accommodating a large number of bilateral zero trade flows.

Conversely, general equilibrium analysts are critical of the popularity of trade creation and diversion, since these concepts are only meaningful in a carefully specified partial equilibrium context. This context is simply too restrictive as the elaborate survey by Panagariya (2000) shows only too well. Thus, Harrison et al. (1993) derive a generalised result in a static, perfect competition context which they call the 'home price effect' and the 'trade tax revenue effect' using vectors of endowments, of specific trade taxes, of world prices and of net imports of the country concerned. The survey by Baldwin and Venables (1995) applies a somewhat analogous approach, but they employ it to derive in a highly general fashion three groups of Single Market effects: three welfare effects in models of perfect competition, three arising in models of imperfect competition and scale, and finally an accumulation term (a higher equilibrium capital stock). The authors start from a general utility function for the economy, which includes vectors of border prices, of trade costs (including the tariff equivalent of import barriers) and of the number of product varieties, plus a scalar representing total spending on consumption. The static welfare effects are: the trade volume effect (linked to the price wedges created by barriers), a trade cost effect and a terms of trade effect. The effects emerging from models with scale and imperfect competition include: the output effect (change in output of sectors having prices different from average costs), a scale effect (value of changes of average costs in case of scale effects) and variety effects (impact on the number of differentiated products). Finally, the accumulation

effect (see also Baldwin 1989) is positive if the ratio of social return to social discounting is larger than one. As a categorisation of types of internal markets effects it is helpful. For example, on checking whether all the mentioned effects are represented in the literature, one finds that the gains of variety had not been analysed empirically for the Single Market until a contribution by Mohler and Seitz (2010). They are able to show that the gains of variety from intra-EU trade are traceable in the EU and matter in particular for 'newer' and smaller Member States in the period 1999–2008: for the smaller countries they range from 1% to 2.5% of GNP.

Price Convergence

With respect to *price convergence*, the Monti report shows (based on national price indices) that there was a general trend of price convergence in the EU-12 over the period 1980–1993. In consumer products, this trend has actually accelerated following EC1992. As expected, the trend of price convergence is sharpest for goods in highly traded sectors, whilst services remain characterised by significant price dispersion, presumably because their tradeability is low. The remaining price disparities (in goods) can be explained by quality aspects, remaining barriers, high levels of concentration in domestic markets in the EU (which enable price discrimination) and to some degree by indirect taxes. The nature of sectoral goods markets, such as homogeneous versus vertically differentiated goods, also matters. In Ilzkovitz et al. (2007), a similar analysis is presented based on the coefficient of variation of comparative price levels (not indices). The overall conclusion is an accelerated price convergence since EC1992 until 2005. Whereas the coefficient dropped from 20% in 1991 to 13% in 2005 for the EU15, it dropped from 39% to 26% in what are now the new EU Member States. The attribution to the Single Market is not easy since, for the EU15 (or the euro zone at least), strict monetary policy by the ECB and the higher price transparency caused by the euro have induced inflation levels to come down. There is a downward bias, too, since consumer goods imported from the world have often become cheaper. For the new Member States, the market discipline of EU accession has to be set against the Balassa–Samuelson effect of rapid catch-up growth, leading to sharper price increases, and quality upgrades in Central Europe, yielding a convergence upwards towards the EU25 average. Engel and Rogers (2004), based on consumer prices in a range of European cities, find that price dispersion falls considerably during the 1990s (confirmed by Hill 2004) and hardly or not at all in the period after the introduction of the euro (1 January 1999). The authors control for income, VAT rates and local labour costs and also employ a special model for dynamic price adjustments. Interestingly, although price disparities in non-tradeables, essentially services, remain larger than for goods in 2003, their decline in dispersion since 1990 is much sharper. Since, besides transport services and financial services, only intra-EU business services grew exceptionally fast in this period, such a convergence may follow from the close association of business services with manufactured output, in turn linked to increased intra-EU FDI.

It is instructive to complement the broad picture of price convergence in the Single Market with two telling sectoral examples: cars and telecom services. In cars, Goldberg and Verboven (2005) find strong evidence of convergence towards both the absolute and the relative version of the law of one price, with firmer evidence of the latter. The EU car market has remained notoriously difficult to integrate over time, first because of initially strong preferences for national cars in the bigger EU countries (Hocking 1980), amplified by an array of technical and fiscal barriers as well as explicit market segmentation via selective distribution systems. Goldberg and Verboven (2005), succeeded in showing that the long battle by the Commission to break down all these barriers, including a significant tightening of the exemption for car dealers from the normal competition rules on selective distribution, is reflected in a gradual but fairly sustained price convergence in both absolute and relative terms (given homogeneous definitions of cars across Member States). The opposite may be noted in telecoms

services. Pelkmans and Renda (2011) show that there is no such thing as an eCommunications Single Market, whether one studies the prices of 11 important telecoms services in the EU27 or the EU rules and institutional framework for that market. What is striking is the great emphasis on liberalisation of *national* telecoms markets in the EU, based on very similar rules and similar details to the (national) application of competition policy to this market. The upshot looks much like 27 liberalised national markets, not a Single Market. As a consequence, when defining a bilateral price disparity of 50% as a ratio of 150, the highest/lowest price ratios for the 11 services move in ranges from over 300 to over 4000, with the second highest/lowest ratios still from over 200 to beyond 2000.

How Integrated the Is Single Market: Can 'Home Bias' Tell Us More?

Market integration, traditionally measured by price convergence and/or trade flows (and to some extent, FDI stocks and people or worker mobility), can also be measured in a very different fashion: a decreasing 'home bias'. Home bias is based on a pure integration benchmark: in a truly integrated single market, economic agents from EU country A would assume an EU-wide outlook in all economic decisions, and hence purchase a share of intermediate and final goods domestically reflecting the relative size of the country in the EU economy; the remainder would be bought in the rest of the EU. One can correct such a benchmark for reasons of a common language (lowering trade costs) between two or more EU countries, contiguity between two or more EU countries (greater familiarity and better information), or business networks (see Combes et al. 2005) and other factors (such as sectoral differences: Chen 2004). Nevertheless, it is shown that 'home bias', defined as an excess of domestic purchases over the benchmark share, is quite high, an indication that market integration is not so deep. Even without customs, intra-EU frontiers still matter for economic conduct. Home bias indicators differ between authors but are invariably high. Thus, Head and Mayer (2000) find a corrected home bias of 25 in the mid-1970s and Nitsch (2000) one of 13 in 1979. But over time they all fall significantly (see also Delgado 2006); For example, Head and Mayer (2000) find 13 in 1995. Thus it would seem that deepening of market integration is reflected in falling home bias. In a comparison with the US Single Market (with pooled data for both and a unique equation for estimation), it turns out that EU countries' home bias is some 3–4 times that of US states (Pacchioli 2011). The key problem in interpreting home bias is that there is no underlying economic theory. Explanations for size and trends of bias remain somewhat arbitrary.

Productivity Effects of the Single Market

A whole literature has sprung up on the productivity and growth effects of the Single Market. In a micro-economic perspective, X-inefficiencies (or managerial slack facilitated by a lack of competitive pressure – see Schmidt (1997) for the state of the art) will be reduced, especially in the case of national incumbents in response to increased competition prompted by deepening of the Single Market. In a more aggregated perspective, Baldwin (1989) suggests a medium-term growth bonus in a simple Solow-type growth model arising from the productivity improvements induced by EC1992. Turning to empirics, not unlike some of the previous empirical contributions, 'the' Single Market is sometimes represented merely by 'the' EU as such. Notaro (2011) focuses primarily on the 'sensitive' sectors defined as expected to be hit by the removal of heavy cross-border barriers to competition. Using industry level panel data, he finds a positive productivity shock for those sectors of around 2% in 1992 and 1993. Bottasso and Sembenelli (2001), based on a panel of Italian firms, come to similar conclusions for Italy. Henrekson et al. (1997) had already found that the old 'customs-union-plus' (i.e. prior to 1985) had exercised a positive effect on EU economic growth. Halkos and Tzeremes (2009) find, not surprisingly, that the new EU Member States have enjoyed a higher growth effect from the

Eastern enlargement than the old Member States, after controlling for various factors and using different measurements. Both the Cecchini and Monti reports comprise a large number of sector studies showing the sectoral dynamics linked, often in detail, with the EC1992 programme. These studies leave no doubt that inter-sectoral reallocation and sectoral consolidation (and possibly, intra-firm improvements) amounted to a boost of technical efficiency and productivity. The extreme case of railway rolling stock, at first totally fragmented between EU countries irrespective of scale or R&D, is telling: of every four workers in 1987, no fewer than three were expected to be redundant once these markets could be subjected to open, competitive tendering, without even considering the impetus for technical progress in the EU railway sector.

The Single Market's Impact on Innovation

As discussed, the Single Market has undoubtedly fuelled competition in the EU. Such heightened rivalry may well strengthen the incentives for innovation in processes and/or products so as to enhance or protect their position in the market or indeed enter other national markets in the EU. This incentive mechanism operates via reduced price/cost margins. Yet another mechanism runs via new entry. In a rich theoretical approach, Vives (2008) finds that increasing market size increases cost reduction expenditure per firm while having ambiguous effects on the number of varieties offered. He also finds that decreasing the cost of entry increases the number of varieties but reduces cost reduction expenditure per variety. Relying on the pro-competitive effect of deepening market integration via EC1992, reducing price/cost margins (and hence average profitability) are observed by Griffith et al. (2006), in turn leading to an increase in R&D investment in manufacturing industry, subsequently translating into faster TFP (total factor productivity) growth. Note that this empirical contribution ignores services. Neither does it relate the Single Market effect on innovation to patents or other intellectual property rights. This means that the untapped potential for innovation effects is much larger still. Once the EU patent comes into being, one should expect a boost (*ceteris paribus*) in the number of patents given the incentives of large market size (all EU countries would always fall under such a patent) and much lower costs (Guellec and van Pottelsberghe 2007).

A complementary approach is to study the rate of diffusion/adoption of innovation, as undertaken by Surinach et al. (2011). Some 52% of firms in the EU rely on innovation adoption rather than self-generation of innovation. The authors employ a two-stage estimation procedure. First, they define the impact of the Single Market on both competition and cooperation of firms. Subsequently, they estimate how these 'channels' induce innovation adoption. The notion that much of EU innovation is actually jointly produced (in interfirm cooperation) and subsequently adopted as a result sits uneasily with the sole emphasis on competition in the literature quoted above. Competition (such as that due to the Single Market) is found to stimulate the adoption of process innovation from outside the firm, but not other forms of innovation. The authors obtain a trade-off: whilst more competitive pressure stimulates market exchanges of processes and technologies, it also tends to impede cooperation of firms, and hence joint innovation. The empirical link with productivity growth is found to be strongest for process innovation.

A Macro-Economic Perspective on Single Market Effects

Already, in the days of the EEC customs union, there had been attempts to come up with estimates of one-off GDP increments induced by EU market integration. The initially trivial gains found (see above) were suggested to be complemented by 'dynamic effects' (as they were called then), although strictly scale economies are analysed as comparative statics; much the same as for technical efficiency improvements. In later analyses higher one-off GDP increments were obtained for the internal market, ranging from a little over

1% up to the 4.5% in Emerson et al. (1988). These approaches are based on much more sophisticated models (e.g. scale and imperfect competition, and later CGE simulation with increasing sophistication, such as Allen et al. (1998), preceded by Harrison et al. (1996) and Gasiorek et al. (1992); see also Baldwin and Venables (1995)). Hoffmann (2000) makes an elaborate attempt to model the Single Market in the late 1990s as a partial one, looking carefully at issues of incomplete implementation. Using a variant of Harrison et al. (1996), he finds an increment of only 0.84% of EU GDP. In Straathof et al. (2008) the EU impact is investigated for a period of more than four decades. The authors are capable of showing that the (trade, FDI and GDP) gains from the Single Market differ over six periods they distinguish. They also demonstrate that the trade impacts of enlargements are higher than that of Single Market deepening. Straathof et al. (2008) first rely on gravity equations to identify the impact of the Single Market in bilateral trade in goods and services as well as FDI. The effects differ significantly between EU countries. Subsequently, the trade-enhancing effect of market integration (goods add mostly, services only a little, because data go until 2005) on GDP is estimated at some 2–3% but, due to expected reallocation, productivity improvements and innovation, the long-run impact for the EU would be nearly 10%.

Conclusions

This compact survey of the economic analysis of the impact of the Single Market shows a wealth of contributions. Analytical sophistication has greatly increased over time, both theoretically and empirically. Following the simple estimates of the effects of the EEC customs union on trade and GNP, more complicated models including several CGE variants and many applications of gravity approaches have been employed. Also macro-econometric models have been utilised in order to obtain macro-economic effects on GNP, price levels and employment. Some of this work has 'redone' customs union effects of the past or addressed the trade effects of various enlargements (which largely hinge on market access, too) but more and more the economic impact of a 'deep' Single Market' has become the central focus.

Nevertheless, the depth and wide coverage of the Single Market of today is hardly captured in these newer approaches – the temptation to reduce the internal market to goods only has remained very strong. The greatest challenge will be the better economic understanding of the EU Single Market in services, both for cross-border intra-EU trade and for establishment, hence, local provision. Moreover, the research agenda can be widened to comprise the economic impact of the EU patent, of the now 'deep' European capital market as well as of foreign direct investment and internal migration.

European Union's Common Agricultural Policy (CAP)

Alan Swinbank

Abstract

The EU's CAP has changed significantly over the years, largely as a result of international pressure through GATT and the WTO, but it still has the support of farm incomes as its main concern. The old CAP of market price support has more or less been displaced by decoupled income support, in the shape of the Single Payment Scheme. Cross compliance applies, addressing concerns about European agriculture's multifunctionality; and there is a renewed anxiety about food security. The CAP's Second Pillar, with targeted support for rural development and environmental protection, plays a subsidiary role.

Introduction

Many have almost believed the *Common Agricultural Policy* (CAP) and the *European Union* (EU) to be synonymous terms. For some, the CAP was an essential building-block of the EU; for others, the perceived economic failures of the policy condemned the whole European endeavour.

From the outset, the Treaty establishing the European Economic Community (the earlier incarnation of today's EU) declared that the common market should 'extend to agriculture and trade in agricultural products', and that one of the activities of the EEC would be 'the adoption of a common policy in the sphere of agriculture' (Articles 38 and 3(d)). Neither the evolution of the EEC into today's EU, following various treaty changes, nor the respective competencies of the EU's institutions – (European) Commission, Council of Ministers, European Council, European Parliament etc. – are discussed here (but see Nugent 2010).

The form that the CAP would take was unclear, but various objectives were laid out in Article 39. These were:

(a) 'to increase agricultural productivity by promoting technical progress and by ensuring the rational development of agricultural production and the optimum utilisation of the factors of production, in particular labour;
(b) thus to ensure a fair standard of living for the agricultural community, in particular by increasing the individual earnings of persons engaged in agriculture;
(c) to stabilise markets;
(d) to assure the availability of supplies;
(e) to ensure that supplies reach consumers at reasonable prices'.

Thus the Treaty set an income objective; although quite who was thought to be included in the 'agricultural community', or 'engaged in agriculture' was never entirely obvious. Despite its lack of clarity, this 'farm income' objective has remained a distinctive feature of the CAP ever since; and differentiates 'farming' from all other economic activities in the EU.

The CAP has changed *substantially*. Other policy objectives such as food safety, animal welfare, and environmental protection have come to the fore, and concerns about food security resurfaced in the late 2000s; but the obsession with 'farm income' has remained throughout. This text first sets out the mechanisms that were put in place in the 1960s, which might be characterized as the *Old CAP* of market price support. Then it explains the policy changes of the early 1990s, which began a decoupling of income support, leading to the establishment of the Single Payment Scheme (SPS) in the 2000s. The fourth section introduces the concept of *multifunctionality*, whilst the fifth outlines the *Second Pillar* of the CAP (the First Pillar being market and income support). At the time of writing the EU is engaged in a review of the role the CAP should play after 2013, and the final section sets out some of the issues raised.

EU legislation impacting the farm, food and rural sectors extends beyond the confines of the CAP, as outlined here. Food safety and animal and plant health regulations are necessary to support the operation of the single market, and its Renewable Energy Directive provides incentives for biomass to be used for energy, particularly biofuels in transport, for example.

The Old CAP: Market Price Support

The creation of the CAP was a protracted, and often contested, process (Knudsen 2009), keenly observed by the EEC's trading partners, but the result in the mid-1960s was a CAP that involved extensive regulation of the markets for farm products and processed foods. This policy dominated CAP budget expenditure, and perceptions of the CAP, until policy reforms were initiated in the early 1990s.

Farm-gate prices were often two or three times world market prices, and the policy was premised on the idea that, by raising farm *revenues*, farm *incomes* would also increase. This ignored three important limitations. First, given the heterogeneity of European agriculture, and in particular the variability in the size of farm businesses, price support had little absolute impact on the revenues of small farms, but considerably influenced those of larger operators. It was not until the early 1990s that the Commission (1991) claimed that 80% of CAP budget support benefited 20% of farms, accounting for 'the greater part of the land used in agriculture'.

Second, it confused revenues with incomes. An increased demand for farm products leads to an increase in the derived demand for inputs, boosting the sales of fertilizer and machinery suppliers, benefiting landowners rather than tenant farmers, and retaining in farming marginal producers who might otherwise have quit, thus perpetuating the farm 'problem'.

Third policy-makers neglected the market regulating effects of the price mechanism and, as productivity improvements fuelled the ability of European farmers to increase supply, surpluses soared, leading to the butter mountains and wine lakes so often associated with the CAP.

Details and terminology differed from one commodity to another, but most had three key policy mechanisms in place (Harris et al. 1983). First, high import taxes were applied. Prior to the conclusion of the Uruguay Round of GATT

(General Agreement on Tariffs and Trade) negotiations, and the new WTO (World Trade Organization) system of international trade regulation that applied from 1995, these often took the form of *variable import levies* that were regularly expanded or contracted to plug the gap between the higher, and EU-determined, minimum import price (often known as a *threshold* price), and the lower, and variable, world market price. These import barriers were converted into fixed tariff equivalents (*tariffication*), and reduced; but for many products (e.g. sugar) they remained prohibitively high. A successful end to the WTO's Doha Round would bring substantial tariff reductions, of up to 70% in some instances (Daugbjerg and Swinbank 2009, pp. 54, 168).

The internal market price was directly supported: farmers (or more usually traders, or manufacturers of first-stage processed products, such as butter) could sell product to the intervention agencies at fixed prices: whence the butter mountains. Once acquired, the product might be sold back onto the EU market if prices strengthened, sold into lower-priced outlets (for example skim milk powder was used for animal feed), or at reduced prices on world markets. Over the years intervention prices have been reduced substantially, not just in real terms but also in nominal terms, and by the beginning of the 2010s intervention played only a limited role in CAP market price support.

The third element in the tripod of support was an export subsidy (known as an *export refund*). Traders could claim this export subsidy if product was sold outside the EU. As production expanded at a faster rate than consumption, the result was, first, a squeezing-out of imports, and then a growing volume of subsidized exports, depressing world market prices and angering other nations that saw their trading interests threatened. It was an anomaly that the GATT allowed export subsidies on agricultural products, but not on manufactured goods. The Uruguay Round agreements imposed more disciplines on the use of export subsidies on agricultural products, whilst leaving the EU largely untroubled; but successive CAP reforms have significantly reduced the EU's reliance on export subsidies, and they will be eliminated from the world trade regime if the Doha Round is concluded.

Simple welfare economic critiques of the CAP, showing that the gains to producers were outweighed by the losses to consumers and taxpayers, were repeated many times, but without a notable impact on policy. This led to the conclusion that the analysis was incomplete for one, or both, of two reasons. First, that political forces were too entrenched to be readily overcome, leading to political economy appraisals of the CAP (e.g. Senior Nello 1984), and attracting the interest of political scientists. Second, that an undue emphasis on perfectively competitive markets overlooked the prevalence of market failure: policy-makers were perhaps acting rationally in their design and defence of the CAP.

A Changed Regime: The Newer CAP of Decoupled Income Support

The old CAP survived the attempts of Sicco Mansholt, the first Commissioner for Agriculture, to reform the policy in 1968, and the accession of the United Kingdom (allegedly antagonistic to the CAP) in 1973. Nonetheless, some modest changes were introduced to try to limit the growth in surpluses and budget expenditure without recourse to significant price cuts, such as milk quotas in 1984.

It had long been assumed that the soaring budget cost of the CAP would breach the EU's budget ceilings, forcing CAP reform. Some authors suggest that this was a major factor in the 1992 reform, whereas others focus upon the constraints imposed by the Uruguay Round of GATT negotiations (Cunha with Swinbank 2011, Ch. 5). All analysts, however, are agreed that this was a political process, in which the rent-seeking interests of the farm lobby were overwhelmed by competing forces, either in a zero-sum game in the allocation of EU budget funds, or as a necessary trade-off to secure other objectives in the Uruguay Round, rather than a considered response to an economic critique.

The exceptional treatment that agriculture had received in the GATT was largely a product of the

exigencies of US farm policy in the GATT's formative years (Josling et al. 1996, Chs. 1 and 2). By the mid-1980s circumstances had changed, and the USA and others were determined to negotiate new disciplines governing farm support in the Uruguay Round negotiations, launched in Punta del Este, Uruguay, in 1986, and finally concluded in a formal ceremony in Marrakesh, Morocco, in 1994 (Croome 1999).

As well as curbs on the use of export subsidies on agricultural goods, and greater market access opportunities, the GATT negotiators set out to *decouple* farm support. If farm policies acted to influence domestic production, and hence a country's net trade position, this impinged on the trading interests of other nations, and was a legitimate GATT concern. Consequently the Uruguay Round Agreement on Agriculture (URAA) slotted farm support policies into one of three broad categories, the so-called *amber*, *blue* and *green boxes*. Policies that *did* distort trade (the amber box) would be subject to new WTO disciplines. Policies deemed to have minimal impact on production would be exempt from subsidy constraints, and fell within the green box (Annex 2 of the URAA) (Daugbjerg and Swinbank 2009, p. 54). This specified that 'decoupled income support' had to satisfy both *ex ante* and *ex post* criteria: policy design must match a set of specifications (that 'payments in any given year shall not be related to, or based on, the type or volume of production. . . undertaken by the producer in any year after the base period', for example), and the over-arching 'fundamental requirement that they have no, or at most minimal, trade-distorting effects or effects on production'.

The EU 'decoupled' the bulk of its farm support in two steps. The MacSharry reforms of 1992 – driven by the then Agriculture Commissioner Ray MacSharry –achieved a partial decoupling. Cereal and beef prices were reduced, and farmers were compensated for the implied revenue loss with area payments on land sown, and in enhanced (headage) payments on beef animals kept. Second, starting with Franz Fischler's reforms of 2003, and subsequently extended to other sectors, these area and headage payments were converted into the more-decoupled SPS (Cunha with Swinbank 2011).

European Union's Common Agricultural Policy (CAP), Fig. 1 The changing structure of CAP budget expenditure 1980–2009, € billion, current prices

The scale of the policy change can be gauged from Fig. 1. Until the 1990s expenditure on export subsidies and other market price support mechanisms dominated, with some expenditure on rural development (now dubbed the *Second Pillar* of the CAP, and discussed further below). With the MacSharry reforms of 1992 direct payments to support farm incomes began to displace market price support; and the Fischler reforms of 2003, and subsequently, switched these into the decoupled SPS, further squeezing, but not quite displacing, the old CAP of market price support. The relative budgetary importance of the three strands of today's CAP can be gauged by the budget allocations for 2011: some h39.8 billion for direct aids (mainly the SPS), with a mere h3 billion allotted to interventions in agricultural markets (the old CAP); and h12.6 billion for rural development (European Commission 2011a). Collectively the CAP still accounts for almost 44% of expected budget payments.

The area and headage payments of the MacSharry reforms were only partially decoupled – crops had to be sown and animals kept – and so did not qualify as green box payments under the URAA. Instead they were classified in an intermediate category, the *blue box*, which like the green box was not subject to expenditure limits, ensuring that the MacSharry reform fitted the new URAA. This was seen by many of the EU's trading partners as a temporary relaxation of the subsidy rules to be swept away in the next (Doha) round of negotiations. In its periodic declarations to the WTO the EU has claimed that the SPS has switched the bulk of its income support into the green box, meeting any new subsidy constraints that the Doha Round might bring.

Despite the claim to be a *common* agricultural policy, there are a number of differences in the way the SPS is applied. One relates to it operating on an historic or a regionalized basis, with Member States (and sometimes regions within them) opting for one or the other.

The original idea was that farm businesses would be entitled to SPS payments based on their claims for area and headage payments in a base period. If the annual claim had averaged h*a* per year, and *b* hectares had been used to justify this claim, then they would receive an SPS allocation of *b* entitlement hectares at a payment rate of h*a*/*b* per hectare. This could be claimed against on an annual basis, provided *b* hectares of farmland were kept in good agricultural and environmental condition (Daugbjerg and Swinbank 2009, p. 136). This meant that not all farmland had an SPS entitlement associated with it – because some farm enterprises, for example outdoor pigs, did not give rise to an entitlement – *and* that per hectare SPS payments varied significantly, depending on the farm's particular enterprise mix in the base period.

Alternatively, Member States were entitled to pool the SPS entitlements for a region, and make flat-rate payments on all eligible land in that region. Compared to the historic model of the previous paragraph, some farms lost high per-hectare payments that they might otherwise have received, whilst others gained. Moreover, more land was brought into the scheme, extending the scope of *cross-compliance* – respect of statutory standards, and good agricultural and environmental practice – which was required for participation.

Although the original intent, back in 1992, was to *compensate* farmers for the cut in intervention prices then experienced, the SPS is now described as 'an income support for farmers' (Article 1, Regulation 1782/2003). This posed a dilemma for the EU contemplating enlargement to embrace (in 2004 and 2007) 10 countries from Central and Eastern Europe (the CEECs). If seen as compensation for past price cuts, it would be illogical to make the same payments to farmers who had not experienced those reductions. Moreover, they might well distort competition if paid in part of the enlarged EU but not throughout, even though justified in the WTO as decoupled payments. Logic suggested that *compensation* should be temporary, and that payments should be phased out. If, however, they were seen as a permanent form of CAP *income* support, with the potential to distort competition, they could not be denied to the new entrants: an incongruous outcome given the EU's declared objective of securing economic and social cohesion.

The debate split the member states, with some (such as France) arguing for an extension of the full CAP to the new members, and others (such as the United Kingdom) arguing for CAP reform, as on previous and subsequent occasions. Eventually the SPS was extended to the new member states (in most in a slightly different format known as the Single Area Payment Scheme, or SAPS); albeit with a phased introduction to lessen the initial impact on the EU's budget, and any disruptions that a sudden inflow of wealth into rural areas might have. EU funding was at 25% of the EU15 rate in the first year, rising to 100% in 2013 (2016 in Bulgaria and Romania), with the possibility of nationally funded 'top-ups' (European Commission 2004). The phased introduction of the payments, and the initial determination of each new member state's basic budgetary entitlement, has been a source of dissatisfaction ever since.

Justifying the continuing need for income support, the European Commission (2010a, p. 5) still claims that agricultural income is 'significantly lower. . . than in the rest of the economy'; which is rather at odds with critics such as Hill (2000, p. 346) who, writing before Eastern enlargement, considered there to be 'considerable evidence' that 'there is no income problem for many farm families, in the sense that their overall incomes are not low but compare favourably with households in general'. Payments are very unequally spread, with no indication that they are targeted at individuals in need. In 2009 for example, in France, 21% of recipients of all direct aids received h2,000 or less, and were collectively paid less than 1% of the funds disbursed, whereas 1.5% of claims were for h100k or more, accounting for over 10% of the monies paid out (European Commission 2011b, Annex 4.1). Commission proposals to cap the annual payment – at, say, h300k per farm – have as yet been rejected by the Council of Ministers.

Multifunctionality

Farming generates both positive and negative externalities; and in the densely populated Old World, where fauna, flora, landscape and culture have been moulded by thousands of years of land use, and few wilderness areas remain, there are concerns that policy change could lead to an unwelcome diminution in positive, and exacerbation of negative, externalities. The SPS, it has been claimed, provides 'support for basic public goods desired by European society' (European Commission 2010a, p. 4).

As with other economic activities, agriculture is subject to a number of legislative provisions that are designed to internalize or curb its negative externalities. Thus, in nitrate vulnerable zones, restrictions are placed on the spreading of animal slurry; and the Welfare of Laying Hens Directive governs caged systems of egg production. But, unlike other industries, and challenging the polluterpays principle and the concept of comparative advantage, the CAP often seeks to compensate additional costs. Many of these environmental requirements are built into the cross-compliance provisions of the SPS.

The concept of *multifunctionality* adds an extra dimension. Here the focus is on positive externalities *jointly* produced with marketable farm outputs in traditional farming systems, which – it is feared – would not be produced if farming practices changed. The European Commission no longer uses the term – although some Member States do – but it was a concept the EU was pushing before the outset of the Doha Round. Perhaps the high point in the Commission's defence of multifunctionality came when it declared: 'The fundamental difference between the European model and that of our major competitors lies in the multifunctional nature of Europe's agriculture and the part it plays in the economy and the environment, in society and in preserving the landscape, whence the need to maintain farming throughout Europe and to safeguard farmers' incomes' (Commission 1998, p. 8). But all this rather assumed that: (1) the counterfactual was a less-preferred outcome; (2) these valued externalities could *only* be supplied if traditional farming practices were preserved; and (3) farmers would continue farming in a traditional way if their incomes were safeguarded; delivering (4) the multifunctional attributes for which European citizens were presumed willing to pay.

The Second Pillar

In addition to the mandatory and altruistic actions of farmers, delivering positive externalities associated with 'diverse forms of agriculture, rich in tradition' (Commission 1998, p. 7), farms are eligible under Pillar II for funding for environmental and rural development schemes. Unlike Pillar I, which is fully funded through the EU budget, member states *co-finance* Pillar II expenditure. The Second Pillar, like the first, has evolved over the years (Thomson et al. 2010, pp. 378–83), and its present incarnation is the Rural Development Regulation (No 1698/2005) covering the period 2007–13. This offers a menu of policy options that Member States can implement, set out in what are referred to as three thematic axes, together with the *Leader* (Liaison Entre Actions de Développement de l'Économie Rurale) programme.

The first axis focuses on the competitiveness of the farm sector, and dates back to the early years of the CAP. It provides for a wide array of on- and off-farm investments, including farm modernization, early retirement, and transitional support for producer groups, for example. The second axis, entitled 'improving the environment and the countryside', has its origins in the Less-favoured Area (LFA) directive of 1975, authorizing additional support in the LFAs, which by 2005 covered 54% of the EU27's utilizable agricultural area (European Commission 2010b, p. 86). LFA payments are still a major form of expenditure under this heading, but other schemes include establishing forests, and agri-environment payments to farmers (and sometimes other land managers) who commit to supplying environmental benefits in addition to those required by cross-compliance under Pillar I.

Axis 3 is concerned with the 'quality of life in rural areas and diversification of the rural economy', with a slighter wider remit than farm households, fostering for example 'village renewal and development'. Leader is a 'bottom-up' approach, allowing for local initiatives to design and implement development programmes across the three thematic axes. A Leader project in the UK, for example, helped in the rejuvenation of reed and sedge harvesting on the Norfolk Broads, a defining characteristic of that local environment (European Commission 2006, p. 21). It is not entirely clear why Axis 3 and Leader are funded through the CAP, rather than forming part of the EU's wider regional and cohesion policies.

There is considerable diversity in the way the Member States implement the Regulation. Their Rural Development Plans for the period 2007–13 are supposed to devote at least 10% of their EU funds to Axis 1, 25% to Axis 2 and 10% to Axis 3. Across the EU, Axis 2 is the most popular at 47%, followed by Axis 1 (reflecting traditional CAP concerns) at 33%, whilst Axis 3 (rural development) at 17% is the least (with Leader funds allocated to the three axes where appropriate). Member states have expressed significantly different preferences: Ireland for example allocates the minimum amount allowed to Axis 3, *all* channelled through Leader, whereas 80% of its funds are spent in Axis 2 (European Commission 2010b, p. 139–40).

The Post-2013 CAP?

The future CAP is closely linked with the EU's *Financial Perspective* for 2014–20. When the current Financial Perspective (for 2007–13) was thrashed out in December 2005, a 'full, wide-ranging review' was promised, 'covering all aspects of EU spending, including the Common Agricultural Policy', which would input into the discussions on the post-2013 Financial Perspective. That debate has been under way for some time (Cunha with Swinbank 2011, p. 183, 195–200). The Commission's initial ideas for the post-2013 CAP were published in November 2010 (European Commission 2010a); but it will be 2012, or even later, before any new legislation is in place. The role that the European Parliament will play, given its enhanced powers over the CAP following ratification of the Treaty of Lisbon, has yet to be experienced. In particular it now shares legislative responsibility with the Council over major CAP decisions – a procedure that used to be known as *co-decision* – in contrast to its earlier simple consultative role; and it has more control

over CAP funding, as the old concept of *compulsory expenditure* – elements of the CAP budget that Parliament could not touch – has lapsed (Cunha with Swinbank 2011, p. 40–2).

A number of themes emerge from the Commission's November 2010 communication. First, as mentioned earlier, it suggests that the farm income problem persists, despite more than forty years of CAP support; and that a continuation of the SPS (or something similar) is needed, albeit with a more 'equitable and balanced' distribution between Member States. Second, that there should be a further 'greening' of support, to enhance the 'environmental performance of the CAP'.

A third theme is the suggestion that a 'strong' CAP is necessary to 'guarantee long-term food security for European citizens' (p. 2), reflecting public concerns about population growth, rising dietary aspirations in China and India in particular, the use of arable land for biofuels, and global warming. Thus it is too soon to say whether the progressive liberalization of the CAP, launched in the early 1990s, will be sustained, or instead there will be retrenchment, and a revival of elements of the old CAP, in the belief that this enhances the food security of Europe's citizens.

A distinguished American mathematician and pioneer mathematical economist, Evans was born on 11 May 1887 in Boston, Massachusetts. Educated in mathematics at Harvard University (AB, 1907; MA, 1908; Ph.D., 1910), he spent two years as a postdoctoral fellow studying with Vito Volterra at the University of Rome, then joined the faculty of the Rice Institute in Houston, Texas, where he taught from 1912 to 1934. In 1934, he became chairman of the mathematics department at the University of California, Berkeley, retaining that position until his retirement in 1954. He died on 8 December 1973, at the age of 86.

Evans's important contributions to mathematics, especially in functional analysis and potential theory, earned him membership in the National Academy of Sciences in 1933, as well as numerous other professional honours. His interest in mathematical economics became evident about 1920, when he gave his first series of lectures on that subject at the Rice Institute, and it continued up to the time of his retirement, his last publication on the subject appearing in 1954. It is likely that his initial contact with mathematical economics took place in Italy and France, for he shows great familiarity with the work of such writers as Pareto, Amoroso and Divisia, who were flourishing during and after his early Continental sojourn. Among earlier writers in mathematical economics, he mainly cities Cournot and Jevons; among his contemporaries, Irving Fisher, Henry Schultz, and Henry Moore.

Evans's most important work in economics is his *Mathematical Introduction to Economics* (1930), which also contains materials from his earlier papers. In the book and his other publications, he applied the calculus and the calculus of variations to problems of monopoly, duopoly and competition, and to a whole range of problems of comparative statics, including the incidence of taxes and the effects of tariffs. His approach was quite different from that of Walras (to whom he does not refer in his book), in that most of his models dealt with one or a few actors in a single market, or a small number of markets. In his 'Maximum Production Studied in a Simplified Economic System' (1934, p. 37), he gave clear expression to his attitude toward general equilibrium models: 'Large numbers of simultaneous equations in a large number of variables convey little information ... about an economic system.'

In Evans's models, supply was generally described in terms of a cost function rather than a production function. To deal with macroeconomic problems, he constructed aggregate models, and, in order to provide a rationale for such models, he and his students made a deep study of the problem of index number construction. Their starting point was the work of Irving Fisher and François Divisia.

Evans's books and his articles were an important resource for early American students with an appetite for mathematical economics, who prior to their publication found an extremely sparse literature on which to graze. Samuelson, for example, mentions Evans as one whose works he 'pored over' when working on the *Foundations of Economic Analysis*. Moreover, Evans's methods of modelling economic situations gave new impetus to the approach of comparative statics, especially in application to macroeconomic problems. He constructed an early (perhaps the first) two-sector aggregative model containing a consumption good and a capital good; and he saw the power of second-order conditions of stability in reasoning about comparative statics, thereby anticipating by more than a decade Samuelson's important contributions to that topic.

Evans did only a little work in non-equilibrium dynamics, although he saw clearly the need for

further development of that subject. In his 'Simple Theory of Economic Crises' (1931, p. 61), he complained that 'the fact of lack of equilibrium in economic systems continually, and practically, stares us in the face; yet the principal discussion from a theoretical point of view has been of equilibrium, and thus at one stroke has eliminated a major issue.'

Evans was a fellow of the Econometric Society, and one of its founders. His principal influence upon the progress of economics came through the methodologies employed in his book, and through the work of his students, among whom were Francis W. Dresch, Kenneth May, C.F. Roos and Ronald W. Shephard, and one step removed, Lawrence W. Klein and Herbert A. Simon, who were colleagues or pupils of these students.

Evolutionary Economics

Ulrich Witt

Abstract

This article reviews the way of thinking about economic problems and the research agenda associated with the evolutionary approach to economics. This approach generally focuses on the processes that transform the economy from within and on their consequences for firms and industries, production, trade, employment and growth. The article highlights the major contributions to evolutionary economics and explains its key concepts together with some of their implications.

Evolutionary economics focuses on the processes that transform the economy from within and investigates their implications for firms and industries, production, trade, employment and growth.

These processes emerge from the activities of agents with bounded rationality who learn from their own experience and that of others and who are capable of innovating. The diversity of individual capabilities, learning efforts, and innovative activities results in growing, distributed knowledge in the economy that supports the variety of coexisting technologies, institutions, and commercial enterprises. The variety drives competition and facilitates the discovery of better ways of doing things. The question in evolutionary economics is therefore not how, under varying conditions, economic resources are optimally allocated in equilibrium given the state of individual preferences, technology and institutional conditions. The questions are instead why and how knowledge, preferences, technology, and institutions change in the historical process, and what impact these changes have on the state of the economy at any point in time.

Posing the questions this way has consequences for the way theorizing is done in evolutionary economics. First, preferences, technology and institutions become objects of analysis rather than being treated as exogenously given. Second, following from the very notion that evolution is a process of self-transformation, the causes of economic change are in part considered to be endogenous, and not exclusively exogenous shocks. More specifically, these causes are identified with the motivation and capacity of economic agents to learn and to innovate. Third, the evolutionary process in the economy is assumed to follow regular patterns on which explanatory hypotheses can be based, rather than forming an erratic sequence of singular historical events.

These three meta-premises are widely shared in evolutionary economics. However, the details of the argument, methods, and even the specification of the attribute 'evolutionary' vary, corresponding to the different theoretical traditions in which evolutionary economics is rooted. The concept of evolution has a long history in economics and social philosophy. This antedates – and, to a certain extent, has influenced – Darwin's theory of the origin of species by means of natural selection. Where the concept of evolution originally stood for a process of betterment (of human society), the Darwinian revolution in the sciences purged these progressive, teleological connotations. Today, evolutionary thought usually defines itself in relation to the Darwinian theory of evolution, the contributions to evolutionary economics not excepted. Some authors consider Darwinian theory to be the master theory. Others borrow from it at a heuristic level for their analogy-driven theorizing in economics. Yet others explicitly dissociate themselves from Darwinian thought.

Schumpeter and the Neo-schumpeterian Synthesis

Schumpeter avoided the term 'evolution'. He considered it a Darwinian concept and denied such concepts any economic relevance. However, in his theory of capitalist development, Schumpeter (1934) clearly subscribes to the three meta-premises above. The restructuring of the economy is explained as emerging endogenously from ever new waves of major innovations implemented by pioneering entrepreneurs with unique capabilities and motivation. Technology and the institutions of capitalism are endogenized. The transformation process of the economy is assumed to be governed by regular patterns, that is, cycles of investment and growth – booms and depressions – triggered by the innovations that occur 'in waves'

and diffuse throughout the economy in competitive imitation processes.

In Schumpeter (1942, p. 83) innovations that 'incessantly revolutionize the economic structure from within' remain central, but the innovating agents change. Previously viewed as achievements of unique promoter-entrepreneurs, innovations now appear as the routine output of trained specialists in large corporations. Correspondingly, the driving force of capitalist development is identified in the risky R&D investments of the large trusts – undertaken only if they expect proper returns to be earned. To protect these returns from being competed away immediately, the large, innovative corporations tend to engage in monopolistic practices. Such practices are incompatible with the ideal of perfect competition, but without them there would be significantly fewer R&D investments and innovations. Moreover, Schumpeter (1942, Ch. 8) claims that monopolistic practices work for only a limited time before innovations are eventually imitated or invalidated by rival innovations. Despite temporary monopolistic practices, competition by innovation thus boosts economic growth and raises prosperity more than fiercer price competition could ever do. This notion of 'Schumpeterian competition' induced a long debate about the relationships between firm size, market structure and innovativeness in which, however, the broader concept of endogenous economic change was lost from sight.

Endogenous change returns to centre stage in Nelson and Winter's (1982) neo-Schumpeterian restatement of evolutionary economics that blends Schumpeter's ideas with Darwinian concepts on the one hand and elements of the behavioural theory of the firm on the other. Schumpeter (1942) had not been specific about the innovative operations of the large corporations. To fill the gap, Nelson and Winter assume that, because of bounded rationality, firms operate on the basis of organizational routines. Different firms develop different routines for producing, investing, price setting, using profits, searching for innovations, and so forth, resulting in a diversity of competitive behaviours in the industry. By analogy with the principle of natural selection, Nelson and Winter argue that this diversity tends to be eroded whenever competing routines lead to differences in the firms' market performance and profitability. The better the firms perform, the more likely they are to grow, and the less reason they have to change their routines. The opposite holds for poorly performing firms. Much as differential reproductive success raises the share of better adapted genes in the gene pool of a population, differential firm growth thus raises the relative frequency of the better adapted routines in the 'routine pool' of the entire industry.

Instead of being a matter of optimal, deliberate substitution between given alternatives, in this view, the firms' competitive adaptations to changing market conditions are forced on them by selection processes operating on their routines. However, in a Schumpeterian spirit, Nelson and Winter also account for innovative moves – a breaking away from old routines – in an industry's response to changing market conditions. New ways of doing things, for example in responding to rising input prices, are established by search processes which are themselves guided by higher-level routines. Modelled as random draws from a distribution of productivity increments, innovations raise the average performance of the industry and regenerate the diversity of firm behaviours for selection to operate on. Some of the firms are driven out of the market, while the surviving ones tend to grow. Under innovation competition, technology and industry structure thus co-evolve and feed a non-equilibrating economic growth process. Regarding the debate on Schumpeterian competition, Nelson and Winter's analysis suggests a reversal of cause and effect: a high degree of concentration within an industry (an indicator of monopolistic power) may evolve as a consequence of, rather than being a prerequisite for, a high rate of innovativeness in the industry.

Selection Principles and Processes

Analogies between natural selection and market competition are not new. Better-adapted variants of firm behaviour have often been argued to prevail in an industry just as better-adapted variants

tend to prevail under natural selection pressure in the population of a species (an argument that has sometimes been misunderstood as vindicating profit-maximizing behaviour). The logic of the argument can be rendered more precise (Metcalfe 1994). Consider an industry with firms $i = 1,\ldots, n$ producing a homogeneous output with unit cost $c_i = \text{const}$. Assume that the firms use different organizational routines which result in a non-degenerate unit cost distribution. Let $s_i(t)$ denote the market share of firm i at time t measured by output. In a competitive market in which trade takes place at a uniform price $p(t)$,

$$p(t) = c(t) = \sum_i s_i(t) \cdot c_i, \qquad (1)$$

with $c(t)$ as the average level of unit cost in the industry. By Eq. 1, the average profit in the industry is zero. For at least one firm i, however, individual profit $\pi_i = p(t) - c_i > 0$ unless the entire market is served by the firm with the lowest level of unit cost.

Let the firm's growth be expressed in terms of the rate of change of its market share $(ds_i(t)/dt)/s_i(t)$ that is assumed to be a monotonic function ϕ of the firm's profit. With (Eq. 1) inserted into the individual profit equation, the rate of change of the firm's market share can therefore be written as

$$\frac{ds_i(t)/dt}{s_i(t)} = \phi(c(t) - c_i) = \phi(\pi_i(t) - \pi(t)). \quad (2)$$

Hence, performance differences across firms and their routines translate into corresponding differential growth rates of the firms.

The 'replicator' Eq. 2 corresponds to what is called 'Fisher's principle' in population genetics (Hofbauer and Sigmund 1988, Ch. 3). Let the fitness of an organism carrying a certain genetic trait be a constant. If it exceeds the average fitness in a population, the relative share of that trait in the population increases and vice versa. Consequently, natural selection raises average fitness over time to the level of the highest individual fitness. The change of the mean population fitness is proportional to the variance of the individual fitness. Analogously, with $c(t)$ as the measure for 'population fitness' in Eq. 2, $dc(t)/dt = f(\text{Var}(c_i)) \leq 0$.

If individual fitness is not constant, Fisher's principle no longer applies.

Suppose individual unit costs decrease with the firms' output, for example because of scale economies. The replicator equation can then have several fixed points representing multiple selection equilibria associated with a different average cost level (Metcalfe 1994). Which of the multiple equilibria the process converges to – and, consequently, whether the *ex ante* most profitable cost practice is eventually selected – depends on the initial conditions. Selection does not necessarily drive fitness or, for that matter, profits to the largest maximum. (Replicator equations with multiple equilibria can also result if the individual fitness terms depend on the population shares of their carriers. Such a frequency dependency is characteristic of models in evolutionary game theory; see Hofbauer and Sigmund 1988, Ch. 16).

To influence the underlying distribution of traits or behaviours, selection requires sufficiently inert conditions. In economic transformation processes this condition is often systematically violated. For example, firms facing a declining market share and/or profitability have strong incentives to modify their operations, that is, to replace inferior routines and/or to search for innovations. In general, with innovations playing a central role – as in Schumpeterian capitalist development – the volatility of the firms' environment increases and makes inertia rather unlikely. Industry dynamics are then more likely to be shaped by the generation and diffusion of innovations following their own time patterns rather than by selection processes. While in the case of selection processes theorizing focuses at the population level ('population thinking'), the explanation of the generation and diffusion of innovations can benefit from reconstructing motives and capabilities at the individual level.

Emergence and Diffusion of Innovations

Important as innovations are for economic transformation processes, the possibilities for

analysing how they emerge are limited because the underlying cognitive processes are basically unknown. What can nonetheless be analysed is why and when agents are motivated to search for innovations, provided their motivation is not made contingent on the – as yet unknown – outcome of the search (as in models of optimal choices between known alternatives that are therefore not applicable here). Often search motivation is triggered by a state of dissatisfaction or deprivation that the agents want to overcome by actions still to be found. Among the causes may be unsatisfied curiosity, a motivation to achieve something (Schumpeter 1934), or an agent's aspiration level that is temporarily not satisfied (Nelson and Winter 1982, Ch. 9). Where individual motivations like these occur in an uncorrelated way, they induce a base rate of innovative activity in the economy. If, in contrast, search motivation arises in a correlated way, for example in an economic crisis or when an industry is exposed to major innovations, the rate of innovative activities can rise far above the base rate. This is the case, for example, when firms need to innovate or be fast imitators with sufficient absorptive capacity in order to survive and therefore routinely engage in R&D.

Once an innovation is created or discovered by an agent, its implications can be grasped. Suppose, after assessing its benefits and costs, an agent implements an innovation. The implementation can usually be observed by competitors and/or other potential users. Since, in the absence of independent, own experience, people often draw conclusions from observing what others do, some observers may thus infer that the innovation is profitable and may start imitating it. Other observers may draw this conclusion only after a number of competitors and/or potential users have also signalled that they expect to benefit from adopting the innovation. Observational learning of this kind implies a dependency of the individual imitation or adoption behaviour – and, hence, the diffusion of the innovation – on the relative frequency of adopters.

The logic of this dependency can be captured by a function $q(t) = g(F(t))$, depicting the probability $q(t)$ that an agent who decides in t will adopt the innovation against the relative frequency of adopters $F(t)$ at time t. For $q(t) > F(t)$ the expected relative share of adopters grows with each additional decision and vice versa for $q(t) < F(t)$. The diffusion dynamics

$$\frac{dF(t)}{dt} = q(t) - F(t) \tag{3}$$

therefore hinge on the shape of the function g. For the quadratic function $q(t) = aF(t) - aF(t)^2$, $a > 1$, for instance, $F(t)$ converges to a fixed point F^a, $0 < F^a \leq 1$, that depends on the size of a. (By integration of Eq. 3 the diffusion path can in this case be shown to follow the well-known S-shaped logistic trend).

For the cubic function $q(t) = 3F(t)^2 - 2F(t)^3$, to take that example, the condition $q(t) = F(t)$ is satisfied if F equals 0, $\frac{1}{2}$, or 1. Inserting the cubic function into Eq. 3, F = 0 and F = 1 can be shown to represent stable fixed points of Eq. 3 while $F^* = \frac{1}{2}$ represents an unstable fixed point. This implies that for $F(t) < F^*$ the probability of adopting the innovation is too small to induce a spontaneous diffusion process. If $F(t)$ were for some reason to exceed F^* – representing a 'critical mass' of adopters – the innovation would however spread. The reason could be fluctuations of $F(t)$ that randomly cumulate, but are not represented in this simple deterministic model. (This explanation also plays a role in evolutionary game theory where the question is, for example, whether a new convention can emerge in a coordination game; see Young 1993). Another reason could be that somebody organizes a collective action by which the critical mass of agents is made to believe that more than the share F^* of agents will adopt the innovation.

With major technological innovations, competing variants or designs that serve the same user needs are often spawned simultaneously. The diffusion processes of the competing variants are interdependent if, for each of the variants, the users' utility varies with the number of adopters. Such 'economies to adoption' of alternative variants have been diagnosed, for example, for electric current transmission, video recorder systems, or the layout of typewriter keyboards.

The underlying pattern is again a frequency-dependency effect that can be analysed as before, if only two rival variants are assumed and the decision of agents who adopt neither of these is neglected.

Let $q(t)$ denote the probability of adopting the first variant and $F(t)$ its share of adopters at time t. Suppose both variants become available simultaneously and offer the same inherent benefits. For the first variant the development is captured by the cubic function above, interpreted as the mean process of a stochastic adoption process. With an identical number of initial adopters, $F(0) = F^* = \frac{1}{2}$ and $q(t) = \frac{1}{2}$. Once $F(t) \neq \frac{1}{2}$ for $t > 0$, economies to adoption raise the individual adoption probability of one of the variants over that of the other. As a consequence, the realization of the stochastic diffusion process initially fluctuates around F^*. Over time, however, small historical events and cumulative random fluctuations drive the process in the direction of either $F = 0$ (first variant disappearing) or $F = 1$ (second variant disappearing). In competitive diffusion processes of this kind, the prevailing state of the technology is thus 'path-dependent', and the process can be 'locked in' to the one variant if it is assumed, in addition, that over time the number of adopters grows beyond all bounds (Arthur 1994, Ch. 3). This means that, for $t \to \infty$, the likelihood of passing F^* by cumulative random fluctuations goes to zero.

The Evolution of Industries and the Institutions Backing Innovativeness

The substitution processes that the diffusion of new products and techniques induces shake up the established production structures. Factor owners and producers are forced to make adjustments – often painful ones that depreciate earlier investments and acquired competencies. While such 'pecuniary externalities' are inevitable concomitants of innovations, the longer-run consequence of innovativeness is – as Schumpeter (1942) had postulated – a rising standard of living of the masses. As a result of innovativeness, labour productivity and per capita income increase. New products and services absorb the growing consumption expenditures where established markets tend to be satiated. New employment opportunities emerge in new industries. To understand the working of the innovative transformation process and its policy implications, it is often useful to reconstruct the historical record of the evolution of entire industries (Malerba et al. 1999). Many of them, like the auto industry or the computer industry, grow out of a few major innovations for which new markets can be established or existing ones can substantially be expanded. Industries continue to grow over time under the pressure of imitative competition, often following a path of technical improvements that evolves within a 'technological paradigm' (cf. Dosi 1988).

Such regular patterns of change at the industry level can for many, though not all, industries be characterized in a stylized way by a life-cycle metaphor (Klepper 1997). Soon after their markets have been established by early innovators, the industries experience heavy entry and exit activities by competitors who partly imitate and partly add new varieties. While the market is expanding, a drastic shake-out in the number of firms occurs so that eventually a few large firms dominate the industry, and diversity in products and processes is reduced. In the beginning, product innovations are a main source of competitive advantages. Over time, however, the importance of process innovations increases. They raise productivity, drive down unit costs, and tend to intensify price competition. One cause of these patterns of industry evolution seems to be increasing returns to process innovations. These favour first movers that have been able to attain a sufficient size to spread development costs over larger output bases. With fiercer price competition, the firms with higher unit costs tend to be driven out of the industry, as in the selection model discussed above. Market concentration rises. With fewer innovations at that stage in the industry, its growth slows down, if the industry is not stagnating or declining.

Industry evolution is often connected with spatial effects. Innovative production techniques and

new products often grow out of initiatives, competencies, endowments, and institutional settings in particular locations (Antonelli 2001). If such complementary and interdependent local innovative activities gain momentum and trigger a self-augmenting process of firm growth and firm founding activities in close spatial proximity, an 'industrial cluster' can emerge. During early phases of the industry life cycle, a substantial share of the corresponding national or international industrial innovative activity may even be concentrated in such locations, Silicon Valley being the paradigmatic case. In such regions, income and employment are boosted. For policymaking the question therefore arises under what conditions innovative industrial clusters emerge and how and when their emergence can be fostered (Brenner 2004).

The early growth of innovative industries creates new employment opportunities. At later stages of the industry life cycle, when price competition and substitution pressure from innovative industries force the industry to raise labour productivity to reduce costs, employment is usually gradually lost. (For this reason, an industrial cluster that dominates a region can, in later stages of the industry life cycle, become a drag on local employment and prosperity). At the macroeconomic level, the stages reached in the life cycles of the industries interact in a complex way with productivity and income growth rates, and with the overall changes in employment (Metcalfe et al. 2006). Although these interactions have not yet been fully explored, it seems clear that at least two conditions must be met to maintain a high level of aggregate employment. First, innovative industries with new employment opportunities must emerge at the right times to compensate for the labour-saving technical progress. Second, the workforce must be able to adjust to the qualification requirements of the innovative industries and technologies. Since there is no self-regulating mechanism fulfilling the first condition, and because of delays and frictions in satisfying the second condition, the evolution of the industries is not necessarily a smooth transformation process. Aggregate employment and domestic income can vary substantially with the pace at which innovative industries emerge and expand. However, high levels of education and training are likely to raise innovativeness and the qualifications of the workforce. Ensuring this with an adequate institutional infrastructure – a productive national system of innovations – is an important policy option in supporting and smoothing the transformation process. This is even more true from a global perspective. A country's growth potential and its competitive advantage in trade hinge on when the country gains access to newly emerging technological opportunities and where in the innovative industries' life cycle it enters the market. History shows that differences between countries in this respect correspond to differences in their national innovation systems (Fagerberg 2002).

Darwinian Perspectives on Economic Evolution

The neo-Schumpeterian approach considers the concept of selection as constitutive for evolutionary economics. Economic selection processes, operating on the diversity of individual behaviours, force adaptations on populations of agents who are prevented by their bounded rationality from deliberately adapting optimally. The import of the selection concept is not meant to extend Darwinism to the economic domain. Such an extension was, however, advocated by Veblen (1898) under the influence of the Darwinian revolution of his time. He coined the term 'evolutionary' economics for such an approach (Hodgson 2004). A Darwinian perspective on the economic domain can indeed help to clarify how evolutionary economics fits with the Darwinian world view now prevailing in the sciences and in this way offer new insights (Witt 2003).

In the economic domain, the bulk of change to be explained occurs within single generations. In contrast, the Darwinian theory of natural selection focuses on inter-generational change and is therefore relevant only for explaining the basis on which economic evolution rests. These are, first, the long-term constraints man-made economic evolution is subjected to and, second, the innate dispositions and adaptation mechanisms in

humans (shaped earlier in human history by natural selection) that define the basic behavioural repertoire. Veblen (1898) focused on habits, including habits of thought, which he assumed to emerge from hereditary traits and past experiences, given the traditions, conventions and material circumstances of the time. (Habits play the crucial role in Veblen's explanation of the 'cumulative causation' of institutions which, in turn, he regarded as the key to understanding the different forms of economic life and their genesis).

In a similar vein one may focus on human preferences that emerge from the interplay of inherited dispositions and innate conditioning learning mechanisms – both of these shared by all humans with the usual genetic variance. A prominent example of innate dispositions is the altruistic attitudes that play a prominent role in evolutionary game theory (Hofbauer and Sigmund 1988, Ch. 14). Other examples of innate dispositions can be found in certain forms of consumption. The genetically fixed learning mechanism accumulates the influence of a lifelong history of reinforcement and conditioning. It is responsible for the emerging variety of individual preferences and keeps them changing over time.

Following Hayek (1988, Ch. 1), innate behaviour can be conjectured to play a key role in the evolution of human institutions. They emerge, he argues, through social learning of 'rules of conduct' that starts from primitive, genetically fixed, forms of social behaviour and add on new elements by trial and error. Over their history, different groups or whole societies thus build up a diversity of rules that regulate their interactions. The group members' innovativeness is channelled into economic activities provided institutional regulations do not discourage this or fail to protect the capital accumulation that is necessary to realize innovations. Those groups that succeed in developing and passing on rules able to better meet these conditions can therefore be expected to grow and prosper in terms of population size and per capita income. Their differential success may enable such groups to conquer and/or absorb less well-equipped, competing groups and thus propagate better adapted institutions.

Economic evolution is, of course, also shaped in an essential way by human intelligence. By cognitive learning, problem solving and inventiveness, knowledge about institutions, opportunities and technologies is created (Mokyr 2002). In the longer run, the enabling effects of cumulative knowledge generation emerging over time matter more than the effects of economizing on scarce resources at each point in time. From a Darwinian perspective the most significant tendency in the use of cumulative knowledge is the manipulation of natural constraints to better accord them with human preferences. This has enlarged the niche for the human species and has improved living conditions for an ever-increasing number of its members. At the same time, however, knowledge accumulation has contributed to dramatically increasing the human share in the use of natural resources. According to Georgescu-Roegen's (1971) evolutionary approach to production theory, this way of solving problems implies a risky long-term impact on nature, the ultimate basis of the human economy. To account for these risks further innovative efforts that transform the economy from within seem indispensable.

The concepts of *ex ante* and *ex post* are the most popular terminological innovations developed by the famous so-called Stockholm School in the 1930s. The terminology was introduced into macroeconomic theory, especially with regard to the savings-investment relation by Gunnar Myrdal (1933, 1939) and clarified and incorporated into sequence or period analysis by Erik Lindahl (1934, 1939b), whose conceptual system of 'prospective' and 'retrospective' values achieved 'world-citizenship' as a method for drawing up national budgets (Hansen 1951, p. 27). The popularization of the method of *ex ante* and *ex post* is due to Ohlin's seminal articles on the Stockholm School (1937) which made it 'generally accepted over the whole world with a rapidity unusual to economics' (Palander 1941, p. 34).

The significance of the distinction between *ex ante* and *ex post* 'as one of the most transforming insights that theoretical economics has had' (Shackle 1972, p. 440) does not follow so much, as often stressed in the literature, from the simple fact that there exist always two alternative definitions of flow-related economic magnitudes like income, production, and so on, depending on whether they are looked at 'from before' or 'from after'. The central idea of the necessity to distinguish between *ex ante* and *ex post* stems rather from the recognition of the fundamental difference, originally expressed by Frank Knight (1921, pp. 35 f.) and definitely formulated by Myrdal (1939, pp. 59 f.), between 'foreseen' and 'unforeseen' changes where only the latter result in 'gains and losses' which, as shown by Lindahl (1939b, pp. 103 f.), have to be 'windfalls'. Therefore, in the analysis of expectations under uncertainty time has to be included in an essential way by two alternative methods of calculation of economic variables: (i) an *ex ante* computation or business calculation which refers to a point of time at the beginning of a period and (ii) an *ex post* computation or bookkeeping referring to the development in time at the end of the period (Myrdal 1939, pp. 45–7). As a consequence,

economic analysis can be divided into (i) an *ex ante* analysis explaining how expectations determine an economic magnitude and (ii) an *ex ante*/*ex post* analysis explaining the possible divergence between the expected and realized value of this variable.

The emergence of the concepts of *ex ante* and *ex post* can be dated to Lindahl's and Myrdal's early writings in the 1920s. In his first treatise in macroeconomic theory (Lindahl 1924, ch. 3) Lindahl stressed the time factor for economic analysis and used the notion of 'subjective calculations of the future' as well as the term *ex post* when he discussed 'a negative investment recognized only ex post' (p. 33). A more coherent analysis of these concepts was given in Myrdal's dissertation on expectations and price changes (Myrdal 1927, pp. 67 f.) where he showed, emphasizing Knight's idea of the difference between certain and uncertain changes, how divergences between incomes and costs of an investment calculated '*before*' will be balanced by gains and losses calculated '*after*'.

The first application of these ideas to macroeconomic problems was made by Lindahl in *Penningpolitikens medel* (Lindahl 1930; cf. 1939a). However, the dynamic method of temporary equilibrium used in this treatise, that is, 'an analysis dividing time into a number of short equilibrium periods during which no changes occur', led to a 'theoretically inadmissible mixture of the *ex ante* and *ex post* analysis' (Myrdal 1939, p. 122). In case of the same but wrong expectations, for example, the equality between savings and investment *ex ante* is not a guarantee for temporary equilibrium (Palander 1941, p. 44; see also Siven 2006, pp. 684–5). As shown by Myrdal in the original Swedish version of *Monetary Equilibrium* (Myrdal 1932, pp. 228–30), this mixture was especially obvious in Lindahl's discussion of the relation between investment and saving, where he could not demonstrate in a satisfactory way how an initial discrepancy due to a shift in the rate of interest will always be balanced by changes in the distribution of income between borrowers and lenders. If, however, Lindahl would give up his method of temporary equilibrium, that is, allow for disequilibrium during a period, his analysis could be interpreted in an *ex ante*/*ex post* framework.

It was exactly this disequilibrium analysis which enabled Myrdal to clarify the relation between investment and saving in his three different versions of *Monetary Equilibrium*, where he introduced the notions of *ex ante* and *ex post* first in the German edition (Myrdal 1933, § 29). In his discussion of these concepts Myrdal (1939, pp. 59–62, 116–25; cf. 1933, §§ 32, 55–6) allowed for a discrepancy between investment and saving *ex ante* based on 'anticipatory calculations' at a point of time demarcating the beginning of a period, while at its end their values were constructed by 'a subsequent "bookkeeping" in such a way that there is *always* an *ex post* balance 'regardless of how short the period'. Therefore, it is not 'this meaningless balance' which is of interest to economic analysis but '*the very changes during the period which are required to bring about this ex post balance*'. Myrdal assumed that these balancing factors arise out of 'unanticipated changes' in 'revenues and costs', that is, in incomes, during the period for which they can be calculated only *ex post*: gains and losses. The reason why *ex ante* and *ex post* values may differ is that expectations formulated in the beginning of a period are *ex ante* values of prices and quantities that may not be realized because expectations may be disappointed during the period (Siven 2006, p. 681). As later shown by Lindahl (1939b, pp. 103 f.; cf. 1958), these values have to be windfalls and must not be confused, as sometimes in Myrdal's analysis (Myrdal 1939, p. 65), with entrepreneurial gains or losses, which are already included in the *ex ante* values and which, therefore, cannot serve as balancing factors.

Although Myrdal always spoke of 'income changes' as the balancing factor *ex post* of discrepancies *ex ante* between investment and saving, his examples implied almost exclusively '*price changes*' (Myrdal 1939, p. 60; cf. Palander 1941, pp. 42f.; Hansson 1982, p. 149). It was left to Lindahl (1934, 1939b) to demonstrate how the *ex post* equality was achieved in a disequilibrium process via a change in quantities.

Lindahl presented his solution in an aggregate demand and supply framework, where demand

was identified with the purchase plans of consumers and producers and supply with the expectations of the sellers of production and consumption goods. In his analysis he made the fundamental assumption that the purchase plans as well as the supply prices of the sellers at the beginning of a period 'have been actually realized during the period' (Lindahl 1934, p. 207, cf. Lindahl 1939b, p. 92). Under this assumption a possible deviation between expected and realized sales, which Lindahl took as given if the future is not foreseen with certainty, must be considered as a result of a difference between investment and saving *ex ante* which in turn will cause a divergence between expected and realized total real income. These changes in income represent gains or losses to the producers which in a form of 'unintentional', not 'forced', saving or dissaving equalize investment and saving *ex post.*

The purpose of Lindahl's rigid assumption that purchase plans are always fulfilled, which made it impossible to apply his analysis to the conditions of full employment (Hansen 1951, pp. 29–32), was to demonstrate that, once prices are given, the *actions* of the economic subjects during the period 'can be directly deduced from the plans at the beginning of the period' (Lindahl 1939b, p. 92). With this demonstration Lindahl had taken the first step to a sequence analysis, that is, a single-period analysis where *ex ante* plans determine *ex post* results. The second step consisted of a continuation analysis where the *ex post* events of the current period lead to revisions of the *ex ante* plans for the consecutive period at the transition point between these periods, 'especially as regards the supply prices and the producers' and consumers' demand' (Lindahl 1934, p. 211). However, as Lindahl 'never succeeded in formulating 'laws of motion' for revisions of plans ... this promising branch of dynamic theory became abortive' (Hansen 1966, p. 3).

Of greater influence for economic analysis was Lindahl's second contribution to the development of the *ex ante*/*ex post* method, his discussion of the relations between 'prospective' and 'retrospective' values of micro- and macroeconomic variables (Lindahl 1939b) which contained 'the germ of many lines in later works' on the methodology of national accounting (Ohlsson 1953, p. 266). Although Lindahl's accounting structure was criticized as 'deficient' (Ohlsson) in the treatment of government accounting, it has been emphasized recently by Hicks (1985, p. 80) that Lindahl's system 'does have some continuing merits ... for the accounting of the public sector': 'In this field at least, it may still be contended, *ex ante ex post* remains respectable.'

For a long time it was argued that the exposition of the Keynesian system 'requires the language of *ex ante* and *ex post*' (Shackle 1972, p. 172; see also Patinkin 1976, pp. 139–40; Siven 2006, p. 700), with the emphasis placed on the possible divergences, due to uncertainty, between disappointed *ex ante* expectations and *ex post* results as one of the relevant factors in determining the level of employment. However, the posthumous publication of Keynes's 1937 lecture notes have shown that Keynes (1937a, p. 183; see also 1937b) emphasized that even under the assumption of an 'identity of *ex post* and *ex ante*', that is, with expectations always fulfilled but without having to assume for this case, as did Myrdal and Lindahl, the absence of uncertainty, 'the theory of effective demand is substantially the same' (p. 181). Moreover, as Keynes regarded the '*time* relationship' between the concepts of *ex ante* and *ex post* as 'incapable of being made precise' (p. 179), he rejected this method as an inadequate tool in handling the problems of uncertainty and time.

Examples

James Bonar

Examples in economics, as elsewhere, are simply cases, real or fictitious, or partly both, supposed to embody a general principle. They may be classified as follows: (1) *Real but general*, as Ricardo's hunters (*Principles*), and Adam Smith's bricklayers, carpenters, and men of letters (*Wealth of Nations*). The examples are taken from a known genus but not from known individuals. Where the genus is perfectly well known, no cavil is possible. Adam Smith's illustration of division of labour could hardly have been improved by a reference to a particular pin-making establishment in a specified place. But, in exposition, the more concrete the genus the more telling the example; e.g. 'blacksmith' seems nearer life than 'workman'. (2) *Real and particular*, as in Cairnes's illustration of the theory of international trade from the Australian gold discoveries. Adam Smith, where he does not use the real and general, uses the real and particular, and falls back on fiction only for his similes (as 'the highway', 'the waggonway through the air', the 'wings', and 'the pond and the buckets', *Wealth of Nations*, II, ii), or his metaphors ('wheel of circulation', 'channel of circulation'). Ricardo and his immediate followers have preferred, as a rule, (3) *Fictitious* examples. These may be illustrations of which the component elements are generically well known, even the favourite 'man on the desert

island', but the combining of the elements is the work of the writer, and is more or less arbitrary, as de Quincey's 'man with the musical box on Lake Superior', and Bastiat's 'plank and plane'. There is also a risk that the construction of the example may involve a begging of the question to be proved. 'Suppose that there are but two nations in the world living side by side, with a population of one million souls in each' (Barbour, *Bimetallism*). 'My object was to elucidate principles, and to do this I imagined strong cases that I might show the operation of those principles' (Ricardo, *Letters*). There is no necessary fallacy in this method of exposition any more than in illustrating the law of gravitation by the action of bodies *in vacuo*. Concrete cases must necessarily exemplify much more than one principle, and, even if they suggested a particular generalization, they may perhaps not clearly illustrate it without a fictitious simplification. The lawfulness of such a method of exposition or, it may be, of proof is discussed elsewhere.

Excess Burden of Taxation

James R. Hines Jr.

Abstract

The excess burden of taxation is the efficiency cost, or deadweight loss, associated with taxation. Excess burden is commonly measured by the area of the associated Harberger triangle, though accurate measurement requires the use of compensated demand and supply schedules. The generation of empirical excess burden studies that followed Arnold Harberger's pioneering work in the 1960s measured the costs of tax distortions to labour supply, saving, capital allocation, and other economic decisions. More recent work estimates excess burdens based on the effects of taxation on more comprehensive measures of taxable income, reporting sizable excess burdens of existing taxes.

The excess burden of taxation is the efficiency cost, or deadweight loss, associated with taxation.

The total economic burden of a tax includes both payments that taxpayers make to the government and any lost economic value from inefficient activities undertaken in reaction to taxes. Since direct tax burdens take the form of revenue that taxpayers remit to governments, the excess burden of taxation is the magnitude of the economic costs of accompanying economic distortions. For example, a tax on labour income typically discourages work by encouraging inefficient substitution of untaxed leisure for taxed paid work. At low tax rates this substitution entails only modest excess burdens, since, in the absence of other distortions, the welfare cost of substituting an untaxed for a taxed activity simply equals the tax rate, the difference between pre-tax and after-tax returns to the taxed activity. At high tax rates this difference is quite large, and as a result residents of economies with high tax rates may face substantial excess burdens of taxation. Indeed, it is entirely possible for the excess burden of a tax to exceed the revenue collected; a tax imposed at so high a rate that it eliminates the taxed activity clearly has this feature.

The excess burden of taxation is commonly measured by the area of the associated 'Harberger triangle' (Hines 1999). The base of the Harberger triangle is the amount by which economic behaviour changes as a result of price distortions introduced by the tax, and the height of the Harberger triangle is the magnitude of the tax burden per unit of economic activity.

The Many Excess Burdens

One of the difficulties that arise in evaluating the excess burden of taxation is that there is more than one possible measure of excess burden. This multiplicity does not imply that all measures are equally desirable or useful. For example, the use of uncompensated (Marshallian) demand and supply curves to construct Harberger triangles produces measures of the excess burden of taxation with a number of known problems. In the (realistic) case in which a government uses multiple taxes, a measure of total excess burden based on uncompensated demand and supply curves is path dependent, meaning that its value depends on the order in which the taxes are imagined to be imposed. As the order of the taxes is perfectly arbitrary, path dependence is troubling – most importantly because it reflects the imprecision of excess burden measures constructed in this way.

Path dependence is one consequence of this imprecision; another is that a tax system that produces a higher level of economic welfare might have a greater measured excess burden than an alternative that raises the same revenue. If excess burden is to be useful in the evaluation and formation of tax policies, it is necessary that the measure should correspond, at least approximately, to the economic cost of taxation – and assign greater excess burden to tax systems that are in fact more burdensome.

Path dependence and inaccurate welfare orderings need not arise if excess burden is measured by Hicksian consumers' surplus, based on schedules that hold utility, rather than income, constant as prices vary. Because actual tax policy changes typically do not hold utility constant, it is necessary to construct a measure based on a conceptual experiment that does. One intuitive experiment is to imagine that, as a tax is imposed, utility is held constant at its pre-tax level. Excess burden is then defined as the amount, in excess of tax revenue, that the government must compensate consumers to maintain initial utility in the face of a tax-induced price change. The amount of compensation, which corresponds to the Hicksian measure of the *compensating variation* of the price change, may be calculated in roughly the same way that Harberger triangles are commonly measured.

An alternative conceptual experiment is to begin with the tax already in place and then remove it, extracting from consumers in lump-sum fashion an amount that prevents them from changing their utility levels while the tax is removed. Because the initial tax is distortionary, it is necessary to extract more from consumers than the tax revenue, the difference representing the excess burden of the initial tax. This differs from the previous measure in corresponding to a Hicksian *equivalent variation* measure of excess burden. One virtue of an equivalent variation measure of excess burden, compared to the compensating variation measure, lies in the fact that, in comparing tax systems that raise equal revenue, the tax system with the lowest excess burden as measured by equivalent variation also produces the highest level of consumer welfare (Kay 1980).

Although these compensating variation and equivalent variation measures are the most intuitive, they are actually just examples drawn from a class of measures based on arbitrary levels of utility and arbitrary reference price vectors. As King (1983) and others note, the use of compensated supply and demand schedules together with fixed reference price vectors guarantees that resulting excess burden measures have desirable properties, though the interpretation of the resulting magnitudes depends on the choice of utility levels and price vectors. These measures then can be naturally generalized to include marginal excess burden, the change in excess burden arising from a given tax change, and to treat excess burden in settings in which costs of production vary with output levels (Auerbach and Hines 2002).

Empirical Measurement of Excess Burden

While the theory of excess burden measurement has a long and colourful history that dates back to the 19th century contributions of Jules Dupuit

(1844) and Fleeming Jenkin (1871–2), economists seldom measured actual excess burdens prior to the pioneering work of Arnold Harberger in the 1960s. In two influential papers published in 1964, Harberger (1964a, b) derived an approximation used to measure excess burden and (1964b) applied the method to estimate excess burdens of income taxes in the United States. Harberger shortly thereafter (1966) produced estimates of the excess burden of US capital taxes. A generation of empirical studies by other scholars followed the publication of Harberger's subsequent survey article (1971).

The empirical work that followed Harberger's efforts focused on the use of simple excess burden formulas to estimate the welfare impact of a wide array of tax- induced distortions, including those to labour supply (Browning 1975), saving (Feldstein 1978), corporate taxation (Shoven 1976), and the consumption of goods, such as housing and non-housing consumption items, that are taxed to differing degrees (King 1983). In addition, some attention was devoted to refining the approximations used in applying estimated behavioural parameters to calculate excess burdens. A variant of the excess burden formula used by Harberger, in which a form of uncompensated demand is used in place of compensated demand, approximates a compensated measure of welfare change. One question of interest to subsequent investigators is the practical difference between results obtained using Harberger-style approximations and those available from more exact measures. As Mohring (1971) and subsequent authors note, it is often the case that the same demand information necessary to calculate approximations can, if properly modified, be used to calculate Hicksian excess burden measures. The extent to which these two methods generate different answers is, of course, an empirical question. Rosen (1978) finds that measures of excess burden based on compensated and uncompensated demand and supply schedules track each other rather closely, but Hausman (1981) offers some examples in which they differ considerably.

A major practical difficulty in measuring the excess burden of a single tax, or of a system of taxes, is that excess burden is a function of interactions that are potentially very difficult to measure. For example, a tax on labour income is expected to affect hours worked, but may also affect the accumulation of human capital, the intensity with which people work, the timing of retirement, and the extent to which compensation takes tax-favoured (for example, pensions, health insurance, and workplace amenities) in place of tax-disfavoured (for example, wage) form. In order to estimate the excess burden of a labour income tax, it is in principle necessary to estimate the effect of the tax on these and other decision margins. Analogous complications are associated with estimating the excess burdens of most other taxes. In practice, it can be very difficult to obtain reliable estimates of the impact of taxation on just one of these variables.

It is in reaction to the complicated nature of the problem of separately estimating the effect of taxation on all of a taxpayer's decision margins that a number of recent studies estimate excess burdens based on the effects of taxation on reported taxable income. Taxable income incorporates not only any effects of taxation on work effort, but also tax avoidance of various forms, including deliberate hiding of income and legal avoidance such as making tax-deductible charitable contributions. Properly measured, excess burden, as calculated by the effect of taxation on taxable income, should accurately capture all the necessary interactions to evaluate the welfare consequences of taxation (Feldstein 1999).

Several empirical studies, including Feldstein (1995), Auten and Carroll (1999), and Goolsbee (2000), consider the responsiveness of taxable income to tax rates, relying on major US tax changes to provide variation in tax rates. The evidence indicates that taxable income is generally quite responsive to tax changes, particularly among the high-income population, thereby implying an excess burden of US taxes considerably greater than that produced by studies using estimated effects of taxation on work hours and saving. The estimates suggest excess burdens of taxation that might be as high as 75 per cent of tax revenue collected (Feldstein 2006), though there is still considerable uncertainty over its true magnitude.

Excess Demand and Supply

Michael Allingham

In general equilibrium theory the economy may be represented by the function which specifies the aggregate excess demands (positive) or excess supplies (negative) which are expressed at all possible price systems.

While the concept of excess demand is implicit in Walras's (1874) framework it is first introduced explicitly in Hicks's (1946) treatment of the general equilibrium system. In the present discussion we first examine how the excess demand function is obtained from the underlying parameters of the economy, that is the preferences and endowments of the various agents in the economy. We then discuss why the concept is useful, and what restrictions economic theory imposes on the excess demand function, and, equally importantly, what it does not.

An economy with n commodities consists of a number of agents, each with given preferences for and endowments of these commodities. An agent's preferences are represented by a complete preordering P on the commodity space R^n_+.

The preordering has the following properties:

Continuity: the set of all x in R^n_+ such that xPy and the set such that yPx are both closed for all y.

Monotonicity: if $x \geq y$ but xy then xPy but not yPx.

Convexity: if xPy and z is a proper linear combination of x and y then zPy but not yPz. The agent's endowment is represented simply by a point e in $S = R^n_+ - 0$.

Given an agent's preferences P and endowment e, and given any price system p in S, there is one and only one $x(P)$ in $R^n{}_+$ such that $x(p)Py$ for all y such that $p \cdot y \geq p \cdot e$; existence of this element can be shown using Weierstrass's theorem, while uniqueness follows immediately from convexity (Debreu 1959). The difference between this $x(p)$ and his endowment that is $x(p) - e$, is his excess demand at the price system p, denoted $g(p)$.

One property which follows immediately from the definition of excess demand is that $g(p)$ is homogeneous (of degree zero), that is $g(tp) = g(p)$ for all positive t. A second property which follows immediately from the definition and monotonicity is that $p \cdot g(p) = 0$ for all p.

A third important property which is less immediate is that g is continuous provided that the value of the agent's endowment, $p \cdot e$, is positive (Debreu 1959). The reason why we need this proviso can be seen by an example. Let $n = 2$ and $e = (1,0)$, and let p tend to (0,1); for all positive p, $g_1(p)$ is non-positive but in the limit when $p = (0, 1)$ g_1(p) is infinite because of monotonicity.

A further property of excess demand is the revealed preference property. Consider two distinct prices p and q, with the corresponding excess demands $g(p)$ and $g(q)$, also assumed to be distinct. If $g(p)$ is available at the price system q, that is if $q \cdot g(p) \leq 0$, then $g(q)$ must not be available at the price system p, that is $p \cdot g(q) < 0$. We thus have $q \cdot g \cdot (p) \leq 0$ implies $p \cdot g(q) > 0$.

Excess demands of individual agents are mainly of interest in that they determine aggregate excess demands. The aggregate excess demand function simply by defining $f(p)$ as the sum of each agent's $g(p)$. $f : S \to R^n_+$ is obtained simply by defining $f(p)$ as the sum of each agent's $g(p)$.

It is immediate that $f(p)$ is homogeneous, that is $f(tp) = f(p)$ for all positive t, and also that $p.f(p) = 0$ for all p, a property known as Walras's Law. It is also clear that f is continuous at any strictly positive p, for then the value of each agent's endowment must be positive, so that each g is continuous. In fact f is continuous everywhere on S, essentially because at any p there must be some agent whose endowment has positive value.

The revealed preference property, which applies to individual agents' excess demands, does not, however, carry over to aggregate excess demands. If all agents are identical, that is, have identical preferences and endowments, then the property carries over, but it may be that individual agents' excess demands are related in a perverse way, which means that the property is lost in aggregation. If the property does apply in aggregate then we may consider the economy to behave as an individual agent.

The excess demand function f provides us with a simple way to define equilibrium, and various of its properties. A price system p in S is an equilibrium price if $f(p) = 0$. Further, for example, an equilibrium price p is unique if, for any q in S, $f(q) = 0$ implies that $q = tp$ for some positive t. Equilibrium and its properties may be defined without the concept of excess demand, but the concept provides a useful framework for their investigation.

For example, with two commodities (and thus effectively one price and one excess demand function) it is intuitively clear that equilibrium will be unique, and indeed stable, if excess demand is everywhere downward-sloping. More generally, uniqueness and stability are typically investigated using generalizations of this idea of downward-sloping excess demand.

We have noted that aggregate excess demands have the properties of homogeneity, Walras's Law and continuity. It is also important to note what is in effect the converse of this: that any function with these properties may be an excess demand function. This is to say that economic theory places no restrictions on excess demand functions other than these three properties.

This property was first investigated by Sonnenschein (1973), but the most powerful result is due to Debreu (1974), who showed that

there is an economy with precisely n agents which generates any continuous homogeneous excess demand function obeying Walras's Law, at least on the set of strictly positive prices. This is proved by first decomposing f into n individual excess demand functions, each having the revealed preference property, and then showing that these individual functions are the result of preference maximization subject to a wealth constraint.

Indeed, if f is restricted to being twice differentiable then there is an economy with n agents, each with homothetic preferences, which generates f as its excess demand function, again on the set of positive prices (Mantel 1976). This is shown by creating indirect utility functions for each agent and then using Roy's Identity to obtain the excess demand functions. However, the extension of this result, and also Debreu's result, to the whole of S, rather than only the set of strictly positive prices, remains open.

Not surprisingly, these results imply that the set of equilibrium prices has little structure. Indeed, it may be any non-empty compact subset of S (Mas-Colell 1977). Thus without further restrictions we can say very little about the set of equilibria.

Excess Volatility Tests

Stephen F. LeRoy

Abstract

Stock prices frequently undergo big changes that do not coincide with commensurate changes in fundamentals (earnings, dividends, interest rates). Shiller and LeRoy and Porter formalized the idea that price volatility is excessive relative to fundamentals by deriving the implications for price volatility of the hypothesis that stock prices equal the present value of discounted dividends. Subsequent discussion focused on the extent to which their results were subject to econometric problems. Also, analysts observed that the adopted version of the present-value model presumed constant discount rates, as would be the case under risk neutrality. This possibly biases the results.

It has been known for many years that stock prices frequently undergo big changes that do not coincide with commensurate changes in prospective corporate earnings or dividends or in variables that can readily be connected to discount factors, such as interest rates (see for example Cutler et al. 1989). The best-known episode occurred on 19 October 1987, when stock prices dropped around the world – by 22 per cent in the United States – in the complete absence of news about fundamentals. Such events appear to conflict with

finance theory: if stock prices equal the present value of future expected dividend streams, changes in prices should be attributable to news about dividends or discount factors. However, it is difficult to draw reliable conclusions about price volatility from individual episodes, if only because there is no obvious way to evaluate statistical significance.

Is Price Volatility Systematically Excessive?

The question is not whether stock price volatility appears to exceed that justified by fundamentals in individual episodes, but whether it does so *systematically*. The latter question was first addressed by Shiller (1981) and LeRoy and Porter (1981). These papers, written independently and approximately contemporaneously, derived the existence of bounds on the volatility of prices and returns that are implied by the present-value relation. They found excess volatility. However, the papers made this point using different analytical methods. Shiller observed that, if stock prices equal the expectation of summed discounted dividends, then stock price volatility should be bounded above by the volatility of what he called ex-post rational stock prices, defined as actual summed discounted dividends. Ex-post rational prices p_t^*, he pointed out, obey the relation

$$p_t^* = \beta\left(p_{t+1}^* + d_{t+1}\right), \tag{1}$$

where β is a discount factor (assumed constant). From (1), a time series for p_t^* can be constructed by a backward recursion, at least given an initial condition. Shiller constructed graphs of p_t^* and p_t and argued from visual inspection of these graphs that the former was much smoother than the latter, proving that volatility is excessive. Since Shiller did not specify the model assumed to generate the data, he had no way to evaluate statistical significance.

LeRoy and Porter, in contrast, adopted a model-based analytical procedure. They specified that dividends, stock prices and any auxiliary variables that serve as predictors for future dividends are generated by a linear vector autoregression (to use a term that was not yet in vogue). They proved that a certain function of the variance of stock price and the variance of stock payoffs can be derived from the parameters describing the bivariate autoregression for dividends and prices. The reason both price volatility and dividend volatility enter the expression is that, if the auxiliary variables are accurate predictors of future dividend innovations, then price volatility will be high but payoff volatility will be low. The opposite will be the case if the auxiliary variables do not give accurate predictions of future dividends.

Using this result, LeRoy and Porter constructed a joint test of price volatility and payoff volatility from a bivariate model for dividends and prices. It was unnecessary to estimate the forecasting power of the auxiliary variables, or even to specify them. LeRoy and Porter conducted this test and reported a confidence interval based on the asymptotic distribution of the coefficients of the bivariate process for dividends and prices. They found excess volatility, but it appeared to be of borderline significance. See LeRoy (1989) for a fuller, but still brief, summary of the variance-bounds tests in the context of the efficient capital markets literature.

Econometric Problems

Both Shiller's and LeRoy and Porter's procedures had econometric problems (for a survey of these problems, see Gilles and LeRoy 1991). These problems were serious enough to invalidate the results, in the opinion of some. Discussion focused on Shiller's paper. Kleidon (1986a, b) and Flavin (1983) pointed out that, while the present-value model implied that the unconditional variance of p_t^* exceeded that of p_t, one would expect the variance of p_t^* conditional on its neighbours p_{t+j}^* to be lower than the corresponding conditional variance of p_t. This is so because p_t^* is much more highly autocorrelated than p_t, as is evident from the absence of an error term in (1). In visually evaluating the volatility of p_t^* and p_t it is not easy to distinguish unconditional

from conditional volatility. This is a major drawback of Shiller's procedure. Kleidon computed simulations of p_t^* and p_t in which the present-value model was true by construction, and argued that they looked much the same as the actual data.

LeRoy and Porter's procedure had the drawback that the assumed linear process for dividends and prices implies that these are stationary in level. That being so, some sort of trend correction to remove the upward trend in both variables must be imposed, and LeRoy and Porter did so. Trend-correction algorithms can easily distort the time-series properties of variables, and that may have happened in this case. It is possible that LeRoy and Porter's finding that excess price and return volatility is only marginally significant statistically reflects difficulties with the trend correction.

Interpreting Excess Volatility

Analysts questioned the interpretation of the variance-bounds tests along other lines. They pointed out that the volatility implications of the present-value relation were just repackaged versions of the fundamental implication of the present-value relation (plus the assumption of rational expectations) that stock returns should be serially uncorrelated. If so, why do direct tests of the return orthogonality implication of the present-value relation tend to accept the null, whereas the variance bounds tests appear to reject it? Part of the resolution of this apparent contradiction is that the evidence on return uncorrelatedness began to look less favourable to the null hypothesis in the late 1980s (see for example Campbell and Shiller 1988). Another possibility, discussed by LeRoy and Steigerwald (1995), is that the volatility tests are more powerful than the return non-autocorrelatedness tests under whatever alternative hypothesis generated the data.

Risk Aversion

Discussion of these issues ended fairly suddenly in the mid-1990s. This happened mostly because of a growing realization that the hypothesis being tested required an assumption of risk neutrality: in general, stock prices equal the discounted value of expected dividends (when the expectation is taken under the natural probabilities) with a non-stochastic discount factor only if agents are risk neutral). If agents are risk averse there is no reason to presume that either the orthogonality implications or the volatility implications of the present-value relation will be satisfied. This dependence on risk neutrality had not been brought out clearly in the major papers developing the orthogonality implications of market efficiency. For example, Samuelson's otherwise superb paper (1965) developing the connection between martingale models and the present-value relation glossed over this point. Similarly, Fama's classic 1970 survey of the efficient capital markets literature observed that 'market efficiency' (meaning, presumably, rational expectations) could be tested only if the analyst committed himself to a particular model specifying how returns are generated, so that the joint hypothesis of efficiency and the assumed model is tested. Despite this, Fama did not go on to observe that the returns model that underlies conventional market efficiency tests took no account of risk aversion. Shortly it became clear that the non-autocorrelatedness of returns would not occur in general if agents are risk averse (LeRoy 1973, 1976; Lucas, 1978).

Initially the dependence of the variance-bounds tests on risk neutrality appeared to be a somewhat abstract point. However, arguments were shortly presented that this might not be so. LaCivita and LeRoy (1981), using a two-state version of Lucas's (1978) tree model, showed that allowing for risk aversion could be expected to increase the predicted volatility of stock prices. Risk-averse agents will try to smooth consumption across time by transferring consumption from low-marginal-utility states to high-marginal-utility states. However, in an exchange economy they cannot do so in the aggregate. The representative agent must consume the aggregate endowment in equilibrium, so prices must counteract preferences. If stock prices are very high when the marginal utility of consumption is low, and vice versa, agents must buy

financial assets when they are expensive and sell them when they are cheap if they are to transfer claims on consumption as desired. This price pattern decreases their desire to do so. If price volatility is high enough, this effect will induce agents to consume the endowment. A related argument was presented by Grossman and Shiller (1981).

Relation to the Equity Premium Puzzle

The excess volatility debate shifted with the arrival of Mehra and Prescott's wellknown paper (1985) on the equity premium puzzle. This paper was relevant to the excess volatility question for several reasons. The Mehra and Prescott paper followed LaCivita and LeRoy in specializing Lucas's tree model to two states, but modified the states so that they described the growth rate of the aggregate endowment rather than its level, as in Lucas and LaCivita and LeRoy. This leads to a tractable model when the representative agent has homothetic utility, as with power utility. A major advantage of Mehra and Prescott's specification is that when consumption growth rates rather than levels are stationary there is no need for trend correction.

Mehra and Prescott imposed drastic simplifications so as to obtain a tractable model. For example, their model did not distinguish among corporate earnings, dividends and aggregate consumption, despite the fact that these variables behave differently. Some analysts expected that Mehra and Prescott's finding that the equity premium is excessive would be reversed when these simplifications were reversed, but that has turned out not to be the case (see, for example, Kocherlakota 1996).

LeRoy and Parke (1992) observed that Mehra and Prescott's framework can be adapted to the investigation of volatility by imposing the assumption that consumption growth rates are independently distributed. This is a special case of the Markov distribution that Mehra and Prescott specified. In that case the ratio of equity value to consumption follows a stationary process. The volatility of that variable depends on how much information agents have about future consumption beyond that contained in present consumption. In the simplest case, when agents have no such information, price is a constant markup of consumption, implying that stock returns have the same volatility as the consumption growth rate. This is true regardless of the degree of risk aversion, implying that the implications of risk aversion for volatility are very different in stationary-growth-rate models than in the stationary-levels models discussed above. This prediction is rejected by the US data: the standard deviation of annual consumption growth is about two per cent, whereas that of annual stock returns is on the order of 20 per cent. In contrast to the equity premium puzzle, which can in principle be resolved with sufficiently high risk aversion, the prediction that equity returns should have standard deviations around two per cent holds for any level of risk aversion.

Even if one accepts that consumption is a geometric random walk, assuming that agents have no information variables for future consumption other than current consumption is unacceptable. If agents do have such information, equity prices will not be a constant markup of consumption. However, LeRoy and Parke showed that in that case the variances of the price–consumption ratio and the return on stock obey a relation similar to that obtained by LeRoy and Porter. They found that the resulting joint test on the volatility of the price–consumption ratio and the volatility of stock returns results in excess volatility for either variable or both.

Most analysts believe that no single convincing explanation has been provided for the volatility of equity prices. The conclusion that appears to follow from the equity premium and price volatility puzzles is that, for whatever reason, prices of financial assets do not behave as the theory of consumption-based asset pricing predicts.

Exchange

Robert B. Wilson

Abstract

Economic studies of exchange examine processes in which agents obtain gains from trade, e.g. bilateral bargaining and contracting, auctions, and multilateral markets. Prominent descriptive theories include idealized versions that assume agents simply respond to prices that clear markets. Realistic versions recognize effects of procedural rules and strategic behavior, and various impediments such as incomplete or unenforceable contracts, insufficient markets, imperfect information, and incomplete observability. Normative versions design market procedures, contract forms, and settlement rules that strengthen incentives and promote efficient outcomes.

The scope of economics includes allocation of scarce resources. Allocation comprises production and exchange, according to a division between processes that transform commodities and those that transfer control. For production or consumption, exchange is essential to efficient use of resources. In production it allows decentralization and specialization; and, for consumption, agents with diverse endowments or preferences require exchange to obtain maximal benefits. Voluntary exchange involves trading bundles of commodities or obligations to the mutual advantage of all parties to the transaction. If two agents have differing marginal rates of substitution, then there exists a trade benefiting both. The advantages of barter extend widely, for example, to trade among nations and among legislators ('vote trading'), but here it suffices to emphasize markets with enforceable contracts for trading private property unaffected by externalities, and with money as a medium of exchange.

In a market economy using money or credit, terms of trade are usually specified by prices denominated in money. Besides purchases at prices posted by producers and distributors, exchange occurs in bargaining, auctions, and other contexts with repeated or competitive offers. In institutionalized 'exchanges' for trading commodities, brokers offer bid and ask prices; and, for trading financial instruments, specialists cross buy and sell orders and maintain markets continually by quoting bid and ask prices and trading for their own accounts.

Theories of Exchange

Records of transaction prices and quantities are the raw data of many empirical studies of economic activity, and explanation of these data is a main purpose of economic theory. Theories of exchange attempt to predict the terms of trade and the resulting transactions from the market structure and the agents' attributes, such as endowments, productive opportunities, preferences, and information. Also relevant are the markets accessible, the trading rules used, and the contracts available. These may depend on property rights, search or transaction costs, and on events observable or verifiable to enforce contracts. If a particular trading rule is used, such as an auction, then it specifies the actions allowed each agent in each contingency, and the trades resulting from each combination of the agents' actions. These features are the ingredients of experimental designs to test theories, and they motivate models used for empirical estimates of market behaviour. Normative considerations are also relevant, so welfare analyses study the distributional consequences of alternative trading procedures and contracts.

Most theories hypothesize that each agent acts purposefully to maximize its (expected utility of) gain from trade. Some behaviour may be erratic, customary, or reflect dependency on a status quo, but experimental and empirical evidence substantially affirms the hypothesis of 'rational' behaviour, at least in the aggregate. Although more general theories are available, the main features are explained by preferences that are quite regular, as assumed here: monotone, convex, and possibly allowing risk aversion and impatience.

Typically there are many efficient allocations of a fixed endowment, since any allocation that equates agents' marginal rates of substitution is efficient. In the case of risk sharing, for example, an allocation is efficient if all agents achieve the same marginal rates of substitution between incomes in every two states. The distribution of endowments among agents evidently matters, however, and a major accomplishment has been the identification of a small set of salient efficient allocations. Named for Léon Walras, this set is a

focus of nearly all theories, in the sense that other allocations are explained by departures from the Walrasian model.

An allocation is Walrasian if it is obtainable by trading at prices such that it would cost each agent more to obtain a preferable allocation. That is, items are bought at uniform prices available to all, and each agent chooses a preferred trade within a budget constraint imposed by the values of goods bought and sold. If markets are complete, then a Walrasian allocation is necessarily efficient, because another allocation preferred by every agent would cost each agent more at the current prices and therefore more in total, which cannot be true if the preferred allocation is a redistribution of the present one. Conversely, each efficient allocation is Walrasian without further trade, since the agents' common marginal rates of substitution serve as the price ratios. The basic formulation considers trade for delivery in all future contingencies, but refined formulations elaborate the realistic case that markets reopen continually and trade is confined to a limited variety of contracts for immediate and future delivery, possibly contingent on events.

Sufficient conditions for Walrasian allocations to exist have been established. Mainly these require that agents' preferences are convex and insatiable, and that each agent has an endowment sufficient to obtain a positive income. For 'most' economies the number of Walrasian allocations is finite, but uniqueness requires strong assumptions on substitution and income effects. Walrasian allocations and prices for a specific model can be computed by solving a fixed-point problem, for which general methods have been devised. The task is complex (for example, linear models with integer data can yield irrational prices) but an important simplifying feature is that Walrasian prices depend only on the distribution of agents' attributes, and in particular only on the aggregate excess demand function. Essentially, any continuous function satisfying Walras's law (at any prices the value of excess demand is zero) and homogeneity in prices is the excess demand for some economy.

The key requirement for a Walrasian allocation is that each agent's benefit is maximized within its budget imposed by the assigned prices, and that markets clear at those prices. However, complete exploitation of all gains from trade may be precluded by incomplete markets, pecuniary externalities (such as absence of necessary complementary goods), insufficient contracts, or strategic behaviour. If producers with monopoly power restrain output to elevate prices, or practise any of the myriad forms of price discrimination, then the resulting allocation need not be Walrasian. Much discrimination segments markets via quality differentiation or bundling, but equally common is discriminatory pricing of the various conditions of delivery (for example, spatial, temporal, service priority) or if purchases can be monitored and resale markets are absent, by nonlinear pricing of quantities (for example, quantity discounts, loyalty programmes, two-part and block-declining tariffs).

The Walrasian model of exchange is substantially defined by the absence of such practices affecting prices. It also relies on a fixed specification of markets, agents, products, and contracts. The theory of economies with large firms having power to influence prices and to choose product designs is significantly incomplete. The deficiencies derive partly from inadequate formulations, and partly from technical considerations – characterizations and even the existence of equilibria depend on special structural features. For example, the simplest models positing simultaneous choices of qualities and prices by several firms lack equilibria; models with sequential choices encounter similar obstacles but to lesser degrees. In addition, if lump-sum assessments imposed on customers are precluded, then recovering firms' large fixed costs may require nonlinear pricing or price discrimination.

Market clearing is also essential to the Walrasian model since prices are determined entirely by the required equality of demand and supply, including inventories in dynamic contexts. In contrast, successive markets with overlapping generations of traders need not clear 'at infinity'. Such markets can exhibit complicated dynamics even if the underlying data of the economy are stationary. Similarly, continually repeated markets where buyers and sellers arrive

at the same rate that others depart after completing transactions (for example, real estate) admit non-Walrasian prices or may have persistent excess on one side of the market if search or dispersed bargaining prevents immediate clearing.

Factors Affecting Exchange

When it is that among the feasible allocations the best prediction might be one of the Walrasian allocations, has been answered in several ways.

Competition is the first answer. On the supply side, for instance, with many sellers each one's incentive to defect from collusive pricing arrangements is increased. Absent collusion, if prices reflect total supplies offered on the market and each seller chooses its optimal supply in response to anticipations of other sellers' supplies, then each seller's optimal percentage profit margin declines inversely with the number of sellers offering substitutes. Price discrimination, such as nonlinear pricing, is inhibited if there are many sellers, resale markets are available, or customers' purchases are difficult to monitor. Absent capacity limitations, direct price competition among close or perfect substitutes erodes profits since undercutting is attractive. Although these conclusions are weakened to the extent that buyers incur search or switching costs, easy entry incurring low sunk costs remains important to ensure that markets are contestable and monopoly rents are eliminated. Monopoly rents are often substantially dissipated in entry deterrence, price wars, and other competitive battles to retain or capture monopoly or oligopoly positions. This is true both when entrants bring perfect substitutes and also more generally, since entrants tend to fill in the spectra of quality attributes and conditions of delivery.

Arbitrage is important in markets for commodities with standardized qualities, especially financial assets and derivatives such as options. To the extent that the contingent returns from one asset replicate those from a bundle of other assets, or from some trading strategy, its price is linked to the latter. Importantly, repeated opportunities to trade contingent on events enable a few securities to substitute for a much wider variety of contingent contracts.

One form of the competitive hypothesis emphasizes that each subset of the traders can redistribute their endowments among themselves. For example, a seller and those buyers who purchase from him are a coalition redistributing their resources among themselves. A core allocation is such that no coalition can redistribute its endowments to advantage every member. The core allocations include the Walrasian allocations. A basic result first explored by F.Y. Edgeworth establishes that as the economy is enlarged by adding replicates of the original traders, the set of core allocations shrinks to the Walrasian allocations. Deeper analyses of core allocations take account of agents' private information, but in this context the relation to Walrasian allocations is tenuous.

Another view emphasizes that in an economy so large that each agent's behaviour has an insignificant effect on the terms of trade, every trader's best option is to maximize its gain from trade at the prevailing prices. For example, any one trader's potential gain from behaviour that influences prices becomes insignificant as the set of traders expands, provided the limit distribution is 'atomless'. Similar results obtain for various models of markets with explicit price formation via auctions or bilateral bargaining. Generally, an efficient allocation is necessarily Walrasian if each agent is unnecessary to attainment of others' gains from trade. An idealized formulation considers an atomless measure space of agents in which only measurable sets of agents matter and thus the behaviour of each single agent is inconsequential. In this case the Walrasian allocations are the only core allocations. Similarly, a Walrasian allocation results from the Shapley value in which each agent shares in proportion to his average marginal contributions to randomly formed coalitions.

Structural features of trading processes suggest alternative hypotheses. Matching problems (for example, workers seeking jobs) admit procedural rules that with optimal play yield core allocations, and for a general exchange economy an appropriately designed auction yields a core allocation. Other games have been devised for which optimal strategies of the agents result

in a Walrasian allocation. Continual bilateral bargaining among dispersed agents with diverse preferences, in which agents are repeatedly matched randomly and one designated to offer some trade to the other, also results in a Walrasian allocation from optimal strategies. In a related vein, several methods of selecting allocations create incentives for agents to falsify reports of their preferences, but if they do this optimally then a Walrasian allocation results. Quite generally, any process that is fair in the sense that all agents enjoy the same opportunities for net trades yields a Walrasian allocation. In one axiomization, some signal is announced publicly and then based on his preferences each agent responds with a message that affects the resulting trades: if a core allocation is required, and each signal could be the right signal for some larger economy, then the signal must be essentially equivalent to announcement of a Walrasian price to which each agent responds with his preferred trade within his budget specified by the price.

Traders' impatience can also affect the terms of trade. In the simplest form of impatience, agents discount delayed gains from trade. Dynamic play is assumed to be sequentially rational in the sense that a strategy must specify an optimal continuation from each contingency – this strong requirement severely restricts the admissible equilibria. For example, if a seller and a buyer alternate proposing prices for trading an item, then in the unique equilibrium trade occurs immediately at a price dependent on their discount rates. As the interval between offers shrinks, the seller's share of the gains from trade becomes proportional to the relative magnitude of the buyer's discount rate; for example, equal rates yield equal division. Extensions to multilateral contexts produce analogous results. A monopolist with an unlimited supply selling to a continuum of buyers might plausibly extract favourable terms, but actually, in any equilibrium in which the buyers' strategies are stationary, as the interval between offers shrinks the seller's profit disappears and all trade occurs quickly at a Walrasian price. Similarly, a durable-good manufacturer lacking control of resale or rental markets has an incentive to increase the output rate as the production period shrinks or to pre-commit to limited capacity. This emphasizes that monopoly power depends substantially on powers of commitment stemming from increasing marginal costs, capacity limitations, or other sources. However, impatience and sequential rationality can produce inefficiencies in product design, since then a manufacturer may prefer inferior durability, or in market structure, since a seller may prefer to rent rather than sell durable goods.

Complete information is a major factor justifying predictions of Walrasian prices. Many theories predict Walrasian outcomes when there is complete information and agents have symmetric trading opportunities, but incomplete information often produces departures from the Walrasian norm.

Although information may be productively useful, in an exchange economy the arrival of information may be disadvantageous to the extent that risk-averse agents forgo insurance against its consequences. A basic result considers an exchange economy that has reached an efficient allocation before some agents receive further private information, and this fact is common knowledge: the predicted response is no further trade, though prices may change.

Each efficient allocation has 'efficiency prices' that reflect the marginal rates of substitution prevailing – in the Walrasian case all trades are made at these prices. They summarize a wealth of information about technology, endowments and preferences. Prices and other endogenous observables are therefore not only sufficient instruments for decentralization but also carriers of information. If information is dispersed among agents then Walrasian prices are signals, possibly noisy, that can inform agents' trading. Models of 'temporary equilibrium' envision a succession of markets, in each of which prices convey information about future trading opportunities. 'Rational expectations' models assume that each agent maximizes an expected utility conditioned on both his private information and the informational content of prices. In simple cases prices are sufficient statistics that swamp an agent's private information. In complex real economies the informational content of prices may be elusive; nevertheless, markets are affected by inferences from prices (e.g. indices of stock and wholesale prices)

and various models attempt to include these features realistically. Conversely, responses of prices to events and disclosures by firms are studied empirically.

The privacy of each agent's information about his preferences and endowment affects the realized gains and terms of trade. In some cases the relative prices of 'qualities' provide incentives for self-selection. An example is a product line comprised of imperfect substitutes, in which price increments for successive quality increments induce customers to select according to their preferences. Several forms of discrimination in which prices depend on the quality (for example, the time, location, priority or other circumstances of delivery) or, if resale is prevented, the quantity purchased, operate similarly.

Absence of the relevant contingent contracts is implicitly a prime source of inefficiencies and distributional effects. Trading may fail if adverse selection precludes effective signalling about product quality: without quality assurances or warranties, each price at which some quality can be supplied attracts sellers offering lesser qualities. Investments in signals, possibly unproductive ones, that are more costly for sellers supplying inferior qualities induce signal-dependent schedules in which the price paid depends on the signal offered. For example, to signal his ability a worker may over-invest in education or work in a job for which he would be underqualified on efficiency grounds. If buyers make repeat purchases based on the quality experienced from trying a product then the initial price itself, or even dissipative expenditures such as uninformative advertising, can be signals used by the seller to induce initial purchases.

Principal–agent relationships in which a risk-averse agent has superior information or his actions cannot be monitored completely by the principal require complex contracts. For example, in a repeated context with perfect capital markets and imperfect insurance, the optimal contract provides the agent with a different reward for each measurable output, and the total remuneration is the accumulated sum of these rewards. Contracting is generally affected severely by limited observation of contingencies (either events or actions relevant to incentives) and in asymmetric relationships nonlinear pricing is often optimal. For example, insurance premia may vary with coverage to counter the effects of adverse selection or moral hazard.

Labour markets are replete with complex incentives and forms of contracting, partly because workers cannot contract to sell labour forward and partly because labour contracts substitute for imperfect loan markets and missing insurance markets (for example, against the risk of declining productivity). Workers may have superior information about their abilities, technical data, or effort and actions taken; and firms may have superior information about conditions affecting the marginal product of labour. Incentives for immediate productivity may be affected by conditioning estimates of ability on current output, or by procedures selecting workers for promotion to jobs where the impact of ability is multiplied by greater responsibilities. The complexity of the resulting incentives and contracts reflects the multiple effects of incomplete markets and imperfect monitoring.

In the context of trading rules that specify price determination explicitly, analyses of agents' strategic behaviour emphasize the role of private information. The trading rule and typically the probability distribution of agents' privately known attributes are assumed to be common knowledge; consequently, formulations pose games of incomplete information. An example is a sealed-bid auction in which the seller awards an item to the bidder submitting the highest price. Suppose each bidder observes an imperfect estimate that is independently and identically distributed (i.i. d.) conditional on the unknown value of the item. With equilibrium bidding strategies, as the number of bidders increases the maximal bid converges in probability to the expectation of the value conditional on knowing the maximum of all the samples; for the common distributions this implies convergence to the underlying value. Alternative auction rules are preferred by the seller according to the extent that the procedures dilute the informational advantages of bidders (for example, progressive oral bidding has this effect) and exploit impatience and risk aversion. Rules can be constructed that maximize the seller's expected revenue: if bidders' valuations are i.i.d. then for the common distributions awarding

the item to the highest bidder at the first or second-highest bid is optimal, subject to an optimal reservation price set by the seller. In such a second-price or oral progressive auction with no reservation price, bidders offer their valuations, so the price is Walrasian.

Another example is a double auction, used in various commodity and financial markets, in which multiple buyers and sellers submit bid and ask prices and then a clearing price is selected from the interval obtained by intersecting the resulting demand and supply schedules. For a restricted class of models, requiring sufficiently many buyers and sellers with i.i.d. valuations, a double auction is incentive efficient, in the sense that there is no other trading rule that is sure to be preferred by every agent; also, as the numbers increase the clearing price converges to a Walrasian price.

The effects of privileged 'inside' information held by some traders have been studied in the context of markets mediated by brokers and specialists, as in most stock and option markets. The results show that specialists' strategies impose all expected losses from adverse selection on uninformed traders. Specialists may further profit from knowledge of the order book and immediate access to trading opportunities.

Private information severely affects bargaining. With alternating offers even the simplest examples have many equilibria, plausible criteria can select different equilibria, and a variety of allocations are possible. In most equilibria, delay in making a serious offer is a signal that a seller's valuation is not low or a buyer's is not high; or the offers made limit the inferences the other party can make about one's valuation. When both valuations are privately known, signalling must occur in some form to establish that gains from trade exist. Typically all gains from trade are realized eventually, but with significant costs of delay. Applications extend beyond purely economic contexts, such as to negotiations to settle a law suit.

In a special case, a seller with a commonly known valuation repeatedly offers prices to a buyer with a privately known valuation: assume that the buyer's strategy is a stationary one that accepts the first offer less than a reservation price depending on his valuation. As mentioned previously for the monopoly context, as the period between offers shrinks the seller's offers decline to a price no more than the least possible buyer's valuation and trade occurs quickly – thus the buyer captures most of the gains. Even with alternating offers, the buyer avoids serious offers if his valuation is high and the periods are short. Thus, impatience, frequent offers, and asymmetric information combine to skew the terms of trade in favour of the informed party.

The premier instance of exchange is the commodity trading pit in which traders around a ring call out bid and ask prices or accept others' offers. These markets operate essentially as multilateral versions of bargaining but with endogenous matching of buyers and sellers: delay in making or accepting a serious offer can again be a signal about a trader's valuation, but with the added feature that 'competitive pressure' is a source of impatience. That is, a trader who delays incurs a risk that a favourable opportunity is usurped by a competing trader. These markets have been studied experimentally with striking results: typically most gains from trade are realized, at prices eventually approximating a Walrasian clearing price, especially if the subjects bring experience from prior replications. However, if complicated 'rational expectations' features are added, then subjects may fail to infer all the information revealed by offers and transactions.

Trading rules can be designed to maximize the expected realized gains from trade, using the 'revelation principle'. Each trading rule and associated equilibrium strategies induce a 'direct revelation game' whose trading rule is a composition of the original trading rule and its strategies; thus in equilibrium each agent has an incentive to report accurately his privately known valuation. In the case that a buyer and a seller have valuations drawn independently according to a uniform distribution, the optimal revelation rule is equivalent to a double auction in which trade occurs if the buyer's bid exceeds the seller's offer, and the price used is halfway between these. Basic theorems establish that private information among buyers and sellers precludes realization of all the gains from trade – but if traders are symmetric, as when a trader might buy or sell depending on the price, then sometimes full efficiency can be attained. Generally, with

many buyers and sellers and an optimal trading rule, the expected unrealized gain from trade declines quickly as the numbers of buyers and sellers increase. Such static models depend, however, on the presumption that subsequent trading opportunities are excluded.

Enforceable contracts facilitate exchange, and most theories depend on them, but they are not entirely essential. Important in practice are 'implicit contracts' that are not enforceable except via threats of discontinuing the relationship after the first betrayal. Similarly, in an infinitely repeated situation, if a seller chooses a product's quality (say, high or low) and price before sale, and a buyer observes the quality only after purchasing, then the buyer's strategy of being willing to pay currently only the price associated with the previously supplied quality suffices to induce continual high quality.

Studies of exchange without enforceable contracts focus on the Prisoner's Dilemma game in which both parties can gain from exchange, but each has an incentive to renege on his half of an agreement. In any finite repetition of this game with complete information the equilibrium strategies predict no agreements, since each expects the other to renege. Infinite repetitions can sustain agreements enforced by threats of refusal to cooperate later. With incomplete information, reputational effects can sustain agreements until near the end. For example, if one party thinks the other might surely reciprocate cooperation then he has an incentive to cooperate until first betrayed, and the other has an incentive to reciprocate until defection becomes attractive near the end. Reputations are important also in competitive battles among firms with private cost information: wars of attrition select the efficient survivors.

In sum, the Walrasian model remains a paradigm for efficient exchange under 'perfect' competition in which equality of demand and supply is the primary determinant of the terms of trade. Further analysis of agents' strategic behaviour with private information and market power elaborates the causes of incomplete or imperfectly competitive markets that impede efficiency, and it delineates the fine details of endogenous product differentiation, contracting, and price formation essential to the application of the Walrasian model.

Game-Theoretic Analysis of Exchange

Studies of exchange rely increasingly on game-theoretic methods. These are useful to study strategic behaviour in dynamic contexts; to elaborate the roles of private information, impatience, risk aversion, and other features of agents' preferences and endowments; to describe the consequences of incomplete markets and contracting limited by monitoring and enforcement costs; and to establish the efficiency properties of the common trading rules. They also integrate theories of exchange with theories of oligopolistic collusion, product differentiation, discriminatory pricing, and other strategic behaviour by producers. Technically, the game-theoretic approach enables a transition from theories of a large competitive economy with a specified distribution of agents' attributes, to theories of an economy with few agents, each having private information and acting strategically to exploit opportunities.

Game-theoretic methods are especially useful in market design, that is, devising trading rules and procedures that yield outcomes that are efficient subject to the limitations imposed by participants' private information and strategic behaviour. Innovative designs are used for auctions of government procurements and privatization of assets (for example, spectrum licences, Treasury securities), for wholesale commodity markets such as electricity and gas among many others, and some markets for transport. Some of these are 'smart markets' in that the allocation is derived from an elaborate optimization that takes account of bids and offers for several commodities and various technical constraints – such as transmission limits and reserve requirements in the case of electricity. With the advent of electronic commerce, innovative designs are also used in some retail markets conducted as auctions.

A salient feature of the developing theory of market design is the role of alternative settlement rules. Unlike the Walrasian rule of settling all transactions at the market clearing prices, these settlements provide incentives for accurate reporting of benefits and costs. Most of these rules are derivatives of one proposed by

W. Vickrey (1961) in which each buyer in an auction pays the highest rejected bid; and more generally (even for public goods), for the allocation he receives each trader is charged for the benefit thereby denied to others. Novel settlement rules that promote 'incentive compatibility' and thus discourage strategic behaviours that impair efficiency are hallmarks of the general theory of 'mechanism design'. Essentially, this approach to exchange replaces the idealized descriptive approach in the Walrasian paradigm with a normative 'engineering' construction of optimal trading and settlement rules, that is, a comprehensive contract that governs participation in the market. Participants' perceptions of the effectiveness of this contract can affect competition for trading volume among alternative market venues.

Exchange Control

Pascal Petit

In a rather narrow sense, we refer to exchange control when monetary institutions (governments, central banks or specialized institutions) impose strictly defined limitations on international transactions or on the exchange of national currency into foreign currency. So exchange control occupies the middle ground between unrestricted convertibility into foreign exchange and the total ban on convertibility which is practised in a number of developing countries and in the socialist countries.

In dealing with balance of payments, these restrictions serve different purposes. The most frequent objectives consist in balancing trade (the export and import of goods) or the current account.

In all instances, exchange control measures aim at preserving the autonomy of domestic policies threatened by trade deficits, foreign debts, or a switch in control of the national productive capital. At all times, the primary purpose of exchange controls, as well as that of the non-convertibility of certain currencies, has consisted in preserving the national autonomy of a country from outside interference. The Sparta of Lycurgus, which in turn inspired Plato's project on non-convertible fiduciary currency, provides us with the first famous example (see Einzig 1962). Here the object was to reduce the possibility of corruption by foreign agents. In times of crisis or war, such measures represent a means to control trade or to guarantee the supply of primary strategic materials. But such practices are relatively recent. Einzig (1934) rightly points out that only after 1917 did the World War I belligerents attempt to control exchange. A return to unlimited convertibility occurred only during the second half of the 1920s, after the return to the gold standard in 1925. But the experience gained during World War I facilitated a quick return to control measures during the crises of the 1930s and especially during World War II.

During the decades following the end of World War II, the purpose of controls consisted in limiting any imbalance which in some countries went hand in hand with the development of trade. Basically, controls are introduced when monetary exchange systems fail to fulfil their role as regulators in the international market.

Due to the diversity in exchange control measures, it is difficult to measure their impact. The role of most controls is to keep the current balance of payments in check. In this sense, controls affect the financing of imports (prior demand, necessary deposits, specific rates of exchange), terms of payment (fixed payment delays for export or imports) or limits to travel spending. The exercise of some form of control is the norm rather than the exception.

In the first half of the 1980s – a period characterized by the liberalization of capital movements – only the United States, Switzerland, Britain (since 1979) and the Federal Republic of Germany (since 1984) allowed the free circulation of capital. Japan, which applied vigorous exchange controls until the end of the 1970s, turned to a gradual liberalization spurred by the US–Japanese negotiations in 1984. While improving convertibility, France, Italy and Belgium have kept certain restrictions relating to the circulation of capital.

The rationale underlying such restrictive practices can first of all be found in the limitations imposed by the two traditional regimes of exchange at fixed and flexible rates. We cannot expect such systems to lead to unique equilibrium rates of exchange (a fantasy already denounced by Joan Robinson in 1937). The purpose of such systems is to prevent the development of strong creditor or debtor positions. From time to time these limitations force the countries in question to inhibit the application of free convertibility regimes.

But this is not the sole reason for restricting exchange. Certain control measures aim to shield the development of domestic industries from foreign competition. Here it is useful to distinguish measures bearing on the exchange of commodities and those having effect on the movement of capital, in order to perceive the different stages in a policy geared towards protecting national economies.

In order to understand the advantages or disadvantages of such measures, an attempt will be made to define the limits to exchange regimes and the diversity in control measures.

Exchange Controls as a Reaction to Limitations of the Two Classical Exchange Regimes

For some countries, standard exchange regimes lead to long-lasting imbalances (excessively high debts, inflation triggered by depreciation of the national currency) which can inhibit the autonomy of domestic policies, and so may lead to control measures. The character of these disturbances varies according to the current exchange regime, as demonstrated by the experience of the principal market economies since 1945; at the beginning of the 1970s, these market economies passed from a system of fixed exchange to a system of floating exchange.

In a system of fixed exchange, the defence of parities leads to vast movements of currency reserves by the central banks, inciting speculative movements by private capital, in turn staking on the sudden realignment of parities. The destabilizing effect produced by credit balance or imbalance necessitates parity adjustments or drastic economic measures.

In a system of flexible exchange, where financial markets are largely integrated, domestic economic policies are bounded in terms of prices and rates of interest. This leads to instability in the adjustment of the balance of payments. On the one hand, the increase in the cost of imports in the case of depreciation of the national currency stimulates inflationary pressures and inhibits the re-establishment of foreign debt. On the other hand, the integration of financial markets forces national real interest rates to align with international levels. Speculation then is a measure of the ability of an economic policy to accommodate any pressures on prices and on rates of interest.

The fixed rate regime followed by the flexible rate experience demonstrated the instability generated by free convertibility regimes for medium sized countries, faced with either the risk associated with the issue of a standard currency, i.e. the dollar, or with the erratic speculative movements resulting from its decline.

The gold convertibility of the American currency (at a fixed price of 35 dollars an ounce) constituted one of the pillars of the system of fixed exchange inaugurated at Bretton Woods in 1944. The United States then held eighty per cent of the world gold stock. From the 1960s onwards, military expenses abroad and investment abroad, as well as the balance of trade deficit, led to a sharp decrease in gold reserves and to accumulation by European and Japanese central banks. In early 1971, gold reserves corresponded to only a third of foreign holdings in dollars and the flight of capital increased. In March 1973, an

intensification in speculative movements – encouraged by the announcement by the US Secretary of State of the future total liberalization of capital movements – forced the central banks to endorse the general free floating of currencies under the auspices of the International Monetary Fund.

For current critics of the system of fixed parities (Johnson 1969; Mundell 1968), only a system of flexible exchange could allow for a degree of autonomy and stability in domestic policies. Yet after more than a decade, the system of floating exchange seems conducive to remarkable instability and interdependence between national policies.

With the change in the hegemonic role of the dollar (see Parboni 1981), the monetary uncertainty which characterized the beginning of the 1970s soon led to inflationary pressures. In terms of domestic policy, it was manifest in the large price increase of raw materials together with the explosion of wage conflicts towards the end of the 1960s. In terms of economic policy, inflation represented the main preoccupation of the decade. In general terms, the new symmetry between internationally used currencies made 'financial markets very sensitive to waves of anticipations, polarised alternatively by political and financial events' (Aglietta 1984).

These arbitrary movements reinforced constraints upon national monetary policies. The development of a whole literature using game theory (under the influence of Hamada, 1974) highlights the development of this interdependence.

When confronted with such uncertain situations, a country whose currency has no international role tends to preserve the autonomy of its domestic policy either by participating in the erection of monetary blocs, or by limiting the convertibility of its currency.

The creation in 1977 of the European Monetary System in order to reduce pressures on the monetary policies of the European countries induced by variations in American interest rates, represents a reaction of the first type. In fact, during the 1960s Mundell and McKinnon advocated the creation of a zone of fixed parities in a system of flexible exchange.

The permanency of exchange control measures (when the growth in trade by nature tends towards the dismantling of such measures) together with recommendations by economists such as Tobin (1978) in favour of some control on short-term movements of capital, represents a reaction of the second type.

In exchange regimes which permit the development of important imbalances or which cannot cope with sudden crises of confidence, restriction on free convertibility appears as one of the only means at the disposal of an isolated country which aims at preserving a degree of autonomy in the elaboration of its economic policy. No exchange regime can dispose of the plurality of currencies and the predominance of one of these currencies, such as the dollar. This is a continuous source of conflict (Brunhoff 1986). The attempt by monetarists such as Friedman to present a flexible exchange system as a means to merge the diversity of national currencies into one neutral international currency turned out to be irrelevant.

It is against this background, and in the face of imbalances in terms of employment or external payments, that the relative maintenance of control measures has to be seen, especially since in the postwar years organizations such as the International Monetary Fund or OECD have concurrently been aiming at the liberalization of trade and the convertibility of currencies.

This retention of restrictive practices is all the more remarkable in view of the fact that since the postwar period trade has been more multilateral and diversified than at any other time. In the more segmented world trade system illustrated by the three trade blocs – dollar, pound, gold – in the late 1930s, or in a trade system involving economies at very different stages of development, the limitations to free convertibility appear even more obvious. In fact, there is a strong relationship between circulation of commodities and means of payment. This link plays a decisive role in the evolution in exchange practices.

The Double Nature of Exchange Controls

Commercial and financial aspects of international economic relations are largely dissociated in a tradition which ex-post can be qualified as monetarist-inspired. Bergsten and Williamson (1983) attribute this bias mainly to the implicit (and erroneous) hypothesis of an automatic and regulating adjustment of parities. This dichotomous approach to international economic relations is also apparent in the distribution of roles between international institutions in the immediate postwar period. While the role of GATT consists in reducing barriers to trade, the role of the IMF consists of reducing limitations on the free convertibility of currencies (according to Article 1 of its 1944 Statute).

Yet it is clear that these two aspects – commercial and monetary – of international relations are linked. The orientation and the level of commercial exchange is influenced by financial conditions and conditions of payment. Reciprocally, the development of commercial exchange stimulates the extension of banking networks and financial innovation. In the case of so-called invisible trade, the two areas tend to merge.

This is evident in the case of exchanges of investment revenues realized externally. But it is also applicable to specialized services calling for the establishment of subsidiaries abroad (in the case of financial and insurance activities, consultancies, chambers of commerce etc.). The freedom of capital movements and the right to settle are thus pre-conditions for more advanced specialization by developed countries in the exchange of services. But these specialized services also play a strategic role in commercial exchanges: they are mainly produced by multinational firms and mainly used by other multinational firms which occupy a dominant position in world trade (see Clarimonte and Cavanagh 1984).

The liberalization of invisible trade is therefore not automatic since it implies ample liberalization of capital movements. Since the Tokyo Round the United States has led a campaign within GATT for the liberalization of invisible trade. OECD, which already in the 1950s defined a liberalization code for invisible trade, has noted its ineffectiveness, particularly in the case of the right to do business in a foreign country. Opposition to such policies is manifest in developing countries, where control over the exchange of services is considered strategic (in the early 1980s, liberalization in the area of transport is still a very touchy question).

To this basic complementarity between exchanges of goods and capital movements must be added an interdependence between the different forms of control on monetary exchange and on commercial transactions. Monetary authorities and private agents use the former in order to complement or to thwart the latter. To this end, juggling terms of payment goes hand in hand with fictional or falsified commercial transactions in order to avoid measures that control exchange. Quotas imposed on commercial transactions are sometimes aimed principally at reducing monetary transfers (as illustrated by French experience in the 1930s according to Einzig 1934).

So it is possible like Krueger (1978), Bhagwati (1978) and McKinnon (1979) to consider together all the different forms of controls on commercial and monetary relations between economies in order to define the different forms of foreign trade ‘regimes’. On the basis of national studies of practices which inhibit the freedom of trade (and exchange) in eleven developing countries, Krueger (1978) and Bhagwati (1978) have identified five (not necessarily consecutive) stages. The first stage is characterized by the establishment of generalized and undifferentiated control over imports; this kind of control often follows an unbearable balance of payments deficit. During the second stage there is a large differentiation in the measures of control according to the way in which imports are utilized. A third stage implements a reduction of direct controls (or quotas) together with a sharp devaluation of the national currency. Following this stage there is either a return to the situation described in the second stage or an attempt to liberalize trade by replacing some quotas by tariffs. Finally, the fifth stage is characterized by free convertibility of the national currency for current transactions, which now are only subject to customs duties. So it is only during

this last stage that the commercial and monetary aspects of foreign relations are dissociated.

To this must be added the possibility of controlling capital movements (and therefore of controlling exchange) that influence the trade dynamics mentioned above in respect to developed countries.

Krueger and Bhagwati measure the degree of liberalization of trade according to the disappearance of all types of quotas – despite an increase in customs duties – but nevertheless stress the damaging effects of restrictive practices. Such a position raises two paradoxes.

First, according to a classical theorem in international economics, quotas and customs dues have equivalent effects. Second, why are practices that are hardly 'optimal' so widespread? Krueger and Bhagwati clearly stress that conditions required by the theorem of equivalence so to speak never coincide. The distribution of import licences in the case of quotas, with endogenous effects on supply and demand, modifies resource allocation resulting from custom taxation. The authors also stress the great variety of distributive criteria which lead to distortions. Finally we must consider the question of the rationale for control measures which, according to McKinnon (1979), is hardly considered in the theoretical literature or in case studies. McKinnon brings up the question of political power created by controlling foreign trade in developing countries. Such discretionary power in the distribution of licenses favours 'clientisme', especially if the informal character of domestic activities limits the possibility for internal control. But the importance of such controls is principally derived from the possibility of selecting productive activities. An import licence ensures the viability of an enterprise, in turn giving it access to other limited resources such as capital. The absence or weakness of a financial market, capable of directing sufficient funds toward activities having priority, is according to McKinnon (1979) an essential factor in the origin of trade control practices. The volatility of domestic capital is a sign of this weakness in the financial market.

This explanation for protectionist policies appears to be applicable to the analysis of exchange controls practised in developed countries. The weakness or narrowness of financial markets seems to be one of the major causes for restrictions on the free circulation of currencies. This is indeed suggested by the history of exchange controls.

Past and Present Reasons for Exchange Control Policies

It is seldom asked what imperatives lead to the application of such obviously inconvenient exchange control practices, which simultaneously contain vast opportunities for fraud, potentially ad hoc measures and weak global coherence. Indeed, it is too often a question of faith on the part of opponents of exchange control, who blame a pernicious propensity to bureaucratize to explain the choice of easy direct controls in the place of rigorous but unpopular policies. Their position is not without foundation. But it remains secondary in the face of the risks involved in massive movements of capital. The financial pressures mentioned by McKinnon (1979) do not constitute a marginal phenomenon. No financial market is safe from the flight of capital, feeding itself rapidly to the extent of changing the policies pursued or putting an end to the free circulation of capital. It has been stressed that standard exchange systems do not have the stabilizing effects necessary to prevent speculative moves. On the contrary, there is clear evidence that orthodox exchange systems allow for the maintenance of 'over-evaluation' or 'under-evaluation' of parities. It is within these limits to exchange regimes that major necessary conditions for restrictive practices must be found.

The importance of financial markets and the voluntarist and innovative character of current economic policies constitute sufficient conditions for the elaboration of these control policies. Here margins are fixed by the amplitude and stability of the domestic financial market; the need for autonomy is defined by the type of policies pursued.

The history of exchange controls emphasizes this double aspect: the impact of current economic policies, and the importance of the financial market with its international links.

One of the first experiences of exchange control in modern times took place in 17th-century England. The Royal Exchange was then introduced, together with the Navigation Acts, in order to secure a basis for growing British power in the face of the decline of Spain and the Netherlands, at a time when the City did not yet carry the weight required for such a rise to power. In Germany in the 1930s, rigorous exchange controls were due to the autarkic tendencies pursued by the national-socialist government. Yet in France, the introduction of such controls after 1936 when the tripartite alliance (with the US and Britain) had failed, calls into question the ability of the financial market to withstand speculative moves such as those following the 1930s crisis.

In the immediate postwar period, generalized controls in Europe revealed the fragility of financial markets in a period when reconstruction absorbed most resources. The progressive and partial liberalization of capital movements (see Einzig 1962) had to rely on massive and conditional Marshall Plan aid and on the regulatory action of institutions such as the IMF, OECD and GATT.

This attempt to insulate a fragile financial market from competition by foreign capital (without the evolution of the rates of exchange correcting this distortion) can explain the relative continuity of restrictions on the movement of capital in France (see Claassen and Wyplosz 1982).

In the growing integration of financial markets there might be seen a stabilizing factor which enables the opening up of relevant economies to the free circulation of capital. The development of new information techniques in the area of communication has largely contributed to the acceleration of this integration of financial markets (initiated in the 1930s by the opening of the first transatlantic communication line): a world market in currency transactions was established in the 1970s; a securities market was in turn established during the 1980s. But the extension of these information networks has also considerably increased the amplitude and scope for short-term speculative movements, thereby increasing global instability in the financial international system. The resulting prospect of international crisis renders unlikely a definite liberalization of monetary movements. If crises can break out more rapidly than in the past, the possibility of introducing rapid and efficient exchange control can play an important role in deterring speculation and the development of a major exchange crisis.

Exchange Market Pressure

Henk Jager and Franc Klaassen

Abstract

Currencies can be under severe pressure in the foreign exchange market, but in a fixed (or managed) exchange rate regime that is not fully visible via the change in the exchange rate. Exchange market pressure (EMP) is a concept developed to nevertheless measure the pressure in such cases. This article describes EMP and its measurement.

Keywords

Central bank; Currency crisis; Exchange rate regime; Interest rate; Intervention; Monetary policy

Definition and Relevance

Exchange market pressure (EMP) on a currency is its excess supply in the foreign exchange market if monetary authorities did not try to influence the exchange rate; this excess supply is expressed in the relative depreciation required to remove it.

Under a floating exchange rate the monetary authorities (usually the central bank) are indeed passive to the exchange rate, so EMP is the actual depreciation. In any other regime the monetary authorities ward off depreciation by policy measures, such as setting a higher official interest rate, or buying domestic currency in the foreign exchange (forex) market. Then the actual depreciation does not coincide with EMP, and correct EMP measurement requires adding the depreciation-counteracting policy actions. The question in the EMP literature, originating from Girton and Roper (1977), is how to do that.

Focusing on EMP rather than sheer exchange rate changes is practically relevant, as 82 per cent of the world's currencies have some sort of peg or managed float (IMF 2009). A first application of EMP exploits the fact that EMP covers the whole spectrum of exchange rate regimes, from floating to fixed. As exchange rate and balance of payment theories essentially focus on tensions in the forex market, under either floating or fixed rates, EMP can integrate both types of theory. Second, EMP can be more relevant than exchange rate changes as a determinant of other phenomena. For instance, IMF (2007) takes EMP to study adequate policy responses to surges in capital inflows. Since EMP better signals forex tensions than exchange rate changes, EMP also helps speculators to find profit opportunities, and policy makers to take timely moves to counteract contagion from other countries.

Measure

A crucial element in the EMP definition is that EMP is a counterfactual concept. That is, it is not the actual situation, where the central bank may ward off pressure, that matters, but the hypothetical situation where the central bank (unexpectedly) does not try to influence the exchange rate, as stressed in Weymark (1995). This makes EMP unobservable (except for a pure float). However, we do observe the policy responses to pressure, besides the exchange rate change. This provides an opportunity to quantify EMP in an indirect way.

One typically includes three pressure-offsetting variables, namely the exchange rate, interest rate, and official forex intervention, though some authors exclude the interest rate. Let s_t denote the (logarithm of the) nominal spot exchange rate at time t, defined as the domestic currency price of one unit of foreign currency. The interest rate i_t is supposed to summarize the use of all money market instruments by the central bank, so it is typically a short-term rate. Finally, c_t is the central bank purchase of domestic currency in the forex market, usually approximated by the decrease in official reserves scaled by a proxy of forex market turnover. This all concerns policy of the domestic central bank. For simplicity, the foreign central bank is assumed not to try to affect the exchange rate.

The pressure-offsetting variables lead to EMP measure

$$EMP_t = \Delta s_t + w_i \tilde{i}_t + w_c \tilde{c}_t,$$

where Δ is the first-difference operator, Δs_t, $\tilde{i}_t$, and $\tilde{c}_t$ are the EMP components based on s_t, i_t and c_t, to be specified below, and w_i and w_c are the EMP weights. This measure does not depend on the sources of pressure, nor is a model of exchange rate determination needed to derive it, as Klaassen and Jager (2008) show using just a few assumptions.

Components

The presence of Δs_t is logical given the EMP definition. It has weight unity, so that indeed the EMP measure is in units of depreciation and coincides with the actual depreciation in case of a floating exchange rate regime. A zero counterfactual official forex intervention implies $\tilde{c}_t = c_t$.

The interest rate component $\tilde{i}_t$ differs across studies. The traditional choice is $\tilde{i}_t = \Delta i_t = i_t - i_{t-1}$, which can essentially be traced back to Girton and Roper (1977). It implies that during a speculative attack where the interest rate is set at, say, 100 per cent for two consecutive days, $\Delta i_t = 0$ on day two, so this EMP component would suggest there is no pressure on that day.

The underlying reason for this counterintuitive result is that in the counterfactual, as prescribed by the EMP definition, the interest rate is not i_{t-1}. The true counterfactual rate is the one the central bank would choose to achieve other targets than the exchange rate, usually domestic targets, such as inflation and output. Therefore, Klaassen and Jager (2008) introduce i_t^d as the counterfactual interest rate and $\tilde{i}_t = i_t - i_t^d$ as a component to obtain an EMP measure that is consistent with the EMP definition. A natural proxy for i_t^d is a Taylor-type rule, but in practice simply taking the foreign interest rate (possibly adjusted by the inflation differential) can be a satisfying approximation.

Weights

The weights w_i and w_c in the EMP measure above state how effective the components are in taking away pressure. The weights are assumed to be positive, but they are not observed.

One way to quantify the weights is by a structural economic model in the spirit of Girton and Roper (1977) and Weymark (1995). A popular choice is a model based on the monetary model of exchange rate determination. The advantage is that the weights have a clear economic meaning, which is useful to the extent that the specification of the model is correct.

Another popular approach is the volatility-smoothing method due to Eichengreen et al. (1996). Here a weight is estimated by the ratio of the sample standard deviation of Δs_t to that of the component involved, so that no component dominates the others in terms of volatility. These weights no longer depend on a structural model and are easier to compute, though they now reflect not only the effectiveness of the monetary policy instruments – as they should – but also how intensively the instruments are used.

Exchange Rate Dynamics

Nelson C. Mark

Abstract

Exchange-rate dynamics refers to the response path of the exchange rate following the revelation of some economic shock when the country in question operates under a pure flexible exchange-rate system. The issue attracts research attention because of the volatile nature of the exchange rate and the belief that the exchange rate may affect the allocation of resources across countries and over time. If observed exchange-rate dynamics cannot be shown to have a rational basis, efficiency will suffer from decisions made conditioned on disequilibrium values of the exchange rate.

Exchange-rate dynamics refers to the response path of the exchange rate following the revelation of some economic shock (news) when the country in question operates under a pure flexible exchange-rate system.

The topic has attracted research attention since 1973 when the industrialized world abandoned the Bretton Woods system of fixed exchange rates. The initial experience in the 1970s with this new exchange-rate system surprised economists along two dimensions. The first surprise was that exchange-rate returns turned out to be much more volatile than expected. This volatility, which is similar in magnitude to the volatility of stock returns, is much higher than the volatility of macroeconomic fundamentals such as the growth rate of money or income. The second surprise was the very high persistence of the exchange rate. The logarithm of the exchange rate evolves approximately as a random walk so that all shocks appear to have a permanent effect on the exchange rate level. As a result, percentage changes of the exchange rate (returns) over short horizons are nearly unpredictable. These features of quarterly data from 1973Q1 to 2002Q1 are illustrated in Table 1.

Academic and policy interest in understanding exchange-rate dynamics stems from the belief that the exchange rate affects the current account, a country's international indebtedness, and the rate of capital formation, and is therefore an important

Exchange Rate Dynamics, Table 1 Volatility (sample standard deviation) and autocorrelations of selected currencies, and other variables, 1973–2002

	DM	£	¥	S&P	M1	US GDP	T-Bill
Volatility	23.384	25.040	20.660	31.719	12.200	3.384	3.118

macroeconomic variable that has real allocative implications for the open economy. An important question is whether observed exchange-rate dynamics have a rational basis or if it reflects an irrational overreaction to shocks. If it is the latter, economic efficiency may be compromised when allocative decisions are made conditional on disequilibrium or non-fundamental values of the exchange rate.

Due to limited experience with flexible exchange rates combined with high degrees of capital mobility during the Bretton Woods era, the volatile nature of exchange rates was difficult to anticipate. Moreover, the generally accepted framework at the time, for modeling the open economy, was the static Mundell–Fleming model which was poorly equipped for understanding these issues. The immediate post Bretton Woods experience stimulated a large body of theoretical work aimed at improved modelling the exchange rate. This work culminated with Dornbusch's (1976) celebrated exchange-rate overshooting model which provided a rational explanation for high exchange-rate volatility in the presence of relatively stable macroeconomic fundamentals. The overshooting model is a deterministic perfect-foresight dynamic generalization of Mundell–Fleming. The critical features are the differential speeds of adjustment between the goods (gradual) and asset (immediate) markets, uncovered interest parity, and the central importance of monetary shocks as the underlying source of uncertainty. Subsequent econometric work and quantitative analyses of dynamic general equilibrium models known as the 'new open-economy macroeconomics' suggest that an exact understanding of the mechanism that generates overshooting and excess exchange-rate volatility remains elusive.

Exchange-Rate Overshooting

Let e denote the natural logarithm of the home-currency price of the foreign currency. Under this definition of the nominal exchange rate, an increase in e means the home currency has weakened. Let the forward-looking steady state log exchange rate be $\bar{e}$. Assume that commodity prices are sticky, output is fixed, real money demand is inversely related to the interest rate i, financial capital is perfectly

internationally mobile and domestic and foreign currency assets are perfect substitutes. In a deterministic setting, the perfect foresight instantaneous change in the exchange rate e can be shown to be proportional to the current exchange-rate gap $(\bar{e} - e)$. Let the exogenous foreign interest rate be i^*. Then uncovered interest parity, which says that an excess yield on domestic nominal assets is offset by an expected capital loss on the domestic currency through movements in the exchange rate, can be expressed as

$$i - i^* = \theta(\bar{e} - e).$$

This is the asset market equilibrium condition.

Now consider a one-time permanent surprise increase of one per cent in the home country's

money supply. At the instant the shock is revealed, $\overline{e}$ increases by 0.01 in accordance with long-run monetary neutrality. Noting that the price-level is instantaneously fixed, the monetary shock creates a liquidity effect that lowers the interest rate i. To maintain uncovered interest parity, the instantaneous exchange rate e must increase by more than the 0.01 increase in $\overline{e}$, thereby 'overshooting' its long-run steady state value. Thus, the short-run variability of the exchange rate is seen to exceed the variability of the macroeconomic fundamentals in response to monetary shocks. In order to provide a general explanation for exchange rate volatility, however, it must be the case that nominal shocks are relatively important drivers of aggregate uncertainty because the model does not generate overshooting in response to real shocks such as shifts in the aggregate expenditure function. The overshooting model represented a significant contribution by giving an explanation for high exchange-rate variability in the context of a rational equilibrium model.

In stochastic generalizations of this model, as considered by Mussa (1982) and Obstfeld (1985), one would say that the exchange rate exhibits excess volatility in the sense that the volatility of the exchange rate exceeds that of the macroeconomic fundamentals (money supply and income). Moreover, in the stochastic environment the equilibrium exchange rate has a present-value representation that discounts the expected future flow of the macroeconomic fundamentals. The analogy to the present-value model of stock and bond pricing rationalizes why the exchange rate and other asset prices have many common properties.

Emerging Doubts About the Overshooting Mechanism

Doubts about the precise mechanism that generates overshooting have been raised in vector autoregression (VAR) studies. Eichenbaum and Evans (1995) modelled monetary shocks both as innovations to non-borrowed reserves and as innovations in the federal funds rate, and used a recursive ordering strategy to identify the VAR. Following a monetary shock, their impulse–response analysis did now show the immediate overshooting and the subsequent exponential decay of the exchange rate predicted by the overshooting model. Instead, they found a 'hump-shaped' response in the exchange rate: while it did overshoot the long-run equilibrium value, it did so gradually. This so-called 'delayed overshooting' result was confirmed in subsequent studies with structural VARs, such as Clarida and Gali (1994).

While such VAR studies create a dilemma for the overshooting mechanism, there is the possibility that the appearance of delayed overshooting was created by imposing false restrictions in the identification of VARs. Faust and Rogers (2003) argue that restrictions implied by recursive orderings employed in VAR analyses are implausible because they rule out contemporaneous responses of many important variables, such as the foreign interest rate, to domestic monetary policy shocks. Experimenting with alternative sets of more plausible restrictions on contemporaneous interactions, they find that immediate overshooting sometimes occurs and sometimes does not. In those situations where immediate overshooting does occur, they find that it is driven by deviations in uncovered interest parity. The implication then is that, if immediate overshooting is actually present in the data, it does not appear to be generated by the mechanism articulated by Dornbusch.

The preceding development of overshooting was discussed in terms of the nominal exchange rate, but the qualitative predictions would not be affected if it were recast in terms of the real exchange rate. At this point, we see that three pillars of the overshooting explanation of exchange-rate volatility are sticky nominal goods prices, uncovered interest parity, and the principal importance of monetary shocks. The question of whether prices are sticky is a tough problem that macroeconomists struggle to answer. Some international macroeconomic evidence has emerged to suggest that sticky goods prices are an important feature of the data. It has been pointed out by Mussa (1986) that the real exchange rate eP^*/P is much more volatile under flexible exchange rates than under fixed exchange rates. When the exchange rate is flexible, the correlation between nominal and real exchange rate movements is

exceedingly high over relatively short horizons, say, from a month to a year (except in very high-inflation countries). It has also been observed that international violations of the law of one price are more severe than within-country violations. Engel and Rogers (1996) find that the volatility of the difference between the log price of a particular good sampled in two locations is much higher if the sample points are in different countries than if they are within the same country.

Exchange-Rate Dynamics in 'New Open-Economy Macroeconomic' Models

The exchange-rate models of the 1970s and 1980s were typically built from sets of ad hoc macroeconomic relations that lack rigorous microeconomic foundations. As exchange-rate models have evolved towards dynamic general equilibrium analysis, the research continues to try to understand the necessary conditions for an equilibrium rational-expectations monetary model to explain observed exchange-rate volatility and persistence. A major vein of this work is done within the 'new open-economy macroeconomics' (NOEM) class of theories that features rational optimizing agents, imperfect competition and sticky goods prices in a dynamic general equilibrium open-economy setting.

The NOEM began with the Obstfeld and Rogoff (1995) Redux model. Money is introduced through the utility function, and agents maximize expected lifetime utility defined over consumption, leisure and real money balances. Goods prices are set one period in advance by monopolistically competitive firms that produce output with labour but no physical capital. The precise way in which the exporting firm sets the price of output for foreign and domestic buyers has significant implications for exchange-rate dynamics.

In the Redux model, firms engage in 'producer-currency pricing'. That is, an exporter will set the domestic price of the good at P and foreigners pay P/e units of the foreign currency. While P is fixed for the period, e is not, so a within-period change in the nominal exchange rate will alter the relative price between home and foreign goods. This is the basis of the 'expenditure-switching' effect of the exchange rate stressed in the Mundell–Fleming model. Even though goods prices are sticky, the Redux model generates the surprising result that a monetary shock causes the nominal exchange rate to jump immediately to its long-run value. In other words, there is no overshooting or excess volatility of the exchange rate in the Redux model.

An alternative to producer-currency pricing is 'pricing-to-market' (also known as 'local-currency pricing'). In this scenario, segmentation between the domestic and foreign goods markets allows firms to set a foreign currency export price that is different from the domestic currency price of the good. Here, foreigners pay the pre-set price P^* and the exporting firm receives eP^* units of home currency. Within-period changes in the exchange rate affect firm revenues but not the relative price between imported and domestic goods. Betts and Devereux (2000) apply this idea in modifying the Redux model and find that increasing the fraction of firms that price-to-market reduces the strength of the expenditure-switching effect, which attenuates the allocative role of the exchange rate. As a result, a larger change in the exchange rate is required to restore equilibrium following a monetary shock. Accordingly, if the degree of pricing-to-market is sufficiently high, the overshooting result can be restored.

Some NOEM modellers ask their models to quantitatively match the data. A quantitative analysis of the exchange-rate dynamics implied by an NOEM model might suppose that agents operate in a complete markets setting where they can trade a full set of state-contingent claims, which allows complete international risk-sharing in a model. Production requires labour and durable physical capital. There is a final good that is not traded internationally and produced in a competitive industry. Intermediate goods are traded internationally and produced by monopolistically competitive price-setting firms that change prices according to a staggered price-setting rule. The period utility is defined over consumption C_t, real money balances M_t/P_t, and leisure L_t. With asterisks denoting foreign country variables, the

exchange rate is determined by the equilibrium risk-sharing condition

$$\frac{E_t P_t^*}{P_t} = \Gamma \frac{U_{c^*}\left(C_t^*, M_t^*/P_t^*, L_t^*\right)}{U_c(C_t, M_t/P_t, L_t)}.$$

where E_t is the nominal exchange rate level and U_c is the marginal utility of consumption. The real exchange rate is proportional to the ratio of foreign to domestic marginal utility. If utility is separable in its arguments and has the constant relative risk-aversion form, the real exchange rate will be proportional to relative consumption levels in the two countries and the factor of proportionality Γ will be increasing in the coefficient of relative risk aversion. This exchange-rate pricing condition is invariant to whether commodity prices are sticky or flexible. The question is under what conditions will the model generate consumption responses to monetary shocks to create exchange-rate dynamics like those found in the data.

Chari, Kehoe and McGrattan (2002) calibrate this two-country model to the United States and an aggregate 'European' country which they employ to simulate model-implied observations of the endogenous variables. Using the staggered-price setting rule of Taylor (1999), they find that firms cannot be allowed to change prices more frequently than once a year and that the coefficient of relative risk aversion must be at least 5 in order for the model-generated real exchange rate to match the persistence and volatility found in the data. While these are not unreasonable conditions, the degrees of price stickiness and of risk aversion required both seem to be on the high side. Kollman (2001), on the other hand, is able to obtain exchange-rate overshooting with a relative risk-aversion coefficient of 2, but uses the Calvo (1983) rule for price setting.

While this line of work shows that the interaction of monetary shocks and sticky prices is able to explain volatile and persistent exchange-rate behaviour, the models often generate counterfactual predictions for other dimensions of the data. One of these counterfactuals, obtained from the exchange-rate determination equation, is that the real exchange rate should be nearly perfectly correlated with relative foreign-to-home consumption levels. In the data, however, the real exchange rate and relative consumption levels are uncorrelated – a problem known as the Backus and Smith (1993) puzzle.

The restrictive feature of models with complete markets is the international risk-sharing condition which constrains the extent to which the exchange rate can move. One might think that limiting the menu of tradable assets and working in an incomplete markets environment might loosen up this restriction. A common specification of an incomplete markets environment is to allow only a non-state-contingent bond to be internationally traded. However, as demonstrated by Baxter and Crucini (1995), the quantitative properties of dynamic general equilibrium models are little affected when full risk sharing is replaced by this version of incomplete markets, especially when shocks to the environment are not permanent. The reason is that uncovered interest parity replaces the risk-sharing condition in determining the exchange rate, so relatively smooth interest rates replace smooth consumption levels in limiting the range of exchange-rate movements.

Accordingly, studies by Devereux and Engel (2002), Kollman (2001) and Duarte and Stockman (2005) of exchange-rate dynamics in dynamic general equilibrium models under incomplete markets find it necessary to allow exogenous deviations from uncovered interest parity in order to explain exchange-rate volatility in the presence of smooth fundamentals. There is ample empirical work, surveyed by Hodrick (1987), Engel (1996), and Lewis (1995), to justify these violations, and theoretical work by Mark and Wu (1998) and Jeanne and Rose (2002) gives an explanation for the deviations through participation of noise traders in the foreign-exchange market.

High exchange-rate volatility, persistence, and overshooting can be generated from fully specified dynamic stochastic general equilibrium models. However, a fully convincing story about exchange-rate dynamics remains elusive because an accepted model that provides reasonably good ability to account for all of the salient features of the data is not yet available.

Exchange Rate Exposure

Kathryn M. E. Dominguez and Linda L. Tesar

Abstract

Exchange rate exposure describes the influence of exchange rate movements on the value of a firm or sector of the economy. Exposure is typically measured as the correlation of firm or industry stock returns and exchange rate changes in the context of a market model. Exposure appears to be most prevalent in firms that are small (these are less likely to engage in hedging activities) or involved in international activities. While studies have linked *ex ante* exchange rate risk with firm investment strategies, it has proven difficult to

identify the *ex post* consequences of exposure on firm or industry behaviour.

Exchange rate exposure measures the extent to which firm value is influenced by exchange rate movements. Narrow definitions of exchange rate exposure, such as transaction exposure, translations exposure, or operating exposure, focus on the effect of the exchange rate on specific components of a firm's balance sheet or on different types of transactions. More broadly, economists use the term 'economic exposure' to describe the impact of exchange rate movements on a firm or a sector of the economy. A firm's 'exposure' could be measured as the responsiveness of profits, cash flow, operating costs, total assets or liabilities, markups or even wage-setting behaviour to fluctuations in the exchange rate.

If one has detailed information about a firm's operations, it may be possible to trace the effect of exchange rate shifts on a specific line item in the firm's accounting data, with other factors controlled for. More generally, however, measures of exchange rate exposure involve an indirect test of the link between the exchange rate and a firm's stock return, where the return is taken as a measure of the firm's profitability. Under the capital asset pricing model (CAPM), the expected risk premium on a company's share price is proportional to its covariance with the market portfolio. In theory, investors will require a return only on the non-diversifiable portion of firm risk and, if the market return captures all systematic risk, no variable other than the market return should play a role in determining asset returns. Therefore, a test for exchange rate exposure involves including the change in the exchange rate on the right-hand side of a standard CAPM regression and testing whether its coefficient is significantly different than zero (Adler and Dumas 1984):

$$R_{i,t} = \beta_{0,i} + \beta_{1,i} R_{m,t} + \beta_{2,i} \Delta s_t + \varepsilon_{i,t} \qquad (1)$$

where $R_{i,t}$ is the return on firm i at time t, $R_{m,t}$ is the return on the market portfolio, $\beta_{1,i}$ is the firm's beta, Δs_t is the change in the relevant exchange rate and $\beta_{2,i}$ measures a firm's exposure to exchange rate movements after the overall market's exposure to currency fluctuations is taken into account. If $\beta_{2,i}$ is zero, this implies that firm i has the same exchange rate exposure as the market portfolio (not necessarily that the firm has no exposure). Alternatively, if one rejects the hypothesis that $\beta_{2,i}$ is, on average, zero, this indicates that the firm is more exposed to exchange rate movements than the market. Note that the interpretation of $\beta_{2,i}$ as a measure of exposure is conditional on Eq. 1 being the 'true' model of asset returns. Evidence that $\beta_{2,i}$ is non-zero can be interpreted as evidence against the joint hypothesis that the CAPM holds (that is, the market efficiently prices systematic risk) and that exchange rate risk is unimportant for stock returns.

An alternative approach is to measure total exposure, or the unconditional correlation of exchange rates and returns that would involve omitting the market return as an explanatory variable in Eq. 1. The advantages to measuring total exposure are that it allows one to measure the exposure of all firms as a group rather than individual firms relative to the group average, and it requires no assumption about the validity of the CAPM. The disadvantage of total exposure is that it does not allow one to distinguish between the direct effect of exchange rate changes and the effects of macroeconomic shocks that simultaneously affect firm value and exchange rates (which we assume are captured in Eq. 1 by the market return).

Predicting which firms are likely to be affected by changes in the exchange rate and the direction that exposure might take can be quite complicated. There are a number of channels through which the exchange rate might affect the profitability of a firm. Firms that export to foreign markets may benefit from a depreciation of the

local currency if their products become more affordable to foreign consumers. On the other hand, firms that rely on imported intermediate products may see their profits shrink as a consequence of increasing costs of production. Firms with foreign subsidiaries may shift activities across national boundaries, taking on exchange rate risk to take advantage of tax differentials. Firms that do no international business may be influenced indirectly by foreign competition. Furthermore, firms in the non-traded as well as the traded sectors of the economy compete for factors of production, whose returns may be affected by changes in the exchange rate.

A number of specific issues arise when implementing Eq. 1 as a test for exchange rate exposure. First, one must identify the relevant exchange rate. Many studies use a trade-weighted exchange rate to measure exposure. The problem with using a trade-weighted basket of currencies in exposure tests is that the results lack power if the nature of firm exposure does not correspond to the exchange rates (and the relative weights) included in the basket. More generally, one should expect variation in individual firm and industry exposure to various exchange rates. Dominguez and Tesar (2001a) find that any test that restricts the measurement of exposure to one exchange rate (whether it be a trade-weighted rate or a bilateral rate) is likely to be biased downward. Exposure may also be a function of horizon. It may be that firms can use financial derivatives to hedge exchange rate risk in the short run, but remain exposed to low-frequency movements in exchange rates over long horizons. Dominguez and Tesar (2006) find that exposure generally increases with return horizon.

A second issue is sample selection – which firms should be included in empirical tests for exposure. Much of the literature has focused on exposure in multinational firms (Jorion 1990; He and Ng 1998), or in firms that actively engage in international trade (Bodnar et al. 2002). However, there are good reasons to think that exposure will not be limited to these firms. Dominguez and Tesar (2001b) find that firms that engage in greater trade exhibit *lower* degrees of exposure, reflecting the fact that they are also the most aware of exchange-rate risk and, therefore, the most likely to hedge their exposure. Exposure may also be affected by the competitive structure at the industry level. Less competitive industries with higher markups can adjust prices in response to exchange rates, and the impact on profitability and returns will thus be smaller. Allyanis and Ihrig (2001) show that the extent of exposure varies systematically with the extent of industry-level markups.

A third issue that arises in tests for exchange rate exposure is the specification of the market index. Empirical tests of the standard CAPM model generally include a country-specific value-weighted market return to proxy for 'the market'. Value-weighted market returns are likely to be dominated by large firms that are more likely to be multinational or export-oriented, and are more likely than other firms to experience negative cash flow reactions to home currency appreciations. In a world of perfectly integrated capital markets the 'market return' should be proxied by a global portfolio. Dominguez and Tesar (2006) sort out the impact of the choice of market index on exposure for a sample of firms in eight (non-US) markets and find little difference in estimated exposure level using value-weighted and equal-weighted indices, but find a significant increase in measured exposure using a global index. Part of the explanation for this is that the global index generally does a poor job of explaining returns, so that more firms appear to be exposed simply because the exchange rate is picking up more of the variability in returns, and the (global) market index is picking up substantially less.

A final issue is whether exposure is predictable. The standard way to test this is to run a second-stage regression that takes the estimated exposure betas from Eq. 1 and regresses these on a variety of potential explanatory variables. Using this approach Dominguez and Tesar (2006) find that exposure is more prevalent in small (rather than large or medium-sized) firms, and in firms engaged in international activities (measured by multinational status, holdings of international assets, and foreign sales).

Once one has identified a set of firms that are exposed to exchange rate risk, the question remains whether such exposure affects firm behaviour in

some way, such as its level of investment or market entry. In general, it has proven difficult to identify a link between *ex post* exposure (as measured by estimates of exposure in Eq. 1) and such economic outcomes. Numerous studies, however, have linked firm strategies for handling exchange rate risk *ex ante* with their investment decisions in domestic and foreign markets.

Exchange Rate Target Zones

John Driffill

Abstract

A target zone attempts to limit the movement of an exchange rate, avoiding the pitfalls of both a pegged rate and a freely floating rate. The European Monetary System was the prime example. An elegant model of Paul Krugman demonstrates that in theory a target zone does indeed stabilize an exchange rate. But in practice it has been substantially rejected empirically. Williamson's 'crawling bands' around a 'fundamental equilibrium exchange rate' develop the concept. Target zones survive among candidates for membership of the Eurozone who take part in the Exchange Rate Mechanism mark II.

An exchange rate target zone is a scheme intended to limit the flexibility of an exchange rate without going as far as fixing or pegging the value of one currency against another. It is a band, or zone, of values for the exchange rate, around a central or target rate. Within the zone, the exchange rate is allowed to fluctuate freely without any intervention from the authorities or, at least, with less intervention than there is elsewhere. At the edge of the band, and outside, if the rate strays there, there is more vigorous intervention to keep the rate within, or return it to, the band. There are many varieties of target zone. The edges may be hard or soft. It may be defined in terms of nominal or real exchange rates. The central rate – the target – may be either constant over time, possibly with provision for occasional discrete changes; or it may be adjusted continuously. The bands may be narrow or wide.

The most celebrated and ambitious target zones were those introduced in 1979 by the European Monetary System (EMS). They operated until the end of 1998. Under the EMS, member states were initially required to keep their bilateral exchange rates within a band of ±2.25 per cent around a grid of central parities (Giavazzi and Giovannini 1989). They were required to use unlimited intervention in the foreign exchange markets to defend the bands if an exchange rate strayed to the edge. Member countries could adjust central parities occasionally by mutual agreement when perceived misalignments had built up. The system evolved over time. As capital controls were progressively removed, orderly realignments became more difficult to manage. The system became less flexible, notably after 1987. The gradual movement towards complete fixity of exchange rates, intended to prevail under Economic and Monetary Union, was thrown off course by massive speculative attacks in September 1992 and August 1993. The system was unable to withstand them and the bands were widened to 15 per cent. But they were subsequently narrowed again and the EMS gave way to the euro on the 1 January 1999.

The use of target zones sprang from a desire to avoid the pitfalls of fixed rates and free floating. Under the fixed exchange rates of the Bretton Woods System (1944–73), exchange rate misalignments had become progressively worse as inflation rates diverged, and weak currency countries put off devaluation, deterred by costly speculation. Under floating exchange rates during the 1970s, exchange rates fluctuated excessively, unrelated to fundamentals like relative price levels and current accounts. The 'disconnect' between exchange rates and economic fundamentals has been confirmed by widespread experience and has become a central tenet of international macroeconomics.

The EMS was intended to allow exchange rates to offset inflation differentials among members. Realignments were to be sufficiently timely to avoid giving the markets a one-way bet. The bands were intended to enable markets to determine exchange rate movements without official intervention for most of the time, at the same as discouraging destabilizing speculation.

The questions of how target zones might work in theory, whether they worked in practice as the theory predicted, and whether they did indeed cut exchange fluctuations, have generated enormous amounts of research.

The key theoretical contribution is that of Krugman (1991). He showed that a fully credible target zone would reduce the volatility of an exchange rate and reduce its sensitivity to fundamentals. His theoretical model assumes a monetary theory of the exchange rate for a small open economy in a world of perfectly flexible prices and perfect capital mobility, in which purchasing power parity and uncovered interest parity hold good. Then the log of the exchange rate (e) can be expressed as a function its own anticipated rate of change over time ($E_t(de)/dt$) and a driving fundamental (f)

$$e = f + \alpha E_t(de)/dt$$

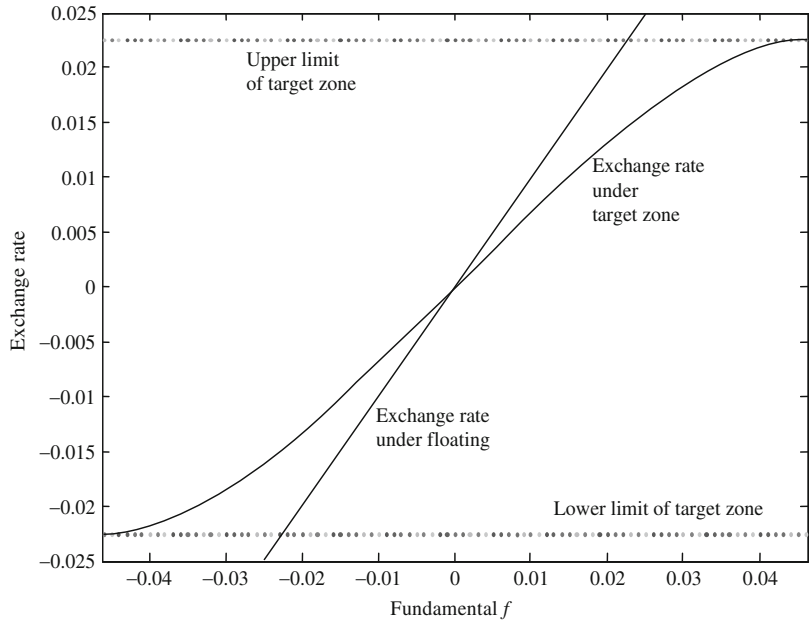
The parameter α denotes the semi-elasticity of money demand with respect to the interest rate. The fundamental reflects money supply and demand. He considers a stochastic model in continuous time, in which the fundamental (f) follows Brownian motion, the continuous-time analogue of a random walk. That is

$$df = \sigma dz$$

where dz is the innovation in a standard Wiener process, and σ is the variance of the innovation in the fundamental per unit time. dz has mean zero and variance $E(dz^2) = dt$. When the exchange rate is allowed to float freely, the exchange rate will be a linear function of the fundamental

$$e = f.$$

But, when a target zone limits movements of the exchange rate, this solution does not apply. Assume for simplicity that under the target zone the central parity for the logarithm of the exchange rate is equal to zero and the limits of the zone are $\bar{e}$ and $\underline{e}$. Further assume that the zone is symmetrical and $\bar{e} = -\underline{e}$. Using stochastic calculus and methods widely used in the theory of



Exchange Rate Target Zones, Fig. 1 *Source*: Krugman (1991)

options pricing, Krugman shows that the exchange rate is related to the driving fundamental by the relationship

$$e = f + A(\exp(\xi f) - \exp(-\xi f))$$

where

$$\xi = \sqrt{\frac{2}{\sigma^2 \alpha}}.$$

The constant A is such that at the top and bottom of the band the value-matching conditions

$$\overline{e} = \overline{f} + A\left(\exp\left(\xi \overline{f}\right) - \exp\left(-\xi \overline{f}\right)\right)$$

and

$$\underline{e} = \underline{f} + A\left(\exp\left(\xi \underline{f}\right) - \exp\left(-\xi \underline{f}\right)\right)$$

hold, and the smooth pasting conditions also hold. These require that the derivative of the exchange rate with respect to the fundamental at the edges of the band is equal to zero. Viz.

$$1 + A\left(\xi \exp\left(\xi \overline{f}\right) + \xi \exp\left(-\xi \overline{f}\right)\right) = 0$$

and

$$1 + A\left(\xi \exp\left(\xi \underline{f}\right) + \xi \exp\left(-\xi \underline{f}\right)\right) = 0.$$

From these conditions the value of the constant A, and the value of the fundamental at the limits of the band ($\overline{f} = -\underline{f}$), can be determined. The value of the parameter A that emerges from this analysis is negative. Thus the value of the exchange rate, corresponding to any particular value of the fundamental, is closer to the parity rate under a target zone than it would be under a free float.

Krugman's analysis establishes that the exchange rate within the target zone enjoys the 'bias in the band' or the 'honeymoon effect'. The relationship between the fundamental and the exchange rate in the target zone is an S-shaped curve. It is flatter everywhere than the relationship under a free float, which is a 45 degree line. The perfectly credible commitment of the authorities to intervene, should the exchange rate ever reach the edge of the band, so as to prevent any movement beyond it, discourages deviations from the central parity even without any actual intervention. It is illustrated in Fig. 1.

This elegant theory has very strong empirical predictions. Three predictions that do not rely on any assumptions about the value of the unobserved fundamentals are as follows. First, the exchange rate should spend a lot of time near the edges of the band, and relatively little near the centre. The unconditional distribution of the fundamental within the band is uniform, and the distribution of the exchange rate is U-shaped. Second, the uncovered interest parity condition implies that, when the exchange rate is strong (e is close to $\underline{e}$) and thus likely to weaken, the domestic interest rate should exceed the foreign rate, while when the exchange rate is weak, the domestic interest rate should be relatively low. And third, the converse of the second prediction, at any point in time the expected future exchange rate implied by the uncovered interest parity condition

$$E_t(e_{t+dt}) = e_t + \left(r_t - r_t^*\right)dt$$

(r_t is the domestic instantaneous nominal interest rate and r_t^* the foreign one) should lie within the band.

Unfortunately, all three of these predictions are comprehensively rejected by empirical evidence, of which a great deal has been accumulated. The work of Flood et al. (1991) led the way in this. They and many subsequent studies have found that exchange rates had tended to be concentrated near the middle of the band, not at the edges, as predicted. They also found that, when the exchange rate was weak, there was no tendency for the interest rate to be relatively low. The expected future exchange rate implied by uncovered interest parity was found to spend a great deal of time outside the band, suggesting a lack of credibility of the target zone.

Direct tests of the relationship between the exchange rate and the fundamental driving variable have generally found very little evidence of non-linearity or Sshapedness. There appears to be little evidence of any 'honeymoon effect'. Svensson (1992) remarks that the comprehensive rejection of this theory looks like what T.H. Huxley called 'the great tragedy of science – the slaying of a beautiful hypothesis by an ugly fact'. But in fact, while descriptively unrealistic, Krugman's model of target zones maintains its conceptual grip. A number of minor amendments to the theory have gone some way to reconciling it with the evidence while leaving its central ideas intact. The theory makes many clearly unrealistic assumptions. Two changes that have been particularly important are allowing for imperfect credibility of the target zone and allowing for intra-marginal intervention. Intra-marginal intervention in particular alters the process driving the fundamentals and can cause the theoretically predicted distribution of the exchange rate within the zone to have the empirical humped shape. Expectations that a zone is not fully credible and that the authorities might adjust the central parity rather than defend the zone also have the effect of reducing the curvature of the S-shaped curve and bringing it closer to the 45-degree line that would prevail under free floating.

With the empirical failure of the theory and the disappearance of the most prominent practical example when the euro replaced the EMS in 1999, interest in target zones has subsided. Nevertheless, John Williamson (1998) emphasizes the empirical observation that within a target zone the forward rate responds less than one-for-one with a change in the spot rate, whereas the same is not true of a floating exchange rate, as an indication that even an imperfectly credible target zone exerts a stabilizing influence on exchange rates. He has proposed looser arrangements for exchange rates, such as 'crawling bands' and 'monitoring bands', in which the band is defined around an equilibrium real exchange rate (his concept of the fundamental equilibrium exchange rate), which naturally implies a central nominal exchange rate that crawls over time. While a crawling band involves a commitment to keep the exchange rate within a wide announced band, a monitoring band involves a weaker commitment. A number of countries used crawling bands during the 1990s, including Chile, Colombia, Israel, Indonesia, Ecuador, and Russia. The IMF (2006) reports that by the end of 2005 no countries were using crawling bands. Several countries were using 'pegged exchange rates within horizontal bands', mostly countries in ERM II, the revised form of the Exchange Rate

Mechanism of the former EMS: Cyprus, Denmark, the Slovak Republic, Slovenia, and Hungary; with Tonga alone outside ERM II.

Exchange Rate Volatility

Roberto Rigobon

Abstract

Exchange rate volatility is at the forefront of academic, policy, and market participant discussions in developed and developing economies. This article reviews the benefits and cost of exchange rate variations, and its implications for the economy. It also summarizes the general understanding that exists regarding the relationship between real and nominal exchange rates.

The volatility of the exchange rate is perhaps one of the most studied topics in international economics; from the real exchange rate to the nominal exchange rate, from the theories of exchange rate volatility to the predictability of exchange rate movements, from the explanations of the volatility to its implications, and from the independence of exchange rates around the world to contagion, it can be argued that all dimensions have been heavily scrutinized in the literature. (As it is virtually impossible to cite all the relevant sources, I will mostly refer to the classics and to relevant surveys in the literature.)

Why is so much attention paid to exchange rate volatility? For a start, exchange rate volatility has almost unanimously been seen as a *bad thing* by policymakers, practitioners, and academics – whatever 'bad' or 'thing' means. Indeed, an important policy objective in the recent past, for several emerging and developed nations, has been exchange rate stability. The road to this stability, however, has been long and with many bumps and pitfalls. For instance, one of the goals of the Bretton Woods system was to control the

excessive exchange rate variability that surfaced during the interwar period – it was unsuccessful, and in the early 1970s the world abandoned fixed exchange rates. After teasing the world with flexible rates for less than a decade, the European nations moved again to controlling their exchange rates with the Exchange Rate Mechanism (ERM) in early 1980s. It was a more comprehensive set of rules devoted to enhance cooperation and coordination among the members with the purpose of reducing exchange rate variability. It was a good idea, but unfortunately the system did not last, and it collapsed in the early 1990s. Europe stirred itself in 1999 to adopt an even stronger set of rules to foster even more cooperation and coordination – the European Monetary Union (EMU). Will it last? Too close to call, yet.

Emerging markets show even stronger variability of exchange rates, and more frequent failures of fixed regimes. Countries usually embark on periods of controlled nominal exchange rates in the hope that they can achieve stability, both internal and external. Those efforts rarely last, and most such countries are forced to devalue. In the end, the search for the Holy Grail of exchange rate stability looks more like an electrocardiogram than a smooth path.

Interestingly, this path has been frustrating enough that some countries have given up their exchange rate stabilization objective. The recent shift towards inflation targeting by many central banks is an indication that today they are assigning a smaller weight to exchange rate stabilization in the design of monetary policy than in the past. However, as the present global imbalances debate on the sustainability of the US current account deficit and the Asian and European current account surpluses shows, the exchange rate is still at the forefront of the concerns of policymakers, practitioners and academics.

Several questions come to mind. First, from the economics point of view, which volatility is the relevant one: nominal or real? Second, what are the costs and benefits of exchange rate stability? Third, what causes exchange rate instability, and how can it be controlled? The following sections answer these questions.

Nominal vs Real Exchange Rate Volatility

If we were to analyse the impact of higher exchange rate volatility on growth or trade, the first question would be whether the nominal or the real exchange rate should be considered. In practice, nominal and real exchange rates are closely intertwined. In his seminal paper, Mussa (1986) reports one of the most robust facts in international economics: the nominal and real exchange rates move almost one to one; periods of nominal exchange rate stability are always associated with periods of stable real exchange rates, while periods of nominal exchange rate instability are accompanied by excessive real exchange rate variability. Furthermore, a country that shifts from a fixed nominal exchange rate to a flexible nominal exchange rate experiences an increase in the variance of both nominal and real exchange rates. This is particularly true at shorter frequencies (quarterly or monthly). This evidence points to two important lessons. First, prices are sticky in the short run, so that nominal and real exchange rates are driven by the same factor, namely, shocks to the nominal exchange rate. Second, demand shocks – or nominal shocks – govern the short-run dynamics of the nominal exchange rate.

An active recent area of research has been the collection of empirical evidence regarding the degree of stickiness of prices using micro data. The seminal paper in this area is by Bils and Klenow (2004), who study price stickiness in the items used to construct the consumer price index (CPI) for the United States. They find that the median stickiness is four to five months. By contrast, Alvarez et al. (2005) find a degree of stickiness of about a year in European items constituting the CPI. Furthermore, for the US prices used to construct the import and export indexes, Gopinath and Rigobon (2006) find that the degree of stickiness is greater than a year. The significance of sticky prices and the degree of stickiness continue to be an important area of research. The recent evidence suggests a substantial degree of stickiness, meaning that short-run movements of the nominal rate will be transmitted one-to-one to the real exchange rate.

Finally, this short-run volatility pans out in the long run, at least in terms of real exchange rate deviations. As summarized by Rogoff (1996), the consensus view in the profession is that purchasing power parity holds in the long run. The average half-life of real exchange rate deviations from trend is around three to four years. More recent evidence has challenged this view. Imbs et al. (2005) have found that at the sectoral level the mean reversion is even stronger (half-lives of around a year). They argue that the very strong persistence of the aggregate real exchange rate measures is due to aggregation bias. The jury is still out on this matter. Nevertheless, it is clear that fluctuations of the real exchange rate are short-lived – where short is to be determined.

In summary, short-run fluctuations of the nominal and real exchange rates come in tandem, and therefore, from the policy point of view, stabilizing one is equivalent to stabilizing the other.

Implications of Exchange Rate Volatility

What are the advantages or disadvantages of exchange rate volatility? Because the variance is regime dependent – meaning fixed exchange rate regimes will have lower variance and flexible regimes will have higher variance – answering this question is closely linked to the advantages and disadvantages of the different exchange rate regimes. To simplify the discussion, let us concentrate on the two extremes: fixed and flexible.

As highlighted by Friedman (1953), one of the main advantages of flexible exchange rates is that they allow an independent monetary policy. Under fixed exchange rates, shifts in the demand for currency imply portfolio recompositions that are met instantaneously by changes in the international reserves. In this sense, when exchange rates are fixed an expansion of the monetary base implies an immediate loss of reserves. Therefore, if the fixed exchange rate regime is credible, the interest rate differential between the domestic rate and the international rate has to be zero, or small, limiting the scope of monetary policy management.

Under a flexible regime, the appreciation or depreciation of the exchange rate, and the risk premium implied by those movements, entails the possibility that domestic and international interest rates differ. Hence, in the presence of a supply shock and sticky prices, flexible nominal rates allow for an easier adjustment of the external account and unemployment. Conversely, in a fixed exchange rate regime, a negative shock implies that the economy would need large fluctuations in real activity to produce the desired price and wage changes – that is, under fixed exchange rates a negative shock implies a large increase in unemployment to achieve a drop in the real wage.

Finally, as has been argued by Tornell and Velasco (1995), flexible regimes react immediately to any shock – hence, irresponsible fiscal policy (for example) is felt immediately through a nominal depreciation, instead of a prolonged decline in international reserves, and an ultimate collapse.

In all these dimensions, a flexible exchange rate – and therefore a volatile exchange rate – seems to be superior to a fixed exchange rate. Can the exchange rate be excessively volatile, and generate costs to the economy?

Indeed, it is possible that exchange rates are excessively volatile. The first explanation was provided by Dornbusch, and the second was advanced by Mussa.

As Rudiger Dornbusch used to say in most seminars at Massachusetts Institute of Technology, 'exchange rates are determined in stock markets', emphasizing the asset price view of the exchange rate he shared, and developed. Indeed, one of the most influential theories in international economics was Dornbusch's (1976) *overshooting* theory of the exchange rate. (In my view, his paper is the most influential idea in international open macroeconomics since the mid-1970s.) The simple intuition of the overshooting model is that the nominal exchange rate has to satisfy two equations or restrictions: first, an asset equation (in this case the uncovered interest rate parity); and second, a 'real' equation (long-run purchasing power parity). In a world of fixed prices in the short run, changes in the stance of monetary policy create excessive volatility of the nominal exchange rate – where excess is here defined as

overshooting. For instance, after a loosening of monetary policy, we know that in the long run the exchange rate has to depreciate. However, the current increase in the money supply implies a reduction of the nominal interest rate. In order to satisfy the uncovered interest rate parity while prices adjust, the exchange rate should be appreciating (instead of depreciating). Therefore, the exchange rate has to depreciate excessively today, so that it can appreciate on the path towards the new equilibrium. This theory implies that exchange rates in the short run are more volatile than fundamentals.

The second theory explaining excessive exchange rate volatility is based on the fact that speculation in the market can be destabilizing. In standard models with flexible prices, speculation in the market is usually good because price movements will reveal the fundamentals that private agents are using to value the asset. However, if there is no full price revelation, speculation might destabilize the exchange rate market. This has been called in the literature the *magnification effect* (Mussa 1976). The reason is that expectations might not imply that speculators purchase assets when prices are going down, and sell them when prices are going up. Their actions depend on the properties behind the exchange rate stochastic process, and how agents form their expectations. Therefore, it is possible that excessive volatility of the nominal exchange rate is due to shocks to expectations, and not to fundamentals. This *noise* in the nominal exchange rate plays no role in the adjustment process.

It is possible to argue that excess exchange-rate volatility has real costs. The change in the real exchange rate has implications for production allocation – tradable versus non-tradable sectors, on hedging, on investment, and so on. It has been documented that a more volatile exchange rate reduces the amount of trade (Frankel and Wei 1993), increases the pressures toward protectionism (see Dornbusch and Frankel 1987, for a survey of the protectionist forces that appeared during the 1980s in the United States), increases the degree of persistence of inflation or deflation, so slowing the adjustment of the real exchange rate (Obstfeld 1995), and reduces the development of the financial sector (Aghion et al. 2005; Eichengreen et al. 2003). It is important to highlight that this empirical evidence is mostly suggestive. There are problems of simultaneous equations and omitted variables in answering any of these questions. Furthermore, there are no available instruments for the exchange rate volatility – leaving the literature mainly reporting correlations as opposed to causal relationships. Indeed, this is perhaps an area of research that will need to be revived in the future. However, the 'consensus' points to the costs emphasized before. Interestingly, even if the academic literature does not have a clear view on whether the volatility of the exchange rate is good or bad for the economy, it seems that policymakers and practitioners agree that exchange rate volatility is costly.

Dealing with Exchange Rate Volatility

Is exchange rate volatility a policy choice? Can exchange rate volatility be controlled? In other words, if we were to accept that exchange rate volatility is detrimental to the economy because it is excessive, then what is the policy advice? How can it be reduced?

These questions are related to the theories behind exchange rate determination. For example, if fundamentals determine the exchange rate, is should be the case that the exchange rate, and its volatility, can be controlled, or at least ameliorated, by changing the fundamentals. On the other hand, if exchange rates and their volatility are unrelated to fundamentals, then very little can be done from the policy point of view.

A substantial literature reports a 'disconnect' between exchange rates and fundamentals in the short run. The seminal paper by Messe and Rogoff (1983) argues that the best predictor of tomorrow's exchange rate is today's exchange rate. They show that in the short run the random-walk assumption beats most models of the exchange rate. Recently, however evidence has emerged that models of the exchange rate have performed better than the random walk for medium- and long- run horizons. (See Chin and Messe 1995, for the first paper in this area, and see the

subsequent papers by Menzie Chin on the subject.) This disconnect implies that very little can be done in the short run to control for the exchange rate volatility – other than fixing it. In fact, Evans and Lyons (2002) show that 70 per cent of the variation of the nominal exchange rate in the short run is explained by order flows in the market – meaning that market microstructure factors dominate the fluctuations of the exchange rate.

More interesting is the fact that in small open economies the exchange rate is governed by the fundamentals of other countries. The very well-known anomaly called 'contagion' implies that excess exchange rate volatility is affected by crises experienced by trading partners and in countries that share financial linkages. (See Forbes and Rigobon 2001, 2002, and Kaminsky et al. 2003, for detailed surveys of the empirical literature, and see Pavlova and Rigobon 2006, 2007, for the theories of contagion.) These are rarely subject to the influence of policymakers, and very little can be done in this respect.

In summary, the short-run volatility of a flexible exchange rate cannot be controlled by policymakers. The short-run fluctuations depend either on market participants' views or on other countries' fundamentals. In both cases, the only response open to the monetary authorities is to move toward a fixed regime – which is indeed what most countries do. This is a very imperfect policy measure, but unfortunately the only one available. Hence, there are two types of country. In the first, market participants' views are very volatile, or are subject to massive external shocks; these countries end up adopting fixed exchange rate regimes. For those countries the short-run fluctuation of the exchange rate is so costly that giving up monetary policy seems a minor issue. The second type of country consists of those that can bear the cost of the short-run exchange rate volatility, and have been moving towards a flexible rate – and towards inflation targeting. In fact, in the life of a single country it is easy to think of times in which nominal shocks dominate the economy (Argentina in the 1990s), which they responded to by fixing the exchange rate. However, after they introduced a fixed exchange rate the economy was mostly governed by supply shocks (high unemployment) and needed a flexible regime, which Argentina also implemented in 2002.

Final Remarks

Exchange rate volatility is one of the most important policy matters in developed economies, and possibly *the* topic in developing ones. The rhetoric of public policy is that exchange rate volatility is costly. In this article we have tried to understand the economic forces behind this claim.

First, we observed that in the short run the nominal exchange rate and the real exchange rate move in tandem. This is mainly due to the presence of sticky prices and real rigidities. This means that the discussion about volatility must embrace both the real and the nominal exchange rate.

Second, we have reviewed some of the evidence pointing out that exchange rate volatility is indeed costly for the economy. Investment is lower, growth is lower, real interest rates are higher, there are costly resource allocations between tradable and non-tradable sectors, and so on. This evidence, however, is not conclusive. There are econometric challenges, such as simultaneity and omitted variable biases, that have not yet been overcome. Nevertheless, it seems fair to say that the consensus points out to exchange rate volatility being costly to economies.

Third, we have observed that, even if we were to accept that exchange rate volatility is costly, there is very little that policymakers can do. There is a tremendous disconnect between exchange rates and fundamentals in the short run, and therefore policymakers are left with only one instrument to deal with exchange rate volatility: to fix it. That implies that only countries that face large demand shocks end up fixing their exchange rates, while most countries have been moving towards more flexible regimes.

Exchange Rates

Robert Z. Aliber

The large movements in the price of the US dollar in terms of the German mark, the Japanese yen, the British pound, and various other currencies since the breakdown of the Bretton Woods system in the early 1970s again raises the question of how exchange rates are determined. This question tends to be dormant when the major countries peg their currencies – and then reappears when their currencies float. Approaches to explaining the movement of the exchange rate must recognize that the range of variation in the price of the US dollar in terms of the currencies of various other countries has been substantially larger than the contemporary change in the differential between the increase in the US price level and the increase in the price levels in these other countries. Moreover, deviations between market exchange rates and real (or price-level adjusted) exchange rates have been substantially larger with

the floating exchange rate system than with the pegged exchange rate system of the 1950s and the 1960s. A second observation is that at times countries with strong and appreciating currencies have had large trade deficits (the United States in the early 1980s) and the countries with weak and depreciating currencies have had large trade surpluses (the United States in the late 1970s) – even though large trade deficits frequently are associated with weak or depreciating currencies, and large trade surpluses with strong or appreciating currencies. A third observation is that the range of variation in the price of the US dollar in terms of various foreign currencies does not appear to have declines during the first decade of experience with the floating exchange rate system. A fourth observation is that the differences in interest rates on comparable assets denominated in the US dollar and various foreign currencies have proven to be poor predictors of the rate of change of the price of the US dollar in terms of each of these currencies. Similarly, forward exchange rates have not proven to be effective predictors of future spot exchange rates at the maturity of the forward contracts.

The experience with floating exchange rates has proved very different from the experience with the Bretton Wood system of pegged exchange rates in the 1950s and the 1960s. Then countries devalued their currencies when their trade deficits were excessively large; changes in currency parities generally were consistent with the changes in international competitiveness. The countries which devalued their currencies, like France in 1959 and again in 1969 and Great Britain in 1967, had experienced higher rates of inflation than their major trading partners. And the countries which revalued their currencies, like Germany in 1961 and again in 1969, generally experienced lower rates of inflation than their major trading partners.

The next section discusses five approaches toward explaining the level of the exchange rate and changes in exchange rates. Then a disequilibrium toward analysing exchange rate movements is contrasted with an equilibrium approach. Then the relation between the determinants of exchange rates under a floating exchange rate system is compared with the determinants of the exchange rate under a pegged exchange rate system.

Approaches Toward Modelling the Determination of Exchange Rates

Most of the approaches toward explaining changes in the exchange rate were developed to explain phenomena at particular times. Five approaches are distinguished: purchasing power parity, elasticities, absorption, portfolio balance, and the asset market approach. The purchasing power parity approach is identified with Cassel, who sought to develop a way for European governments to determine the equilibrium values for their currencies if they again were to peg them to gold after World War I. During the war, inflation rates varied extensively among countries. Either the countries with the more rapid inflation would have to accept large declines in their price levels, or they would be obliged to peg their currencies to gold at new parities that would reflect that their inflation rates had been higher than those of their major trading partners. Cassel's insight was that changes in exchange rates should conform to differences in national inflation rates – in effect an extension of the arbitrage proposition known as the Law of One Price from individual goods to national market baskets of goods (traded) and services (non-traded). The terms *undervaluation* and *overvaluation* are the layman's expression that the value for the exchange rate seems inconsistent with the relationship between the domestic price level and the price levels in the major trading partners. Subsequent analysis has been directed at whether the equilibrium exchange rate should be inferred from absolute price levels or whether instead the exchange rate should be based on changes in price levels from data when the exchange market was in equilibrium should provide the basis for determining the new equilibrium exchange rate.

The elasticities approach to the determination of the exchange rate developed the 1930s in response to the observation – or at least to the stylized fact – that countries which devalued their currencies were not successful in increasing their exports relative to their imports. The devaluation improved competitiveness in that the price of domestic goods fell relative to the price of foreign goods, but the improvement in

competitiveness did not lead to the desired reduction in the trade deficit. The explanation was that the spending on imports might increase if domestic demand were price inelastic and export receipts might decline if foreign demand for domestic goods were price inelastic. This 'elasticity pessimism' view led to the conclusion that changes in exchange rates would prove ineffective in improving the trade balance, which was formalized in the Marshall–Lerner condition (that a devaluation would reduce the trade deficit if the sum of the elasticities is greater than one). An alternative interpretation for the observation that the devaluation of one country's currency would not reduce its trade deficit in the 1930s was that the subsequent devaluations of the currencies of its trading partners effectively neutralized its own devaluation.

The absorption approach to the determination of the exchange rate was developed in the period after World War II to highlight that changes in exchange rates would not lead to a permanent improvement in the trade balance unless the devaluating country adopted a sufficiently contractive monetary and fiscal policy. This approach followed the Keynesian tradition that the trade balance was the residual between domestic consumption and domestic production; a trade deficit occurred when domestic consumption exceeded domestic production, which meant that imports exceeded exports. Unless consumption declined relative to production as domestic currency was devalued, the trade deficit would persist. Thus a devaluation might be necessary to reduce a trade deficit; if excess demand remained after the devaluation, then domestic price level would rise, and the improvement in competitiveness effected by the devaluation would be negated by the subsequent increase in consumption and in imports.

Both the absorption approach and the elasticities approach provide explanations of why a devaluation would be ineffective in improving the trade balance in terms of the levels of demand. Thus the elasticities approach highlighted a deficiency of demand associated with the Great Depression, while the absorption approach reflects excess demand of the years immediately after World War II. In both cases, however, the equilibrium exchange rate was determined by the need to have national price levels aligned so that there would be equilibrium in the goods market; the change to price-level competitiveness was necessary for a permanent improvement in the trade balance, but not a sufficient condition.

The Bretton Woods decades were marked by infrequent changes in exchange parities of the industrial countries. Inflation rates in most countries were low. For most of this period, the United States incurred payments deficits; the problem was to explain the persistence of the US payments deficit despite a variety of measures adopted to reduce the imbalance. The payments surpluses of other industrial countries were explained by their demand for international reserves, or by their demand for money. The portfolio balance approach emphasized that payments balances and hence the exchange rate, reflected trade in securities as well as trade in goods. Trade in securities would involve a stock adjustment in the volume of foreign securities owned by domestic residents. The Monetary Theory of the Balance of Payments emphasized that payments surpluses and deficits reflected imbalances between the demand for money in each country and the supply of reserves that results from the monetization of domestic assets; if the demand for money increased more rapidly than the supply based on the expansion of the domestic assets owned by the central bank, then the country would realize a trade and payments surplus, since the supply of goods will exceed the demand. The inflow of gold and foreign exchange would lead to increases in the assets of the central bank, and thus lead to an increase in the money supply. Both the portfolio balance approach and the monetary theory placed payments surpluses and deficits in a general equilibrium framework. The monetary approach was generally mute on whether the payments surplus reflected the trade account or the capital account. In contrast, the portfolio balance approach could explain the US payments in terms of the desire of residents of other countries to borrow long and lend short in their transactions with the United States.

The observations about the wide variation in the price of national currencies since the early 1970s are similar to the observations about the

movements in exchange rates in the early 1920s. In both cases, the movements of exchange rates were much larger than the movement that would be inferred from the changes in the relationship among national price levels. In both periods, countries with relatively high inflation rates experienced a significantly more rapid reduction in the foreign exchange value of their currencies than would be inferred from the relative price level movements alone.

The dominant explanation for the large variations in market exchange rates derives from Irving Fisher's observation in *The Theory of Interest* that the interest rate differential between bonds payable in gold and bonds payable in rupees or silver reflected the anticipated rate of change in the price of gold in terms of silver. Thus the current spot exchange rate at any moment is the anticipated spot exchange rate for various future dates discounted to the present by the differential between interest rates on domestic securities and interest rates on similar securities denominated in the foreign currency. If the current spot exchange rate differed substantially from the anticipated spot exchange rate adjusted for the interest rate differential, investors would have a virtually riskless profit opportunity. The implication is that the spot exchange rate changes whenever the anticipated spot exchange rate changes, or whenever the differential between interest rates on comparable securities denominated in the domestic currency and foreign currency changes.

The Asset Market Approach to the Exchange Rate places the Fisherian observation in a general equilibrium framework. The exchange rate is the price of two national monies. Changes in the exchange rate reflect changes in the demand for securities denominated in each currency relative to the supply. The changes in the exchange rate that occur to obtain equilibrium in the asset market may induce disequilibrium in the goods market; the goods produced by the countries subject to capital outflows will become undervalued. In effect, the capital outflow can occur only if the country can generate a current account surplus. The asset market approach slights the role of trade in goods in determining the value of the exchange rate today, on the presumption that the daily volume of transactions in assets across national borders is so much larger than the volume of trade in goods. However, the anticipated exchange rate may reflect the value that would lead to goods market equilibrium at the anticipated price levels during future years.

The exchange rate necessary to achieve asset market equilibrium leads to disequilibrium in the goods market. The anticipated spot exchange rate reflects the value that will clear the goods markets at some future date; this anticipated value may be extrapolated from current or recent movements in the domestic and foreign inflation rate. In this way, changes in the inflation rate can have a major impact on the current spot exchange rate as the revised anticipated values are discounted to the present.

A Disequilibrium Approach to Exchange Rate Determination

Sudden large movements of exchange rate during particular episodes have been explained in terms of extrapolation by investors of the future exchange rate from the direction of movement in the exchange rate in the recent past. For a while, at least, some participants in the exchange market rely on a 'follow-the-leader' approach; changes in exchange rates thus reflect a bandwagon effect. Hence there may be 'speculative bubbles' in the exchange rate. Momentum models of exchange rate forecasting are based on this view. In such cases, the exchange rates may move away from an equilibrium value, and eventually these sharp movements will be reversed.

The approach toward explaining changes in exchange rates raises the question whether the foreign exchange market is efficient, or whether instead period-to-period movements in the exchange rate are serially correlated. The serially correlated movements in exchange rates could explain why the exchange rate tends to overshoot the ultimate equilibrium. In a few brief episodes, exchange rate movements appear serially correlated.

The momentum approach toward the determination of the exchange rate can be reconciled with

the Asset Market Approach in that new information about inflation rates may lead to sharp revisions in anticipated exchange rates and, to a lesser extent, in interest rates. Frequently this new information will develop over a period of weeks and months; each revision will lead to a new value for the current spot exchange rate. If the trend-like movement is sufficiently strong, then momentum-based approaches to forecasting exchange rates may be triggered, and the exchange rate movement may become abrupt, and overshoot its ultimate equilibrium.

Exchange Rate Determination – Pegged Rate Periods and Floating Exchange Rate Periods

The amplitude and suddenness of movements in exchange rates under the floating rate period highlights the conditions necessary for the successful operation of a pegged exchange rate regime – and for a floating exchange rate system in which movements in spot exchange rates are gradual, and conform with differences in inflation rates. A pegged exchange rate system can be maintained if the anticipated exchange rates are more or less identical with the current spot exchange rate – because the authorities are committed to maintaining their parities, and manage their policies accordingly. And for most periods, this commitment was credible. In contrast, during the floating rate periods, the authorities generally have had no such commitment about a particular value for the future spot exchange rate.

The sharp movements in the price of the US dollar in terms of various foreign currencies during the floating exchange rates reflects that various types of shocks affect the anticipated spot exchange rates, domestic interest rate and foreign interest rates. Most of these shocks reflected changes in monetary policy in the United States and in other countries.

The number and magnitude of monetary disturbances has been substantially larger during periods associated with floating exchange rates. In part, this reflects that many of the moves to floating exchange rates occur in an inflationary environment: the early 1920s and the 1970s were both periods of divergent movement in national price levels. During the 1950s and the early 1960s, inflation rates were low and similar among the industrial countries; the anticipated price of foreign exchange more or less approximates the parity. Interest rates differed modestly among countries. Capital flows occur primarily in response to national differences in savings and investment rates. The exchange rate at the level necessary to maintain the approximate balance in trade accounts flow of capital were modest in size relative to flows of goods.

Exchangeability

David Draper

Abstract

Exchangeability is an invariance property of probability distributions that is central to the process of specifying Bayesian statistical models. Exchangeability judgements play a role in Bayesian modelling analogous to judgments in frequentist modelling that observable quantities may be regarded as realizations of independent identically distributed (IID) random variables. Judgements of conditional exchangeability (given the values of relevant covariates), when combined with Bayesian nonparametric modelling, provide a principled and rather general approach to Bayesian model specification that can lead to well-calibrated inferences and predictions; other approaches to achieving this goal include cross-validation and Bayesian model averaging.

Definition A sequence $y = (y_1, \ldots, y_n)$ y of random variables (for $n \geq 1$) is (*finitely*) *exchangeable* if the joint probability distribution $p(y_1, \ldots, y_n)$ of the elements of y is invariant under permutation of the indices $(1,\ldots, n)$, and a countably infinite sequence $(y_1, y_2, \ldots)$ is (*infinitely*) *exchangeable* if every finite subsequence is finitely exchangeable.

The idea of exchangeability seems (Good 1965; Bernardo and Smith 1994) to be traceable back to Johnson (1924), who used the term *permutable*, and independently to Haag (1924). Other writers who made early use of the concept include Khintchine (1932); Fréchet (1943); Savage (1954), who called an exchangeable sequence *symmetric*; and Hewitt and Savage (1955). But the deepest implications of the idea are due to de Finetti (1930), who in (1938) still referred to exchangeable sequences as *equivalent*; by (1970) the word had been translated from the Italian as *exchangeable*, and since then usage has stabilized around this terminology under the influence of de Finetti and his translators.

The concept is important because it plays a fundamental role in the specification of statistical models from a Bayesian point of view. Following the example of Good (1950) by referring to You as a generic rational person making uncertainty assessments, suppose that You will in the future get to see a finite sequence $y = (y_1, \ldots, y_n)$ of binary observables; to illustrate the interplay between context and model, consider as an example the mortality outcomes (within 30 days of admission, say: 1 = died, 0 = lived) for a sequence of n patients with the same admission diagnosis (heart attack, say) at one particular hospital H, starting on the first day of next month. You acknowledge Your uncertainty about which elements in the sequence will be 0 s and which 1 s; suppose further that You find it natural (as in the Bayesian approach to statistics) to use random variables to quantify Your uncertainty. As de Finetti (1970) noted, in this situation Your fundamental imperative is to construct a *predictive* distribution $p(y_1, \ldots, y_n)$ that expresses Your uncertainty about the future observables, rather than – as is perhaps more common – to reach immediately for a standard family of *parametric* models for the y_i (that is, to posit the existence of a vector $\theta = (\theta_1, \ldots, \theta_k)$ of parameters and to model the observables by appeal to a family $p(y_i|\theta)$ of probability distributions indexed by θ).

Even though the y_i are binary, with all but the smallest values of n it still seems a formidable task to *elicit* from Yourself an n-dimensional predictive distribution p $(y_1, \ldots, y_n)$; it was while facing this challenge that de Finetti developed his version of the idea of exchangeability and its implications. As de Finetti observed, in the absence of any further information about the patients, You notice that Your uncertainty about them is exchangeable: if someone (without telling You) were to rearrange the order in which their mortality outcomes become known to You, Your predictive distribution would not change. This still seems to leave p-$(y_1, \ldots, y_n)$ substantially unspecified, but de Finetti (1930) proved a remarkable theorem which shows (in effect) that all exchangeable predictive distributions for a vector of binary observables are representable as mixtures of Bernoulli sampling distributions. More formally,

Theorem 1 (Representation of Exchangeable Predictive Distributions for Binary Observables [de Finetti 1930]) Suppose that You're willing to regard $(y_1, \ldots, y_n)$ as the first n terms in an infinitely exchangeable binary sequence $(y_1, y_2, \ldots)$; then, with $\overline{y}_n = \frac{1}{n}\sum_{i=1}^{n} y_i$,

- $\theta = \lim_{n\to\infty}\overline{y}_n$ must exist, and the marginal distribution (given θ) for each of the y_i must be $p(y_i|\theta) = \text{Bernoulli}(\theta) = \theta^{y_i}(1-\theta)^{1-y_i}$;
- $H(t) = \lim_{n\to\infty} P(\overline{y}_n \le t)$, the limiting cumulative distribution function (CDF) of the $\overline{y}_n$ values, must also exist for all t and must be a valid CDF, where P is Your joint probability distribution on $(y_1, y_2, \ldots)$; and
- Your predictive distribution for the first n observations can be expressed as

$$p(y_1, \ldots, y_n) = \int_0^1 \prod_{i=1}^{n} \theta^{y_i}(1-\theta)^{1-y_i} dH(\theta). \quad (1)$$

When (as will essentially always be the case in realistic applications) Your joint distribution P is sufficiently regular that H possesses a density (with respect to Lebesgue measure), $dH(\theta) = p(\theta)$, (1) can be written in a more accessible way as

$$p(y_1, \ldots, y_n) = \int_0^1 \theta^{s_n}(1-\theta)^{n-s_n} p(\theta)\, d\theta, \quad (2)$$

where $s_n = \sum_{1=1}^{n} y_i = n\overline{y}_n$.

The interpretation of (2) provides a link with non-Bayesian statistical modelling, as follows. In the frequentist (repeated-sampling) approach to statistics, to bring probability into the picture it's necessary to tell a story in which the observable y_i are either literally a random sample from some population $\mathscr{P}$ or like what You would get if You took a random sample from $\mathscr{P}$. This is a somewhat awkward story to tell in the medical example above, because the patients whose mortality outcomes are $(y_1, \ldots, y_n)$ are not a random sample of anything; they're simply the exhaustive list of all patients arriving at hospital H (itself not randomly chosen), with heart attack as their admission

diagnosis, in a particular (not randomly chosen) window of time. In spite of this difficulty, the standard frequentist model (with the same information base as that assumed above) would define θ as the mortality rate in $\mathscr{P}$ (whatever $\mathscr{P}$ might be) and would treat the y_i as measurements on a random sample from $\mathscr{P}$ by regarding random variables Y_i (whose observed values are y_i) as independent and identically distributed (IID) draws from the Bernoulli (θ) distribution $p(Y = y_i) = \theta^{y_i}(1-\theta)^{1-y_1}$, which leads to the joint sampling distribution $p(Y_1 = y_1 \ldots, Y_n = y_n) = \prod_{i=1}^{n} \theta^{y_i}(1-\theta)^{1-y_i} = \theta^{s_n}(1-\theta)^{n-s_n}$.Thus, in interpreting Theorem 1 (with reference to equation (2) above), in Your predictive modelling of the binary y_i You may as well proceed as *if*

- there is a quantity called θ, interpretable both as the marginal death probability $p(y_i = 1|\theta)$ for each patient and as the long-run mortality rate in the infinite sequence $(y_1, y_2, \ldots)$;
- conditional on θ, the y_i are IID Bernoulli (θ); and
- θ can be viewed as a realization of a random variable (this is of course how all unknown quantities are treated in the Bayesian paradigm) with density $p(\theta)$.

In other words, exchangeability of Your uncertainty about a binary process is functionally equivalent to assuming the simple Bayesian *hierarchical* model (see, for example, Draper 2007)

$$\begin{array}{ccc} \theta & \sim & p(\theta) \\ & \text{IID} & \\ (y_i|\theta) & \sim & \text{Bernoulli}(\theta) \end{array} \tag{3}$$

A number of points are worth noting.

First, exchangeability is not a property of the world; it's a judgment by You concerning Your uncertainty about the world. Two reasonable people, with different knowledge bases or different views on how that knowledge should be brought to bear on the issue at hand, may consider the same set of observables, and one may judge her uncertainty about those observables exchangeable while the other may not make the same judgement about his uncertainty (for example, if I know the gender of the patients in the medical example and You do not, and if there's evidence that the mortality rate for male and female heart attack patients differs by an amount that's large in clinical terms, then You may well judge Your uncertainty about the mortality outcomes exchangeable but I would be ill-advised to adopt an exchangeable model; see partial/conditional exchangeability below). This distinction between {the world} and {Your uncertainty about the world} is sometimes blurred by terminology – I might casually say 'These patients are exchangeable' when what I mean is 'my uncertainty about these patients is exchangeable, as far as mortality is concerned' – but failing to observe the distinction can lead to what Jaynes (2003) terms the *mind projection fallacy*, with undesirable consequences for clarity of thought.

Second, in both the frequentist and Bayesian modelling approaches it's helpful to employ a fiction involving random variables, but for different purposes: in the standard frequentist approach, You regard the yi as realizations of random variables (as a way to build a useful probability model), even though (in observational settings like the medical example above) no random sampling was performed to arrive at the observables; and in the Bayesian approach, You regard θ as random (as a way to make good predictions of observables), even though in both the frequentist and Bayesian approaches θ has the same logical status, as a fixed unknown constant.

Third, since, for any random variables X and Y for which the following symbols have meaning, the density of Y can be expressed as $p(y) = \int p(y|x)p(x)dx$ – in other words, Y can be modelled either directly or as a mixture of the conditional distribution $p(y|x)$ with $p(x)$ serving as a mixing distribution – the predictive distribution in Eq. (2) can be regarded as a mixture of Bernoulli sampling distributions with $p(\theta)$ as the mixing weights.

Fourth, mathematically $p(\theta)$ is just a mixing distribution, but (of course) statistically it has a more useful inpt. The second line of Eq. (3) defines the *likelihood function* $l(\theta|y) = c\,p(y|\theta)$ (an arbitrary positive constant c times the joint sampling distribution of the data vector y, reinterpreted as a function of θ for fixed y); this is where all the information about θ internal to the data-set y is stored, and – under the logic of *Bayes's theorem* – the first line of Eq. (3) defines $p(\theta)$ as the place where all the information about θ *external* to the data-set y is stored. It has become traditional to call this $p(\theta)$ a *prior distribution* for θ; this terminology is unfortunate (it sounds as though only information gathered before the data-set y arrives can go into $p(\theta)$, and this is not true), but it has been used for so long that it's unlikely it can be changed now. Equation (3) implies that (*a*) learning about θ on the basis of y can occur via Bayes's theorem: the *posterior distribution* $p(\theta|y)$, which combines the information about θ contained in the prior and the likelihood, is just a renormalized version of their product: $p(\theta|y) = c\,p(\theta)\,l(\theta|y)$, with c chosen so that $p(\theta|y)$ integrates to (1), and (*b*) predictive distributions for future data given past data may also readily be calculated (for example, for $1 < m < n$ the predictive for $y_{m+1}, \ldots, y_n$ based on $(y_1, \ldots, y_m)$ is

$$p(y_{m+1}, \ldots, y_n|y_1, \ldots, y_m) = \int_0^1 \theta^{s_m}(1-\theta)^{n-m(s_n-s_m)}p(\theta|y_1, \ldots, y_m)\,d\theta, \tag{4}$$

in which $s_m = \sum_{i=1}^{m} y_i$ and $p(\theta|y_1, \ldots, y_m)$ is the posterior distribution for θ based only on the first m observations.

Fifth, exchangeability evidently plays a role in Bayesian modelling that's somewhat analogous to the role of IID sampling in the frequentist approach, but exchangeability and IID are not the same: IID random variables are exchangeable, and exchangeable random variables are identically distributed, but they're not independent (for example, if You're about to observe a binary process whose tendency to yield a 1 is not known to You, and You judge Your uncertainty about future outcomes to be exchangeable, the information in the first n outcomes would definitely help You to predict outcome $(n+1)$; it's only when (somehow) the knowledge of the 'underlying' θ becomes available to You that there's no information in any of the outcomes to help predict any other outcomes – this situation might be summarized by saying that the past and the future become conditionally independent given the truth). Exchangeable observables are thus not IID, but they may often be usefully regarded as *conditionally* IID given a parameter vector θ, as in Eq. (3) above.

Sixth, some awkwardness arose above in the frequentist approach to modelling the medical data, because it was not clear what population $\mathscr{P}$ the data could be regarded as *like* a random sample from. This awkwardness also arises in Bayesian modelling: even though in practice You are only going to observe $(y_1, \ldots, y_n)$, de Finetti's representation theorem requires You to extend Your judgement of finite exchangeability to the countably-infinite collective $(y_1, y_2 \ldots)$, and this is precisely *like viewing* $(y_1, \ldots, y_n)$ as a random sample from $\mathscr{P}$. (Finite versions of de Finetti's representation theorem are available – for example, Diaconis and Freedman 1980 – which informally say that, if You're willing to extend Your judgement of exchangeability from $(y_1, \ldots, y_n)$ to $(y_1, \ldots, y_N)$ for $N > n$, the larger N is the harder it becomes for Your predictive distribution p(y1,..., yn) to differ by a large amount from something representable by Eq. (2) without violating the basic rules of probability.) The key point is that the difficulty arising from lack of clarity about the scope of valid generalizability from a given set of observational data is a fundamental scientific problem that emerges whenever purely observational data are viewed through an inferential or predictive lens, whether the statistical methods You use are frequentist or Bayesian.

E

The entire discussion so far has been in the context of binary outcomes y with no covariates; in practice, predictor variables x are also generally available, and extensions to non-binary data are evidently needed as well. An example involving a covariate arose in the discussion of the mind projection fallacy above: if, in the medical setting considered here, the gender x of the patients is available, and if this has a clinically meaningful bearing on mortality from heart attack, then it would be more scientifically appropriate to assert exchangeability separately and in parallel within the two gender groups {male, female}. With this in mind de Finetti (1938) defined the concept of *partial exchangeability*, which is also known as *conditional exchangeability* (Lindley and Novick 1981; Draper et al. 1993); with this newer terminology You would say that Your uncertainty about the mortality observables for these patients is conditionally exchangeable given gender. Conditional exchangeability is related to the notion, introduced by Fisher (1956), of *recognizable subpopulations*.

Suppose now that the observable You will measure on the patients in the medical example is a severity of illness score y_i, scaled as a continuous quantity from $-\infty$ to ∞, and return temporarily to the situation with no covariate information. As before Your uncertainty about the future yi values is (unconditionally) exchangeable, but now a representation theorem is needed for continuous real-valued outcomes; de Finetti (1937) supplied this as well.

Theorem 2 (Representation of Exchangeable Predictive Distributions for Continuous Observables [de Finetti 1937]) If You're willing to regard $(y_1, \ldots, y_n)$ as the first n terms in an infinitely exchangeable sequence $(y_1, y_2 \ldots)$ of continuous values on $\mathbb{R}$, then

- $F(t) = \lim_{n\to\infty} F_n(t)$ must exist for all t and must be a valid CDF, where F_n is the empirical *CDF* based on $(y_1, \ldots, y_n)$ (i.e., $F_n(t) = \frac{1}{n}\sum_{i=1}^{n} I(y_i \le t)$, in which $I(A)$ is the indicator function (1 if A is true, otherwise 0)), and the marginal distribution (given F) for each of the yi must be $(y_i|F) \sim \cong$;
- $G(F) = \lim_{n\to\infty} P(F_n)$ must also exist, where P is Your joint probability distribution on $(y_1, y_2, \ldots)$; and
- Your predictive distribution for the first n observations can be expressed as

$$p(y_1, \ldots, y_n) = \int_{\mathscr{F}} \prod_{i=1}^{n} F(y_i)\, dG(F), \qquad (5)$$

where $\mathscr{F}$ is the space of all possible CDFs on $\mathbb{R}$. Equation (5) says informally that exchangeability of Your uncertainty about an observable processing unfolding on the real line is functionally equivalent to assuming the Bayesian hierarchical model

$$\begin{array}{ccc} F & \underset{\text{IID}}{\sim} & p(F) \\ (y_i|F) & \sim & F, \end{array} \qquad (6)$$

where $p(F)$ is a prior distribution on $\mathscr{F}$.

With binary observables, Theorem 1 (which is evidently a special case of Theorem 2) focuses attention on θ, the underlying rate of 1 s in the population $\mathscr{P} = (y_1, y_2, \ldots)$ from which You're in effect regarding $(y_1, \ldots, y_n)$ as like a random sample; in the continuous case the analogous theorem focuses attention on F, the underlying CDF defined by $\mathscr{P}$. This makes Theorem 2 harder to implement in practice, because it's one thing to specify a prior distribution on a quantity $\theta \in (0, 1)$ and quite another to put a scientifically relevant prior distribution on the space $\mathscr{F}$ of all possible CDFs on the real line. Placing probability distributions on functions is the topic addressed by the field of *Bayesian nonparametric methods* (see, for example, Dey et al. 1998), an area of statistics that has recently moved completely into the realm of day-to-day implementation and relevance through advances (since the early 1990s) in Markov chain *Monte Carlo* (MCMC) simulationbased methods of computation (see, for example, Gilks et al. 1995). Two rich families of prior distributions on CDFs about which a wealth of practical experience has recently accumulated include (mixtures of) *Dirichlet process priors* (see, for example,

Ferguson 1973) and *Pólya trees* (see, for example, Lavine 1992).

As an example of the use of de Finetti's representation theorem for continuous outcomes, consider a randomized controlled trial or observational study with a treatment (T) and a control (C) group in which the outcome of interest y is modelled continuously on $\mathbb{R}$. A judgement of unconditional exchangeability of Your uncertainty about the y values for all subjects in the study would be equivalent to assuming that the T and C conditions had the same effect on the subjects, which (since the point of the study is presumably to see if this is true) would not be a good starting point; instead, in the absence of any other covariate information, it would be reasonable for You to model Your uncertainty about the y values as conditionally exchangeable given the indicator variable x that identifies which group each subject is in. With F_C and F_T as the underlying control and treatment CDFs and y_i^T as the observable for subject i in the treatment group (and similarly for y_j^C), a straightforward extension of Theorem 2 then leads to the following Bayesian nonparametric model for the observables (for $i = 1, \ldots n_T$ and $j = 1, \ldots, n_C$):

$$\left(y_i^T | F_C, F_T\right) \underset{\sim}{\text{IID}} (F_C, F_T) \quad \text{and} \quad \left(y_j^C | F_C, F_T\right) \underset{\sim}{\text{IID}} F_C. \tag{7}$$

A nonparametric joint prior can then be placed on (F_C, F_T) using either of the Dirichlet process prior or Pólya tree methodologies mentioned above, and an appropriate functional of (F_C, F_T) (such as the difference or ratio of the underlying treatment and control means) can be monitored in the MCMC simulation. Note that this model arose solely from exchangeability considerations and (a simple extension of) Theorem 2.

Model specification has been a vexing topic in both frequentist and Bayesian statistics throughout much of the last century. Referring both to the conditional exchangeability judgements and to choices made in specifying the prior on F_C and F_T in the example above as *structural assumptions*, a popular approach to model specification (practised with equal vigour by both frequentists and Bayesians since the work of Tukey 1962, and others on exploratory data analysis) involves (*a*) enlisting the aid of the data to conduct a search among possible structural assumptions, (*b*) choosing a single favourite structural specification S^*, and (*c*) pretending You knew all along that S^* was 'correct', even though it was arrived at via a data-driven search. From a Bayesian perspective this approach is clearly unsound, since it amounts to using the data to specify the prior distribution on the space $\mathscr{S}$ of all possible structural assumptions and then using the same data again to update the prior on $\mathscr{S}$; the result will often be inferences and predictions that are not well *calibrated*, with interval estimates that are not as wide as they need to be to fully acknowledge *model uncertainty*. *Bayesian model averaging* (Leamer 1978; Draper 1995), in which predictive distributions $p(y_f|y)$ for future observables y_f given past data y are computed by averaging over the model uncertainty uncovered by the search through $\mathscr{S}$ (rather than ignoring it), through calculations of the form

$$p\left(y_f|y\right) = \int_S p\left(y_f|y, S\right) p(S|y)\, dS,$$

can provide one principled, satisfying and rather general method for solving the problem of Bayesian model specification in a well-calibrated manner; methods based on *cross-validation* (see, for example, Stone 1974), in which (in effect) part of the data is used to specify the prior on $\mathscr{S}$ and the rest of the data is employed to update that prior, can provide another; and the approach illustrated above in the study with treatment and control groups – which combines conditional exchangeability judgments (driven by the context of the problem) with Bayesian nonparametric methods – can provide yet another.

Excise Taxes

James R. Hines Jr.

Abstract

Excise taxes are selective taxes on the sale or use of specific goods and services, such as alcohol and petrol. Over time, governments have relied less on excise taxes, though, as of 2007, excise taxes still contribute 12 per cent of total government revenues in OECD countries. In addition to generating needed revenue, excise taxes can control externalities and impose tax burdens on those who benefit from government spending. Rather more controversially, they also can be used to discourage consumption of potentially harmful substances (such as tobacco and alcohol) that individuals might over-consume in the absence of taxation.

Excise taxes are selective taxes on the sale or use of specific goods and services, such as alcohol and petrol.

Excise taxes have existed for centuries and are widely used by governments today, at the beginning of the 21st century. The 20th-century spread of income taxation and value-added taxation reduced the significance of excise taxation as a source of government revenue, but most governments still collect sizeable taxes on petroleum products, tobacco products and alcohol. For example, in 2004 the US federal government collected 72 billion dollars in excise taxes, representing four per cent of its total tax revenues, of which petroleum taxes accounted for 33 billion dollars, or 45 per cent of total excises. The United States relies the least on excise taxes of the 30 wealthy nations that are members of the Organisation for Economic Co-operation and Development (OECD), whose excise tax collections in 2000 averaged 12 per cent of total government revenues (Hines 2007). As recently as 1969–71, excise taxes contributed 23 per cent of total tax collections of high-income countries, and 27 per cent of tax collections of developing countries (Cnossen 1977). Among OECD countries in 2000, those with the lowest incomes, the most centralized governments and the greatest openness to international trade had the highest ratios of excise tax collections to total government revenues (Hines 2007).

Excise taxes take the form either of specific taxes or of ad valorem taxes. A specific tax (or unit tax) is defined per unit of the taxed good or service, whereas an ad valorem tax is defined per sales value. Thus, the current US federal taxes of 0.184 dollar per gallon of petrol and 0.39 dollar per pack of cigarettes are specific taxes, while the US tax of 11 per cent of the value of bows and arrows and three per cent of the value of fish-finding sonar devices are ad valorem taxes. In competitive markets specific and ad valorem taxes have identical consequences, other than any differences stemming from compliance and enforcement. In imperfectly competitive markets the difference is more consequential, since ad valorem taxes automatically impose higher per-unit tax rates as firms restrict quantities to drive up prices. Hence, in imperfectly competitive markets, ad valorem taxes produce lower consumer prices and lower deadweight loss than do specific taxes raising the same revenue (Suits and Musgrave 1953; Delipalla and Keen 1992).

Four motivations underlie the use of most excise taxes. The first is revenue generation: excise taxes can produce significant government revenues, and may do so at lower political or economic cost than alternatives such as income taxation. The second motivation is the application of the benefit principle of taxation: excise taxes can be tailored to impose tax burdens on those who benefit from government services financed by excise taxes. Petrol fuel taxes are often justified as user fees for government-provided roads, and the tax on sonar devices is justified by government expenditures to maintain lakes and fisheries. The third motivation is control of externalities, which is the goal of a number of excise taxes on polluting substances, such as taxes on ozone-depleting chemicals. And the fourth motivation is that excise taxes may discourage consumption of potentially harmful substances (such as alcohol and tobacco) that individuals might over-consume in the absence of taxation.

Excise Tax Incidence

It is customary to think of the burden of excise taxes as being borne by consumers of taxed goods and services in the form of higher after-tax prices, but there is considerable scope for the shifting of tax burdens. In a simple competitive partial equilibrium setting, the burden of an excise tax depends on elasticities of demand and supply: if demand for a taxed good or service is elastic, and supply relatively inelastic, then the burden of an excise tax is borne by sellers, whereas buyers bear

the burden of a tax on a good or service with inelastic demand and elastic supply. Similar demand and supply elasticities imply equal sharing of excise tax burdens between buyers and sellers.

There are plausible circumstances in which consumers can bear more than 100 per cent of the burden of an excise tax, or alternatively, might actually benefit from the introduction of a tax. If the market for a good or service is imperfectly competitive, then, depending on the nature of competition and cost conditions, consumers may well bear more than 100 per cent of the burden of an excise tax (Delipalla and Keen 1992). Even with perfect competition, the nature of demand and supply spillovers among multiple markets in general equilibrium can produce anomalous outcomes, such as consumer prices that rise by more than the amount of excise taxes, or (after-tax) prices that even fall with the introduction of excise taxes (Hotelling 1932).

There is mixed evidence of excise tax incidence in practice. Poterba (1996) offers evidence that consumers bear the full burden of US excise and sales taxes in the form of higher prices, but Besley and Rosen (1999) find that many consumer prices rise by more than 100 per cent of excise and sales taxes imposed by US states and localities.

One concern frequently expressed about excise taxation is the potential regressivity of the resulting tax burdens. Excise tax rates do not rise with consumption in the way that income tax rates rise with income; furthermore, since the poor spend higher fractions of their incomes than do the wealthy, taxes based on expenditure rather than income may put greater relative burdens on low-income individuals. This second consideration is considerably diminished by adopting a lifetime perspective, however, since individuals ultimately either spend or give away all of their incomes. Hence the distributional impact of excise taxes depends critically on the income elasticities of demand for goods and services subject to high rates of excise taxation. Poterba (1991) analyses US petrol taxes from the standpoint of lifetime incidence, finding that petrol consumption rises more than proportionately with affluence over much of the range of total spending, suggesting that petrol taxes are progressive, albeit less so than income taxes.

Optimal Excise Taxation

Ramsey (1927) initiated the modern theory of optimal taxation with his analysis of excise taxation in a model with identical consumers, finding that, far from being uniform, optimal excise tax rates vary inversely with elasticities of demand for taxed goods. Ramsey's set-up restricts the government to raising a given amount of revenue exclusively with excise taxes, and the resulting optimal tax pattern reflects that the excess burden of a tax increases with its behavioural impact. Diamond (1975) generalized the Ramsey rule to settings with heterogeneous individuals, showing that the resulting modified optimal excise taxes reflect both efficiency (lower tax rates on elastically demanded goods) and distributional (higher tax rates on goods purchased by wealthy individuals) considerations. As noted by Corlett and Hague (1953–4), the government's inability to tax leisure is what prevents uniform excise taxes from being optimal in the Ramsey model; as a second-best correction, the optimal Ramsey tax configuration entails imposing heavier excise taxes on goods and services that are complementary with untaxed leisure.

Under what circumstances would a government with access to a full range of income tax instruments want to impose excise taxes at differentiated rates? Atkinson and Stiglitz (1976) showed that, if consumers have identical utility functions that are weakly separable in consumption and leisure, then there is nothing to be gained by supplementing an optimal nonlinear income tax with differentiated excise taxes. The reason is that, in such a setting, patterns of commodity consumption fail to convey information to the government that is not already captured by income levels.

Excise taxes can nevertheless serve the function of controlling externalities, a consideration omitted from the Atkinson–Stiglitz framework. Pigou (1920) famously proposed the imposition of corrective excise taxes at rates equal to

marginal external damages, noting that doing so restores economic efficiency, and Sandmo (1975) illustrates the optimal application of Pigouvian excise taxes when the government relies on excise taxes to raise revenue. In practice, governments impose heavy taxes on energy products, motor vehicles and other transport, waste management, ozone- depleting substances, and other products and activities that arguably create externalities in degrading the environment. In 2000, OECD countries raised an average of 5.5 per cent of their total tax revenues from these environmental taxes, with European Union members averaging 6.8 per cent, and the United States the lowest in the OECD at 3.4 per cent (Hines 2007).

Excise taxes can also play a role in discouraging consumption of goods that may not have external effects, but are nonetheless harmful to the individuals who consume them. Examples of such goods include tobacco products, alcohol, and food with poor nutritional content. Irrational consumers may begin consuming these items without fully appreciating the regret they will experience years later, in which case there could be a role for optimal excise taxation to help consumers by making consumption more expensive, and therefore reducing the likelihood of consumers starting early on the path of over-consumption (O'Donoghue and Rabin 2006).

Finally, excise taxes raise enforcement concerns, as do all taxes. In the United Kingdom, which boasts the highest cigarette taxes in Europe, one cigarette out of every five is purchased on the black market (Cnossen and Smart 2005). Hence the choice of excise tax policy needs to be sensitive to smuggling and other evasion opportunities.

Executive Compensation

Michael L. Bognanno

Abstract

Chief executive officer (CEO) compensation is defined as the sum of base pay, bonuses, stock grants, stock options, other forms of

compensation and benefits. Inflation-adjusted, median total CEO compensation in the United States almost tripled between 1992 and 2000, with grants of stock options evolving to be the largest component of compensation. This article presents the arguments for and against this level and composition of CEO compensation.

Keywords

Agency framework; CEO; Executive compensation; Stock options

The level of executive pay has long been a flashpoint with the general public, particularly in periods of macroeconomic or stock market distress. Chief executive officer (CEO) compensation is defined as the sum of base pay, bonuses, stock grants, stock options, other forms of compensation and benefits. Of these components, grants of stock options have evolved to be the largest component of compensation. The near tripling of inflation-adjusted, median total CEO compensation between 1992 and 2000 was produced largely by a fivefold increase in stock options (Murphy 2002). To quantify the relative growth in CEO pay, in 1970 the average S&P 500 CEO earned approximately 30 times the pay of an average production worker. By 2002, this multiple had risen to almost 90 times the earnings of an average production worker in terms of CEO cash compensation (salary and bonus), and exceeded 360 times the earnings of an average production worker in terms of CEO total compensation (cash compensation, stock options and grants, and other compensation) (Hall and Murphy 2003).

In a comparison of 12 OECD countries, Abowd and Bognanno (1995) found that US CEOs were the most highly compensated. A similar result was not found for high-level US managers (human resource directors) or for US manufacturing operatives. (See also Murphy 1999 for international comparisons and a summary of theoretical and empirical research on executive pay.) Conyon and Murphy (2000) found that, controlling for firm size and other factors, US CEOs earned 190 per cent more in total compensation than UK CEOs. The United Kingdom's highest paid executive ranked only 97th on the list of the most highly paid US CEOs. Remarkably, Disney's Michael Eisner exercised options in 1997 worth more than the aggregate compensation of the top 500 UK CEOs.

While there has been an undisputed escalation in US CEO pay in absolute terms and in relation to the earnings of production workers over recent decades, academic researchers have taken positions on both sides of the debate over whether the level of CEO pay is economically justified or is the product of managerial power over the process of CEO pay determination. This article characterizes the basic framework within which CEO pay is viewed, and presents the principal arguments characterizing this debate.

The compensation of CEOs is generally viewed within an agency framework. (The gist of agency theory is found in the Bible, John 10:12: 'He who is a hired hand, and not a shepherd, who is *not the owner* of the sheep, sees the wolf coming, and leaves the sheep and flees, and the wolf snatches them and scatters them.') The separation that exists between the owners and managers in corporations gives rise to an agency problem in which managers have an incentive to pursue their personal interests over the interests of shareholders. The increase in the components of pay that are linked to firm performance, stock option schemes for example, are viewed from this perspective as a mechanism to align the incentives of managers with those of shareholders. Another incentive argument is based in tournament theory. The idea is that high CEO pay levels may increase the effort of those executives below the CEO position who are competing for promotion to the top spot (Lazear and Rosen 1981). However, reasons for caution against the use of intense competition also exist because competition may impede teamwork and spark counterproductive efforts (Lazear 1989).

Jensen and Murphy (1990) and Dow and Raposo (2005) attribute the sharp gain in CEO pay to the adoption of high-powered incentives in compensation packages. Hall and Liebman (1998) document the increasing responsiveness of CEO compensation to firm performance in the period between 1980 and 1994, a sensitivity due almost entirely to holdings of stock and stock

options. The argument has been made that the public focus on the level of CEO pay is misplaced because such concern changes the focus from the more important issue of how CEOs are paid and the link between CEO pay and firm performance (Jensen and Murphy 1990).

While the agency framework has provided a justification for stronger pay for performance and higher levels of contingent compensation, to some extent executives have responded to contingent compensation by seeking to avoid the risk created. A working paper by Ozerturk (2006) touches on the growth in the market for managerial hedging instruments, a growth coinciding with the growth in stockbased compensation in the late 1990s. The extent to which executives are reducing the pay–firm performance sensitivity of their compensation through the use of managerial hedging instruments is unknown, as disclosure rules are loose and participants in the market have no interest in publicizing their actions (Ozerturk 2006). Lavalle (2001) notes that at least 31 company insiders reported hedging in 2000, and for the majority it was a good decision. Hedging removes the agency theory basis for awarding large stock-based compensation packages.

The potential drawbacks of stock options are reviewed in Holden (2005), and include incentives for excessive risk taking and a focus on short-term performance, discouraging the payment of dividends and costing more to the firm than they are valued by risk-averse executives. Another negative feature of performance-based pay is the incentive created to manipulate or misstate the firm's financial performance. Efendi et al. (2007) find that the likelihood of accounting misstatements and severe accounting irregularities increases with the worth of CEO stock options.

The principal argument for the contention that the level of CEO pay is economically justified is that a competitive market for executive talent exists, and the level of CEO pay is a reflection of the intensive bidding by firms for scarce top talent. Tervio (2003) presents a competitive assignment model that determines CEO pay as the outcome of a bidding process between heterogeneous firms. In Gabaix and Landier's (2008) framework, CEOs of varying talent are matched to firms competitively, resulting in the largest firms having the top talent and the largest firms in the largest economies paying the most for CEO talent. Firm scale magnifies the pay discrepancies that result from small differences in CEO talent. High pay for top achievers is seen as appropriate given the value of their talent when magnified through the scale of large corporations. Their model also offers a partial explanation of the international differences in CEO pay.

Murphy and Zabojnik (2004) argue that CEO pay is determined by competitive forces, and the increase in CEO pay was driven primarily by an increase in the importance of general skills in running the modern corporation, as opposed to skills that are not transferable between firms, and the trend towards employing more externally hired CEOs. In the period from the 1970s to the 1990s, they state that the percentage of externally hired US CEOs rose from 15 per cent to more than 26 per cent. Others have also suggested that the trend toward filling the CEO position with external hires has played a role in increasing CEO pay.

In the presence of firms seeking to hire experienced CEOs from the outside labour market, Giannetti (2009) develops a model that offers an explanation of many aspects of managerial compensation, including benchmarking pay against larger firms, providing unrestricted stock awards to highly paid top executives and the use of long-term incentives. His model also offers an explanation of the growth in US CEO pay, and for international differences in CEO pay.

Further explanations arguing that the growth in CEO pay is justified also exist. Research suggests that CEO pay is in accord with historical norms in relation to the size of the firm, and that the marked growth in CEO pay is commensurate with growth in firm size. The link between firm size and CEO pay is very well documented (Murphy 1999). A recent study by Gabaix and Landier (2008) finds that the sixfold increase in CEO pay between 1980 and 2003 can be attributed to the sixfold increase in market capitalization of large US companies during that period.

A contrasting result is found in Bebchuk and Grinstein (2005). They find the growth in CEO

pay between 1993 and 2003 to exceed the increase than can be explained through changes in firm size, performance and industry mix. Mean compensation would have been only half as high in 2003 were the relationships between these factors and pay the same as they were in 1993.

The principal argument for the contention that CEOs are overpaid is the managerial power hypothesis. It argues that the pay-setting process is unduly influenced by the CEO, as the CEO may have substantial influence over the composition of the board of directors and of the compensation committee determining CEO pay (Crystal 1991). Support for this hypothesis is found in that CEO pay is excessive for firms with relatively weak boards of directors, for firms with no dominant outside shareholder, and for firms with a manager who has a relatively large ownership stake (Bebchuk et al. 2002; see Bebchuk and Fried 2003 for a review of the managerial power hypothesis).

The managerial power hypothesis also purports to explain several features of executive compensation, such as why stock option grants may have 'reload' provisions, why executives are allowed to exercise options early and hedge the risk of their options and stock holdings, and why US CEOs receive pay in excess of their international counterparts (Bebchuk et al. 2002). Murphy (2002) provides counter-arguments to the managerial power hypothesis.

CEO pay is both meaningful and growing in relation to firm financials. The ratio of the aggregate compensation paid by public companies to their top five executives to the aggregate earnings of their firms increased from five per cent in 1993–95 to 9.8 per cent in 2001–03 (Bebchuk and Grinstein 2005). This trend makes the debate over CEO pay levels and the policies directed towards CEO pay more important than ever. However, in pondering the regulation of CEO pay, there is a large literature with contrasting viewpoints that demand careful examination.

Exhaustible Resources

Geoffrey Heal

Abstract

This article provides a brief overview of the ideas that have emerged in economics in connection with exhaustible resources. A resource is exhaustible if, the more we consume today, the less will be available for consumption at later dates. The dynamics of resource allocation, and the attainment of efficiency in intertemporal models, are thus key aspects of any economic theory of exhaustibility. The exhaustibility paradigm is widely applicable, including to climate change, biodiversity loss and even such non-environmental phenomena as antibiotic resistance.

Exhaustible resources are among the most important inputs to economic activities. Conventional crude oil and natural gas are good topical examples, with their pricing and availability currently a major source of concern. Of course, all minerals and extractive resources are exhaustible, as the volume of the earth is finite, but for many resources exhaustibility is not a matter of everyday concern as it is for oil and gas. There is a concern that the exhaustibility of low-cost deposits of oil and gas could restrict the long-run growth potential of the industrial world, and understanding the economic implications of exhaustibility is essential to grappling with this issue.

The availability of natural resources is a substantial topic in geology, with an extensive discussion there of the type of information available about resource supplies (see Barnett and Morse 1963; Brobst 1979; Smith 1980; Goeller 1979). Geologists classify resource stocks as proven, probable or possible reserves, which differ in the costs of extraction and the certainty with which their scale is known. An important lesson from the geological perspective is that the size of the total reserves of most resources is unknown. Even today, after many years of intensive prospecting, that remains true for a resource as important as oil.

The paradigm of exhaustibility is not limited in its applications to mineral resources: underground aquifers are exhaustible, and the capacity of the atmosphere to absorb greenhouse gases without radical change to the climate system has also been modelled as an exhaustible resource (Heal 1984). Another related and interesting exhaustible resource is the capacity to store carbon dioxide in underground rock formations: according to some perspectives on climate change, this could be a vitally important – and exhaustible – resource up to about 2050 (Butt et al. 1999). A very different recent application of this paradigm is in the field of drug resistance: Laxminarayan and Brown (2001) have modelled as an exhaustible resource the extent to which a drug can be used before resistance develops among the pathogens it is intended to kill. The world's stock of biodiversity can be seen as an exhaustible resource, too. Every time a species is driven to extinction, this stock falls in an irreversible way. We are depleting

that stock, and do not fully understand the consequences.

The first analytical discussion of exhaustibility can be found in the work of L.C. Gray in 1914, but the work that is regarded as the classic work in this area is that of Harold Hotelling in 1931. In an extraordinarily prescient article he provided the foundations of the modern theory of exhaustible resources, while simultaneously giving one of the earliest applications of calculus of variations in economics and developing an arbitrage-free model of equilibrium pricing. His work was so much ahead of its time that it was 30 years or more before it was fully appreciated. His name is now widely attached to the basic model of resource depletion, the 'Hotelling model', and to the movement of resource prices in a competitive market, which follow the 'Hotelling rule'.

A central feature of exhaustible resources is that they force us to think about resource allocation over time. For an exhaustible resource, the more we consume today, the less will be available for consumption at later dates. The dynamics of resource allocation, and the attainment of efficiency in intertemporal models, are key aspects of any economic theory of exhaustibility. This is probably the main reason why Hotelling's contribution was neglected for so long: in the 1930s economists were not ready to consider these issues analytically. It took the development of theories of growth, descriptive and optimal, to bring these to the fore.

The Hotelling Model

The simplest economic model of the use of an exhaustible resource is as follows. There is an initial stock S_0 of the resource, and we denote by $S_t \leq S_0$ the stock remaining at time t. Consumption of the resource at date t is c_t and the benefits from consumption are represented by a utility function $u(c_t)$, generally assumed to be strictly concave, twice differentiable and to satisfy a boundary condition such as $du/dc \to \infty$ as $c \to 0$ or $lim_{C \to 0}\ u(c) = -\infty$. Either of these conditions penalizes zero consumption very sharply and keeps consumption away from zero. Within this model we seek the time path of resource consumption that maximizes the present value of welfare:

$$\text{Max} \int_0^\infty u(c_t)\, e^{-\delta t} dt \text{ subject to } \int_0^\infty c_t dt \leq S_0 \tag{1}$$

Here $\delta \geq 0$ is a discount rate, and the second integral reflects the constraint imposed on cumulative use of the resource by its exhaustibility. It is this intertemporal conflict between present and future resource use that lies at the centre of theories of exhaustibility. Problem 1 is a classical problem in the calculus of variations, an isoperimetric problem, so called because it was first solved in the context of finding the closed plane curve having a given length and enclosing the greatest area. Economists have reformulated this problem so that it can be solved by methods from control theory rather than calculus of variations, and the reformulation usually used is

$$\text{Max} \int_0^\infty u(c_t)\, e^{-\delta t} dt \text{ subject to } \frac{dS_t}{dt} = -c_t, S_t \geq 0 \tag{2}$$

This replaces an integral constraint with a differential equation and a non- negativity constraint on a state variable. Solving this problem requires use of the Hamiltonian

$$H = u(c_t)e^{-\delta t} + \lambda_t e^{-\delta t}[-c_t]$$

where λ is a current value co-state variable. The first order conditions that a solution must satisfy are

$$u(c_t)' = \lambda_t \text{ and } \frac{1}{\lambda_t}\frac{d\lambda_t}{dt} = \delta \tag{3}$$

where a prime denotes the derivative of a function with respect to its argument, and two primes denote the second derivative. The first condition is intuitively obvious: the marginal utility of consumption must equal the shadow price of the resource. The second condition, which we call the Hotelling rule, states that the shadow price must rise at the discount rate. Another way of

looking at this is that in present value terms the shadow prices must be constant, so the present value of the marginal utility of consumption must be constant. Again, this is an intuitively satisfactory condition. It implies, of course, that consumption must fall over time.

To give an illustration of this result, consider the logarithmic utility function $u\ (c_t) = \ln c_t$. From 3 $\lambda_t = u(c_t)\ \prime = \frac{1}{c_t} = \lambda_0 e^{\delta t}$ so $c_t = c_0 e^{-\delta t}$ and $c_0 = \delta S_0$.

The Hotelling problem has also been known as the 'cake-eating problem' as it can be seen as choosing how to divide a finite cake between different periods. As long as the discount rate is positive there is a well-defined answer, as we have seen above. Matters are different if we try to treat all generations equally and set $\delta = 0$. Then, as we can see from the logarithmic example above, consumption is zero: indeed, it clearly goes to zero at all dates as the discount rate goes to zero. On an optimal path, as the discount rate falls we are trying to spread consumption ever more thinly over time and keep more for the future. This makes sense, except in the limiting case with a zero discount rate, in which it tells us never to consume anything and always to keep everything for the future. In this case problems 1 and 2 have no solution: although they look reasonable they are in fact ill-posed. There is an extensive literature on what exactly goes wrong in this case and what alternative formulations are available (Heal 1985; Gale 1967).

Extensions of the Basic Model

A simple change in the basic model is to allow for extraction costs, something that Hotelling did back in 1931. Consider a corporation extracting resources for a profit, rather than a national planning problem. The rate of extraction is again c_t and there is a cost of extraction of x per unit. The sale price of the resource is given by the demand curve $p(c_t)$, so the company is not a price-taker. The present value of profits is

$$\int_0^\infty [p(c_t)c_t - xc_t]e^{-\delta t}dt$$

and the corporation seeks to maximize this subject to the same constraints as above. The result is that

$$\left[p(c_t)'c_t + p - x\right] = \lambda_t \text{ and } \frac{1}{\lambda_t}\frac{d\lambda_t}{dt} = \delta$$

The first term is just the marginal revenue minus marginal cost: this difference again has to grow at the discount rate. We summarize this by saying that the rent to the resource must grow at the discount rate.

Another simple extension is to place a value on the remaining stock of the resource, $u(c_t, S_t)$. Think here of biodiversity in general or of a slow-growing forest. We value the flow of services that comes from depleting these, but we also value having some of the stock remaining (Krautkramer 1985; Heal 1998). Looking at the problem

$$\text{Max} \int_0^\infty u(c_t, S_t)e^{-\delta t}dt \text{ subject to } \frac{dS_t}{dt} = -c_t, S_t \geq 0 \quad (4)$$

leads to very different results. The first order conditions for optimality are that

$$u_c = \lambda \text{ and } \frac{d\lambda}{dt} - \delta\lambda = -u_s$$

where u_c, u_s are respectively the derivatives of u with respect to c_t and S_t. This solution is analysed at length in Heal (1998): what is interesting is that, provided we drop the boundary condition on $u(0)$ or $u'(0)$, there may be a stationary solution to this system of equations, at which $\frac{d\lambda}{dt} = 0, c_t = 0$ and $\delta = u_c/u_s$. This means that the discount rate equals the slope of an indifference curve in the $c - S$ plane, that is, it equals the marginal rate of substitution between the contributions to welfare of the stock and the flow.

Resources in Production

The natural next step in considering how exhaustible resources affect an economic system is to model how they enter into the production process and whether their exhaustibility acts as a drag on the economy, limiting its long-run growth.

E

This takes into the discussion of 'sustainability' and exhaustibility. The simplest way to do this is to take the basic neoclassical growth model and replace labour as an input by an exhaustible resource. This gives us as a production function $F(K_t, R_t)$ where K_t and R_t are respectively the capital stock and rate of resource use at date t. Typically F is assumed to be twice differentiable and to show constant or diminishing returns to the two inputs. With this formulation we can consider the problem

$$\text{Max} \int_0^\infty (c_t)e^{-\delta t}dt, c = F(K_t, R_t) - I_t, \quad \frac{dK_t}{dt} = I_t, \frac{dS_t}{dt} = -R_t, S_t \geq 0 \tag{5}$$

Here, obviously, I_t is investment at t, the rate of change of the capital stock. This problem is considerably more complex than any of the previous ones, and is analysed at length by Dasgupta and Heal (1974). Let $y_t = \frac{K_t}{R_t}, f(x_t) = F\left(\frac{K_t}{R_t}, 1\right)$, and $\eta(c) = \frac{-cu''(c)}{u'(c)}$ let σ be the elasticity of substitution between capital and the resource,

$$\sigma = \frac{-f'(x)f(x) - xf'(x)}{xf(x)f''(x)}$$

Then we can state the conditions characterizing a solution to Eq. (5) as follows (θ is the price of the produced good):

$$\frac{1}{\theta}\frac{d\theta}{dt} = F_K - \delta, \frac{1}{c}\frac{dc}{dt} = [F_K - \delta]/\eta(c) \tag{6}$$

$$\frac{1}{x}\frac{dx}{dt} = \sigma\frac{f(x)}{x} \text{ and } \lambda_t F_R e^{-\delta t} \text{ is constant} \tag{7}$$

Clearly in an economy with capital that can be reproduced and accumulated, and a resource that is exhaustible, growth must take place through the substitution of capital for resources. Equation (7) captures this process. It tells us that the capital–resource ratio changes at a rate that is the product of the elasticity of substitution and the average product per unit of fixed capital. The former indicates the ease with which substitution can be carried out, and the latter can be thought of as a measure of the importance of capital in production. So the easier it is to substitute, and the more important capital is, the more we substitute capital for resources.

What impact does the resource have on long-run growth possibilities? Clearly if $F(K, 0) > 0$ for $K > 0$ then the exhaustibility of the resource does not matter: we can continue producing when it runs out. The interesting case is $F(K, 0) = 0$ for any K. The fact that no production is possible without the resource does not mean that production must go to zero: consumption of the resource, as we saw in the Hotelling model, can be spread thinly over the indefinite future. If we can produce enough to support a good living standard with only a very small amount of the resource and a lot of capital, again exhaustibility may not matter. And, of course, technical progress may come to the rescue: it could increase the productivity of the scarce resource, or release the constraint that it imposes on production. In the light of these considerations Dasgupta and Heal (1979, p. 198) advance the following definitions: 'We shall regard an exhaustible resource as being *inessential* if there is a feasible program along which consumption is bounded away from zero: or in other words, if a positive sustainable level of consumption is feasible. Likewise, regard a resource as *essential* if feasible consumption must necessarily decline to zero in the long run.' This discussion anticipates many more recent discussions of sustainability. We can explore these issues further in the context of a CES production function, and in this case Dasgupta and Heal show that, if the elasticity of substitution between the resource and capital exceeds one, then the exhaustibility of the resource does not pose a fundamental problem. In the opposite case, an elasticity less than one, output must eventually fall to zero in the absence of technical progress. And in the borderline case, a unit elasticity, we have the Cobb–Douglas production function. In this case, if the elasticity of output with respect to capital exceeds that with respect to the resource, there is a feasible policy on which consumption is bounded away from zero. But in the remaining cases there is not: absent technical progress,

output must fall to zero. In fact, if we have a Cobb–Douglas production function with the elasticity of output with respect to capital greater than that with respect to the resource, not only are there paths on which output is bounded away from zero, but there are paths on which output is constant and on which output grows continuously. The paths on which output is constant may be characterized by a constant level of investment that maintains the total value of all stock constant, with the investment equal to the rent on the exhaustible resource. This is the Hartwick rule (Hartwick 1977; Asheim et al. 2003).

Backstop Technologies

Clearly the issue of substitutability is central to an understanding of the economic consequences of exhaustibility of important inputs. There are several dimensions to substitutability. One dimension, the one that we have discussed so far, is substitutability between capital and the resource. We can reduce oil use by insulating our buildings and wearing warmer clothes: this is substituting capital for oil. So is buying more expensive but more efficient furnaces. Both reduce oil consumption but require more capital. But there is another aspect of substitutability. Conventional crude oil is exhaustible and will be fully depleted at some point. But then there will be alternatives. For example, we can extract oil from coal – this is what Germany did during the Second World War and what South Africa did while it was subject to a trade embargo because of its apartheid policies. It is expensive by the standards of historical oil prices – perhaps $40 per barrel – but completely feasible. Similarly, oil can be extracted from tar sands – indeed, it is currently so extracted – but again at a cost that is high by historical oil price standards. And there are vast reserves of tar sands – they can probably provide more oil than all the conventional crude oil deposits in the Middle East. So other resources can replace oil when it runs out. This is a form of substitutability. Dasgupta and Heal (1974) modelled this by assuming that at a date T, which was unknown, the constraint imposed by the exhaustible resources would be lifted and an abundant substitute would become available. This is not unlike the situation described above with respect to oil and coal or tar sands. Another interpretation is that T is when nuclear fusion finally becomes a reality and, in the much-quoted phrase of the 1960s, energy finally becomes 'too cheap to meter'. (See also Nordhaus 1973, for simulation models of the effect of a backstop technology.)

To formalize this, assume that prior to T the technology is as in the previous section, but that after T there is a new technology that does not depend on the resource as an input. We can think of this as a dramatic technical change (such as fusion) or the appearance of an abundant substitute for the resource (such as tar sands for oil). Production from T onwards depends only on the capital stock available at T and not on the resource stock at that date. So we can write a state valuation function $V(K_T)$ giving the present value of welfare along an optimal policy from T onwards, discounted back to T. Then the overall problem is to

$$\text{Max} \int_0^T u(c_t)e^{-\delta t}dt + V(K_T), \text{ with for } t \in [0,T],$$
$$c = F(K_t, R_t) - I_t,\ \frac{dK_t}{dt} = I_t,\ \frac{dS_t}{dt} = -R_t, S_t \geq 0$$

Dasgupta and Heal assumed that T was unknown with density function ω_t. Then the maximand is the expected value of $\int_0^T u(c_t)e^{-\delta t}dt + V(K_T)$, which is

$$\int_0^\infty w_t \int_0^T \left[u(c_t)e^{-\delta t}dt + V(K_T)\right]$$

which on integration by parts and letting $\Omega_t = \int_t^\infty \omega_\gamma d\tau$ can be written as

$$\int_0^\infty e^{-\delta t}[u(c_t)\Omega_t + \omega_t V(K_t)]dt$$

Dasgupta and Heal (1974) explore possible solutions to this problem in some special cases, and characterize paths that are optimal. In the special case in which the valuation function V is independent not only of the resource stock ST (which we have assumed) but also of the capital stock K_T (so that the new source makes all existing capital obsolete) the optimum path satisfies

E

$$\frac{1}{x}\frac{dx}{dt} = \sigma\frac{f(x)}{x} \tag{8}$$

$$\frac{1}{c}\frac{dc}{dt} = \frac{F_K - \delta - \psi}{\eta(c)} \tag{9}$$

where $\psi_t = \frac{\omega_t}{\Omega_t}$. These are very similar to Eqs. (6) and (7) from the deterministic case with no backstop technology, except for the term Ψ that is added to the discount rate. Dasgupta and Heal also establish a certainty-equivalence theorem showing when the possibility of a backstop arriving can be subsumed entirely into a modification of the discount rate, by the addition of a term Ψ_t to the discount rate that reflects the conditional probability of the backstop arriving now, given that it has not yet arrived.

Of particular interest is the behaviour of the resource price when there is a possibility of a substitute arriving. A more direct way of understanding this is to look at a different model (Heal 1976), again with a backstop technology available as a replacement for the resource. Assume that there is a cost to extraction of the resource, and that this depends on and increases with the amount extracted to date. This is in many ways a natural assumption, in keeping what we know about the grade-tonnage distribution for most minerals. There are small amounts available at low extraction costs, more at larger costs and almost unlimited amounts if we are prepared to pay a sufficiently high cost. There is also a backstop available at a fixed unit cost, and in effectively unlimited supply.

One way of formalizing this is to let $z_t = \int_0^t c_\tau d\tau$ be the amount extracted to date, and have the current unit extraction cost depend on this:

$$\begin{aligned}&\text{extraction cost} = g(z),\\ &g' > 0 \text{ for } 0 \le z \le \overline{z} \text{ and}\\ &g(z) = \beta = g(\overline{z}) > 0 \text{ for } z \ge \overline{z}\end{aligned}$$

So the unit extraction cost is an increasing function of cumulative extraction up to a certain total extraction and a corresponding extraction cost, at which point a backstop becomes available in more or less unlimited amounts at a constant cost of β. In the case of a fixed extraction cost, which is the classic Hotelling model considered above, the price rises away from the marginal extraction cost at the discount rate – the rent on the resource satisfied Hotelling's rule and increases exponentially. This is natural: the rent on the resource reflects its scarcity, and this scarcity is rising over time, so it is natural for the rent to rise too. In the present case we should expect a different outcome. Overall the resource is not scarce: high-cost sources, to which we move over time, are abundant. It is only low-cost sources that are scarce. During the depletion of these, scarcity reigns, but once they have gone there is no longer scarcity in the sense of a limited availability. Any amount is available at the right price. So the dynamics of scarcity are in effect reversed. The solution reflects this, and is found by piecing together the solutions to two distinct problems:

$$\begin{aligned}&\text{Max}\int_0^\infty u(c_t)e^{-\delta t}dt \text{ subject to } c_t + \frac{dK_t}{dt}\\ &= F(K_t, R_t) - g(z_t)R_t\end{aligned} \tag{10}$$

and

$$\begin{aligned}&\text{Max}\int_0^\infty u(c_t)e^{-\delta t}dt \text{ subject to } c_t + \frac{dK_t}{dt}\\ &= F(K_t, R_t) - \beta R_t\end{aligned} \tag{11}$$

Problem 10 reflects the constraints on the economy up to the time when the backstop comes into use, and problem 11 represents the economy after all lower-cost reserves are depleted and once it is dependent on the backstop. We expect that a path that is optimal overall will first follow a solution to 10 and then one to 11, and this intuition can be verified formally (Heal 1976). Clearly, once we are in the second regime, we expect that the price of the resource will equal its marginal extraction cost β. What is less clear is how price and extraction cost are related during the phase corresponding to the solution to 10. It is possible to show the following: if λ is the price of the resource and θ that of the produced good, then

$$\frac{1}{\lambda}\frac{d\lambda}{dt} = \delta\left(1 - \frac{\theta g(z)}{\lambda}\right) + \frac{\theta g(z)}{\lambda}\left(\frac{1}{\theta}\frac{d\theta}{dt}\right) \tag{12}$$

Although it looks complicated, Eq. (12) in fact bears a simple and intuitive interpretation. It expresses the rate of change of the price of the resource as the weighted average of two terms, where the weights are $\left(1-\frac{\theta g(z)}{\lambda}\right)$ and $\frac{\theta g(z)}{\lambda}$, which respectively the fraction of the price that is pure rent and the fraction that is extraction cost. The two terms whose weighted average equals the rate of change of the resource price are the discount rate and the rate of change of the price of the produced good. So, if most of the price of the resource is rent, then its price rises at close to the discount rate, whereas if most of the price is extraction costs, then it rises at the rate at which extraction costs rise. This suggests a path of price movements rather different from the classic Hotelling model: in the present case prices will contain a large rent element early in the life cycle of the resource and then no rent at all towards the end of the life cycle.

The relationship between price and extraction cost, and so the movement of the scarcity rent over time, has been the subject of many additional papers, including Solow and Wan (1976), Hanson (1980), Farzin (1992) and Oren and Powell (1985). Oren and Powell extend the basic model presented above to consider a class of related issues, and Farzin focuses on the issue of whether the movement of scarcity rent must be monotonic. He concludes that there are reasonable cases in which the scarcity rent moves non-monotonically over time.

Imperfect Competition and Resource Use

So far we have considered patterns of resource use that are socially optimal, which are also the patterns of resource use that would emerge from a set of complete competitive markets with no elements of market failure present. While the answers to these questions are interesting and informative, it is clearly necessary to understand the impact of market imperfections on this picture. There is, not surprisingly, an extensive and sophisticated literature on this. I have space for only one or two basic insights.

We expect that moving from competition to monopoly will raise the prices of a good. To the extent that this is true for exhaustible resources, then monopoly will reduce the rate of extraction. Hence Robert Solow's comment that 'The monopolist is the conservationist's best friend'. But, with a fixed stock to sell, as in the basic Hotelling model, if the monopolist sells less now because of a higher price, then he must sell more in the future, when the benefits are discounted. This is unattractive to him: the intertemporal substitutability inherent in any choices about a time pattern of resource use brings a new dimension to the impact of monopoly or imperfect competition on price and output.

An interesting illustration of this is seen clearly in the simplest possible case, that of a monopolistic supplier of a resource with a zero marginal extraction cost. In this case, whether the monopolist charges a higher or a lower price initially than the competitive price depends on the behaviour of the price elasticity of demand for the resource along the demand curve. Consider the family of constant-elasticity demand curves, $p(c) = Ac^{-B}$ where $1 > B > 0$. The monopolist's problem is to

$$\text{Max} \int_0^\infty p(c)ce^{-\delta t}dt$$

subject to the usual constraint on the total availability of the resource. This requires that the marginal revenue from sale of the resource grows over time at the discount rate. Now, letting $\varepsilon(c)$ be the demand elasticity when consumption is c we can write marginal revenue as

$$MR_t = p_t(1 + 1/\varepsilon(c_t)) = p_t\gamma_t \text{ where } \gamma = (1 + 1/\varepsilon(c_t))$$

Hence

$$\frac{d\ln MR}{dt} = \delta = \frac{d\ln p}{dt} + \frac{dln\gamma}{dt}$$

and so

$$\frac{d\ln p}{dt} = \delta - \frac{dln\gamma}{dt}$$

For a constant elasticity demand curve it is easy to check that $\frac{dln\gamma}{dt} = 0$ so that in this case a

monopolist will want the price to rise at the discount rate – just as in the competitive case. More generally, we can show that

$$\text{If } \frac{d\eta}{dc} > (<)0 \text{ then } \frac{d\ln p}{dt} < (>)\delta$$

so that the nature of the bias from first best introduced by monopoly depends on the way the demand elasticity changes along the demand curve (Dasgupta and Heal 1979; Stiglitz 1976).

The case of a monopoly supplier is the simplest entry point to imperfect competition, but does not do justice to the sophistication of the results that are available in this area. One of the most interesting developments was motivated by the role of the OPEC cartel in the oil market, and a desire to understand its real long-run impact. This is the development of models of a market with a cartel and a 'competitive fringe', which seems to describe accurately the relationship between OPEC and non-OPEC members. Closely associated with this is the idea of limit pricing to keep a backstop technology out of the market. Models incorporating these ideas are summarized in Dasgupta and Heal (1979), and some of the key original articles are by Sweeney (1977), Gilbert (1978) and Pindyck (1978).

Conclusions

Exhaustible resources are economically important. In addition, exhaustibility is an analytically interesting property: it forces us to think even in the very simplest case about intertemporal issues, about the present versus the future. Without this conflict there is no exhaustible resource. So dynamics are integral in even the most basic thinking here, which is one reason why serious discussion of exhaustibility was so slow to emerge. It is not surprising that exhaustibility has featured centrally in discussions of sustainability, and earlier in the neo-Malthusian diatribes of the Club of Rome. Many of the issues that have emerged in the debates about sustainability have in fact been analysed by economists in the discussions of exhaustibility in the 1970s (see Heal 2003), usually with an emphasis on substitutability and technical progress as long-run solutions to the constraints imposed by exhaustibility, solutions that are typically more apparent to economists than to most others, though no less realistic for that. As I emphasized in the introduction, an interesting aspect of exhaustibility is the rather widespread applicability of the paradigm – to climate change, biodiversity loss and even such totally non-environmental phenomena as antibiotic resistance.

In this article I have been able to review only a fraction of a large and original literature on exhaustibility. I have certainly short-changed the literature on imperfect competition in markets for exhaustible resources, and have not touched at all on work on the empirical testing of the models of price movements discussed here (Heal and Barrow 1980; Miller and Upton 1985; Slade 1982; Agbeyegbe 1989). Another big gap is the theory of non-optimal growth with exhaustible resources, which asks how a market economy with imperfect futures markets will evolve. Because of the intrinsically intertemporal nature of the allocation problem with exhaustibility, the absence of a complete set of futures markets has particularly serious consequences. Again, there is an interesting and original literature on this (for a review, see Dasgupta and Heal 1979).

Existence of General Equilibrium

Gerard Debreu

Abstract

This article summarizes the history of the attempts to prove the existence of general equilibrium from those of Wald and others in Vienna in the 1930s to those of von Neumann and Nash, and of the solutions provided by Arrow, Debreu and McKenzie in the 1950s and their subsequent development.

Léon Walras provided in his *Eléments d'économie politique pure* (1874–7) an answer to an outstanding scientific question raised by several of his predecessors. Notably, Adam Smith had asked in *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776) why a large number of agents motivated by self-interest and making independent decisions do not create social chaos in a private ownership economy. Smith himself had gained a deep insight into the impersonal coordination of those decisions by markets for commodities. Only a mathematical model, however, could take into full account the interdependence of the variables involved. In constructing such a model Walras founded the theory of general economic equilibrium.

Walras and his successors were aware that his theory would be vacuous in the absence of an argument supporting the existence of its central concept. But for more than half a century that argument went no further than counting equations and unknowns and finding them to be equal in number. Yet for a non-linear system this equality does not prove that there is a solution. Nor would it provide a proof even for a linear system, especially when some of the unknowns are not allowed to take arbitrary real values.

A successful attack on the problem of existence of a general equilibrium was made possible by an exceptional conjunction of circumstances in Vienna in the early 1930s. It started from the formulation of the Walrasian model in terms of demand functions which had been given by Gustav Cassel in 1918. As Hans Neisser (1932) noted, certain values of commodity quantities and prices appearing in the solutions of Cassel's system of equations might be negative in such a way as to render those solutions meaningless. Heinrich von Stackelberg (1933) also made a cogent remark. Let x_i be the quantity of the ith final good demanded by consumers, a_{ij} the fixed technical coefficient specifying the input of the jth primary resource required for a unit output of the ith final good, and r_j the available quantity of the jth primary resource. The equality of demand and supply for every resource is expressed by

$$\sum_i a_{ij}x_i = r_j \text{ for all } j.$$

Von Stackelberg observed that if there are fewer final goods than primary resources, the preceding linear system of equations in $(x_1, \ldots, x_m)$ has, in general, no solution. Karl Schlesinger (1933–4) then remarked that equalities should be replaced by inequalities

$$\sum_i a_{ij}x_i \leqq r_j \text{ for all } j.$$

with the condition that a resource for which the strict inequality holds has a zero price. This suggestion, which had already been hinted at by Frederik Zeuthen (1932) in a different context, was essential to the proper formulation of the existence problem.

The problem thus posed received its first solution from Abraham Wald (1933–4), whose work on the existence of a general equilibrium gave rise to three published articles. The first two appeared in *Ergebnisse eines mathematischen Kolloquiums* in 1933–4 and in 1934–5. The third appeared in *Zeitschrift für Nationalökonomie* (1936) and was translated into English in *Econometrica* (1951). In that body of work Wald separately studied a model of production and a model of exchange and proved the existence of an equilibrium for each one.

By the standards prevailing in economic theory at that time, his mathematical arguments were of great complexity, and the major contribution that he had made did not attract the attention of the economics profession. A two-decade pause followed, and when research on the existence problem started again after 1950 it was under the

dominant influence of work done, also in the early 1930s, by John von Neumann. His article on the theory of growth, published in *Ergebnisse eines mathematischen Kolloquiums* (1935–6) and translated into English in the *Review of Economic Studies* (1945), contained in particular a lemma of critical importance. That lemma was reformulated in the following far more convenient form, and was also given a significantly simpler proof, by Shizuo Kakutani (1941). Let K be a non-empty, compact, convex set of finite dimension. Associate with every point x in K a non- empty, convex subset $\varphi(x)$ of K, and assume that the graph $G = \{(x, y) \in K \times K | y \in | \ \varphi(x) \}$ of the transformation φ is closed. Then φ has a fixed point x^*, i.e., a point x^* that belongs to its image $\varphi(x^*)$.

Kakutani's theorem was applied by John Nash, in a one-page note of 1950, to establish the existence of an equilibrium for a finite game. It can be used as well (Debreu 1952) to prove the existence of an equilibrium for a more general system composed of n agents. The ith agent chooses an action a_i in a set A_i of *a priori* possible actions. A state of the social system is therefore described by the list $a = (a_1, ..., a_n)$ of the actions chosen by the n agents. The preferences of the ith agent are represented by a real-valued utility function u_i defined for every a in the set of states $A = \times_{i=1}^{n} A_i$. Moreover the ith agent is restricted in the choice of his action in A_i, by the actions chosen by the other agents. Formally let N denote the set $\{1, \ldots, n\}$ of all the agents and N/i denote the set of the agents other than the ith. Let also $a_{N/i}$ denote the list of the actions $(a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n)$ chosen by the agents in N/i. The ith agent is constrained to choose his own action in a subset $\varphi_i(a_{N/i})$ of A_i depending on $a_{N/i}$. In these conditions the ith agent, considering $a_{N/i}$ as given, chooses his action in $\mu_i(a_{N/i})$, the set of the elements of $\varphi_i(a_{N/i})$ at which the maximum of the utility function $u_i(\cdot, a_{N/i})$ in $\varphi_i(a_{N/i})$ is attained. Consider now the transformation $a \mapsto \mu(a) = \times_{i=1}^{n} \mu_i(a_{N/i})$ associating with any element a of A, the subset $\mu(a)$ of A. A state a^* is an equilibrium if and only if for every $i \in N$, the action a^*_i of the ith agent is best according to his preferences given the actions $a^*_{N/i}$ of the others, that is, if and only if for every $i \in N$, $a^*_i \in \mu_i(a^*_{N/i})$, that is, if and only if $a^* \in \mu(a^*)$. Thus the concept of an equilibrium for the social system is equivalent to the concept of a fixed point for the transformation $a \mapsto \mu(a)$ of elements of A into subsets of A. Ensuring that the assumptions of Kakutani's theorem are satisfied for the transformation μ yields a proof of existence of an equilibrium for the social system.

In the revival of interest in the problem of existence of a general economic equilibrium after 1950, the first solutions were published in 1954 by Kenneth Arrow and Gerard Debreu, and by Lionel McKenzie. The article by McKenzie emphasized international trade aspects, and the article by Arrow and Debreu dealt with an integrated model of production and consumption. Both rested their proofs on Kakutani's theorem. They were followed over the next three decades by a large number of publications (a bibliography is given in Debreu 1982) which confirmed the concept of a Kakutani fixed point as the most powerful mathematical tool for proofs of existence of a general equilibrium.

A simple prototype of the various economies that were the subject of those numerous existence results is (following Arrow–Debreu) composed of m consumers and n producers, producing, exchanging and consuming l commodities. The consumption of the ith consumer ($i = 1, \ldots, m$) is a vector x_i in R^l whose positive (or negative) components are his inputs (or outputs) of the l commodities. Similarly the production of the jth producer ($j = 1, \ldots, n$) is a vector y_j in R^l whose negative (or positive) components are his inputs (or outputs) of the l commodities. The ith consumer has three characteristics. (1) His consumption set X_i, a non-empty subset of R^l, is the set of his possible consumptions. (2) A binary relation $\precsim_i$ on X_i defines his preferences, and '$x_i \precsim_i x_i'$' is read as 'x_i' is at least as desired as x_i by the ith consumer'. Formally the preference relation of the ith consumer is the set $\{(x, x') \in X_i \times X_i | \ x \precsim_i x'\}$. (3) A vector e_i in R^l describes his initial endowment of commodities. The jth producer has one characteristic, his production set Y_j, a non-empty subset of R^l defining his possible productions. Finally the $\theta_{ij} \geq 0$ specifies the fraction of

E

the profit of the jth producer distributed to the ith consumer. These numbers satisfy the equality $\Sigma_{i=1}^{m}\theta_{ij} = 1$ for every j. In summary, the economy $\mathscr{E}$ is characterized by the list of mathematical objects

$$\left[(X_i, \precsim_i, e_i)_{i=1,\ldots,m}, (Y_j)_{j=1,\ldots,n}, (\theta_{ij})_{\substack{i=1,\ldots,m \\ j=1,\ldots,n}}\right].$$

Given a price-vector p in R^l different from 0, the jth producer ($j = 1, \ldots, n$) chooses a production y_j in Y_j that maximizes his profit, that is, such that the value $p \cdot y_j$ of y_j relative to p satisfies the inequality $p \cdot y_j \geq p \cdot y$ for every y in Y_j. Thus the ith consumer receives in addition to the value $p \cdot e_i$ of his endowment, $\Sigma_{j=1}^{n}\theta_{ij}\, p \cdot y_j$ the sum of his shares of the profits of the n producers. The value $p \cdot x$ of his consumption x is therefore constrained by the budget inequality $p \cdot x \leqq p \cdot e_i + \Sigma_{j=1}^{n}\theta_{ij}\, p \cdot y_j$. Under that constraint he chooses a consumption x_i in X_i that is best according to his preferences. The list $[p, (x_i)_{i=1,\ldots,m}, (y_j)_{j=1,\ldots,n}]$ of a non- zero price-vector, m consumptions and n productions forms a general equilibrium of the economy $\mathscr{E}$ if for every commodity, the excess of demand over supply vanishes,

$$\sum_{i=1}^{m} x_i - \sum_{j=1}^{n} y_j - \sum_{i=1}^{m} e_i = 0.$$

The existence of a general equilibrium can be proved (following Arrow–Debreu) by casting the economy $\mathscr{E}$ in the form of a social system of the type defined above. For this it suffices to introduce, in addition to the m consumers and to the n producers, a fictitious price-setting agent whose set of actions and whose utility function are now specified. Note first that the definition of a general equilibrium is invariant under multiplication of the price-vector p by a strictly positive real number. In the simple case where all prices are non-negative, one can therefore restrict p to be an element of the simplex $P = \left\{p \in R^l_+ \mid \Sigma^l_{h=1} p^h = 1\right\}$, the set of the vectors in R^l whose components are non-negative and add up to one. The set of actions of the price-setter is specified to be P. Given the consumptions $(x_i)_{i=1,\ldots,m}$ chosen by the m consumers, and the productions $(y_j)_{j=1,\ldots,n}$ chosen by the n producers, there results an excess demand

$$z = \sum_{i=1}^{m} x_i - \sum_{j=1}^{n} y_j - \sum_{i=1}^{m} e_i.$$

The utility function of the price-setter is specified to be $p \cdot z$. Maximizing the function $p \mapsto p \cdot z$ over P carries to one extreme the idea that the price-setter should choose high prices for the commodities that are in excess demand, and low prices for the commodities that are in excess supply.

Some of the assumptions on which the theorems of Arrow–Debreu (1954) are based are weak technical conditions: closedness of the consumption-sets, of the production-sets and of the preference relations, existence of a lower bound in every coordinate for each consumption-set, possibility of a null production for each producer. Other assumptions were later shown to be superfluous for economies with a finite set of agents: irreversibility of production (if both y and $-y$ are possible aggregate productions, then $y = 0$), free disposal (any aggregate production $y \leq 0$ is possible), and completeness and transitivity of preferences. Convexity of preferences can be dispensed with, and convexity of consumption-sets can be weakened, in economies with a large number of small consumers. Insatiability of consumers is an acceptable behavioural postulate. There remain, however, two overly strong assumptions. They are the hypothesis that for every i, the endowment e_i yields a possible consumption for the ith consumer (after disposal of a suitable commodity- vector if need be), and the assumption of convexity on the total production-set $Y = \Sigma_{j=1}^{n} Y_j$ which implies non-increasing returns to scale in the aggregate.

An alternative approach to the problem of existence of a general equilibrium, closer to traditional economic theory, is centred on the concept of excess demand function, or of excess demand correspondence. Given an economy $\mathscr{E}$ defined as before, consider a price-vector p in R^l_+ different from 0. The productions $(y_1, \ldots, y_n)$ chosen by the producers, and the consumptions $(x_1, \ldots, x_m)$ chosen by the consumers in reaction to the

price-vector p result in an excess demand z in the commodity-space R^l. If z is uniquely determined, the excess demand function f from $R^l_+/0$ to R^l is there by defined. If z is not uniquely determined, the set of excess demands in R^l associated with p is denoted by $\varphi(p)$, and the excess demand correspondence φ is thereby defined on $R^l_+/0$. Both f and φ are homogeneous of degree zero since $f(p)$ and $\varphi(p)$ are invariant under multiplication of p by a strictly positive real number. This permits various normalizations of p. For instance, p may be restricted to the simplex P. Moreover, for every $i = 1, ..., m$, one has $p \cdot x_i \leq p \cdot e_i + \Sigma_{j=1}^{n} \theta_{ij} p \cdot y_j$. By summation over i, one obtains

$$p \cdot \sum_{i=1}^{m} x_i \leq p \cdot \sum_{i=1}^{m} e_i + p \cdot \sum_{j=1}^{n} p.y_j,$$

or equivalently $p \cdot z \leq 0$. Therefore for every p in $R^l_+/0$, one has either $p \cdot f(p) \leq 0$ or $p \cdot \varphi(p) \leq 0$. This observation leads to the following proof of existence of a general equilibrium (Gale 1955; Nikaidô 1956; Debreu 1956). Let φ be a correspondence transforming points of the simplex P into non-empty convex subsets of R^l. If φ is bounded, has a closed graph and satisfies $p \cdot \varphi(p) \leq 0$ for every p in P, then, by Kakutani's theorem, there are a point p^* in P and a point z^* in R^l such that $z^* \in \varphi(p^*)$ and $z^* \leq 0$. In economic terms, there is a price-vector p^* in P yielding an associated excess demand z^* in $\varphi(p^*)$, all of whose components are negative or zero.

If all the consumers in the economy $\mathscr{E}$ are insatiable, every individual budget constraint is binding, and one has for every $i, p \cdot x_i = p \cdot e_i + \Sigma_{j=1}^{n} Y \theta_{ij} p \cdot y_j$. By summation over i, $p \cdot z = 0$. Thus in the case where the vector z associated with p is uniquely determined, the excess demand function satisfies

Walras's Law: for every p in $R^l_+/0$, $p \cdot f(p) = 0$.

In geometric terms, in the commodity-price space R^l the vectors p and $f(p)$ are orthogonal. This prompts one to normalize the price-vector p so that it belongs to the positive part of the unit sphere $\overline{S} = \{p \in R^l_+ | \, \|p\| = 1\}$, for then $f(p)$ can be represented as a vector tangent to $\overline{S}$ at p. The excess demand function is now seen as a vector field on $\overline{S}$. This in turn suggests another proof of existence of a general equilibrium (Dierker 1974) for the particular case of an exchange economy E whose consumers have continuous demand functions, monotone preferences and strictly positive endowments of all commodities. In that case for every $i = 1, ..., m$, the consumption-set X_i of the ith consumer is R^l_+ and $x < x'$ implies $x \prec_i x'$ (if x' is at least equal to x in every component and $x' \neq x$, then x' is preferred to x). Since the demand of a consumer with monotone preferences is not defined when some prices vanish, one must restrict the price-vector p to be strictly positive in every component, that is, to belong to $S = \{p \in \text{Interior } R^l_+ | \, \|p\| = 1\}$. Moreover let p_q be a sequence of price-vectors in S converging to p_0 in the boundary $\overline{S} / S$ of S. Thus for every q, the vector p_q is strictly positive in each component, while, in the limit, p_0 has some zero components. Then the associated sequence of excess demands $f(p_q)$ is unbounded. As a consequence, the vector field f points inward towards S near the boundary of S. In these conditions Brouwer's fixed point theorem yields the existence of an equilibrium price-vector p^* in S for which excess demand vanishes, $f(p^*) = 0$.

The preceding solutions of the problem of existence of a general equilibrium all rest directly on fixed point theorems. Three different lines of approach are provided by (1) combinatorial algorithms for the computation of approximate general equilibria, (2) differential processes converging to general equilibria, (3) the theory of the fixed point index of a mapping.

1. The past two decades have witnessed the development of algorithms of a combinatorial nature for the computation of an approximate general equilibrium (*see* computation of general equilibria). Given any number $\varepsilon > 0$, a constructive procedure thereby yields a price-vector p such that the norm $|f(p)|$ of the associated excess demand is smaller than ε. A compactness argument then gives a sequence of price-vectors p_q in S converging to p_0 for which $|f(p_q)|$ tends to 0. In the limit, $f(p_0) = 0$.
2. Global analysis was introduced into economic theory at the beginning of the 1970s to study

the set of general equilibria of an economy and the manner in which it depends on the economy. In that framework Stephen Smale proposed in (1976) a differential process which starts from a point in the boundary of the set of normalized price-vectors, and which converges to the set of equilibria provided that the initial point does not lie in a negligible exceptional set (*see* global analysis in economic literature). Another constructive procedure thus gives, from a differentiable viewpoint, conditions under which the set of general equilibria is not empty.

3. In the same differentiable framework Egbert Dierker (1972) used the theory of the fixed point index of a mapping to prove that a regular economy (as defined by him in regular economies below) whose excess demand points inward near the boundary of S has an odd (hence non-zero) number of general equilibria. The significance of this theorem rests on the fact that under its assumptions almost every economy is regular.

The previous existence results have been extended in many directions. The study of the core of an economy led to the consideration of a set of agents, all of whom are negligible relative to their totality. This concept was formalized first as an atomless measure space of agents, and later by means of non-standard analysis. In both cases the existence of a general equilibrium had to be proved for economies with infinitely many agents.

In order to specify a commodity one lists its physical characteristics, the date, the location, and the event at which it is available. As soon as one of those four variables can take infinitely many values, the analysis of general equilibrium must be set in the framework of infinite-dimensional commodity spaces. Several existence results were obtained in that context.

In yet another direction, external effects called for extensions. When the characteristics of each agent (e.g. his preferences, his production set, . . .) depend on the actions chosen by the other agents, formulating the economy as a social system of the type described earlier immediately yields an existence theorem. Still other extensions have covered economies with public goods, with indivisible commodities, and with non-convex production sets.

Exit and Voice

Albert O. Hirschman

Abstract

Exit and voice are alternative responses to an unsatisfactory relationship: exit is the withdrawal from it, voice is the attempt to improve it through communication. They are not mutually exclusive responses: thus, the market is the archetypal exit mechanism, yet it usually involves voice. When available jointly, exit and voice may reinforce or undercut each other: the exit option enhances the influence of customers' voice on an unsatisfactory supplier but also reduces its volume. Exit–voice analysis has been applied to trade unions, hierarchies, public services, migration and political action, political party systems, marriage and divorce, and adolescent development.

A central place is held in economics and social science in general by principles and forces making for order or equilibrium in economic and social systems. Disorder and disequilibrium are then understood as resulting from some malfunction of these principles or forces. Explanations of order–disorder or equilibrium–disequilibrium have typically been discipline-bound, dealing with either the political or the economic world. Since the two are interrelated it would be useful to have a construct that bridges them. Such is the claim of the exit–voice perspective. It addresses the changing balance of order and disorder in the social world by pointing out that social actors who experience developing disorder have available to them two activist reactions and perhaps remedies: *exit*, or withdrawal from a relationship that one has built up as a buyer of merchandise or as a member of an organization such as a firm, a family, a political party or a state; and *voice*, or the attempt at repairing and perhaps improving the relationship through an effort at communicating one's complaints, grievances and proposals for improvement. The voice reaction belongs in good part to the political domain since it has to do with the articulation and channelling of opinion, criticism and protest. Much of the exit reaction, on the contrary, involves the economic realm

as it is precisely the function of the markets for goods, services, and jobs to offer alternatives to consumers, buyers and employees who are for various reasons dissatisfied with their current transaction partners.

The exit–voice alternative was proposed and explored in *Exit, Voice, and Loyalty: Responses to Decline in Firms, Organizations, and States (Hirschman* 1970*, henceforth EVL).* Attempts to apply the book's perspective were made over many areas of social life. In the following, the basic concepts will be recapitulated and, where necessary, reformulated. Subsequently some major applications of the exit–voice polarity will be reviewed.

Basic Concepts

Exit

Exit means withdrawal from a relationship with a person or organization. If this relationship fulfils some vital function, then the withdrawal is possible only if the same relationship can be re-established with another person or organization. Exit is therefore often predicated on the availability of choice, *competition*, and well functioning *markets*.

Exit of customers (or employees) serves as a signal to the management of firms and organizations that something is amiss. A search for causes and remedies will then be undertaken and some plan of action designed to restore performance will be adopted. This is one way in which markets and competition work to prevent decay and to maintain and perhaps improve quality.

Exit is a powerful but indirect and somewhat blunt way of alerting management to its failings. Most of the time, those customers and members of organizations who exit have no interest in improving them by their withdrawal, so that exit does not provide management with much information on what is wrong.

Voice

The direct and more informative way of alerting management is to alert it: this is *voice*. Its role is, or should be, paramount in situations where exit is either not available at all or is difficult, costly, and traumatic. This is so for certain primordial groupings one is born into – the family, the ethnic or religious community, the nation – or for those organizations one joins with the intention of staying for a prolonged period – school, marriage, political party, firm. With regard to buying and selling, voice should take over from exit when competition is weak or nonexistent as in the case of goods and services being produced under oligopolistic or monopolistic conditions, or when exit is expensive for both parties as in certain interfirm relations.

Unlike exit in the case of well-functioning markets, voice is never easy. It can even be dangerous. Many organizations and their agents are not at all keen on being told about their shortcomings by members and the latter often expose themselves to reprisals if they utter any criticism (Birch 1975). Even in the absence of reprisals, the cost of voice to an individual member will often exceed, in terms of time and effort, any conceivable benefit from voicing. Frequently, moreover, any effective channelling of individual voices requires a number of members to join together so that voice formation depends on the potential for collective action.

In spite of these problems, voice exists or, rather, it has come into being. Its history is to a considerable extent the history of the right to dissent, of due process, of safeguards against reprisal, and of the advance of trade unions and of consumer and many other organizations articulating the demands of individuals and groups who once were silent. Similarly, the history of exit is the history of the broadening of the market, of the right to move freely, to emigrate, to be a conscientious objector, to divorce, etc. Being two basic, complementary ingredients of democratic freedom, the right to exit and the right to voice have on the whole been enlarged or restricted jointly. Yet, there are important instances of unilateral advances or retreats of either the one or the other response mechanism (Rokkan 1975; Finer 1974).

Interaction of Exit and Voice

As noted, exit is paramount as a reaction to discontent in some circumstances and voice holds a

similarly privileged position in others, but frequently both mechanisms are available jointly. In such situations they may either reinforce or undercut each other. The availability and threat of exit on the part of an important customer or group of members may powerfully reinforce their voice. On the other hand, the actual recourse to exit will often diminish the volume of voice that would otherwise be forthcoming and, should the organization be more sensitive to voice than to exit, the stage could be set for cumulative deterioration. For example, after an incipient deterioration of public schools or inner cities, the availability of private schools or suburban housing would lead, via exit, to further deterioration – a turn of events that might have been prevented if the parents sending their children to private school or the inner city residents who move to the suburbs had instead used their voice to press for reform. In their aggregate effects, the individual exit decisions are harmful – an instance of the 'tyranny of small decisions' – also because they are likely to be taken on the basis of a short-run private-interest calculus only and do not take into account the 'public bad' that will be inflicted, even on those who exit, by decaying inner cities and segregated education (Levin 1983; Breneman 1983).

These kinds of situations are sufficiently numerous and important to be of interest not only as curious paradoxes showing that under some circumstances the availability of exit (that is, of competition) could have undesirable effects. In this connection, *EVL* stressed the value of *loyalty* as a factor that might delay over-rapid exit. Loyalty would make a member reluctant to leave an organization upon the slightest manifestation of decline even though rival organizations were available. Provided it is not 'blind', loyalty would also activate voice as loyal members are strongly motivated to save 'their' organization once deterioration has passed some threshold.

The difficulties of combining exit and voice in an optimal manner are in a sense 'problems of the rich': they relate to situations and societies where exit and voice are both forthcoming more or less abundantly, but where, for best results, one would wish for a different mix. Historically more frequent are cases where exit and voice are both in short supply, in spite of many reasons for discontent and unhappiness. There is no doubt, as many commentators have pointed out, that passivity, acquiescence, inaction, withdrawal, and resignation have held sway much of the time over wide areas of the social world. This is largely the result of repression of both exit and voice – a repression that has flourished in spite of the fact that all human organizations could put to good use the feedback provided by the two reaction modes.

E

Problems in Voice Formation

The development of voice among customers of firms or members of organizations poses a number of problems that were not fully explored in *EVL*. Critics have asserted that, in its endeavour to present voice as a ready alternative to exit, the book understated the difficulties of voice formation. In examining this issue it is useful to start with the extreme no-voice case: the authoritarian state which is dedicated to repressing and suppressing voice. This situation has given rise to a useful distinction between *horizontal* and *vertical* voice (O'Donnell 1986). The latter is the actual communication, complaint, petition, or protest addressed to the authorities by a citizen and, more frequently, by an organization representing a group of citizens. Horizontal voice is the utterance and exchange of opinion, concern and criticism *among* citizens: in the more open societies it is today regularly ascertained through opinion polls revealing the approval rating of presidents, prime ministers, mayors, etc. Horizontal voice is a necessary precondition for the mobilization of vertical voice. It is the earmark of the more frightful authoritarian regimes that they suppress not only vertical voice – any ordinary tyranny does that – but horizontal voice as well. The suppression of horizontal voice is generally the side-effect of the terrorist methods used by such regimes in dealing with their enemies.

The distinction between vertical and horizontal voice is relevant to the 'free ride' argument in relation to voice formation (Barry 1974). For *vertical* voice to come about, that is, for members of the organization to engage management in

meaningful dialogue, it is frequently necessary for members to forge a tie among themselves, to create an organization which will agitate for their demands, etc. But the hoped-for result of collective voice is a freely available public good; hence, so goes the critical argument, self-interested, 'rational' individuals may well withhold their contribution to the voice enterprise in the expectation that others will take on the entire burden. Important as it is, this argument has its limitations. First of all, it is addressed only to vertical voice which it mistakenly equates (as *EVL* did) with voice in general. Horizontal voice is not subject to the strictures of the free-rider argument: it is free, spontaneous activity of men and women in society, akin to breathing. As just noted, extraordinary violence has to be deployed if it is to be suppressed. Under ordinary circumstances, horizontal voice is continuously generated and has an impact even without becoming vertical: in many environments managers of organizations cannot help noticing and reacting to critical opinions and hostile moods of the members, whether or not organized protest movements break out. That the planned economies of Eastern Europe function to the extent they do has been explained on precisely this ground (Bender 1981, p. 30).

Another limitation of the free-rider argument lies in its assumption that individuals will always act instrumentally. Just because the desired result of collective voice is typically a *public* good – or, better, some aspect of the *public* happiness – participation in voice provides an alternative to self-centred, instrumental action. It therefore has the powerful attractions of those activities that are characterized by the fusion of striving and attaining and can be understood as investments in individual or group identity (Hirschman 1985).

Some Areas of Application

Trade Unions

In economics, the major application of the exit–voice theme has been the analysis of trade unions as collective voice by Freeman and Medoff in their book *What Do Unions Do?* (1984). Instead of looking at unions as a monopolistic device raising wages for unionized workers beyond the 'market-clearing' equilibrium level or – much the same zero-sum interpretation in different language – as a tool in the class struggle serving to reduce the degree of exploitation, the book finds that a major function of unions is that of channelling information to management about workers' aspirations and complaints. Collective voice, in the form of union bargaining, is more efficient in conveying information about workers' discontent – and in doing something about it – than individual decisions to quit, as voice carries more information than exit. The presence of union voice is shown to reduce costly labour turnover. Moreover, the fringe benefits, workplace practices, and seniority rules which unions negotiate often result in offsetting labour productivity increases.

Markets and Hierarchies vs. Exit and Voice

Renewed attention has been given in recent years to the question why some kinds of economic activities are carried on through many independent firms while others, to the contrary, are tied together through bureaucratic and hierarchical relations. In accounting for hierarchy, one approach has directed attention to such matters as uncertainty about the evolution of the market and the technology and in particular to asymmetric availability of information to buyer and seller, creating opportunities for deceitful behaviour (Williamson 1975). Hierarchy is then seen as superior to markets whenever there is need for a sustained and frank dialogue between the contracting parties. Critics of this position have argued: (1) relations between independent firms, such as contractors and subcontractors, are often quite effective in discouraging malfeasance; (2) correlatively, hierarchy frequently leads to characteristic patterns of concealment and control evasion (Eccles 1981; Granovetter 1985); and (3) industry structure varies substantially from one country to another as well as within the same country over time: in Japan, for example, subcontracting is much more widely practised than in the West and in Italy subcontracting has become more widespread in the last 10–20 years.

A formulation in terms of exit–voice is helpful here. The characteristics which are said to justify hierarchy – incomplete information, considerable apprenticing of one firm by the other, openings for 'opportunistic' (i.e., dishonest) behaviour, etc. – all make for situations in which there is need for voice: the firms contracting together must intensively consult with, and watch over, each other. *But the need for voice does not necessarily imply that hierarchy is in order.* Whether voicing is done best within the same organization or from one independent firm to another is by no means a foregone conclusion. Moreover, when the two parties are independent and resort a great deal to voice, the possibility of exit from the relationship often looms in the background. The implicit threat of exit could carry as much clout as that of sanctions in hierarchical relationships.

The argument for hierarchy in cases where voice has an important role to play may arise from thinking of market relationship only in terms of the ideal, anonymous market where voice is wholly absent. But most markets involve voice: commerce *is* communication, and is premised on frequent and close contact of the contracting parties who deliver promises, trust them, and engage in mutual adjustment of claims and complaints – all of this was implicit in the eighteenth-century notion of *doux commerce* (Hirschman 1977, 1982). Adam Smith even conjectured that it was man's ability to communicate through speech that lies at the source of his 'propensity to truck and barter'. How odd, then, that the need for frequent and intensive communication should be adduced as a conclusive argument for hierarchy.

Public Services: Education, Health, Others

The organization of public services represents a privileged area for the application of exit–voice reasoning – significantly the exit–voice idea had its origin in the analysis of a public service in trouble, the Nigerian railroads (*EVL*, Preface). Public services are typically sold or delivered by a single public or publicly regulated supplier, for various well-known reasons.

With the production of most public services being thus deprived of the 'discipline of the market', problems of productive efficiency and quality maintenance arise necessarily. An obvious way of mitigating these problems is to attempt to reintroduce market pressures in some fashion. For example, when certain categories of goods and services are to be made available either to all citizens regardless of their income or to some deprived social groups, the state and its agencies can sometimes refrain from producing or distributing these goods directly, and instead issue special purpose money or *vouchers* enabling the beneficiaries to acquire the goods or services through ordinary market channels. In this manner the voucher system reintroduces the market and the possibility of exit. A particularly successful example of the voucher system is the distribution of Food Stamps to low-income persons in the United States. Instead of creating and administering its own food distribution network the state hands out vouchers (food stamps) which the beneficiaries can then use at existing, competitive commercial outlets.

In part because of the success of this programme and in part because of the belief in 'market solutions' as the remedy for all that ails government programmes, voucher schemes have been proposed for a large number of other public services, from education to low-cost housing to the supply of certain health services. Voucher systems are appropriate primarily under the following conditions (Bridge 1977): (1) there are widespread differences in tastes and these differences are recognized as legitimate; (2) individuals are well informed about quality and different qualities are easily compared and evaluated; (3) purchases are recurrent and relatively small in relation to income so that buyers can learn from experience and easily switch from one brand and supplier to another.

These conditions are ideally present in the case of foodstuffs, but much less so in the case of, say, health and educational services. Hence the development of voice constitutes here an important alternative strategy for assuring and maintaining product quality. In other words, the beneficiaries of certain public services should be induced to become active on their own behalf, individually or collectively As always, development of voice is

arduous because of apathy and passivity of the members, but also because it will often be resisted by the organizations that have been set up to deliver the services. A number of proposals and attempts have been made to introduce more voice into the administration of both health and educational services (Stevens 1974; Klein 1980).

EVL had insisted on the see-saw character of exit and voice interventions in these fields. Education and health systems seemed particularly exposed to the danger that premature exit – of the potentially most influential members – would undermine voice. The opposite relation may also occur, however, for the opening up of the exit perspective could serve to strengthen voice: parents who have been wholly passive because of feelings of powerlessness and fear of reprisals may feel empowered for the first time once they are given vouchers that could be used 'against' the schools currently attended by their children, and will be more ready than before to speak out with regard to desirable changes in those very schools.

Spatial Mobility (Migration) and Political Action

Another substantial area of exit–voice applications opens up when exit is taken in the literal, spatial sense. Here exit–voice boils down to the familiar flight or fight alternative. While often institutionalized among nomadic groups (Hirschman 1981, ch. 11), this alternative is not necessarily available in sedentary societies. Here the traditionally available choice is fight or submit in silence. The option of removing oneself from an oppressive environment has become available on a massive scale only in modern times, with the advances in transportation and the *uneven* opening up of economic opportunity, religious tolerance, and political freedom. Where the option has existed, the interaction of exit and voice has been on display in three principal types of migration: (1) that from the countryside to the city, the oldest and no doubt largest of the modern migrations; (2) the migration from the city to the suburbs, which was most intense in the United States during the fifties and sixties, owing to the spread of the automobile and also to the large-scale migration of blacks and Hispanics *into* the cities; (3) finally, of course, international migration with its numerous economic and political determinants and constraints. Under this rubric, the international movement of capital also deserves attention.

Looking at the varieties of exit-voice interplay in these diverse settings, it is possible, on the basis of the numerous studies now available, to distinguish the following patterns:

(1) In accordance with the basic hypothesis of *EVL,* exit-migration deprives the geographical unit which is left behind (countryside, city, nation) of many of the more activist residents, including potential leaders, reformers, or revolutionaries. Exit weakens voice and reduces the prospects for advance, reform, or revolution in the area that is being left.

Something of this pattern can be observed in all three types of migration. Massive rural-urban migration could obviously reduce the potential as well as the need for land reforms which the voice of the countryside might otherwise have precipitated (Huntington and Nelson 1976, pp. 103ff.). The large outward migration from Europe to the United States in the 19th century up to World War I probably functioned as a political safety-valve for the rapidly industrializing European societies of that period, as has been shown for Italy (MacDonald, 1963–1964). In a similar vein, the possibility of westward migration within the United States has been invoked as an explanation for the lack of a militant working-class movement in that country. Finally, the city-to-suburbs migration in the United States has led, at least initially, to cumulative deterioration in the urban areas affected by out-migration in spite of, and in some cases because of, reduced density. At times, the voice-weakening effect of exit is consciously utilized by the authorities: permitting, favouring, or even ordering the exit of enemies or dissidents has long been one – comparatively civilized – means for autocratic rulers to rid themselves of their critics, a practice revived on a large scale by Castro's Cuba and, on a more selective basis, by the Soviet Union.

(2) But the basic see-saw pattern – the more exit the less voice – does not exhaust the rich historical material. The mechanism through which voice is strengthened rather than weakened as a result of exit is distinctive in the case of migration. In some societies the accumulated social pressures could be so high that authoritarian political controls will only be relaxed if a certain amount of out-migration takes place concurrently. This is what happened in the fifty years prior to World War I when the franchise was extended in many European states from which large contingents of people were departing. In other words, the state accommodated some of the pressures toward democratization because it could be reasonably surmised, in part as a result of out-migration, that opening the door slightly to voice would not blow away the whole structure. A similar positive relation between exit and voice may exist today with regard to such southern European countries as Spain, Portugal, and Greece: here the large-scale emigration to northern Europe may also have eased the transition to a more democratic (more vociferous) order.

(3) Exit–voice theory posits remedial or preventive responses to any large-scale out-migration on the part of the entity that is being left. A firm losing customers or a party losing members will normally undertake a search for the reasons of such declines in fortune and then determine upon a strategy for recovery. For out-migration such reactions are not easy to identify. In the case of massive rural–urban migration, for example, there is usually no organized entity such as the 'countryside' that registers the flight from it and can undertake corrective action. With regard to migration from the city to the suburbs, the situation is not too different. Here entities exist – city administrations – but they have generally been ineffective in modifying the individual decisions of millions of people to move into their own homes in the suburbs.

The analogy to the firm is – or should be – most applicable when the geographic entity losing residents is the State, which is after all a highly organized, self-reflective body with considerable means of action. There is, of course, the already noted possibility that out-migration relieves economic or political stress in a country, is therefore *welcome,* and may even be encouraged by the state. But massive emigration is at some point bound to be viewed as dangerous. Just like a business firm, the state may then take measures to make itself more attractive to its citizens. One example of this reaction is the national plan for economic recovery and industrialization adopted by Ireland in 1958, in the midst of very high levels of emigration, mostly to England (Burnett 1976). It has also been shown that the pioneering welfare state measures of the late 19th and early 20th century, starting in Bismarck's Germany in the eighties and then spreading to the Scandinavian countries and Great Britain, were all taken in countries with high rates of overseas migration. These measures can be seen as attempts of states to make themselves more attractive to their citizens (Kuhnle 1981).

The international movement of capital was first commented upon from the exit perspective in the 18th century. Montesquieu and Adam Smith both thought that the threat of exit on the part of movable capital could play a useful role in preventing arbitrary and confiscatory measures against the legitimate interests of commerce and industry. The threat of exit or exit itself was expected to function, like the customer's exit, as a curb on misconduct, this time on the part of the state. While this relationship is still pertinent, exit of capital often plays a less constructive role today. In the more peripheral capitalist countries the owners of capital have become fully alive to the possibility of removing part of their holdings to the United States or other reliable places in case they become unhappy about the 'investment climate'. In this manner, capital exit (or flight) will often be practised on a large scale as soon as the state undertakes some, perhaps long overdue, reforms with respect to such matters as land tenure or fiscal equity. Instead of preventing arbitrary and ill-considered policies, exit can thus complicate and render more hazardous certain *needed* reforms. Moreover, exit undercuts voice: as long as the capitalists are able to remove their

patrimony to a safe place, they will have that much less incentive to raise their voice for the purpose of making a responsible contribution to national problem-solving. Capital mobility and propensity to exit may thus be a major reason for the instability of states in the capitalist periphery (Hirschman 1981, ch. 11).

Political Parties

Two principal propositions were put forward by *EVL* with regard to the dynamics of political parties in a democracy:

(1) In a two-party system, the tendency of the parties to move toward the nonideological centre in order to capture the (allegedly) voluminous middle-of-the-road vote is countered by those party members and militants who are on the parties' ideological fringes, have 'nowhere else to go', but just because of that are maximally motivated to exert influence inside the party, by forceful uses of voice.
(2) In a multi-party system, with the ideological distance from one part to the next being presumably shorter than in two-party systems, dissatisfaction with party performance is more likely to lead to exit than in two-party systems; in the latter, voice will play the more important role as switching to the other party requires too big an ideological jump. One inference is that parties in two-party systems may be expected to exhibit more internal divisions, but also more internal democracy and less bureaucratic centralism than parties in multiple-party systems.

The first of these propositions has been strongly supported by events subsequent to the publication of the book. At that time, only the nomination of Barry Goldwater to be the standard bearer of the Republican Party in 1964 could be cited in support. Since then, additional evidence has accumulated: from the nomination by the Democrats of George McGovern to contend the Presidential elections in 1972 to the increasing power of the more radical wing of the Labour party and the ascendancy of Margaret Thatcher within the Conservative party and of Ronald. Reagan among the Republicans. The theory that in a two-party system the two parties would increasingly converge toward some middle ground has been amply disconfirmed.

The second proposition on political parties which was deduced from the *EVL* framework has undergone several qualifications. For example, in democracies with old cleavages along ethnic, linguistic, and religious lines, the distances between the several parties rooted in ethnic, etc., identities could actually be wider than that between the parties of two-party systems. Under these conditions, the exit voice logic would in fact predict that member participation (voice) in parties of multi-party systems would also be vigorous and exit infrequent (Lorwin 1971; Hirschman 1981, ch. 9).

A more serious complication is being stressed in a work by S. Kernell still in progress. In two-party systems, exit is a particularly powerful move for dissatisfied members as by casting their vote for the other party they are doubling its impact, something they cannot be sure of in multi-party systems. Hence, in case of disappointment with the performance of one's own party, there could arise a special temptation in two-party systems to switch to the other party so as to *punish* one's own. Such a preference for exit is likely to come to the fore primarily when a party in power is perceived as having seriously mishandled its mandate. Under the circumstances, the prospect of being able to punish that party retrospectively could overcome party loyalty and past ideological commitment. This constellation was an important factor in the sharp defeat of the Democratic ticket in the 1980 Presidential elections in the United States.

The Family: Marriage and Divorce

Modern marriage is one of the simplest illustrations of the exit–voice alternative. When a marriage is in difficulty, the partners can either make an attempt, usually through a great deal of voicing, to reconstruct their relationship or they can divorce. The complexities of the interplay between exit and voice are well in evidence here. Just as the threat of strike in labour-management relations, so is the threat of divorce important in inducing the parties to 'bargain seriously'; but as exit becomes ever easier and less costly (and

perhaps even profitable to one of the parties – see Weitzman 1985), its availability will undermine voice: rather than being an action of last resort, divorce could become the automatic response to marital difficulty with less and less effort made at communication and reconciliation.

This is exactly what appears to have happened in the United States during the last fifteen years, i.e. since *EVL* stated that 'the expenditure of time, money and nerves' necessitated by complicated divorce procedures serves the useful, if unintended purpose of 'stimulating voice in deteriorating, yet recuperable organizations which would be prematurely destroyed through free exit' (p. 79). In 1970 California adopted a new 'no-fault' law on divorce which spread, though often in attenuated form, to most other states (Weitzman 1985). The California law drastically altered divorce procedures: instead of requiring proof that one of the parties was guilty of some specific type of behaviour constituting grounds for divorce, the new law permitted divorce when both *or just one* of the two parties asserted that the marriage had irretrievably broken down. The possibility of a unilateral decision, of just 'walking out', is symbolic of the way in which the California law undercuts the recourse to voice.

With the new regime, the pendulum has swung quite far in the direction of facilitating exit and of thereby weakening voice. It was of course a reaction to the many abuses of the older fault-based system which required costly and degrading adversarial proceedings, and in effect discriminated against the poor. But the framers of the new legislation probably did not realize the extent to which the earlier obstacles to divorce indirectly encouraged attempts at mending the so easily frayed conjugal relationship and how much the new freedom to exit would torpedo such attempts, with the results that one of every two new marriages now ends in divorce.

The Family: Adolescent Development

This is another family situation for whose analysis a formulation in terms of exit and voice has been found useful (Gilligan 1986). Adolescent development has often been portrayed as a process through which the 'dependent' child becomes an 'independent' adult through progressive 'detachment' from the parents. Freud saw this as 'one of the most significant, but also one of the most painful psychic accomplishments of the pubertal period . . . a process that alone makes possible the opposition, which is so important for the progress of civilization, between the new generation and the old' (1905, p. 227). Here is a celebration of exit; Freud's statement neglects a complementary aspect and task of adolescent development which is to maintain and enrich the bond with the older generation through continued, if conflict-ridden, communication. In other words, voice has an important role to play in transforming the adolescent's relationship to the parents. The peculiar poignancy of the adolescent–parents conflict resides in fact in the impossibility of relying *wholly* on voice in resolving it: given the closeness of the relationship, a full accord that would be the outcome of successful voicing risks ending up in incest, as the 'meeting of minds would suggest a meeting of bodies' (Gilligan 1986). It is because of the incest taboo that exit must be part of the solution, but different generations of adolescents are likely to achieve emancipation by practising very different characteristic mixes of exit and voice. Moreover, as Gilligan stresses, the balance of exit and voice differs according to gender. Girls place a greater value than boys on continued attachment to the family, and are therefore less attracted to the masculine ideal of independence-isolation. Hence they experience a greater tension between exit and voice.

With this imaginative use of the exit–voice concept, the outer limits of its sphere of influence may have been reached.

Expectations

Robert J. Shiller

Abstract

The modelling of economic expectations is central to economics. Expectations of future economic conditions can be represented in econometric models by survey data, expectations proxies such as adaptive expectations,

expert forecasts, or market expectations. The theory that expectations are rational, that is, optimal forecasts given the model, can be a useful modelling device, but evidence from behavioural economics shows that it has important limitations.

Most decisions that economic agents must make involve uncertainty about the future. Thus, any economic model that is intended to be descriptive of human behaviour is likely to involve human expectations about uncertain future economic variables. Areas in economics that involve expectations in fundamental ways include the theories of intertemporal consumption or labour supply decisions, theories of firms' pricing, sales, investment, or inventory decisions, theories of financial markets and money, theories of insurance, and of search behaviour, signalling, agency and bidding. If our purpose is to describe human behaviour, then the study of human expectations is inseparable from the study of the behavioural models in which these expectations are embedded. Only a few general observations can be discussed here.

Economic Expectations, Surveys and Proxies

Applied econometric research often relies on simple models involving *expectations variables* that represent the expectations of economic agents for some specified economic variables. For example, the total savings of individuals may be related to a variable purporting to measure their expectations for their pension benefits on the date of their retirement, years in the future. Or an individual's decision whether to purchase a long-term or short-term bond may be related to a variable representing expectations as to the course of future short-term interest rates over the life of the long-term bond.

Expectations variables included in such models are often referred to as measuring, perhaps imperfectly, some idealized *economic expectations.* What economic expectations actually represent is usually not spelled out. Different people have different perceptions about the outlook for future variables, and so there is an index number problem in reducing their divergent opinions into a single measure. Moreover, when asked for their expectation for some economic variable people may answer that they have no expectation. If pressed, they may hazard a guess. Certainly, most individuals make some economic decisions without making an effort to learn about relevant economic variables. From time to time, circumstances require making difficult or important decisions, and then people may trouble themselves more to find out about economic variables. Economic models that speak of 'the' expectation of an economic variable presumably are talking about some average of the expectations of some people and guesses other people would make if pressed, or about averages of the better or worse forecasts of the same people at different times.

The expectations variables used in econometric work to measure economic expectations may be *survey expectations,* representing the average expectation respondents reported on a public opinion survey, or they may be *expectations proxies*, consisting of transformations of other variables that appear to the econometrician to be

plausible guesses as to the public expectations. For example, a moving average of lagged inflation rates may serve as an expectations proxy for future inflation.

Expectations surveys commonly take two forms: those that survey individuals representative of the general population and those that sample experts. The former provide measures of expectations that are relevant to decisions, like individual decisions as to how much to save in a given month or whether to put money in a savings account as against corporate bonds, on which decision-makers do not attach great importance. The latter provide measures of expectations that are relevant to decisions, such as firm decisions on whether to market a new product or invest in a new plant, on which decision-makers are likely to spend the resources to obtain informed forecasts.

Day-To-Day Expectations of the General Population

According to Katona (1975), survey research finds that most people can be induced to make a guess as to the direction of change in the near future of major macroeconomic variables, but are reluctant to give quantitative estimates of the extent of the change. The information on which most people base their expectations is fragmentary. Based on decades of survey research on the general public in the United States, Katona concluded that the majority knew whether unemployment had increased or decreased in the preceding months, whether profits or retail sales had gone up or down, and also whether interest rates had risen or fallen, but did not know how much larger or smaller any of these magnitudes were. The extent of knowledge about macroeconomic variables is generally greater the more important or dramatic the recent changes in these variables, and of course, the more the variable has been emphasized in the mass media.

Since we generally want to incorporate expectations variables in an economic model that describes human behaviour, we are likely to want any variable measuring economic expectations to represent the actual thoughts of individuals *before* they were forced to sit down at a questionnaire and carefully think about how to forecast an economic variable. In modelling, say, income expectations for the purpose of studying the saving decision, we want to get into the individual's frame of mind at the times when saving decisions are made.

When we try to characterize a person's frame of mind at these times, we should recognize that the expectations are likely to differ through time qualitatively as well as quantitatively. For example, an expectation of a future rise in income may become more vividly impressed on individuals' consciousness by some public event that reminds that person of the reasons to expect income to rise. At the same time, the expectation as measured on a survey may be unchanged. Psychologists who study the saving decision have emphasized the importance of changing *aspirations* as distinct from changing expectations.

Individuals who are not thinking at all about economic theories and who are merely confronted with economic variables whose stochastic properties are difficult to comprehend may fall back on simple expectations mechanisms such as that proposed by Fisher (1930). In his, expected inflation is a *distributed lag* or weighted average, with weights that decline linearly with time, of actual inflation. A variation on Fisher's expectation mechanism is *adaptive expectations* (Cagan 1956) in which expectations are formed as a weighted average, with weights that decline exponentially with time into the past, and that sum to 1, of actual past inflation. The rate at which weights decline might be determined by the rate at which human memory decays. It may be natural to form expectations of a future variable (for example, inflation) by thinking back over the recent past of experience of the variable, and hence such memory decay may result in a distributed lag pattern like that hypothesized by Cagan.

With adaptive expectations, the change in the expectations variable is proportional to the difference between its previous value and the latest value of the variable to be forecasted. This construction resembles that of the *error-learning hypothesis* (Meiselman 1962). However, in the error learning hypothesis the change in the

expectation for a variable at a specific future date is proportional to the error just discovered in the forecast for the variable for today's date.

Alternatives to adaptive expectations are *regressive expectations*, in which variables are expected to return gradually to a fixed level independent of their recent past behaviour (this term has also been used as a synonym for adaptive expectations), and *extrapolative expectations* in which the recent direction of change in the variables is expected to continue (see for example Modigliani and Sutch 1966.) Any of these expectations mechanisms may be consistent with optimal forecasts of the future variables under certain special circumstances (see Sargent and Wallace 1973).

We may not want to use such simple models of expectations in periods when individuals may think a great deal about economic theories. During a period of hyperinflation, for example, it is perhaps unlikely that people will form expectations adaptively, since the inflation affects them so noticeably. They may seek out the opinions of experts at such times.

Expectations of Experts

It is often the case that it is much easier for surveyors to find the expectations of randomly sampled individuals than the expert opinions. Expert opinions may be generated only at the time a crucial decision is made, and not when an expert is asked to fill out a questionnaire. Moreover, experts may feel that their time is too valuable to merit attending carefully to a questionnaire.

It is now the case that economic forecasting has become a profession in which practitioners regularly publish their forecasts of macroeconomic variables, and thereby open themselves up to systematic evaluation by outsiders. Usually these forecasts have some basis in econometric models subject to judgmentally introduced 'add factors'.

Professional forecasters now make available regularly tabulated forecasts of macroeconomic variables for the succeeding few years. The accuracy of these forecasts is now regularly computed by independent evaluators, and this provides a genuine incentive to forecast well. The marketplace will tend to reduce the numbers of those who do not forecast well. Professional forecasts made in organizations, when not made in anticipation of the kind of 'forecasting race' judged by outside evaluators, may not be serious individual attempts to predict. Instead, they may be 'conventional' forecasts using methods and information that are perceived as having sanction in the organization. Organizations may stipulate what information a forecaster is to use and how the information is to be translated into a forecast. The aim of such sanctions may be to produce uniformity in the organization as to factual premises on which decisions are made, but they may also lead to forecasts that are not accurate. The costs to individuals of violating the assumptions of the organization may be very large relative to the possible benefits of forecasting well.

The distinction between day-to-day expectations of individuals and the expectations of experts may in practice not be an important one. The advantages that experts have, of access to data, understanding of economic theory and use of statistical methods, may confer little advantage in circumstances when the structure of the economy is changing. Then the data may be viewed as of little help, as it is generated by a different model, and statistical analysis also may be of little help. Experts may then fall back on adaptive expectations or other methods of producing guesses like those of ordinary individuals.

Mathematical Expectations

When we use the term *mathematical expectations,* we are referring to a probabilistic model, from which we can compute the expectations as first moment conditioned on the information set available to agents. There are of course other candidates to represent economic expectations, for example, other measures of central tendency such as the median or mode, or measures of central tendency applied to transformations of the random variable.

Ultimately, many of economic models that involve mathematical expectations as economic

expectations derive from the assumption of maximization of the mathematical expectation of a utility function. The mathematical expectations operator is initially brought into the assumptions of the model because such expected utility maximization is viewed as a good way to represent human behaviour. Expected utility maximization has been shown to follow from some plausible axioms representing an idealization of 'rational' human behaviour. But it is only in certain special cases that maximization of expected utility produces simple behavioural relations involving mathematical expectations as 'economic expectations' of the kind that many applied econometricians have been using.

Linear utility functions representing risk-neutral agents may give rise to models in which agents care only about the mathematical expectations of variables, as in the models in finance in which the mathematical expectations of returns on various assets are equalized. A quadratic expected utility function may also produce models that depend on mathematical expectations. It is a result of Simon (1956) that if there are no terms of degree higher than two in control variables and exogenous stochastic processes then optimal behaviour depends linearly on a 'certainty equivalent' equal to the conditional expected value of future values of the stochastic process, and not on any other characteristics of their conditional distribution. Simon set up a problem in which there was nothing that could be done by the maximizing agent about the variance of the outcome. In contrast, in the capital asset pricing model in finance, a utility function quadratic in wealth (but where there are terms of degree higher than two in control variables and wealth) yields a behavioural relation that involves both a mathematical expectation and a variance matrix of the underlying stochastic variables.

More generally, expected utility function models that are not linear or quadratic will produce Euler-equation type first-order conditions involving the mathematical expectation operator and economic variables. These models can then give rise to relations involving mathematical expectations that may be interpreted as economic expectations. Suppose economic agents at time t maximize subject to a budget constraint an intertemporal utility function $\sum_{k=0}^{\infty} \beta^k u(C_{t+k})$ where β is the subjective discount factor, u represents instantaneous utility and C_{t+k} represents consumption k periods after time t. Then the Euler equation implied by agents' optimization states that, for any liquid asset whose price is P_t at time t that pays no dividend between t and $t+1$, $P_t = E_t\left(\beta \frac{u'(C_{t+1})}{u'(C_t)} P_{t+1}\right)$ where E_t denotes mathematical expectation. If we can find some reason to assume that the term $\beta \frac{u'(C_{t+1})}{u'(C_t)}$ can be disregarded, such as by assuming either that the time interval is small and that there is little variation in consumption over this time interval, then the price P_t itself can be interpreted as the mathematical expectation of price P_{t+1} next period.

Many models start from behavioural relations involving mathematical expectations and do not derive these from the hypothesis of expected utility maximization. In these cases, the popularity of mathematical expectations as representations of economic expectations may derive from some intuitively desirable and convenient properties of mathematical expectations, properties that are not shared by other measures of central tendency. The mathematical expectation of the sum of two random variables is equal to the sum of their mathematical expectations whether or not the two variables are independent, a property not shared by the median or mode, even if the variables are independent. If we have a joint distribution of two random variables, x and y, and we define the conditional distribution of x given y, then the mathematical expectation $E(x|y)$ of x in the conditional distribution is a function of y. The *law of iterated projections* states that the mathematical expectation of the mathematical expectation of x, $E(E(x|y))$ equals the mathematical expectation of x, $E(x)$. In simple terms, this law might be described as saying that people do not expect to change their expectations. Again, this law does hold in general for the mode or median of x. On the other hand, the median has the desirable property that the median of any monotonic transformation of a random variable is the transformation of the median, a property not shared by the mathematical expectation.

Market Expectations

In 1907, the statistician Francis Galton did a statistical analysis of a contest in which participants paid, for the possibility of a monetary prize, to play a game in which they guessed the weight of an ox. His conclusion that the average guess was very close to the actual weight of the ox led over the years to a general public appreciation of the idea that markets may predict very well, and hence that market expectations represent optimal forecasts.

Economic theory may, under some conditions, support the idea that financial market prices may represent mathematical expectations conditioned on public information. If we have a security whose value in the near future P_{t+1} unambiguously represents some economic value that is highly variable, then we might conclude that its price today is its mathematical expectation. (If we assume itis variable relative to the potential variability in $\beta \frac{u'(C_{t+1})}{u'(C_t)}$in the Euler equation, then the price today P_t might be regarded as approximately the mathematical expectation of that economic value.) On the other hand, if the security represents a claim on the distant future, then these assumptions seem problematic, and even the validity of the Euler equation itself becomes questionable (Shiller 2005).

The Iowa Political Stock Market was created in 1988 by Robert Forsythe, Forrest Nelson and George Neumann at the University of Iowa to allow participants to buy securities that pay one dollar plus the candidate's final vote margin in an election in the near future. The price of such a security may be interpreted under our assumptions as 1 plus the mathematical expectation of the candidate's vote margin.

Their market, now renamed the Iowa Electronic Market, also trades securities that pay one dollar if an event occurs, otherwise nothing. Then the price of that security has a possible interpretation as the probability that the event will occur.

In fact, of course, not everyone has the same subjective probability of the event. The differences of opinion may be necessary for a market to function, for it may be only the differences of opinion that make the market interesting to traders. Manski (2006) shows that there is no theoretical support for the idea that the market prices should represent the average (over all market participants) subjective probability of the event, and, according to his assumptions, theory allows us to define only a (rather broad) interval within which this average subjective probability lies. Still, the market prices might turn out to be useful in helping us to judge probabilities of future events (Wolfers and Zitzewitz 2006).

The Iowa people have claimed that the prices of their securities representing final vote margins have produced remarkably accurate forecasts, better than that generated by public opinion polls of voter intentions (Berg et al. 2008). However, the economics profession has not yet generated many studies that test the interpretation of these new markets as generators of optimal expectations.

Interest in market expectations remains very high, and there has been an explosion of prediction markets. Some are related to universities: the Austrian Electronic Market run by Vienna University; the University of British Columbia Election Stock Market. Others are private companies such as intrade.com; cityindex.co.uk; igindex.co.uk; tradesports.com; hedgestreet.com; newsfutures.com; and ideosphere.com.

The Economic Derivatives Market was created in 2002 by Deutsche Bank and Goldman Sachs to trade claims that pay out a fixed sum if an economic variable falls in a specified range, using a trading platform created by Longitude, Inc. that allows people to express complex demands for this security (Lange and Economides 2005). The market is now managed in a partnership between Goldman Sachs and the Chicago Mercantile Exchange. Today US non-farm payrolls, the Institute of Supply Management's Purchasing Managers Index (PMI), weekly initial jobless claims, retail sales, the European harmonized index of consumer prices (HICP), the international trade balance and gross domestic product (GDP) are currently traded. Preliminary studies, with only limited data available as yet, support the notion that these markets yield useful forecasts (Gurkaynak and Wolfers 2006).

In 2006 the Chicago Mercantile Exchange with MacroMarkets LLC (a company I helped found) created futures and options markets that are cash-settled based on the Standard & Poor's/ Case-Shiller Home Price Indices, and has plans to create such markets based on a commercial property price index. These markets are beginning to offer market expectations for real estate prices.

Other examples of potential new markets for economic variables are described in Shiller (2003). The value of these markets for generating market expectations or optimal forecasts will not be in until many more years' data are at hand.

Modelling Rational Expectations

Even if we can use markets or surveys to measure expectations, if we are to understand their movements through time we need to model their determination. The idea that expectations are rational has been an important modelling device.

Why does the idea sound plausible that economic expectations of future inflation may be proxied fairly well by adaptive expectations or other distributed lag on actual inflation? Is it just because of the theory of psychologists that human memory decays gradually through time and the notion that casual guesses of future inflation would correspond to recent memories of inflation? Perhaps it is instead that a distributed lag on inflation is not a bad way to forecast inflation.

Suppose people were asked on a monthly basis to forecast the rate of increase of the price of some seasonal commodity, let us say, fresh tomatoes. Certainly, many of them would be aware that fresh tomatoes are more expensive in the winter, when they must be grown in hothouses or brought in from greater distances. Not all people would know this, and many who did know about the seasonality in price would not know its magnitude. But certainly a distributed lag with smoothly declining coefficients on actual tomato price changes is not what we would think of first to model their expectations. Such a distributed lag would imply some seasonality in expectations but would also generally imply that people misforecast the month of highest price.

If there is any doubt as to the value of simple expectations proxies for modelling the expectations of tomato consumers, there is certainly no doubt that it would be inappropriate to use such proxies to model the expectations of tomato producers. Some producers specialize in producing hothouse tomatoes, and time their production for the winter months. Surely they know in which month prices are higher, and by how much they tend to be higher.

How then should we build a model that describes the supply of tomatoes over time? Since tomatoes must be planted months in advance of the anticipated demand for them, the supply function for tomatoes must depend on expectations formed at this time by producers, as well as on seasonal factors affecting the cost of production. We might then model the supply of tomatoes by finding a good way to predict the price of tomatoes (using, say, seasonal dummies and other information) and substituting the prediction in place of the expectation in the supply function. The result would be a *rational expectations model.*

One could use such a model to predict the supply response to some variable that has been found to predict price. If, let us say, we found that bad weather in Mexico, which might later reduce supply of winter tomatoes to the United States, tended to cause the seasonal peak in tomato prices in the United States to be higher than usual, then we might in these circumstances forecast the supply of domestic tomatoes in the United States to be higher than usual. A rational expectations model would produce such a forecast if the model was based on an empirical forecasting relation for price that used the weather variable as an explanatory variable.

Of course, for the purpose of forecasting supply we might also have used the 'naive' approach of estimating a forecasting equation directly for supply (without the intermediate step of developing a forecasting equation for price) depending on such variables as earlier weather and on seasonal dummies. Such a method may also satisfactorily predict supply, but it might not do as well since it would not make use of the information in economic theory that weather affects supply only

through its effect on rationally expected price. For example, suppose we had a long time series of data on various weather variables and prices but only a few observations on quantities supplied. We could not include all the weather variables directly in a 'naive' forecasting equation for supply, since we would thereby exhaust degrees of freedom. But we could first find how these weather variables predict price and then use a single price expectations variable to predict supply.

Rational Expectations in Equilibrium Models

The above example of the use of a rational expectations model was very special in that the model consisted only of a single equation relating supply to an earlier expectation of price. Moreover, the equation was used only to forecast supply in a situation where we expect the correlations observed in the past with explanatory variables to continue. Very often we wish instead to predict the effect on supply of some change in government policy or other structural change that is expected to change the correlations with other variables.

Suppose for example we wish to know the effect on the seasonal pattern of tomato supply in the United States of a government policy of blocking the further international trade of tomatoes. Here, the naive forecasting model that related tomato supply to weather and seasonal dummy variables would be of no value. An estimated rational expectations model relating supply to expected price might still be of value. We need to model only the determination of expected price.

Suppose we then also estimate (using a sample period in which some tomatoes were imported) a domestic demand function for tomatoes, relating, say, total quantities demanded in the United States to contemporaneous price. Consider, then, a two-equation model consisting of this demand equation and the rational expectations domestic supply equation for tomatoes described above. In the sample period domestic demand did not equal domestic supply because of imports. After the policy change the domestic supply and demand will be equal. Can we now predict how the seasonal pattern of quantities supplied may be changed by the government policy?

To answer this question, we cannot just solve the two-equation model with the two endogenous variables, quantity and price, because both price and expectations appear separately in the model. However, the expectation of price, if it is a rational expectation, ought to be determined by the very model in which it appears. How can we find the rational expectation of price?

One approach is first to guess a function relating expected price to the exogenous variables in the model, in our example, the seasonal dummies and weather variable. If one substitutes this guess into the model in place of the expected price, one then has an ordinary simultaneous equation model in price and quantity in terms of exogenous variables. However, unless one made a lucky guess, one would then find that the model that resulted from the guess was inconsistent with the guess, in that the model implies that a different way of forecasting price is optimal, given the expectations function.

What we need to find is an equation defining the expectation of price which, on substituting into the model, produces a model in which that equation gives the optimal forecast of price. Muth (1961) showed how this can be done if the simultaneous equations model is linear and if rational expectations are defined as mathematical expectations conditioned on variables in the model that are in the public's information set.

Using such a solution method, we might find how the seasonality of both quantities and price will be changed under the new government policy. In this simple example, doing this would seem to be preferable to using a model with an expectations proxy for price that did not take into account how the changing seasonal pattern of price would change the way expectations are formed.

Rational Expectations Models, Stochastic Processes and Optimal Control

The advent of rational expectations in econometric models has marked a revolution in economic thinking that is comparable in the magnitude of

its impact on the economics profession to the Keynesian revolution in the mid-twentieth century.

Muth (1961) and those who carried on the rational expectations literature have borrowed heavily from another literature that was once outside economics, namely the theory of stochastic processes and optimal control. What is substantially new about the rational expectations models derives ultimately from these theories, which were developed for the most part since 1950. The implications of these theories were so profound that it was inevitable that they should make themselves felt in economics, just as they have in many fields in science and engineering.

The rational expectations revolution is not primarily the result of any failure of conventional econometric models to forecast well, as some (for example, Lucas and Sargent 1981) have argued. It is true that initial optimism for the forecasting ability of such models has been tempered by experience, but it has not been established that shortcomings of the expectations modelling methods has been the major fault. It has certainly not been established empirically that rational expectations models can predict better.

Interest by economists in optimal control and the theory of stochastic processes was initially expressed in their efforts to apply control methods to existing econometric models, to achieve their stabilization. However, the optimal control of conventional 'Keynesian' econometric models involving expectations proxies like adaptive expectations has never became as influential in the profession as its developers had hoped. Perhaps the general profession thought that the methods of control were too refined for the crude models that they were applied to. More concern was felt for improving the models themselves.

The idea that optimal control might be applied to conventional Keynesian econometric models did have the effect of generating hopes that the macroeconomy might be controlled very well, 'fine tuned' so to speak, and thus great importance was placed on the structural stability of these models. Much of the polemics against 'Keynesian' economics waged by those who promoted rational expectations models as alternatives was really directed against these efforts to apply optimal control systematically to the models (see for example Sargent and Wallace 1981). A central criticism of these models was their heavy reliance on crude expectations proxies such as adaptive expectations.

The rational expectations models applied stochastic optimal control theory by assuming in effect that human behaviour could be modelled as if everyone all along had been applying the principles of optimal control to their own economic decisions. Given the natural interest of economists in rational behaviour, the optimal filtering and extrapolation that was developed as part of the theory of stochastic processes would naturally be used in modelling how individuals forecast.

Of course, there are strict limits to the extent to which people's actual behaviour can be described in such terms. Rational expectations models thus often sacrifice descriptive accuracy with the hope that the models would exhibit stability in the presence of interventions of the kind envisioned by makers of government macroeconomic policy. The models may not be generally well suited to forecasting when the policy regime is unchanged. They are most appropriately considered as policy analysis tools.

Criticisms of Rational Expectations Models

The simple supply and demand model for tomatoes described above was chosen as an ideal example of the application of rational expectations models. In this example there is substantial seasonal variation in price, which ought to be forecastable. Moreover, as the model was set up, only producers' expectations entered the model, and producers are far more likely than others to have rational expectations about price. But few of the applications of the theory of rational expectations have been to such ideal examples.

The best-known application of rational expectations models has been to an interpretation of the observed relation between unemployment and inflation. A.W. Phillips (1958) noted a negative

relation between the unemployment rate and the wage inflation rate in the United Kingdom between 1861 and 1957. A similar relation was found also in the United States for much of the same sample period. Since then, the negative relation has broken down. Lucas (1976) and Sargent and Wallace (1973) offered interpretations of the Phillips relation and its subsequent breakdown. In its simplest terms, this interpretation asserts that there may be a stable relation between unemployment and *unexpected* inflation. Unexpected inflation may cause job seekers to misperceive the real value of wage offers they have received, and thus to accept offers that they would not have accepted if they had known the true real wage they were getting. By accepting these jobs, they lower the unemployment rate. In the period Phillips studied the price level might have been well-enough approximated by a random walk that actual inflation may have approximately equalled unexpected inflation. Since then, when inflation has become much more serially correlated, actual and expected inflation may have diverged widely.

In its general idea, the Lucas–Sargent–Wallace theory of the Phillips curve sounds like an appealing possibility. The question for econometric testing of the theory is whether we want to assume that expectations of unemployed workers are fully rational.

The tests Sargent (1976) made of the model are illustrative of the manner in which rational expectations models are often tested. Sargent tested whether the model holds under the assumption that unemployed workers are making optimal use in their forecasts of inflation of current and lagged values of the real government surplus, real and money government expenditures, the price level, the money supply, and a wage index. It is commonplace today in the rational expectations literature to see similar extravagant assumptions about the information sets of ordinary individuals.

The most basic criticism of many rational expectations models is that they make implausible claims for individual economic agents' ability and willingness to compute. But the criticism of these models goes beyond that: see for example Friedman (1979), Tobin (1980).

The rational expectations models assume that economic agents behave as if they know the structure of the economy so that they can compute the optimal forecasts that represent their expectations. But the structure of the economy is always changing, as technology, tastes and government interventions change. These changes themselves vary qualitatively from time to time, and so it may not be possible for economic agents to group instances in such a way as to allow dealing with the changes in statistical terms. If these changes occur frequently relative to the speed at which people can figure out the economy, it may never be appropriate to assume that their forecasts are optimal forecasts.

In most rational expectations models, the behaviour of the economic variables that individual economic agents must forecast is itself affected by the way the economic agents form expectations. This fact was noted above in connection with our efforts to solve the supply and demand rational expectations model for tomatoes. Thus, if economic agents learn something about how to forecast an economic variable, the random properties of the economic variable may change in consequence. A rational expectations equilibrium is achieved only when people have adopted a way of forecasting that is consistent with the implications for the economy of their own way of forecasting. How do they find such a way of forecasting? Achievement of a rational expectations equilibrium might take place as a consequence of a long iterative process, each step representing the learning by economic agents of how to forecast in the preceding step, and thereby necessitating the next step of learning anew how to forecast. In models that are more complicated than the simple supply and demand models, for example, models of the entire macroeconomy, the time required for each step may need to be enormous. The problem of convergence of forecasting methods to a rational expectations equilibrium recalls the problem in mathematical economics of the convergence of a price vector to Walrasian equilibrium. However, the former problem has received much less attention. Moreover, convergence may well be orders of magnitude slower in the former. It would appear likely, given the

complexity of the macroeconomy, that economic agents learn very slowly about how to forecast given the present structure of the economy. Each step in the iteration requires sifting through large amounts of data and learning how these are related statistically.

The behavioural economics revolution, still very much under way since its beginnings around 1980, can be described as groping for alternatives to rational expectations models, alternatives that have some structure from research in psychology and that do not impose unrealistic complexity on individual decisionmaking. Akerlof and Yellen (1985) have argued for 'near-rational expectations' models. Richard Thaler (1991) has argued that we must turn to something he calls 'quasi-rational economics'. Frydman and Goldberg (2007) have argued that we must work towards something they call 'imperfect knowledge economics'. These are important beginnings, though today none of the alternatives has yet won widespread acceptance among economists.

Despite the criticisms, rational expectations models may well be useful for some applications when compared with alternative models based on expectations proxies. As regards the assumptions in the models for the ability and willingness of economic agents to store and process information, there is no alternative for model builders to that of judging for plausibility on a case-by-case basis.

Expected Utility and Mathematical Expectation

David Schmeidler and Peter Wakker

Expected utility theory deals with choosing among acts where the decision-maker does not know for sure which consequence will result from a chosen act. When faced with several acts, the decision-maker will choose the one with the highest 'expected utility', where the expected utility of an act is the sum of the products of probability and utility over all possible consequences.

The introduction of the concept of expected utility is usually attributed to Daniel Bernoulli (1738). He arrived at this concept as a resolution of the so-called St Petersburg paradox. It involves the following gamble: A 'fair' coin is flipped until the first time heads up. If this is at the *k*th flip, then the gambler receives $\$2^k$. The question arose how much to pay for participation in this gamble. Since the probability that heads will occur for the first time in the *k*th flip is 2^k (assuming independence of the flips), and the gain then is $\$2^k$, the 'expected value' (i.e. the *mathematical expectation* of the gain) of the gamble is infinite. It has been observed though that gamblers were not willing to pay more then \$2 to \$4 to participate in such a gamble. Hence the 'paradox' between the mathematical expectation of the gain, and the observed willingness to pay.

Bernoulli suggested that the gambler's goal is not to maximize his expected gain, but to maximize the expectation of the logarithm of the gain which is $\sum_{j=1}^{\infty} 2^{-j}\log 2^j$, i.e. $2\log 2 (= \log 4)$. Then the gambler is willing to pay \$4 for the gamble. The idea that *homo economicus* considers the expected utility of the gamble, and not the expected value, is a cornerstone of expected theory.

In the next section the approach of Savage to decisions under uncertainty is presented. In section "Expected Utility when Applied to Decisions under Risks; The Von Neumann–Morgenstern Approach" the von Neumann-Morgenstern characterization of expected utility maximization for the context of decisions under risk is given. Section "Other Approaches and Bibliographical Remarks" briefly mentions some related approaches. Section "Appendix: Mathematical Expectation", the Appendix, defines (mathematical) expectation.

Expected Utility when Applied to Decisions Under Uncertainty; Savage's Approach

The main ingredients of a decision problem under uncertainty are acts consequences and states of nature. Suppose that a decision-maker has to choose one of three feasible acts *f, g, h*. Act *f* leads to one (only) of the two consequences a and b. Act *g* leads to a or c, act *h* to b or d. Thus the set of consequences, *C*, is in this example {a, b, c, d}.

The matching of feasible acts to consequences is expressed by the concept of 'state of nature', or 'state' for short. More precisely, a given state of nature indicates for each feasible act what the resulting consequence will be. In the above example, there are three feasible acts *f, g, h*, each leading to one of two possible consequences. See Table 1.

A state of nature completely resolves the uncertainty relating acts to consequences. If the decision-maker would know for sure which state of nature is the true one, then he would choose an act which results in a most desirable consequence.

Expected Utility and Mathematical Expectation, Table 1 The eight logically possible matchings of feasible acts to *consequences*

	States							
Acts	s_1	s_2	s_3	s_4	s_5	s_6	s_7	s_8
f	*a*	*a*	*a*	*a*	*b*	*b*	*b*	*b*
g	*a*	*a*	*c*	*c*	*a*	*a*	*c*	*c*
h	*b*	*d*	*b*	*d*	*b*	*d*	*b*	*d*

The desirability of a consequence neither depends on the act nor on the state of nature leading to it.

In constructing a table like Table 1 some of the states of nature may be deleted if the decision-maker is certain that they cannot occur.

The next step in the process of selecting the best act is to construct 'conceivable' acts, which are not feasible. Thus the set of acts, *F*, in Savage's set-up consists of all functions from the set of states of nature, *S*, to the set *C* of consequences. In our example there are 4^8 acts. Of these, three acts *f, g* and *h* are actually feasible: The additional 65533 acts are only conceivable. The construction of the conceivable acts and the possibility of ranking all acts of *F* is a basic assumption of the present approach. For the sake of presentation we will in the next subsection assume the validity of the expected utility theory and then we will return to the rationale of our construction.

Suppose for the present that the decision-maker, in choosing between acts, indeed computes the expected utility of each act, and selects a feasible act with the highest expected utility. Thus we are assuming that he has assigned probability $P(s)$ to every state of nature s in S, and the utility $U(c)$ to every consequence c in C. So, given an act f in F, the expected utility $EU(f)$ of f equals $\sum_{s \in S} P(s)U[f(s)]$. More generally, if the set S is infinite, then P is a finitely additive probability measure defined on all events (i.e. subsets of S), and $EU(f)$ equals $\int U[f(s)]\, dP(s)$ (assuming the integral to exist; say U is bounded; see the Appendix, on Mathematical Expectation, section "Appendix: Mathematical Expectation"). So in fact in this case the decision-maker has a well-defined 'preference relation' (i.e. binary relation) $\geq$ on the set of acts *F*, with, for all *f, g* in *F*:

$$f \gtrsim g \text{ iff } \mathrm{EU}(f) \geq EU(g) \tag{1}$$

It is easily seen that the preference relation, defined in (1), is not affected when the utility function $U \rightarrow C\ R$ is replaced by any positive linear transformation of it (say $(\bar{U}: c \rightarrow \alpha U(c) + \beta$, for some real β and positive α).

If a preference relation, $\gtrsim$, over acts is derived from comparisons of expected utility as in (1), then it must satisfy several properties. We follow the terminology and order of Savage (1954). He listed seven postulates, five of which (P1 up to P4, and P7) are implied by (1). Postulate P1 says that the preference relation is complete ($f \gtrsim g$ or $g \gtrsim f$ for all acts *f, g*) and transitive. Postulate P2 is referred to as the sure-thing principle. It says that, when comparing two acts, only those states of nature matter, on which these acts differ. In other words, for the comparison between two acts, if they coincide on an event A, it really does not matter what actually the consequence is for each state in A. Thus P2 makes it possible to derive a preference relation over acts, conditioned on the event A^c; this for any event A.

Postulate P3 entails that the desirability of a consequence does not depend on the combination of state and act that lead to it; hence the possibility to express the desirability of consequences by a utility function on *C*.

P4 guarantees that the preference relation over acts induces a qualitative probability relation ('at least as probable as') over events, which is transitive and complete. P7 is a technical monotonicity condition.

P5 and P6 are Savage's only postulates which are not a necessary implication of (1). P5 simply serves to exclude the trivial case where the decision-maker is indifferent between any two acts. P6 implies some sort of continuity of the preference relation, and non-atomicity of the probability measure; the last term means that any non-impossible event can be partitioned into two non-impossible events. Hence there must be an infinite number of states.

Savage's great achievement was not to *assume* (1), but to show that his list of postulates P1–P7 *implies* that the preference relation over acts has

an expected utility representation as in (1). Savage argued compellingly for the appropriateness of his postulates. Furthermore, Savage showed that the probability measure in (1) is uniquely determined by the preference relation $\geq$, and that the utility function is unique up to a positive linear transformation.

The significance of Savage's achievement is that it gives the first, and until today most complete, conceptual foundation to expected utility. Savage's conclusion, to use expected utility for the selection of optimal acts, can be used even if we do not have the structure and the seven postulates of Savage. Indeed, the assumption needed on consequences, states, acts, and preferences, is that they can be extended so as to satisfy all requirements of Savage's model. Also other models, as mentioned in section "Other Approaches and Bibliographical Remarks", can be used to obtain expected utility representations.

Given a decision problem under uncertainty, if we assume that it can be embedded in Savage's framework, then it is not necessary to actually carry out this embedding. In other words, if the decision-maker is convinced that in principle it is possible to construct the conceivable acts as in subsection and the ranking of all acts in accordance with the postulates, then this construction does not have to be made. Instead one can directly try to assess probabilities and utilities, and apply the expected utility criterion. As an example, suppose a market-vendor has to decide whether to order 50 portions of ice-cream (f), or not (g). One portion costs \$1, and is sold for \$2. If the weather will be nice the next day, the school nearby will allow the children to go to the market, and all 50 portions, if ordered, will be sold, yielding a profit of \$50. If the weather is not nice, no portion will be sold. We assume that the ice-cream cannot be kept in stock and hence bad weather will yield a 'gain' of $\$ - 50$ if the portions have been ordered.

Instead of embedding the above example into Savage's framework, the market salesman may immediately assess P_1 (or $1 - P_1$), the probability for good (bad) weather; next assess the utilities of gaining \$50, \$0 and –\$50; finally order the 50 portions if $P_1 U(\$50) + (1 - P_1)\, U(-\$50) > U(\$0)$.

Theoretical conclusions can be derived from the mere assumption of expected utility maximization, without an actual assessment of the probabilities and utilities. Examples are the theories of attitudes towards risk, with applications to insurance, portfolio choice, etc. The validity of these applications depends on expected utility theory, which in turn depends on the plausibility of Savage's model (or other derivations of expected utility).

Another important theoretical application of Savage's model is to neo-Bayesian statistics. For applied statistics, in this vein, the availability of a 'prior distribution,' as proved by Savage's approach, is essential.

Expected Utility when Applied to Decisions Under Risks; The Von Neumann–Morgenstern Approach

Special and extreme cases of decisions under uncertainty are decisions in 'risky' situations. In decisions under uncertainty, as exposited in the previous section, the decision-maker who follows the dictum of expected utility has to assign utilities to the consequences and probabilities to the states. He can do it by mimicking the proof of Savage's theorem, or more directly by organizing his information, as the case may be.

Decision-making under risk considers the special case where the formulation of the problem for the decision-maker includes probabilities for the events, so that he only has to derive the utilities of consequences. As an example, consider a gambler in a casino who assumes that the roulette is really unbiased, so that each number has probability 1/37 (or 1/38). Another example is the St Petersburg paradox, described in subsection.

Within the framework of expected utility theory, for the evaluation of an act, only its probability distribution over the consequences has to be taken into account. Thus, for decision-making under risk, with probabilities known in advance, one may just as well describe acts as probability distributions over consequences instead of as functions from the states to the consequences.

Let us denote by L the set of probability distributions over C with finite support. We refer to them as lotteries. Von Neumann and Morgenstern (1947, Appendix) suggested conditions on a preference relation $\geq$ between lotteries, necessary and sufficient for the existence of a real-valued utility function U on C, such that for any two lotteries P and Q in L:

$$P \geq Q \text{ iff } \sum_{c \in C} P(c)U(c) \geq \sum_{c \in C} Q(c)U(c) \quad (2)$$

It is easy to see that the utility function, U, is unique up to positive linear transformations. Before we present a version of von Neumann-Morgenstern's theorem, recall that for any $0 \leq \alpha \leq 1$, and for any two lotteries P and W, $R := \alpha P + (1 - \alpha)Q$ is again a lottery, assigning probability $R(c) = \alpha P(c) + (1 - \alpha)Q(c)$ to any c in C. Also note that the assumption that all lotteries are given, is sometimes as heroic as Savage's assumption that all functions from S to C are conceivable acts.

The first axiom of von Neumann-Morgenstern, NM1, says that the preference relation over the lotteries is complete and transitive. NM2, the continuity axiom, says that, if $P \succsim Q \succ R$, then there are α, β in]0, 1[, such that $\alpha R + (1 - \alpha)P \succ Q \succ \beta P + (1 - \beta)R$. Here the strict preference relation $\succ$ is derived from $\succsim$ in the usual way: $P \succ Q$ if $P \succsim Q$ and not $Q \succsim P$.

The third axiom NM3 is the independence axiom. It says that for α in]0,1], P is preferred to Q iff $\alpha P + (1 - \alpha)R$ is preferred to $\alpha Q + (1 - \alpha)R$. This condition is the antecedent of Savage's sure-thing principle, and is the most important innovation of the above axioms.

Von Neumann and Morgenstern originally stated their theorem for more general sets than L. They did it for so-called mixture spaces, i.e. spaces endowed with some sort of convex combination operation. This has been done more precisely by Herstein and Milnor (1953).

Von Neumann and Morgenstern introduced their theory of decision-making under risk as a normative tool for playing zero-sum games in strategic form. There the 'player' (i.e. decision-maker) can actually construct any lottery he wishes over his pure-strategies (but not over his consequences).

The theorem of von Neumann and Morgenstern, stated above, is a major step in the proof of Savage's theorem.

Recently there has been much research on decision making under risk for its own end. Some of this research is experimental, subjects are asked to express their preferences between lotteries. These experiments, or polls, reveal violations of most of the axioms. They lead to representations different from expected utility.

Other Approaches and Bibliographical Remarks

The first suggestion for expected utility theory in decision-making under uncertainty in the vein of Savage was Ramsey's (1931). His model was not completely formalized. The work of Savage was influenced by de Finetti's approach to probabilities, as in de Finetti (1931, 1937). The decision theoretic framework to which Savage's expected utility model owes much is that of Wald (1951), who regards a statistician as a decision-maker.

A model which can be considered intermediate between those of Savage and von Neumann and Morgenstern is that considered by Anscombe and Aumann (1963). Formally it is a special case of a mixture set, but like Savage it introduces states of nature, and gives a simultaneous derivation of probabilities for the states, and of utilities for the consequences. A consequence in this model consists of a lottery over deterministic outcomes; this involves probabilities known in advance, as in the approach of von Neumann and Morgenstern. The Anscombe and Aumann theory, as well as most of the technical results up to 1970, are presented in detail in Fishburn (1970).

In the expected utility theory, described above, the desirability (utility) of consequences does not depend on acts or states of nature. This is a restriction in many applications. For example the desirability of family income may depend on whether the state of nature is 'head of family alive' or 'head of family deceased'. Karni (1985) summarized and developed the expected utility theory

without the restrictive assumption of state-independent preferences over consequences.

Ellsberg (1961) argued against the expected utility approach of Savage by proposing an example, inconsistent with it. A way of resolving the inconsistency is to relax the additivity property of the involved probability measures. Schmeidler (1984) formulated expected utility theory with non-additive probabilities for the framework of Anscombe and Aumann (1963). Gilboa (1985) did the same for the original framework of Savage. Wakker (1986) obtained expected utility representation, including the non-additive case, for a finite number of states of nature and non-linear utility.

Appendix: Mathematical Expectation

Expectation with respect to finitely additive probability. A non-empty collection $\sum$ of subsets (called events) of a non-empty set S is said to be an algebra if it contains the complement of each set belonging to it, and it contains the union of any two sets belonging to it. A (finitely additive) probability P on $\sum$ assigns to every event in $\sum$ a number between 0 and 1 such that $P(S) = 1$ and for any two *disjoint events* A and B, $P(A \cup B) = P(A) + P(B)$.

A random variable X is a real-valued function on S such that, for any open or closed (bounded or unbounded) interval I, $\{s \in S \mid X(s) \in I\}$ (or $[X \in I]$ for short) is an event i.e., in Σ. Given such a random variable X, its (mathematical) expectation is:

$$E(X) = \int_0^\infty P[X \geq \alpha]\,\mathrm{d}\alpha - \int_{-\infty}^0 (1 - P[X \geq \alpha])\,\mathrm{d}\alpha \qquad (3)$$

where the integration above is Riemann-integration and it is assumed that the integral exist. The integrands in (3) are monotonic, so $E(X)$ exist *if* X is bounded. If the random variable X has finitely many values, say $x_1, \ldots, x_n$ then (3) reduces to

$$E(X) = \sum_{i=1}^{n} P(X = x_i)x_i, \qquad (4)$$

However, an equation like that above may not hold if the random variable obtains countably many different values. An example will be provided in subsection.

σ-additive probability. Kolmogorov (1933) imposed an additional continuity assumption on probability P on $\sum$: To simplify presentation he first assumed that Σ is a σ-algebra, i.e., an algebra such that for every sequence of events $(A_i)_{i=1}^{\infty}$ it contains its union $\mathrm{U}_{i=1}^{\infty} A_i$. He then required that $P\left(\mathrm{U}_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} P(A_i)$ if the A_i's are pairwise disjoint.

This last property is referred to as σ -additivity of the probability P. In this way Kolmogorov transformed large parts of probability theory into (a special case of) measure theory. Thus an expectation of a random variable X is

$$E(X) = \int_s X(s)\mathrm{d}P(s) \qquad (5)$$

where the right side is a Lebesgue integral (if it exists. . .), defined as a limit of integrals of random variables with countably many values. Let Y be such a random variable with values $(y_i)_{i=1}^{\infty}$, then

$$E(Y) = \sum_{i=1}^{\infty} P(Y = y_i)y_i \qquad (6)$$

if the right side is absolutely convergent.

An example will now be introduced of a finitely additive probability, i.e. a probability for which (4) holds but (6) does not hold. Let S be the set of rational numbers in the interval [0, 1] and let Σ be the algebra of all subsets of S. (It is in fact a σ-algebra.) For $0 \leq \alpha \leq \beta \leq 1$ define $P(S \cap [\alpha,\beta]) = \beta - \alpha$ and extend P to all subsets of Σ. For each s in S, $P(s) = 0$. Since S is countable we can write $S = \{s_1, s_2, \ldots\}$ and $1 = P(S) > \Sigma_{i=1}^{\infty} P(si) = 0$. Defining $Y(s_i) = 1/i$ for all i, we get a contradiction to (6). The finitely additive probability P has also the property implied by Savage's P6 (see 2.4): If $P(A) > 0$ then there is an event $B \subset A$ such that $0 < P(B) < \mathrm{P(A)}$.

Distributions. A non-decreasing right continuous function on the extended real line is called a distribution function if $F(-\infty) = 0$ and $F(\infty) = 1$. Given a random variable X, its distribution function F_x is defined by $F_x(\alpha) = P(X \leqq \alpha)$ for all real α. Then

$$E(X) = \int_0^\infty [1 - F_X(\alpha)]\mathrm{d}\alpha - \int_{-\infty}^0 F(\alpha)\mathrm{d}\alpha \quad (7)$$

which is the dual of formula (3). If the distribution F_x is smooth we say that the random variable X has a density f_x: $R \to R$, which is the derivative of F_x. In this case

$$E(X) = \int_{-\infty}^\infty = \alpha f(\alpha)\mathrm{d}\alpha \quad (8)$$

Non-additive probability. A function P: $\Sigma \to [0, 1]$ is said to be *non-additive* probability (or capacity) if $P(S) = 1$, $P(\phi) = 0$ *and for* $A \subset B$, $P(A) \leq P(B)$. Choquet (1954) suggested to integrate a random variable with respect to non-additive probability by formula (3).

Expected Utility Hypothesis

Mark J. Machina

Abstract

The expected utility hypothesis – that is, the hypothesis that individuals evaluate uncertain prospects according to their expected level of 'satisfaction' or 'utility' – is the predominant

descriptive and normative model of choice under uncertainty in economics. It provides the analytical underpinnings for the economic theory of risk-bearing, including its applications to insurance and financial decisions, and has been formally axiomatized under conditions of both objective (probabilistic) and subjective (event-based) uncertainty. In spite of evidence that individuals may systematically depart from its predictions, and the development of alternative models, expected utility remains the leading model of economic choice under uncertainty.

The expected utility hypothesis is the predominant descriptive and prescriptive theory of individual choice under conditions of risk or uncertainty.

The expected utility hypothesis of behaviour towards risk is the hypothesis that the individual possesses (or acts as if possessing) a 'von Neumann–Morgenstern utility function' $U(\cdot)$ or 'von Neumann–Morgenstern utility index' $\{U_i\}$ defined over some set $\mathscr{X}$ of alternative possible outcomes, and when faced with alternative risky prospects or 'lotteries' over these outcomes, will choose the prospect that maximizes the expected value of $U(\cdot)$ or $\{U_i\}$. Since the outcomes could be alternative wealth levels, multidimensional commodity bundles, time streams of consumption, or even non-numerical consequences (such as a trip to Paris), this approach can be applied to a tremendous variety of situations, and most theoretical research in the economics of uncertainty, as well as virtually all applied work in the field (for example, insurance or investment decisions) is undertaken in the expected utility framework.

As a branch of modern consumer theory (for example, Debreu 1959, ch. 4), the expected utility model proceeds by specifying a set of objects of choice and assuming that the individual possesses a preference ordering over these objects which may be represented by a real-valued maximand or 'preference function' $V(\cdot)$, in the sense that one object is preferred to another if and only if it is assigned a higher value by this preference function. However, the expected utility model differs from the theory of choice over non-stochastic commodity bundles in two important respects. The first is that, since it is a theory of choice under uncertainty, the objects of choice are not deterministic outcomes but rather uncertain prospects. The second difference is that, unlike in the non-stochastic case, the expected utility model imposes a very specific restriction on the functional form of the preference function $V(\cdot)$.

The formal representation of the objects of choice, and hence of the expected utility preference function, depends upon the set of possible outcomes. When the outcome set $\mathscr{X} = \{x_1, \ldots, x_n\}$ is finite, we can represent any probability distribution over this set by its vector of probabilities $\boldsymbol{P} = (p_1, \ldots, p_n)$ (where $p_i = \text{prob}(x_i)$) and the expected utility preference function takes the form

$$V(\boldsymbol{P}) = V(p_1, \ldots, p_n) \equiv \sum U_i p_i.$$

When the outcome set consists of the real line or some interval subset of it, probability distributions can be represented by their cumulative distribution functions $F(\cdot)$ (where $F(x) = \text{prob}(\tilde{x} \leq x)$), and the expected utility preference function takes the form $V(F) \equiv \int U(x)\mathrm{d}F(x)$ (or $\int U(x)f(x)\mathrm{d}x$

when $F(\cdot)$ possesses a density function $f(\cdot)$). When the outcomes are commodity bundles of the form $(z_1, \ldots, z_m)$, cumulative distribution functions are multivariate, and the preference function takes the form $\int \ldots \int U(z_1, \ldots, z_m)\, dF(z_1, \ldots, z_m)$. The expected utility model derives its name from the fact that in each case the preference function consists of the mathematical expectation of the von Neumann–Morgenstern utility function $U(\cdot)$, $U(\cdot, \ldots, \cdot)$ or utility index $\{U_i\}$ with respect to the probability distribution $F(\cdot)$, $F(\cdot, \ldots, \cdot)$ or $\boldsymbol{P}$.

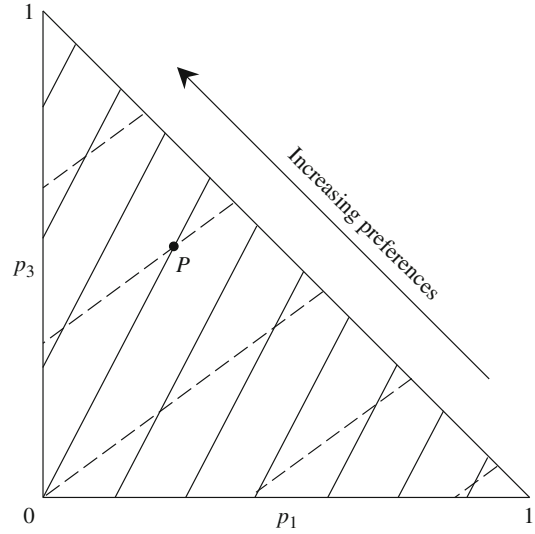
Mathematically, the hypothesis that the preference function $V(\cdot)$ takes the form of a statistical expectation is equivalent to the condition that it be 'linear in the probabilities', that is, either a weighted sum of the components of $\boldsymbol{P}$ (i.e. $\sum U_i p_i$) or else a weighted integral of the functions $F(\cdot)$ or $f(\cdot)$ ($\int U(x)\mathrm{d}F(x)$ or $\int U(x)f(x)\mathrm{d}x$). Although this still allows for a wide variety of attitudes towards risk depending upon the shape of the utility function $U(\cdot)$ or utility index $\{U_i\}$, the restriction that $V(\cdot)$ be linear in the probabilities is the primary empirical feature of the expected utility model, and provides the basis for many of its observable implications and predictions.

It is important to distinguish between the preference function $V(\cdot)$ and the von Neumann–Morgenstern utility function $U(\cdot)$ (or index $\{U_i\}$) of an expected utility maximizer, in particular with regard to the prevalent though mistaken belief that expected utility preferences are somehow 'cardinal' in a sense not exhibited by preferences over non-stochastic commodity bundles. As with any real-valued representation of a preference ordering, an expected utility *preference function* $V(\cdot)$ is 'ordinal' in that it may be subject to any increasing transformation without affecting the validity of the representation – thus, the preference functions $\int U(x)\mathrm{d}F(x)$ and $[\int U(x)dF(x)]^3$ represent identical risk preferences. On the other hand, the von Neumann–Morgenstern utility function $U(\cdot)$ is 'cardinal' in the sense that a different utility function $U^*(\cdot)$ will generate an ordinally equivalent preference function $V^*(F) \equiv \int U^*(x)\mathrm{d}F(x)$ if and only if it satisfies the cardinal relationship $U^*(x) \equiv a \cdot U(x) + b$ for some $a > 0$ (in which case $V^*(F) \equiv a \cdot V(F) + b$. However, the same distinction holds in the theory of preferences over non-stochastic commodity bundles: the Cobb–Douglas preference function $\alpha \cdot \ln(z_1) + \beta \cdot \ln(z_2) + \gamma \cdot \ln(z_3)$ (written here in its additive form) can be subject to any increasing transformation and is clearly ordinal, even though a vector of parameters $(\alpha^*, \beta^*, \gamma^*)$ will generate an ordinally equivalent additive form $\alpha^* \cdot \ln(z_1) + \beta^* \cdot \ln(z_2) + \gamma^* \cdot \ln(z_3)$ if and only if it satisfies the cardinal relationship $(\alpha^*, \beta^*, \gamma^*) = \lambda \cdot (\alpha, \beta, \gamma)$ for some $\lambda > 0$.

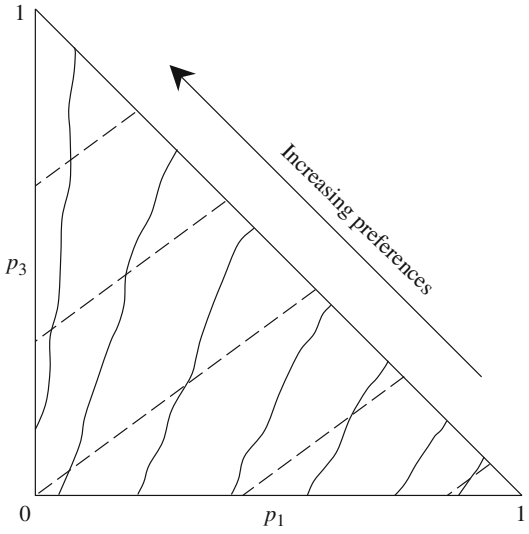
In the case of a simple outcome set of the form $\{x_1, x_2, x_3\}$, it is possible to graphically illustrate the 'linearity in the probabilities' property of expected utility preferences. Since every probability distribution (p_1, p_2, p_3) over these outcomes must satisfy $p_1 + p_2 + p_3 = 1$, we may represent such distributions by points in the unit triangle in the (p_1, p_3) plane, with p_2 given by $p_2 = 1 - p_1 - p_3$ (Figs. 1 and 2). Since they represent the loci of solutions to the equations

$$\begin{aligned} U_1p_1 + U_2p_2 + U_3p_3 &= U_2 - [U_2 - U_1] \cdot p_1 \\ &\quad + [U_3 - U_2] \cdot p_3 \\ &= \text{constant} \end{aligned}$$

for the fixed utility indices $\{U_1, U_2, U_3\}$, the indifference curves of an expected utility maximizer consist of parallel straight lines in the triangle,



Expected Utility Hypothesis, Fig. 1 Expected utility indifference curves



Expected Utility Hypothesis, Fig. 2 Non-expected utility indifference curves

with slope $[U_2 - U_1]/[U_3 - U_2]$, as illustrated by the solid lines in Fig. 1. Indifference curves which do *not* satisfy the expected utility hypothesis (that is, are not linear in the probabilities) are illustrated by the solid curves in Fig. 2.

When the outcomes consist of different wealth levels $x_1 < x_2 < x_3$, this diagram can be used to illustrate other possible features of an expected utility maximizer's attitudes towards risk. On the principle that more wealth is better, it is typically postulated that any change in a distribution (p_1, p_2, p_3) which increases p_3 at the expense of p_2, increases p_2 at the expense of p_1, or both, will be preferred: this property is known as 'first-order stochastic dominance preference'. Since such shifts of probability mass are represented by north, west, or north-west movements in the diagram, first-order stochastic dominance preference is equivalent to the condition that indifference curves are upward sloping, with more preferred indifference curves lying to the north-west. Algebraically, this is equivalent to the condition $U_1 < U_2 < U_3$.

Another widely (though not universally) hypothesized aspect of attitudes towards risk is that of 'risk aversion' (for example, Arrow 1974, ch. 3; Pratt 1964). To illustrate this property, consider the dashed lines in Fig. 1, which represent loci of solutions to the equations

$$\begin{aligned} x_1p_1 + x_2p_2 + x_3p_3 &= x_2 - [x_2 - x_1] \cdot p_1 \\ &\quad + [x_3 - x_2] \cdot p_3 \\ &= \text{constant} \end{aligned}$$

and hence may be termed 'iso-expected *value* loci'. Since north-east movements along any of these loci consist of increasing the tail probabilities p_1 and p_3 at the expense of the middle probability p_2 in a manner which preserves the mean of the distribution, they correspond to what are termed 'mean-preserving increases in risk' (Rothschild and Stiglitz 1970, 1971). An individual is said to be 'risk averse' if such increases in risk always lead to less preferred indifference curves, which is equivalent to the graphical condition that the indifference curves be steeper than the iso-expected value loci. Since the slope of the latter is given by $[x_2 - x_1]/[x_3 - x_2]$, this is equivalent to the algebraic condition that $[U_2 - U_1]/[x_2 - x_1] > [U_3 - U_2]/[x_3 - x_2]$. Conversely, individuals who *prefer* mean-preserving increases in risk are termed 'risk loving': such individuals' indifference curves will be flatter than the iso-expected value loci, and their utility indices will satisfy $[U_2 - U_1]/[x_2 - x_1] < [U_3 - U_2]/[x_3 - x_2]$.

Note finally that the indifference map in Fig. 1 indicates that the lottery $\boldsymbol{P}$ is indifferent to the origin, which represents the degenerate lottery yielding x_2 with certainty. In such a case the amount x_2 is said to be the 'certainty equivalent' of the lottery $\boldsymbol{P}$. The fact that the origin lies on a lower iso-expected value locus than $\boldsymbol{P}$ reflects a general property of risk-averse preferences, namely, that the certainty equivalent of any lottery will always be less than its mean. (For risk lovers, the opposite is the case.)

When the outcomes are elements of the real line, it is possible to represent the above (as well as other) aspects of preferences in terms of the shape of the von Neumann–Morgenstern utility function $U(\cdot)$, as seen in Figs. 3 and 4. In each figure, consider the lottery which assigns the probabilities 2/3:1/3 to the outcome levels x': x''. The expected value of this lottery, $\overline{x} = 2/3 \cdot x' + 1/3$

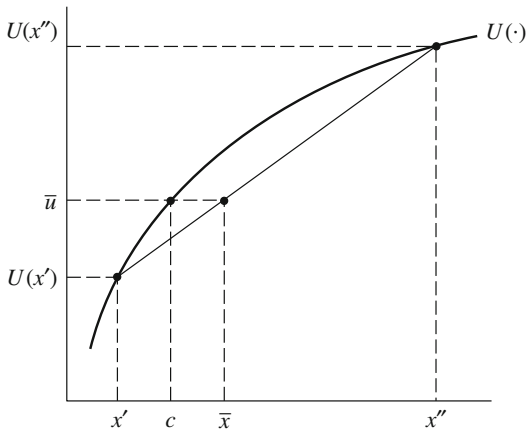
$\cdot x''$, lies between these two values, two-thirds of the way towards x'. The expected *utility* of this lottery, $\overline{u} = 2/3 \cdot U(x') + 1/3 \cdot U(x'')$ lies between $U(x')$ and $U(x'')$ on the vertical axis, two-thirds of the way towards $U(x')$. The point $(\overline{x},\overline{u})$ thus lies on the line segment connecting the points $(x', U(x'))$ and $(x'', U(x''))$, two-thirds of the way towards the former. In each figure, the certainty equivalent of this lottery is given by the sure outcome c that also yields a utility level of $\overline{u}$.

The property of first-order stochastic dominance preference can be extended to the case of distributions over the real line (Quirk and Saposnick 1962), and it is equivalent to the condition that $U(x)$ be an increasing function of x, as in Figs. 3 and 4. It is also possible to generalize the notion of a mean-preserving increase in risk to density functions or cumulative distribution functions (Rothschild and Stiglitz 1970, 1971), and the earlier algebraic condition for risk aversion generalizes to the condition that $U''(x) < 0$ for all x, that is, that the von Neumann–Morgenstern utility function $U(\cdot)$ be concave, as in Fig. 3. As before, risk aversion implies that the certainty equivalent of any lottery will lie below its mean, as seen in Fig. 3; the opposite is true for the convex utility function of a risk lover, as in Fig. 4. Two of the earliest and most important analyses of risk attitudes in terms of the shape of the von Neumann–Morgenstern utility function are those of Friedman and Savage (1948) and Markowitz (1952).

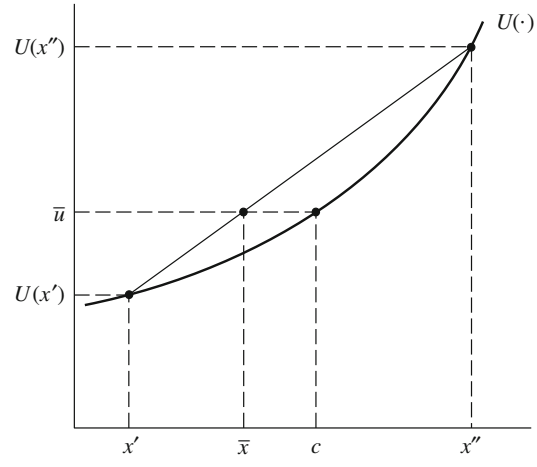
Analytics

The tremendous analytic capabilities of the expected utility model derive largely from the work of Arrow (1974) and Pratt (1964), who showed that the 'degree' of concavity of the utility function provides a measure of an expected utility maximizer's 'degree' of risk aversion. Formally, the Arrow–Pratt characterization of comparative risk aversion is the result that the following conditions on a pair of (increasing, twice differentiable) von Neumann–Morgenstern utility functions $U_a(\cdot)$ and $U_b(\cdot)$ are equivalent:

- $U_a(\cdot)$ is a concave transformation of $U_b(\cdot)$ (that is, $U_a(x) \equiv \rho(U_b(x))$ for some increasing concave function $\rho(\cdot)$),
- $-U_a''(x)/U_a'(x) \geq -U_b''(x)/U_b'(x)$ for each x,
- if c_a and c_b solve $U_a(c_a) = \int U_a(x)\mathrm{d}F(x)$ and $U_b(c_b) = \int U_b(x)\mathrm{d}F(x)$ for some distribution $F(\cdot)$, then $c_a \leq c_b$,



Expected Utility Hypothesis, Fig. 3 Von Neumann–Morgenstern utility function of a risk averse individual



Expected Utility Hypothesis, Fig. 4 Von Neumann–Morgenstern utility function of a risk loving individual

and if $U_a(\cdot)$ and $U_b(\cdot)$ are both concave, these conditions are in turn equivalent to:

- if $r > 0$, $\mathrm{E}[\tilde{z}] > r$, $\mathrm{prob}(\tilde{z} < r) > 0$, and α_a and α_b maximize $\int U_a((I - \alpha) \cdot r + \alpha \cdot z)\mathrm{d}F(z)$ and $\int U_b((I - \alpha) \cdot r + \alpha \cdot z)\mathrm{d}F(z)$ respectively, then $\alpha_a \leq \alpha_b$.

The first two of these conditions provide equivalent formulations of the notion that $U_a(\cdot)$ is a more concave function than $U_b(\cdot)$. The curvature measure $R(x) \equiv -U''(x)/U'(x)$ is known as the 'Arrow–Pratt index of (absolute) risk aversion', and plays a key role in the analytics of the expected utility model. The third condition states that the more risk averse utility function $U_a(\cdot)$ will never assign a higher certainty equivalent to any lottery $F(\cdot)$ than will $U_b(\cdot)$. The final condition pertains to the individuals' respective demands for risky assets. Specifically, assume that each must allocate $\$I$ between two assets, one yielding a riskless (gross) return of r per dollar, and the other yielding a risky return $\tilde{z}$ with a higher expected value but with some chance of doing worse than r. This condition says that the less risk-averse utility function $U_b(\cdot)$ will generate at least as great a demand for the risky asset as the more risk-averse utility function $U_a(\cdot)$. It is important to note that it is the *equivalence* of the above concavity, certainty equivalent and asset demand conditions which makes the Arrow-Pratt characterization such an important result in expected utility theory. (Ross 1981, provides an alternative, stronger, characterization of comparative risk aversion.)

Although the applications of the expected utility model extend to virtually all branches of economic theory (for example, Hey 1979), much of the flavour of these analyses can be gleaned from Arrow's (1974, ch. 3) analysis of the portfolio problem of the previous paragraph. If we rewrite $(I - \alpha) \cdot r + \alpha \cdot z$ as $I \cdot r + \alpha \cdot (z - r)$, the first-order condition for this problem can be expressed as:

$$\int z \cdot U'(I \cdot r + \alpha \cdot (z - r))\mathrm{d}F(z) - \int r \cdot U'(I \cdot r + \alpha \cdot (z - r))\mathrm{d}F(z) = 0,$$

that is, the marginal *expected* utility of the last dollar allocated to each asset is the same. The second-order condition can be written as:

$$\int (z - r)^2 \cdot U'''(I \cdot r + \alpha \cdot (z - r))\ \mathrm{d}F(z) < 0$$

and is ensured by the property of risk aversion (i.e. $U''(\cdot) < 0$).

As usual, we may differentiate the first-order condition to obtain the effect of a change in some parameter, say initial wealth I, on the optimal level of investment in the risky asset (the optimal value of α). Differentiating the first-order condition (including α) with respect to I, solving for $d\alpha/dI$, and invoking the second-order condition and the positivity of r yields that this derivative possesses the same sign as:

$$\int (z - r) \cdot U''(I \cdot r + \alpha \cdot (z - r))\ \mathrm{d}F(z).$$

Substituting $U''(x) \equiv -R(x) \cdot U'(x)$ and subtracting $R(I \cdot r)$ times the first-order condition yields that this expression is equal to:

$$-\int (z - r) \cdot [R(I \cdot r + \alpha \cdot (z - r)) - R(I \cdot r)] \cdot U'(I \cdot r + \alpha \cdot (z - r))\mathrm{d}F(z).$$

On the assumption that α is positive and $R(\cdot)$ is monotonic, the expression $(z - r) \cdot [R(I \cdot r + \alpha \cdot (z - r)) - R(I \cdot r)]$ will possess the same sign as $R'(\cdot)$. This implies that the derivative $\mathrm{d}\alpha/\mathrm{d}I$ will be positive (negative) whenever the Arrow–Pratt index $R(x)$ is a decreasing (increasing) function of the individual's wealth level x. In other words, an increase in initial wealth will always increase (decrease) demand for the risky asset if and only if $U(\cdot)$ exhibits decreasing (increasing) absolute risk aversion in wealth. Further examples of the analytics of the expected utility model may be found in the above references, as well as the surveys of Hirshleifer and Riley (1979), Lippman and McCall (1981), Machina (1983) and Karni and Schmeidler (1991).

Axiomatic Development

Although there exist dozens of formal axiomatizations of the expected utility model, most proceed by specifying an outcome space and postulating that the individual's preferences over probability distributions on this outcome space satisfy the following four axioms: completeness, transitivity, continuity and the Independence Axiom. Although it is beyond the scope of this entry to provide a rigorous derivation of the expected utility model in its most general setting, it is possible to illustrate the meaning of the axioms and sketch a proof of the expected utility representation theorem in the simple case of a finite outcome set $\{x_1, \ldots, x_n\}$.

Recall that in such a case the objects of choice consist of probability distributions $\boldsymbol{P} = (p_1, \ldots, p_n)$ over $\{x_1, \ldots, x_n\}$, so that the following axioms refer to the individuals' weak preference relation $\succcurlyeq$ over these prospects, where $\boldsymbol{P}^* \succcurlyeq \boldsymbol{P}$ is read '$\boldsymbol{P}^*$ is weakly preferred (that is, preferred or indifferent) to $\boldsymbol{P}$' (the associated strict preference relation $\succ$ and indifference relation $\sim$ are defined in the usual manner):

- *Completeness*: For any two distributions $\boldsymbol{P}$ and $\boldsymbol{P}^*$, either $\boldsymbol{P}^* \succcurlyeq \boldsymbol{P}$, $\boldsymbol{P} \succcurlyeq \boldsymbol{P}^*$, or both.
- *Transitivity*: If $\boldsymbol{P}^{**} \succcurlyeq \boldsymbol{P}^*$ and $\boldsymbol{P}^* \succcurlyeq \boldsymbol{P}$, then $\boldsymbol{P}^{**} \succcurlyeq \boldsymbol{P}$.
- *Mixture continuity*: If $\boldsymbol{P}^{**} \succcurlyeq \boldsymbol{P}^* \succcurlyeq \boldsymbol{P}$, then there exists some $\lambda \in [0, 1]$ such that $\boldsymbol{P}^* \sim \lambda \cdot \boldsymbol{P}^{**} + (1 - \lambda) \cdot \boldsymbol{P}$.
- *Independence*: For any two distributions $\boldsymbol{P}$ and $\boldsymbol{P}^*$, $\boldsymbol{P}^* \succcurlyeq \boldsymbol{P}$ if and only if $\lambda \cdot \boldsymbol{P}^* + (1 - \lambda) \cdot \boldsymbol{P}^{**} \succcurlyeq \lambda \cdot \boldsymbol{P} + (1 - \lambda) \cdot \boldsymbol{P}^{**}$ for all $\lambda \in [0, 1]$ and all $\boldsymbol{P}^{**}$

where $\lambda \cdot \boldsymbol{P} + (1 - \lambda) \cdot \boldsymbol{P}^{**}$ denotes the $\lambda : (1 - \lambda)$ 'probability mixture' of $\boldsymbol{P}$ and $\boldsymbol{P}^{**}$, that is, the lottery with probabilities $(\lambda \cdot p_1 + (1 - \lambda) \cdot p_1^{**}, \ldots, \lambda \cdot p_n + (1 - \lambda) \cdot p_n^{**})$.

The completeness and transitivity axioms are analogous to their counterparts in standard consumer theory. Mixture continuity states that if the lottery P^{**} is weakly preferred to P^* and P^* is weakly preferred to P, then exists some probability mixture of the most and least preferred lotteries which is indifferent to the intermediate one.

As in standard consumer theory, completeness, transitivity and continuity serve to establish the existence of a real-valued preference function $V(p_1, \ldots, p_n)$ which represents the relation $\succcurlyeq$, in the sense that $\boldsymbol{P}^* \succcurlyeq \boldsymbol{P}$ if and only if $V(p_1^*, \ldots, p_n^*) \geq V(p_1, \ldots, p_n)$. It is the Independence Axiom which gives the theory its primary empirical content by implying that $\succcurlyeq$ can be represented by a linear preference function of the form $V(p_1, \ldots, p_n) \equiv \sum U_i p_i$. To see the meaning of this axiom, assume that individuals are always indifferent between a two-stage compound lottery and its probabilistically equivalent single-stage lottery, and that $\boldsymbol{P}^*$ happens to be weakly preferred to $\boldsymbol{P}$. In that case, the choice between the mixtures $\lambda \cdot \boldsymbol{P}^* + (1 - \lambda) \cdot \boldsymbol{P}^{**}$ and $\lambda \cdot \boldsymbol{P} + (1 - \lambda) \cdot \boldsymbol{P}^{**}$ is equivalent to being presented with a coin that has a $(1 - \lambda)$ chance of landing tails (in which case the prize will be $\boldsymbol{P}^{**}$) and being asked *before the flip* whether one would rather win $\boldsymbol{P}^*$ or $\boldsymbol{P}$ in the event of a head. The normative argument for the Independence Axiom is that either the coin will land tails, in which case the choice won't have mattered, or it will land heads, in which case one is 'in effect' facing a choice between $\boldsymbol{P}^*$ and $\boldsymbol{P}$ and one 'ought' to have the same preferences as before. Note finally that the above statement of the axiom in terms of the weak preference relation $\succcurlyeq$ also implies its counterparts in terms of strict preference and indifference.

In the following sketch of the expected utility representation theorem, expressions such as '$x_i \succcurlyeq x_j$' should be read as saying that the individual weakly prefers the degenerate lottery yielding x_i with certainty to that yielding x_j with certainty, and '$\lambda \cdot x_i + (1 - \lambda) \cdot x_j$' will be used to denote the $\lambda : (1 - \lambda)$ probability mixture of these two degenerate lotteries.

The first step in the proof is to define the von Neumann–Morgenstern utility index $\{U_i\}$ and the expected utility preference function $V(\cdot)$. Without loss of generality, we may order the outcomes so that $x_n \succcurlyeq x_{n-1} \succcurlyeq \ldots \succcurlyeq x_2 \succcurlyeq x_1$. Since $x_n \succcurlyeq x_i \succcurlyeq x_1$ for each outcome x_i, mixture

continuity implies that there exist scalars $\{Ui\} \subset [0, 1]$ such that $x_i \sim U_i \cdot x_n + (1 - U_i) \cdot x_1$ for each i (which implies $U_1 = 0$ and $U_n = 1$). Given this, define $V(\boldsymbol{P}) = \sum U_i p_i$ for each $\boldsymbol{P}$.

The second step is to show that each lottery $\boldsymbol{P} = (\boldsymbol{p}_1,\ldots,\boldsymbol{p}_n)$ is indifferent to the mixture $\lambda \cdot x_n + (1 - \lambda) \cdot x_1$ where $\lambda = \sum U_i p_i$. Since $(p_1,\ldots,p_n)$ can be written as the n-component probability mixture $p_1 \cdot x_1 + p_2 \cdot x_2 + \ldots + p_n \cdot x_n$, and each outcome x_i is indifferent to the mixture $U_i \cdot x_n + (1 - U_i) \cdot x_1$, an n-fold application of the Independence Axiom yields that $\boldsymbol{P} = (p_1,\ldots,p_n)$ is indifferent to the mixture

$$p_1 \cdot [U_1 \cdot x_n + (1 - U_1) \cdot x_1] + p_2 \cdot [U_2 \cdot x_n + (1 - U_2) \cdot x_1] + \ldots + p_n \cdot [U_n \cdot x_n + (1 - U_n) \cdot x_1],$$

which is equivalent to $\left(\sum_{i=1}^{n} U_i p_i\right) \cdot x_n + \left(1 - \sum_{i=1}^{n} U_i p_i\right) \cdot x_1$.

The third step is to demonstrate that a mixture $\lambda^* \cdot x_n + (1 - \lambda^*) \cdot x_1$ is weakly preferred to a mixture $\lambda \cdot x_n + (1 - \lambda) \cdot x_1$ if and only if $\lambda^* \geq \lambda$. This follows immediately from the Independence Axiom and the fact that $\lambda^* \geq \lambda$ implies that these two lotteries may be expressed as the respective mixtures $(\lambda^* - \lambda) \cdot x_n + (1 - \lambda^* + \lambda) \cdot \boldsymbol{Q}$ and $(\lambda^* - \lambda) \cdot x_1 + (1 - \lambda^* + \lambda) \cdot \boldsymbol{Q}$, where $\boldsymbol{Q}$ is defined as the lottery $(\lambda/(1 - \lambda^* + \lambda)) \cdot x_n + ((1 - \lambda^*)/(1 - \lambda^* + \lambda)) \cdot x_1$.

The completion of the proof is now simple. For any two distributions $\boldsymbol{P}^* = \left(p_1^*,\ldots,p_n^*\right)$ and $\boldsymbol{P} = (p_1, \ldots, p_n)$, transitivity and the second step imply that $\boldsymbol{P}^* \succcurlyeq \boldsymbol{P}$ if and only if

$$\left(\sum_{i=1}^{n} U_i p_i^*\right) \cdot x_n + \left(1 - \sum_{i=1}^{n} U_i p_i^*\right) \cdot x_1 \succcurlyeq \left(\sum_{i=1}^{n} U_i p_i\right) \cdot x_n + \left(1 - \sum_{i=1}^{n} U_i p_i\right) \cdot x_1,$$

which by the third step is equivalent to the condition $\sum U_i p_i^* \geq \sum U_i p_i$, or in other words, that $V(\boldsymbol{P}^*) \geq V(\boldsymbol{P})$.

As mentioned, the expected utility model has been axiomatized many times and in many contexts. The most comprehensive accounts of the axiomatics of the model are undoubtedly Fishburn (1982) and Kreps (1988).

Subjective Expected Utility

In addition to the above setting of 'objective' (that is, probabilistic) uncertainty, it is possible to define expected utility preferences under conditions of 'subjective' uncertainty. In this case, uncertainty is represented by a set $\mathscr{S}$ of mutually exclusive and exhaustive 'states of nature,' which can be a finite set $\{s_1,\ldots, s_n\}$ (as with a horse race), a real interval $[\underline{s}, \overline{s}] \subseteq R^1$ (as with tomorrow's temperature), or a more abstract space. The objects of choice are then 'acts' $a(\cdot)$: $\mathscr{S} \rightarrow \mathscr{X}$ which map states to outcomes. In the case of a finite state space, acts are usually expressed in the form $\{x_1 \text{ if } s_1;\ldots; x_n \text{ if } s_n\}$. When the state space is infinite, finite-outcome acts can be expressed in the form $a(\cdot) = [x_1 \text{ on } E_1;\ldots; x_m \text{ on } E_m]$ for some partition of $\mathscr{S}$ into a family of mutually exclusive and exhaustive 'events' $\{E_1,\ldots, E_m\}$. Except for casino games and state lotteries, virtually all real-world uncertain decisions (including all investment or insurance decisions) are made under conditions of subjective uncertainty.

In such a setting, the 'subjective expected utility hypothesis' consists of the *joint* hypothesis that the individual possesses *probabilistic beliefs*, as represented by a 'personal' or 'subjective' probability measure $\mu(\cdot)$ over the state space, and *expected utility risk preferences*, as represented by a von Neumann–Morgenstern utility function $U(\cdot)$ over outcomes, and evaluates acts according a preference function of the form $W(x_1 \text{ if } s_1;\ldots;x_n \text{ if } s_n) \equiv \sum_{i=1}^{n} U(x_i) \cdot \mu(s_i)$, $W(x_1 \text{ on } E_1;\ldots;x_m \text{ on } E_m) \equiv \sum_{i=1}^{m} U(x_i) \cdot \mu(E_i)$, or more generally, $W(a(\cdot)) \equiv \int U(a(s))\mathrm{d}\mu(s)$. Whereas all individuals facing a given *objective* prospect $\boldsymbol{P} = (x_1, p_1;\ldots; x_n, p_n)$ are assumed to 'see' the same probabilities $(p_1,\ldots, p_n)$ (though they may have different utility functions), individuals facing a given *subjective* prospect $\{x_1 \text{ if } s_1;\ldots; x_n \text{ if } s_n\}$ or $[x_1 \text{ on } E_1;\ldots; x_m \text{ on } E_m]$ will generally possess differing subjective probabilities over these states or events, reflecting their different beliefs, past experiences, and so on.

Researchers such as Arrow (1974), Debreu (1959, ch. 7) and Hirshleifer (1965, 1966) have shown how the analytics of the objective expected

utility model can be extended to both the positive and normative analysis of decisions under subjective uncertainty. As a simple example, consider an individual deciding whether to purchase earthquake insurance, and if so, how much. A simple specification of this decision involves the state space $\mathscr{S} = \{s_1, s_2\} = \{\text{earthquake; no earthquakeg}$, the individual's von Neumann–Morgenstern utility of wealth function $U(\cdot)$, their subjective probabilities $\{\mu(s_1), \mu(s_2)\}$ (which sum to unity), and the price γ of each dollar of insurance coverage. An individual with initial wealth w would then purchase q dollars' worth of coverage, where q was the solution to

$$\max_q \left[U(w - \gamma q + q) \cdot \mu(s_1) + U(w - \gamma q) \cdot \mu(s_2)\right]$$

Note that this formulation does not require that the individual and the insurance company agree on the likelihood of an earthquake.

As in the objective case, subjective expected utility can be derived from axiomatic foundations. Completeness and transitivity carry over in a straightforward way, and continuity with respect to mixture probabilities is replaced by continuity with respect to small changes in the events. The existence of additive personal probabilities is obtained by the following axiom:

Comparative likelihood: For all events A, B and outcomes $x^* \succ x$ and $y^* \succ y$, $[x^* \text{ on } A; x \text{ on } \sim A] \succcurlyeq [x^* \text{ on } B; x \text{ on } \sim B]$ implies $[y^* \text{ on } A; y \text{ on } \sim A] \succcurlyeq [y^* \text{ on } B; y \text{ on } \sim B]$.

This axiom states that if the individual 'reveals' event A to be at least as likely as event B by their preference for staking the preferred outcome x^* on A rather than on B, then this likelihood ranking will hold for all other pairs of ranked outcomes $y^* \succ y$. Finally, under subjective uncertainty the Independence Axiom is replaced by its subjective analogue, first proposed by Savage (1954):

Sure-Thing Principle: For all events E and acts $a(\cdot)$, $a^*(\cdot)$, $b(\cdot)$ and $c(\cdot)$, $[a^*(\cdot) \text{ on } E; b(\cdot) \text{ on } \sim E] \succcurlyeq [a(\cdot) \text{ on } E; b(\cdot) \text{ on } \sim E]$ implies $[a^*(\cdot) \text{ on } E; c(\cdot) \text{ on } \sim E] \succcurlyeq [a(\cdot) \text{ on } E; c(\cdot) \text{ on } \sim E]$.

where $[a(\cdot) \text{ on } E; b(\cdot) \text{ on } \sim E]$ denotes the act yielding outcome $a(s)$ for all $s \in E$ and $b(s)$ for all $s \in \sim E$.

Under subjective uncertainty, an individual's utility of outcomes might sometimes depend upon the particular state of nature. Given a health insurance decision with a state space of $\mathscr{S} = \{s_1, s_2\} = \{\text{cancer; no cancer}\}$, an individual may feel a greater need for \$100,000 in state s_1 than in state s_2. This can be modelled by means of a 'state-dependent' utility function $\{U(\cdot|\, s)|\, s \in \mathscr{S}\}$ and a'state-dependent expected utility' preference function $\hat{W}(x_1 \text{ if } s_1; \ldots; x_n \text{ if } s_n) = \sum_{i=1}^{n} U(x_i|\, s_i) \cdot \mu(s_i)$or $\hat{W}(a(\cdot)) = \int U(a(s)|\, s) d\mu(s)$. The analytics of state-dependent expected utility preferences have been extensively developed by Karni (1985).

History

The hypothesis that individuals might maximize the expectation of 'utility' rather than of monetary value was proposed independently by mathematicians Gabriel Cramer and Daniel Bernoulli, in each case as the solution to a problem posed by Daniel's cousin Nicholas Bernoulli (see Bernoulli 1738). This problem, now known as the 'St Petersburg Paradox', considers the gamble which offers a 1/2 chance of \$1, a 1/4 chance of \$2, a 1/8 chance of \$4, and so on. Although the expected value of this prospect is

$$\begin{aligned}(1/2) \cdot \$1 + (1/4) \cdot \$2 + (1/8) \cdot \$4 + \ldots\ldots \\ = \$0.50 + \$0.50 + \$0.50 + \ldots = \$\infty,\end{aligned}$$

common sense suggests that no one would be willing to forgo a very substantial certain payment in order to play it. Cramer and Bernoulli proposed that, instead of using expected value, individuals might evaluate this and other lotteries by means of their expected 'utility', with utility given by a function such as the natural logarithm or the square root of wealth, in which case the certainty equivalent of the St Petersburg gamble becomes a moderate (and plausible) amount.

Two hundred years later, the St Petersburg paradox was generalized by Karl Menger (1934), who

noted that, whenever the utility of wealth function was unbounded (as with the natural logarithm or square root functions), it would be possible to construct similar examples with infinite expected utility and hence infinite certainty equivalents (replace the payoffs \$1, \$2, \$4 ... in the above example by $x_1, x_2, x_3 \ldots$, where $U(x_i) = 2^i$ for each i). In light of this, von Neumann–Morgenstern utility functions are typically (though not universally) postulated to be bounded functions of wealth.

The earliest formal axiomatic treatment of the expected utility hypothesis was developed by Frank Ramsey (1926) as part of his theory of subjective probability, or individuals' 'degrees of belief' in the truth of alternative propositions. Starting from the premise that there exists an 'ethically neutral' proposition whose degree of belief is 1/2, and whose validity or invalidity is of no independent value, Ramsey proposed a set of axioms on how the individual would be willing to stake prizes on its truth or falsity, in a manner which allowed for the derivation of the 'utilities' of these prizes. He then used these utility values and betting preferences to determine the individual's degrees of belief in other propositions. Perhaps because it was intended as a contribution to the philosophy of belief rather than to the theory of risk bearing, Ramsey's analysis did not have the impact among economists that it deserved.

The first axiomatization of the expected utility model to receive widespread attention was that of John von Neumann and Oskar Morgenstern, presented in connection with their formulation of the theory of games (von Neumann and Morgenstern 1944, 1947, 1953). Although this development was recognized as a breakthrough, the mistaken belief that von Neumann and Morgenstern had somehow mathematically overthrown the Hicks–Allen 'ordinal revolution' led to some confusion until the difference between 'utility' in the von Neumann-Morgenstern and the ordinal (that is, non-stochastic) senses was illuminated by writers such as Ellsberg (1954) and Baumol (1958).

Another factor which delayed the acceptance of the theory was the lack of recognition of the role played by the Independence Axiom, which did not explicitly appear in the von Neumann–Morgenstern formulation. In fact, the initial reaction of researchers such as Baumol (1951) and Samuelson (1950) was that there was no reason why preferences over probability distributions must *necessarily* be linear in the probabilities. However, the independent discovery of the Independence Axiom by Marschak (1950), Samuelson (1952) and others, and Malinvaud's (1952) observation that it had been implicitly invoked by von Neumann and Morgenstern, led to an almost universal acceptance of the expected utility hypothesis as both a normative and positive theory of behaviour towards risk. This period also saw the development of the elegant axiomatization of Herstein and Milnor (1953) as well as Savage's (1954) joint axiomatization of utility and subjective probability, which formed the basis of the state-preference approach described above.

While the 1950s essentially saw the completion of foundational work on the expected utility model, subsequent decades saw the flowering of its analytic capabilities and its application to fields such as portfolio selection (Merton 1969), optimal savings (Levhari and Srinivasan 1969; Fleming and Sheu 1999), international trade (Batra 1975; Lusztig and James 2006), environmental economics (Wolfson et al. 1996), medical decision-making (Meltzer 2001) and even the measurement of inequality (Atkinson 1970). This movement was spearheaded by the development of the Arrow–Pratt characterization of risk aversion (see above) and the characterization, by Rothschild–Stiglitz (1970, 1971) and others, of the notion of 'increasing risk'. This latter work in turn led to the development of a general theory of 'stochastic dominance' (for example, Whitmore and Findlay 1978; Levy 1992), which has further expanded the analytical powers of the model.

Although the expected utility model received a small amount of experimental testing by economists in the early 1950s (for example, Mosteller and Nogee 1951; Allais 1953) and continued to be examined by psychologists, economists' interest in the empirical validity of the model waned from the mid-1950s through the mid-1970s, no doubt due to both the normative appeal of the Independence Axiom and model's analytical successes.

However, since the late 1970s there has been a revival of interest in the testing of the expected utility model; a growing body of evidence that individuals' preferences *systematically* depart from linearity in the probabilities; and the development, analysis and application of alternative models of choice under objective and subjective uncertainty. It is fair to say that today the debate over the descriptive (and even normative) validity of the expected utility hypothesis is more extensive than it has been in over half a century, and the outcome of this debate will have important implications for the direction of research in the economics of uncertainty.

Expenditure Tax

A. P. Thirlwall

The idea of an expenditure tax has a long ancestry, dating back at least to Hobbes, who argued that people should be taxed according to the resources of the community they absorb not according to what they contribute. The case was later taken up by J.S. Mill, Marshall, Pigou and Irving Fisher. In modern times, the advocacy of an expenditure tax is most associated with the Cambridge economist Nicholas Kaldor (1955). Recently it has been espoused by the Meade Committee (Meade 1978), and separately by two members of that Committee, Kay and King (1978).

There are efficiency and equity arguments for considering an expenditure tax as an alternative to income taxation. As far as efficiency is concerned, there is a commonly held view that because income tax involves the double taxation of saving, and therefore lowers the rate of return on saving below the rate of return on investment, this distorts the choice between consumption and saving, and represents a wasteful distortion. However, recent work, using optimal tax theory, has questioned this conclusion. The theory of the second best teaches that alternative tax systems cannot be evaluated according to the number of distortions: the magnitude of the distortions and their interaction also needs to be taken into account. Using optimal tax theory in an intertemporal context, Atkinson and Sandmo (1980) have shown that no firm conclusions can be reached on the relative efficiency of expenditure and income taxes from a welfare point of view: it all depends on the form of the social

welfare function, what other instruments governments can use to achieve a desired intertemporal allocation of consumption, and on crucial parameters of the model such as the interest elasticity of labour supply.

As far as equity is concerned, the case for an expenditure tax may be stronger. The principle of progressive income taxation rests on the concept of taxable capacity or ability to pay. The question is, does 'income' approximate to this concept? There are three main difficulties. First, income is only one measure of taxable capacity. Secondly, income itself is not an unambiguous concept. Thirdly, the actual definition of income for tax purposes can introduce inequities into the system by some receipts being treated as income and others not. Income is taken as a proxy for 'spending power', but there are other sources of spending power (e.g. wealth) and it is not easy to express them all in a single measure of taxable capacity. There are particular problems associated with irregular receipts and capital gains. It can be argued that many of the problems created by the non-comparability of different forms of income, wealth and capital gains would be resolved by taxing expenditure rather than income. The individual himself would declare his spending power when he spends. Since there is no objective definition of income that can provide a true measure of spending power, there can be no presumption that any income tax system would be superior from an equity point of view to an expenditure tax.

Kaldor was the first to argue in a comprehensive way that the measurement of income as a measure of taxable capacity is inevitably ambiguous and is likely to be a bad proxy for the measurement of spending power, so that the taxation of spending as such may be regarded at least as equitable as income tax, if not more so, with other positive advantages – particularly, an expenditure tax would be a more efficient instrument for controlling the economy, so that there is no necessary conflict between an egalitarian system of taxation, efficiency and growth. The Meade Committee, as well as mentioning the traditional arguments concerning the difficulty of defining income and measuring accruals, placed most emphasis on the elimination of capital market distortions, particularly those associated with various concessions in the existing income tax system which have differential and distorting effects on rates of return to saving outlets, and with having to correct nominal capital gains and losses for inflation. Such problems automatically disappear with an expenditure tax.

Kaldor also discussed at length the effect that a switch to an expenditure tax is likely to have on risk bearing, the supply of effort, saving and economic progress. It turns out that it is impossible to predict the net effects with any degree of certainty. As far as risk bearing is concerned it is impossible to say whether an expenditure tax is better or worse than an income tax yielding the same revenue, since on the one hand it is less discriminating against risk in so far as part of taxable income is saved, but on the other hand is more discriminating in so far as part of the capital gain is spent. Likewise, as far as the supply of effort is concerned, it is possible to reach different conclusions according to the assumptions made concerning the relative stability of income and consumption, and whether taxation is progressive or proportional. Kaldor did not pay much attention to the argument that an expenditure tax would avoid the double taxation of saving under income tax, and therefore avoid distortions and encourage saving, but it has other advantages relating to enterprise and economic progress. For example, without a capital gains tax, income tax puts a premium on speculation compared with an expenditure tax where both yield and capital gains are equally taxed if spent, or equally exempt if saved. An expenditure tax which discouraged speculation would enhance the supply of risk capital.

Several theoretical objections have been raised against the expenditure tax, but none is very convincing. The main difficulty concerns the practical implementation of the tax. In evidence to the 1929 Colwyn Committee on National Debt and Taxation, Keynes had earlier described the expenditure tax idea as theoretically sound but 'practically impossible'. This was the prevailing view (see also Pigou 1928) largely because of the difficulty of getting taxpayers to keep accurate records of personal expenditure and checking returns. It was Irving Fisher (1937) who first showed that this

would not be necessary since a person's expenditure is the difference between what he has available for spending and what he has left at the end of the accounting period. Thus in theory the only information required is the size of a person's bank balance at the beginning of the year plus income and other receipts, and from this is then deducted net investments, exempted expenditure and the size of the bank balance at the end of the year, and the difference is chargeable expenditure. The major problems concern the definition of chargeable expenditure, and evasion through the avoidance of the use of bank accounts.

In his original exposition of the expenditure tax, Kaldor perhaps overestimated the drawbacks of income tax and understated the difficulties of the expenditure tax. Conceptually the dividing line between what is consumption and what is saving may be said to be as arbitrary and fraught with difficulties, as in answering the question, when does income accrue? In defence, he admitted, however, that comparing the expenditure tax with a more *comprehensive* income tax, the balance between the two is much more finely poised: the conclusion which Prest (1979) also comes to in his review of the Meade Committee Report.

Experimental Economics

Vernon L. Smith

E

Abstract

Experimental methods have features in common across all the sciences. All tend to use the framework of falsification, but there is inherent ambiguity in knowing which of the many hypotheses necessary to construct a test are negated by observations contrary to predictions. This ambiguity tends to engender much discussion, contestability and the design of new experiments that attempt to resolve the open qsts. This social process is not part of the logic of scientific testing, but it explains what scientists do and how new results become established.

> But I believe that there is no philosophical highroad in science, with epistemological signposts. . .we are in a jungle and find our way out by trial and error, building our road *behind* us as we proceed. We do not *find* signposts at crossroads, but our scouts *erect them,* to help the rest.
> —Max Born, *Experiment and Theory in Physics* (1943)

> . . . they were criticized [those studying observational learning in a social context] for being unscientific and performing *uncontrolled* experiments. In science, there's nothing 'worse' than an experiment that's uncontrolled.
> —Temple Grandin, *Animals in Translation* (2005, bracketed comments added).

The subject matter of this article is rationality in science particularly as it applies to experimental methods. In this context 'rationality' is commonly used to refer to a particular conception that Hayek (1967, p 85) has called:

> *Constructivist Rationality,* which, applied to individuals, associations or organizations, involves the conscious deliberate use of reason to analyze and prescribe actions judged to be better than alternative feasible actions that might be chosen; applied to institutions it involves the deliberate design of rule systems to achieve desirable performance. The latter include 'optimal design' where the intention is to provide incentives for agents to choose better actions than would result from alternative arrangements.

Rationality in socioeconomic systems, including scientific communities, cannot be adequately understood by restricting one's perspective to this traditional Cartesian framework. In the discussion that follows I want to draw upon a second conception of rationality:

> *Ecological rationality* refers to emergent order in the form of practices, norms and rules governing action by individuals, groups and institutions that are part of our cultural and biological heritage, created by human interactions, but not by conscious human design.

I have argued (Smith 2003) that rationality in the economy depends on individuals whose behaviour is conditioned by cultural norms and emergent institutions that evolve from human experience, neither of which is ultimately derived from constructivist reason; although, clearly, constructivist ideas are important sources of variation for the gristmill of ecological selection. Parallel considerations apply to rationality in scientific method, the extension to be treated here.

Stated briefly, here is the argument that I will present: scientific methodology reveals a predominately constructivist theme largely guided by the following:

- falsification criteria for hypotheses derived from theories;
- experimental designs for testing hypotheses;
- statistical tests; and
- liturgies of reporting style that have become standard in scientific papers.

But all tests of theory are necessarily joint tests of hypotheses derived from theory and the set of auxiliary hypotheses necessary to implement, construct and execute the tests: this is the well-known Duhem–Quine (D–Q) problem. Thus, whatever might be the testing rhetoric of scientists, they do not reject hypotheses, and their antecedent theories, on the basis of falsifying outcomes. But this is not cause for despair, let alone retreat into a narrow postmodern sea of denial in which science borders on unintended fraud. D–Q is a property of inquiry, a truth, and as such a source for deepening our understanding of what *is,* not a clever *touché* for exposing the rhetorical pretensions of science. But the failure of all philosophy of science programs to articulate a rational constructivist methodology of science that serves to guide scientists, or explain what they do, as well as what they say about what they do, does not mean that science is devoid of rationality or that scientific communities fail to generate rational programmes of scientific inquiry. Thus, scientists engage in commentary, reply, rebuttal and vigorous discussions over whether the design is appropriate, the test adequate, whether the procedures and measurements might be flawed, and the conclusions and inpts correct. One must look to this conversation in the scientific community in asking whether and how science sorts out competing primary and auxiliary hypotheses after each new set of tests results are made available. If this conversation does not read like a theorem and its proof, and fails to reduce methodology to a consciously rigorous science of

inquiry, this is because we can never reduce the testing enterprise to a simple up or down test of an isolated non-trivial hypothesis; so be it.

If emergent method is rational in science it must be a form of ecological rationality; this means that it rightly and inevitably grows out of the norms, practices and conversation that characterize meaningful interactions in the scientific community. Listen not only to what scientists say about what they do, ignoring the arrogant tone in their little knowledge, but also examine what they do. The power behind the throne of accomplishment in the human career is our *sociality*, and the unintended mansions that are built by that sociality. The long view of that career is in sharp focus: our accumulation of knowledge and its expression in technology enabled us to survive the Pleistocene, people the Earth, penetrate the heavens, and explore the ultimate particles and forces of matter, energy and life. That achievement hardly deserves to be described as either irrational or non-rational.

What does it mean to test a theory or a hypothesis derived from a theory? Scientists everywhere say and believe that the unique feature of science is that theories, if they are to be acceptable, require rigorous support from facts based on replicable observations. But the deeper one examines this belief the more elusive becomes the task of giving it precise meaning and content in the context of conventional rational programs of inquiry.

Can We Derive Theory Directly from Observations?

Prominent scientists through history have believed that the answer to this question is 'yes', and that this was their modus operandi. Thus, quoting from two of the most influential scientists in history:

> I frame no hypotheses; for whatever is not deduced from the phenomena … have no place in experimental philosophy … (in which) … particular propositions are inferred from the phenomena … (Isaac Newton, *Principia,* 1687; quoted in Segrè 1984, p. 66)

> Nobody who has really gone into the matter will deny that in practice the world of phenomena uniquely determines the theoretical system, in spite of the fact that there is no theoretical bridge between phenomena and their theoretical principles. (Einstein 1934, pp. 22–3)

But these statements are without validity. 'One can today easily demonstrate that there can be no valid derivation of a law of nature from any finite number of facts' (Lakatos 1978, vol. 1, p. 2). Yet in economics critics of standard theory call for more empirical work on which to base development of *the* theory, and generally the idea persists that the essence of science is its rigorous observational foundation.

But how are the facts and theories of science to be connected so that each constructively informs and enriches the other?

Newton passionately believed not just that he was proffering lowly hypotheses, but that his laws were derived directly, by logic, from Kepler's discovery that the planets moved in ellipses. But Newton only showed that the path was an ellipse if there are $n = 2$ planets. Kepler was wrong in thinking that the planets followed elliptical paths, and to this day there is no solution for the $n(>2)$-body problem, and in fact the paths can be chaotic. Thus, when he published the *Principia,* Newton's model could not account for the motion of our nearest and most accurately observable neighbour, the moon, whose orbit is strongly influenced by both the sun and the earth.

Newton's sense of his scientific procedure is commonplace: one studies an empirical regularity (for example, the 'trade-off' between the rate of inflation and the unemployment rate), and proceeds to articulate a model from which a functional form can be derived that yields the regularity. In the above confusing quotation, Einstein seems to agree with Newton. At other times he appears to articulate the more qualified view that theories make predictions, which are then to be tested by observations (see his insightful comment below on Kaufmann's test of special relativity theory), while on other occasions his view is that reported facts are irrelevant compared to theories based on logically complete meta theoretical principles, coherent across a broad spectrum of

fundamentals (see Northrup 1969, pp. 387–408). Thus, upon receiving the telegraphed news that Eddington's 1919 eclipse experiments had 'confirmed' the general theory, Einstein showed it to a doctoral student who was jubilant, but he commented unmoved: 'I knew all the time that the theory was correct.' But what if it had been refuted? 'In that case I'd have to feel sorry for God, because the theory is correct' (quoted in Fölsing 1997, p. 439).

The main theme I want to develop in this and subsequent sections is captured by the following quotation from a lowbrow source, the mythical character Phaedrus in *Zen and the Art of Motorcycle Maintenance,* '. . . the number of rational hypotheses that can explain any given phenomena is infinite' (Pirsig 1981, p. 100).

Proposition 1 Particular hypotheses derived from any testable theory imply certain observational outcomes; the converse is false (Lakatos 1978, vol. 1, pp. 2, 16, *passim*).

Theories produce mathematical theorems. Each theorem is a mapping from postulated statements (assumptions) into derived or concluding statements (the theoretical results). Conventionally, the concluding statements are what the experimentalist uses to formulate specific hypotheses (models) that motivate the experimental design that is implemented. The conditions that underpin the hypotheses are the objects of control in an economics experiment, insofar as they can be controlled. Since not every assumption can always be reproduced in the experimental design the problem of the 'controlled experiment' is one of trying to minimize the risk that the results will fail to be interpretable as a test of the theory because one or more assumptions were violated. An uncontrolled assumption that is postulated to hold in interpreting test results is one of many possible contingent auxiliary hypotheses to be discussed below.

The wellspring of testable hypotheses in economics and game theory is to be found in the marginal conditions defining equilibrium points or strategy decision functions that constitute a theoretical equilibrium. In games against nature the subject-agent is assumed to choose among alternatives in the feasible set that which maximizes his or her outcome (reward, utility or payoff), subject to the technological and other constraints on choice. Strategic games are solved by the device of reducing them to games against nature, as in a non-cooperative (Cournot–Nash) equilibrium (pure or mixed) where each agent is assumed to maximize his or her own outcome, given (subject to the constraints of) the maximizing behaviour of all other agents. The equilibrium strategy when used by all but agent i reduces i's problem to an own maximizing choice of that strategy. Hence, in economics, all testable hypotheses come from the marginal conditions (or their discrete opportunity cost equivalent) for maximization that define equilibrium for an individual or across individuals interacting through an institution. These conditions are implied by the theory from which they are derived, but given experimental observations consistent with (that is, supporting) these conditions there is no way to reverse the steps used to derive the conditions, and deduce the theory from a set of observations on subject choice. Behavioural point observations conforming to an equilibrium theory cannot be used to deduce or infer either the equations defining the equilibrium or the logic and assumptions of the theory used to derive the equilibrium conditions.

Suppose, however, that the theory is used to derive non-cooperative best reply functions for each agent that maps one or more characteristics of each individual into that person's equilibrium decision. Suppose next that we perform many repetitions of an experiment varying some controllable characteristic of the individuals, such as their assigned values for an auctioned item, and obtain an observed response for each value of the characteristic. This repetition of course must be assumed always to support equilibrium outcomes. Finally, suppose we use this data to estimate response functions obtained from the original maximization theory. First order conditions defining an optimum can always be treated formally as differential equations in the original criterion function. Can we solve these equations and 'deduce' the original theory?

An example is discussed in Smith et al. (1991) from first-price auction theory. Briefly the idea is this. Each of N individuals in a repeated auction

game is assigned value $v_i(t)$ ($i = 1,\ldots, N;\quad t = 1,2,\ldots,T$) from a distribution, and on each trial, t, i bids $b_i(t)$. On each trial each i is assumed to choose a bid that maximizes expected utility.

$$\max_{0\le b_i\le v_i} (v_i - b_i)^{r_i} G_i(b_i) \tag{1}$$

where r_i ($0 < r_i \le 1$) is i's measure of constant relative risk aversion, and $G_i(b_i)$ is i's probability belief that a bid of b_i will win. This leads to the first order condition,

$$(v_i - b_i)G_i'(b_i) - r_i G_i(b_i) = 0. \tag{2}$$

If all i have identical common rational probability expectations

$$G_i(b_i) = G(b_i). \tag{3}$$

This leads to a closed form equilibrium bid function (see Cox et al. 1988).

$$\begin{aligned} b_i &= (N-1)v_i/(N-1+r_i), \quad b_i \leqq b \\ &= 1 - G(b)/G'(b), \quad \text{for all } i. \end{aligned} \tag{4}$$

The data from experimental auctions strongly support linear subject bid rules of the form

$$b_i = \alpha_i v_i, \tag{5}$$

obtained by linear regression of b_i on v_i using the T observations on (b_i, v_i), for given N, with $\alpha_i = (N - 1)v_i/(N - 1 + r_i)$. Can we reverse the above steps, then integrate (5) to get (1)? The answer is 'no'. Equation (2) can be derived from maximizing either (1) or the criterion

$$(v_i - b_i)G(b_i)^{1/r}, \tag{1'}$$

in which subjective probabilities, rather than profit, are 'discounted' in computing the expectation. That is, without all the assumptions used to get (4), we cannot uniquely conclude (1). In (1′) we have $G_i(b_i) = G(b_i)^{1/r_i}$ instead of (3), and this is not ruled out by the data.

In fact, instead of (1) or (1′) we could have maximized

$$(v_i - b_i)^{\beta_i} G(b_i)^{\beta_i/r_i}, \quad \text{with} \quad r_i \le \beta_i \le 1 \tag{1'}$$

giving an infinite mixture of subjective utility and subjective probability models of bidding.

There is a special case of the above model that is reversible: all bidders are risk neutral with, $r_i = 1$. While that model is often defended in the abstract, and is the workhorse assumption for deriving theorems under uncertainty, it fails all the lab and field empirical tests known to me. Risk neutrality trivializes decisions by requiring all humans to have identical preferences. It fails because people are inherently heterogeneous in making decisions under uncertainty, and this empirical diversity is captured by an appearance (or a mirage) in the data of non-neutral 'risk'. Equation (1′) above provides a hint of the manner in which individual diversity can appear in data inpts that confound measures of risk with other sources of heterogeneity.

Thus, in general, we cannot backward infer from empirical equilibrium conditions, even when we have a large number of experimental observations, to arrive at the original parameterized model within the general theory. *The purpose of theory is precisely one of imposing much more structure on the problem than can be inferred from the data.* This is because the assumptions used to deduce the theoretical model contain more information, such as (3), than the data – the theory is underdetermined.

Economics: Is It An Experimental Science?

All editions of Paul Samuelson's *Principles of Economics* refer to the inability of economists to perform experiments. This continued for a short time after William Nordhaus joined Samuelson as a coauthor. Thus, 'Economists . . . cannot perform the controlled experiments of chemists and biologists because they cannot easily control other important factors' (Samuelson and Nordhaus 1985, p. 8).

My favourite quotation, however, is supplied by one of the 20th century's foremost Marxian

economists, Joan Robinson. To wit, 'Economists cannot make use of controlled experiments to settle their differences' (Robinson 1979, p. 1319). Like Samuelson, she was not accurate – economists do indeed perform controlled experiments – but how often have they, or their counterparts in any science, used them to 'settle their differences?' Here she was expressing the popular image of science, which is indeed one in which 'objective' facts are the arbiters of truth that in turn 'settle' differences. The caricatured image is that of two scientists, who, disagreeing on a fundamental principle, go to the lab, do a 'crucial experiment', and learn which view is assuredly right. The hypothesis they are testing is not underdetermined by the test data. They do not argue about the result; their question is answered and they move on to a new topic that is not yet 'settled.'

Although these quotations provide telling commentaries on the state of the profession's knowledge of the development of experimental methods in economics since the 1950s, there is a deeper question of whether there are more than a very small number of non-experimentalists in economics that understand key features of our methodology. These are twofold: (*a*) employ a reward scheme to motivate individual behaviour in the laboratory within an economic environment defining gains from trade that are controlled by the experimenter – for example, the supply of and demand for an abstract item in an isolated market or an auction; and (*b*) use the observations to test predictive hypotheses derived from one or more models (formal or informal) of behaviour in these environments using the rules of a particular trading institution – for example, the equilibrium clearing price and corresponding exchange volume when subjects trade under some version of an oral or electronic double auction, posted pricing, sealed bidding, and so on. This differs from the way that economics is commonly researched, taught and practised, which implies that it is largely an a priori science in which economic problems come to be understood by thinking about them. This generates logically correct, internally consistent theories and models. The data of econometrics are then used for 'testing' between alternative model specifications within basic equilibrium theories that are not subject to challenge, or to estimate the supply and/or demand parameters assumed to generate data representing equilibrium outcomes by an unspecified process. (Leamer 1978, and others have challenged the interpretation of this standard econometric methodology as a scientific 'testing' programme as distinct from a programme for specification searches of data.) Theories are not so much subject to doubt as used to impose restrictions on the data that allow parameters to be estimated. *Its constructivism all the way down.*

I want to report two examples indicating how counter-intuitive it has been for prominent economists to see the function of laboratory experiments in economics. The first example is contained in a quotation from Hayek whose Nobel citation was for his theoretical conception of the price system as an information system for coordinating agents with dispersed information in a world where no single mind or control centre possesses, or can ever have knowledge of, this information. His critique and rejection of mainstream quantitative methods, 'scientism', in economics are well known (see, for example, Hayek 1942, 1945). But in his brilliant paper interpreting competition as a discovery process, rather than a model of equilibrium price determination, he argues:

> . . . wherever the use of competition can be rationally justified, it is on the ground that we do not know in advance the facts that determine the actions of competitors . . . competition is valuable only because, and so far as, its results are unpredictable and on the whole different from those which anyone has, or could have, deliberately aimed at. . . . The necessary consequence of the reason why we use competition is that, in those cases in which it is interesting, the validity of the theory can never be tested empirically. We can test it on conceptual models, and *we might conceivably test it in artificially created real situations, where the facts that competition is intended to discover are already known to the observer. But in such cases it is of no practical value, so that to carry out the experiment would hardly be worth the expense.* (F.A. Hayek 1978, p. 255; emphasis added)

Hayek describes with clarity an important use (unknown to him) that has been made of experiments – testing competitive theory 'in

artificially created real situations, where the facts which competition is intended to discover are already known to the observer' – then proceeds to completely fail to see how such an experiment could be used to test his own proposition that competition is a discovery procedure, under the condition that neither agents as a whole nor any one mind needs to know what each agent knows. Rather, his concern for dramatizing what is arguably the most important socio-economic idea of the 20th century seems to have caused him to interpret his suggested hypothetical experiment as 'of no practical value' since it would (if successful) merely reveal what the observer already knew!

I find it astounding that one of the most profound thinkers in the 20th century did not see the demonstration potential and testing power of the experiment he suggests for testing the proposition: with competition *no one in the market* need know in advance the actions of competitors, and that competition is valuable only because, and so far as, its results are unpredictable *by anyone in the market* and on the whole different from those which anyone *in the market* has, or could have, deliberately aimed at. Yet, unknown to me at the time, this is precisely what my first experiment conducted in January 1956, published later as 'Test 1', was all about (Smith 1962).

I assembled a considerable number of experiments for a paper 'Markets as Economizers of Information: Experimental Examination of the "Hayek Hypothesis"', presented at the 50th Jubilee Congress of the Australian and New Zealand Association for the Advancement of Science, in Adelaide, Australia, 12–16 May 1980. A version of this paper was reprinted in Smith (1991, pp. 221–35). Here is what I called the Hayek Hypothesis. Strict privacy together with the trading rules of a market institution (the oral double auction in this case) is sufficient to produce efficient competitive market outcomes. The alternative was called the Complete Knowledge Hypothesis: competitive outcomes require perfectly foreseen conditions of supply and demand, a statement attributable to many economists, including Paul Samuelson who refers to 'foreseen changes in supply and demand' (Samuelson 1966, p. 947 and *passim),* that can be traced back to W.S. Jevons in 1871. (Stigler 1957, provides a historical treatment of the concept of perfect competition.) In this empirical comparison the Hayek Hypothesis was strongly supported. This theme had been visited earlier (before I had become aware or at least fully appreciative of Hayek's 1945 contribution that equilibrium theory was a tautology) in Smith (1976), wherein eight experiments comparing private information with complete information showed that complete information was neither necessary nor sufficient for convergence to a competitive equilibrium: complete information interfered with, and slowed, convergence compared with private information. Shubik (1959, pp. 169–71) had noted earlier, and correctly, the confusion inherent in ad hoc claims that perfect knowledge is a requirement of pure (or sometimes perfect) competition. The experimental proposition that private information increases support for noncooperative, including competitive, outcomes applies not only to markets but also to the two-person extensive-form repeated games reported by McCabe et al. (1998). Hence it is clear that without knowledge of the other's payoff it is not possible for players to identify and consciously coordinate on a cooperative outcome. Thus, as we have learned, payoff information is essential to conscious coordination in two-person interactions, but irrelevant, if not pernicious, in impersonal market exchange. We note in passing that the large number of experiments demonstrating the Hayek Hypothesis in no sense implies that there may not be exceptions (Holt 1989). It's the other way around: this large set of experiments demonstrates clearly that there are exceptions almost everywhere to the Complete Knowledge Hypothesis, and these exceptions were not part of a prior design created to provide a counter example.

Holt and his coauthors have asked, 'Are there any conditions under which double-auction markets do not generate competitive outcomes? The only exception seems to be an experiment with a "market power" design reported by Holt et al. (1986) and replicated by Davis and Williams (1991)' (Davis and Holt 1993, p. 154; also see Holt 1989). The example reported in this exception was a market in which there was a constant

excess supply of only one unit – a market with inherently weak equilibrating properties. Actually, there were two earlier reported exceptions, neither of which required market power: (*a*) one in which information about private circumstances is known by all traders (the alternative to the Hayek Hypothesis as stated above), and (*b*) an example in which the excess supply in the market was only two units. Exception (*a*) was reported in Smith (1980, 1991, pp. 104–5) and (*b*) in Smith (1991, p. 67). The above cited exceptions, attributed to market power, would need to be supplemented with comparisons in which there was just one unit of excess demand, but no market power, in order to show whether or not each exception was driven by market power, and not the fact that there is only one unit of excess supply which may be enabling of above equilibrium prices even is there is no market power. Sometimes missing in the standard toolkit of experimentalists are routines for challenging our own interpretation of data where there are confounding elements in the explanations of the results. But in this respect our methodology keeps getting better.

My second example involves the same principle as the first. It derives from a personal conversation in the early 1980s with one of my favorite Nobel Laureates in economics, a prominent theorist. In response to a qst, I described the experimental public goods research I had been doing in the late 1970s and early 1980s comparing the efficacy of various public good mechanisms: Lindahl, Groves–Ledyard, the so- called auction election or mechanism. (See the public goods papers reprinted in Smith 1991.) He wondered how I had achieved control over the efficient allocation as the benchmark used in these comparisons. So I explained what I had naively thought was commonly understood by then: I give each subject a payoff function (table) in monetary payoffs defined jointly over variable units of a public (common outcome) good, and variable units of a private good. This allows the experimenter to solve for the social optimum and then use the experimental data to judge the comparative performance of alternative public good incentive mechanisms. Incredibly, he objected that if, as the experimenter, I have sufficient information to know what constitutes the socially optimal allocation then I did not need a mechanism! I can just impose the optimal allocation! Baldly stated, economics is about deducing best actions from theory, not finding ways to test its propositions. So there I was, essentially an anthropologist on Mars, unable to convey to one of the best and brightest in the traditional ways of thinking that the whole idea of laboratory experiments was to evaluate mechanisms in an environment where *the Pareto optimal outcome was known by the experimental designer but not by the agents* so that performance comparisons could be made; that in the field such knowledge was never possible, and we had no criteria, other than internal theoretical properties such as incentive compatibility to judge the efficacy of the mechanism. He didn't get it; psychologically this testing procedure is not comprehensible if somehow your thinking has accustomed you to believe that allocation mechanisms require agents to have complete information, but not mechanism designers who presumably slipped through by assuming their agents were fully informed. In fact, with that worldview what is there to test in mechanism theory?

The issue of whether economics is an experimental science is moot among experimental economists who are, and should be, too busy having fun doing their work to reflect on the methodological implications of what they do. But when we do speak of methodology, as in comprehensive introductions to the field, what do we say? Quotations from impeccable sources will serve to introduce the concepts to be developed next. The first emphasizes that an important category of experimental work '… includes experiments designed to test the predictions of well articulated formal theories and to observe unpredicted regularities, in a controlled environment that allows these observations to be unambiguously interpreted in relation to the theory' (Kagel and Roth 1995, p. 22). Experimental economists strongly believe, I think, that this is our most powerful scientific defence of experimental methods: we ground our experimental inquiry in the firm bedrock of

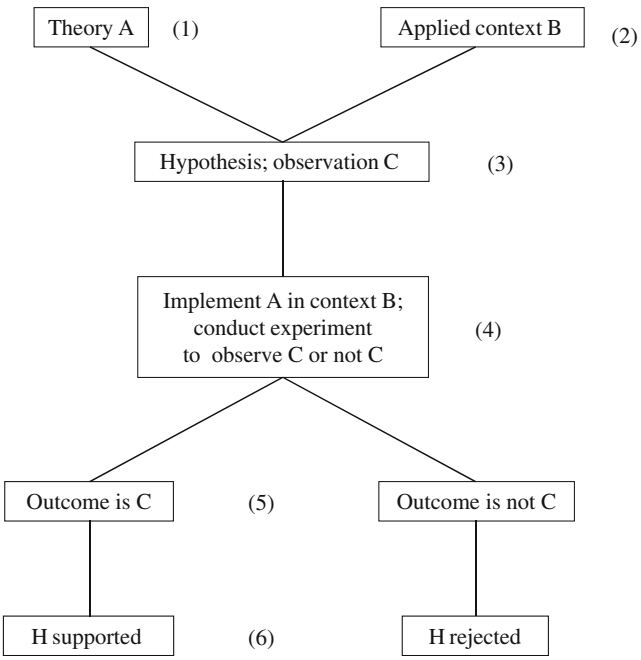
economic or game theory. A second crucial advantage, recognizing that field tests involve hazardous joint tests of multiple hypotheses, is the sentiment that 'Laboratory methods allow a dramatic reduction in the number of auxiliary hypotheses involved in examining a primary hypothesis' (Davis and Holt 1993, p. 16).

Hence the strongly held belief that, in the laboratory, we can test well- articulated theories, interpret the results unambiguously in terms of the theory, and do so with minimal, trivial or at least greatly reduced dependence on auxiliary hypothesis. This view and the idea that theories can be derived directly from observations are not unique to any science, but they are *illusions*. Fortunately, such illusions do not constitute a barrier to great scientific achievement because they appear to affect the rhetoric of science far more than its substance. Perhaps this is because the beliefs of scientists are important in reinforcing their commitment to discovery whether or not they are defensible. I cannot imagine that Newton would have been more accomplished if he had been methodologically more sophisticated.

What Is the Scientist's (qua Experimentalist) Image of What He Does?

The standard experimental paper within and without economics uses the following format in outline form: (1) state the theory; (2) implement it in a particular context (with 'suitable' motivation in economics); (3) summarize the implications in one or more testable hypotheses; (4) describe the experimental design; (5) present the data and results of the hypothesis tests; (6) conclude that the experiments either reject or fail to reject the theoretical hypotheses. This format is shown in Fig. 1. In the case in which we have two or more competing theories and corresponding hypotheses, the researcher offers a conclusion as to which one is supported by the data using some measure of statistical distance between the data and each of the predictive hypotheses, reporting which distance is statistically the shortest.

Suppes (1969; also see Mayo 1996, ch. 5) has observed that there exists a hierarchy of models behind the process in Fig. 1. The primary model or theory is contained in steps (1) and (2), which



Experimental Economics, Fig. 1 The scientist's image of scientific procedure

generate particular topical hypotheses that address primary qsts. Experimental models are contained in (3) and (4). These serve to link the primary theory with data. Finally, we have data models, steps (5) and (6), that link operations on raw data (not the raw data itself) to the testing of experimental hypotheses.

This process describes much of the rhetoric of science, and reflects the self-image of scientists, but it does not adequately articulate what scientists actually do. Furthermore, the rhetoric does not constitute a viable, defensible and coherent methodology. But what we actually do, I believe, is highly defensible and on the whole positively affects what we think we know from experiment. Implicitly, as experimentalists, we understand that every step, (1)–(6), in the above process is subject to judgments, learning from past experiments, our knowledge of protocols and technique, and to error. This is reflected in what we do as a professional community, if not in what we say about what we do in the standard scientific paper, or when we try to describe the science that we do.

As I have noted, the problem with the above image is known as the 'D–Q problem': experimental results always present a joint test of the theory (however well articulated, formally) that motivated the test, *and all the things you had to do to implement the test.* (For good discussions of the D–Q thesis and its relevance for experimental economics, see Soberg 2005, and Guala 2005, pp. 54–61 and *passim.* Soberg provides interesting theoretical results showing how the process of replication can be used, in the limit, to inductively eliminate clusters of alternative hypotheses and lend increasing weight to the conclusion that the theory itself is in doubt.) Thus, if theoretical hypothesis H is implemented with context specific auxiliary hypotheses required to make the test operational, A_1, A_2, . . ., A_n; then it is (H|A_1, A_2, . . ., A_n) that implies observation C. If you observe not-C, this can be because any of the antecedents (H; A_1, . . ., A_n) can represent what is falsified. Thus, the interpretation of observations in relation to a theoretical hypothesis is *inherently and inescapably ambiguous,* contrary to our accustomed rhetoric.

The reality of what we do, and indeed must do, is implied by the truth that 'No theory is or can be killed by an observation. Theories can always be rescued by auxiliary hypotheses' (Lakatos 1978, vol. 1, p. 34).

A D–Q Example from Physics

Here is a historical example from physics: in 1905 Kaufmann (cited in Fölsing 1997, p. 205), a very accomplished experimentalist (in 1902 he showed that the mass of an electron is increased by its velocity!), published a paper 'falsifying' Einstein's special theory of relativity the same year in which the latter was published (Einstein 1905). Subsequently, Einstein (1907) in a review paper reproduced Kaufmann's Figure 2, commenting that

> The little crosses above the [Kaufmann's] curve indicate the curve calculated according to the theory of relativity. In view of the difficulties involved in the experiment one would be inclined to consider the agreement as satisfactory. However, the deviations are systematic and considerably beyond the limits of error of Kaufmann's experiment. That the calculations of Mr. Kaufmann are error-free is shown by the fact that, using another method of calculation, Mr. Planck arrived at results that are in full agreement with those of Mr. Kaufmann. Only after a more diverse body of observations becomes available will it be possible to decide with confidence whether the systematic deviations are due to a not yet recognized source of errors or to the circumstance that the foundations of the theory of relativity do not correspond to the facts. (Einstein 1907, p. 283.

Kaufmann was testing the hypothesis that (H|A) implies C, where H was an implication of special relativity theory, A was the auxiliary hypothesis that his context-specific test and enabling experimental apparatus was without 'a not yet recognized source of errors', C was the curve indicated by the 'little crosses', and not-C was Kaufmann's empirical curve (Einstein 1907, Figure 2, p. 283).

Einstein's comment in effect says that either of the antecedents (H|A) represents what is falsified by Kaufmann's results. Others, such as Planck and Kaufmann himself, however, acknowledged that the observation might conceivably be in error

(Fölsing 1997, p. 205). Such acknowledgements are not unusual in the scientific community, which means that scientists informally recognize the D–Q problem as it arises in particular contexts, that it is part of the scientific conversation and that they seek solutions even if this modus operandi is not part of their rhetoric. Thus, in less than a year, Bucherer (see Fölsing 1997, p. 207) showed that there indeed had been a 'problem' with Kaufmann's experiments and proceeded to obtain new results supporting Einstein's theory.

There is an important lesson in this example if we develop it a little more fully. Suppose Bucherer's experiments *had not changed Kaufmann's results enough to change the conclusion* (There is never a shortage of claims that a given experimental result may be in doubt: see Mayo 1996, for the imaginative arguments proffered by the Newtonians in response to Eddington's eclipse observations). Then Einstein could still have argued that there may be 'a not yet recognized source of errors'. If so, the implication is that H is not falsifiable, for the same argument can be made after each new test in which the new results are outside the range of error for the apparatus! Recall that the deviations were alleged to be 'considerably beyond the limits of error of Kaufmann's experiment'. But here 'error' is used in the sense of internal variations arising from the apparatus and procedure, not in the sense that there is a problem with the apparatus or procedure itself. We can go still further in explicating the problem of testing H conditional on any A. The key is to note in this example the strong dependence of any test outcome on the *state of experimental knowledge:* Bucherer found a way to 'improve' Kaufmann's experimental technique so as to rescue Einstein's 'prediction'. But the predictive content of H (and therefore of the special theory) was inextricably bound up with A. Einstein's theory did not embrace any of the elements of Kaufmann's (or Bucherer's) *apparatus:* A is based on experimental knowledge of testing procedures and operations in the physics laboratory, and has nothing to do with the theory of relativity, a separate and distinct body of theoretically coherent knowledge.

A Proposition and An Economics Example

Here is the most common casual empiricist objection to economics experiments: the payoffs are too small. This objection is one of several principal issues in a target article by Hertwig and Ortmann (2001), with comments by 34 experimental psychologists and economists. This objection sometimes is packaged with an elaboration to the effect that economic or game theory is about situations that involve large stakes, and you 'can't' study these in the laboratory (Actually, of course, you can, but funding is not readily available).

Suppose, therefore that we have the following:

H (from theory): subjects will choose the equilibrium outcome (for example, Nash or subgame perfect).

A (auxiliary hypothesis): payoffs are adequate to motivate subjects.

Proposition 2 Suppose a specific rigorous test rejects (H|A), and someone (say, T), protests that what must be rejected is A not H. Let E replicate the original experiment with an n-fold increase in payoffs. There are only two outcomes and corresponding inpts, neither of which is comforting to the rhetorical image of science as conducting falsification tests of predictive hypotheses:

1. The test outcome is negative. Then T can imagine a still larger payoff multiple $N > n$, and still argue for rejecting A not H. But this implies that H *cannot be falsified*.
2. After repeated increases in payoffs, the test outcome is positive for some N ^ n*. Then H has *no predictive content.* E, with no guidelines from the theory, has searched for and discovered an empirical payoff multiple, n^*, that 'confirms' the theory, but n^* is an *extra theoretical property of considerations outside H and the theory* that was being tested. Finding this multiple is not something for T or E to crow about, but rather an event that should send T or E back to his desk. The theory is inadequately specified to embrace the observations from all the experiments.

Proposition 2 holds independent of any of the following considerations:

- how well articulated, rigorous or formal the theory is; game theory in no sense constitutes an exception;
- how effective the experimental design is in reducing the number of auxiliary hypotheses – it only takes one to create the problem; and
- the character or nature of the auxiliary hypothesis – *A* can be anything not contained in the theory.

In experimental economics, reward adequacy is just one of a standard litany of objections to experiments in general and to many experiments in particular. Here are three additional categories in this litany:

1. *Subject sophistication.* The standard claim is that undergraduates are not sophisticated enough. They are not out there participating in the 'real world'. In the 'real world' where the stakes are large, such as in the FCC spectrum rights auctions, bidders use game theorists as consultants (Banks et al. 2003) (For an investigation of the hypothesis that undergraduates are insufficiently sophisticated, see McCabe and Smith 2000, who report a comparison of undergraduate and graduate students, and these with economics faculty, in a two-person trust game. The first two groups were indistinguishable, and both earned more than the faculty because with greater frequency they risked defection in offering to cooperate, as against opting for the subgame perfect outcome).
2. *Subjects need an opportunity to learn*. This is a common response from both experimentalists and theorists when you report the results of single play games in which 'too many' people cooperate. The usual proposed 'fix' is to do repeat single protocols in which distinct pairs play on each trial, and apply a model of learning to play non-cooperatively (See McCabe et al. 1998, for a trust game with the option of punishing defection in which support for the cooperative outcome does not decrease in repeat single relative to single play across trials, and therefore subjects *do not* 'learn' to play non-cooperatively). But there are many unanswered qsts implicit in this auxiliary hypothesis: since repeat single protocols require large groups of subjects (20 subjects to produce a 10-trial sequence), have any of these games been run long enough to measure adequately the extent of learning? In single play two-person anonymous trust games data have been reported showing that group size matters; that is, it makes a difference whether you are running 12 subjects (6 pairs) or 24 subjects (12 pairs) simultaneously in a session (Burnham, McCabe and Smith 2000). Also, in the larger groups pairs were found to be less trusting than in the small groups – perhaps not too surprising. But in repeat single games, in which a game is repeated with distinct pairs of subjects on each repetition, larger groups are needed for longer trial sequences. Hence, learning and group size as auxiliary hypotheses loses independence, and we have knotty new problems of complex joint hypothesis testing. The techniques, procedures and protocol tests we fashion for solving such problems are the sources of our experimental knowledge. All testing depends on, and is limited by, the state of that experimental knowledge at any given time. Over time it expands incrementally in the design problem-solving context of particular new testing challenges. This is a community development enterprise that is largely outside individual conscious awareness, but an integral part of the sociality of scientific change.
3. *Instructions are adequate* (or decisions are robust with respect to instructions, and so on). What does it mean for instruction to be adequate? Clear? If so, clear about what? What does it mean to say that subjects understand the instructions? Usually this is interpreted to mean that they can perform the task, which is judged by how they answer qsts about what they are to do. In two-person interactions, instructions often matter so much that they must be considered a (powerful) treatment (Thus, Hertwig and Ortmann 2001, section 2, argue that scripts – instructions – are important for replication, and that 'ad-libbing'

should be avoided). Instructions can be important because they define context, and context matters. Ultimatum and dictator game experiments yield statistically and economically significant differences in results due to differing instructions and protocols (Hoffman et al. 1994; Hoffman et al. 1996).

Positive Economics: Judge Theories by Their Predictions Not Their Assumptions

There is a methodological perspective associated with Milton Friedman (1953), which fails to provide an adequate foundation for experimental (field or laboratory) science, but which influenced economists for decades and still has some currency. Friedman's proposition is that the truth value of a theory should be judged by its testable and tested predictions not by its assumptions. This proposition is deficient for at least three reasons:

1. If a theory fails a test, we should ask why, not always just move on to seek funding for a different new project; obviously, one or more of its assumptions may be wrong, and it behoves us to design experiments that will probe conjectures about which assumptions failed. Thus, if first price auction theory fails a test is it a consequence of the failure of one of the axioms of expected utility theory, for example, the compound lottery axiom? If a subgame perfect equilibrium prediction fails, does the theory fail because the subjects do not satisfy the assumption that the agents choose dominant strategies? Or did the subjects fail to use backward induction? Or was it none of the above because the theory was irrelevant to how some motivated agents solve such problems in a world of bilateral (or multilateral) reciprocity in social exchange? When a theory fails there is no more important question to ask than what it is about the theory that has failed.
2. Theories may have the if-and-only if property that one (or more) of their 'assumptions' can be derived as implication(s) from one (or more) of their 'results'. These cases if trivial lead to the reversible property of testing illustrated above for risk-neutral agents bidding in first price auctions with linear density functions on value.
3. If a theory passes one or more tests, this need not be because its assumptions are correct. A subject may choose the subgame perfect equilibrium because she believes she is paired with a person that is not trustworthy, and not because she always chooses dominant strategies, or assumes that others always so choose or that this is common knowledge. This is why you are not done when a theory is corroborated by a test. You have examined only one point in the parameter space of payoffs, subjects, tree structure, and so on. Your results may be a freak accident of nature due to a complex of suitabilities or in any case may have other explanations.

In View of Proposition 2, What Are Experimentalists and Theorists to Do?

Consider first the example in which we have a possible failure of A: rewards are adequate to motivate subjects. Experimentalists should do what comes naturally, namely, do new experiments that increase rewards and/or lower decision costs by simplifying experiment procedures. The literature is full of examples (for surveys and inpts see Smith and Walker 1993; Camerer and Hogarth 1999; Holt and Laury 2001; Harrison et al. 2005).

Theorists should ask whether the theory is extendable to include *A*, so that the effect of payoffs is explicitly modelled. It is something of a minor scandal when economists – whose models predict the optimal outcome independently of payoff levels, and however gently rounded the payoff in the neighbourhood of the optimum is – object to an experiment because the payoffs are inadequate. What is adequate? Why are payoff inadequacies a complaint rather than a spur to better and more relevant modelling of payoffs? A step toward modelling both H and A (as payoffs) is provided in Smith and Szidarovszky (2004). Economic intuition tells us that payoffs should matter. But if they do, it must mean that some cost, which is impeding equilibrium, is being overcome at the margin by higher payoffs.

The natural psychological assumption is that there are cognitive costs of getting the best outcome, and more reward enables higher cognitive cost to be incurred to increase net return.

Generally, both groups must be aware that for any H, any A and any experiment, one can say that if the outcome of the experiment rejects (H|A), then both should assume that either H or A may be false, which is an obvious corollary to Proposition 1. This was Einstein's position concerning the Kaufmann results, and was the correct position, whatever later tests might show. After every test, either the theory (leading to H) is in error or the circumstances of the test, A, is in error.

The experimentalist has much to do, but primarily more experiments, which is precisely what experimentalists do in response to the many conjectures about what is wrong with the experiment – re-examine the instructions, payoffs, subjects, anything and everything the experimentalist did to formulate the test.

The theorist should also ask, especially if further tests continue to reject (H|A), whether the auxiliary hypothesis can be incorporated into the theory.

If the outcome fails to reject (H|A), the experimentalist should escalate the severity of the test. At some point does H fail? This identifies the limits of the theory's validity, and gives the theorist clues for modifying the theory.

Experimental Knowledge Drives Our Methods

Philosophers have written eloquently and argued intently over the implications of D–Q and related issues for the interpretation of science. Popper tried to demarcate science from pseudoscience with the basic rule requiring the scientist to specify in advance the conditions under which he will give up his theory. This is a variation on the idea of a so-called 'crucial experiment', a concept which cannot withstand examination (Lakatos 1978, vol. 1, pp. 3–4, 146–8), as is evident from our Proposition 2.

The failure of all programmes attempting to articulate a defensible rational science of scientific method has bred postmodern negative reactions to science and scientists. These exercises and controversies make fascinating reading, and provide a window on the social context of science, but I believe they miss the essence of what is most important in the working lives of all practitioners. Popper was wrong in thinking he could demarcate science from pseudoscience by an exercise in logic, but that does not imply that the Popperian falsification rule failed as a milestone contribution to the scientific conversation; nor does it mean that 'anything goes' (Feyeraband 1975). Rather, what one can say is much less open ended: anything goes only in so far as what can be concluded about *constructive rationality in science.* But the scientific enterprise is also about *ecological rationality in science,* which is about discovery, about probes into Max Born's 'jungle', about thinking outside the box and, as I shall argue below, about the technology of observation in science that renders obsolete long-standing D–Q problems while introducing new ones for a time.

You do not have to know anything about D–Q and statements like Proposition 2 to appreciate that the results of an experiment nearly always suggest new qsts precisely because the interpretation of results in terms of the theory are commonly *ambiguous.* This ambiguity is reflected in the discussion whenever new results are presented at seminars and conferences. Without ambiguity there would be nothing to discuss. What is the response to this ambiguity? Invariably, if it is a matter of consequence, experimentalists design new experiments with the intention of confronting the issues in the controversy, and in the conflicting views that have arisen in interpreting the previous results. This leads to new experimental knowledge of how results are influenced, or not, by changes in procedures, context, instructions and control protocols. The new knowledge may include new techniques that have application to areas other than the initiating circumstance. This ecological process is driven by the D–Q problem, but practitioners need have no knowledge of the philosophy of science literature to take the right next steps, subject to error, in the laboratory.

This is because the theory or primary model that motivates the qsts tells you nothing definitive

or even very useful about precisely how to construct tests. Tests are based on extra theoretical intuition, conjectures, and experiential knowledge of procedures. The context, subjects, instructions, parameterization, and so on are determined outside the theory, and their evolution constitutes the experimental knowledge that defines our methodology. The forms taken by the totality of individual research testing programmes cannot be accurately described in terms of the rhetoric of falsification, no matter how much we speak of the need for theories to be falsifiable, stating in advance the conditions under which the theory will be rejected, the tests discriminating or 'crucial' and the results robust.

Whenever negative experimental results threaten perceived important new theoretical tests, the resulting controversies galvanize experimentalists into a search for different or better tests – tests that examine the robustness of the original results. Hence, Kaufmann's experimental apparatus was greatly improved by Bucherer, although there was no question about Kaufmann's skill and competence in laboratory technique. The point is that with escalated personal incentives, and a fresh perspective, scientists found improved techniques. This scenario is common as new challenges bring forth renewed effort. This process generates the constantly changing body of experimental and observational knowledge whose insights in solving one problem often carry over to applications in many others.

Just as often experimental knowledge is generated from curiosity about the properties of phenomena that we observe long before a body of theory exists that deals specifically with the phenomenon at issue. An example in experimental economics is the continuous double auction trading mechanism (Smith 1962, 2003).

An example from physics is Brownian motion, discovered by the botanist Robert Brown in 1827, who first observed the unpredictable motion of small particles suspended in a fluid. This motion is what keeps them from sinking under gravity. This was 78 years before Einstein's famous paper (one of three) in 1905 developed the molecular kinetic theory that was able to account for it, although he did not know that the applicable observations of Brownian motion were already long familiar (see Mayo 1996, ch. 7, for references and details). The long 'inquiry into the cause of Brownian motion has been a story of hundreds of experiments . . . [testing hypotheses attributing the motion]. . .either to the nature of the particle studied or to the various factors external to the liquid medium . . . '(Mayo 1996, pp. 217–18). The essential point is 'that these early experiments on the possible cause of Brownian motion were not testing any full-fledged theories. Indeed it was not yet known whether Brownian motion would turn out to be a problem in chemistry, biology, physics, or something else. Nevertheless, a lot of information was turned up and put to good use by those later researchers who studied their Brownian motion experimental kits' (Mayo 1996, p. 240). The problem was finally solved by drawing on the extensive bag of experimental tricks, tools and past mistakes that constitute 'a log of the extant experimental knowledge of the phenomena in qst' (1996, p. 240).

Again, 'the infinitely many alternatives really fall into a few categories. Experimental methods (for answering new qsts) coupled with experimental knowledge (for using techniques and information already learned) enable local qsts to be split off and answered' (Mayo 1996, p. 242).

The bottom line is that good-enough solutions emerge to the baffling infinity of possibilities, as new measuring systems emerge, experimental toolkits are updated, and understanding is sharpened. This bottom line also goes far towards writing the history of experimental economics and its many detailed encounters with data, and the inevitable ambiguity of subsequent inpt. And in most cases the jury remains in session on whether we are dealing with a problem in psychology (perception), economics (opportunity cost and strategy), social psychology (equality, equity or reciprocity), neuroscience (functional imaging and brain modeling) or all of the above. So be it.

The Machine Builders

Mayo's (1996) discussion and examples of experimental knowledge leave unexamined the

question of how technology affects the experimentalist's toolkit. The heroes of science are neither the theorists nor the experimentalists but the unsung tinkers, mechanics, inventors and engineers who create the new generation of machines that make obsolete yesterday's observations and heated arguments over whether it is T or A that has been falsified. Scientists, of course, are sometimes a part of this creative destruction, but what is remembered in academic recognition is the new scientific knowledge they created, not the instruments they invented that made possible the new knowledge. Michael Faraday, 'one of the greatest physicists of all time' (Segrè 1984, p. 134), had no formal scientific education. He was a bookbinder, who had the habit of reading the books that he bound. He was preeminently a tinker for whom 'some pieces of wood, some wire and some pieces of iron seemed to suffice him for making the greatest discoveries' (quoted from a letter by Helmholz in Segrè 1984, p. 140). Yet he revolutionized how physicists thought about electromagnetic phenomena, invented the concept of lines of force (fields), and inspired Maxwell's theoretical contributions. 'He writes many times that he must experience new phenomena by repeating the experiments, and that reading is totally insufficient for him' (Segrè 1984, p. 141). This is what I mean, herein, when I use the term 'experimental knowledge'. It is 'can do' knowledge acquired by trial, error and discovery. And it is what Mayo (1996) is talking about. It is also why doing experiments changed the way I thought about economics.

Technology and Science

With the first moon landing, theories of the origin and composition of our lunar satellite, contingent on the state of existing indirect evidence, were upstaged by direct observation; the first Saturn probe sent theorists back to their desks and computers to re-evaluate her mysterious rings, whose layered richness had not been anticipated. Similar experiences have followed the results of ice core sampling in Greenland, and instrumentation for mapping the genome of any species. Galileo's primitive telescope opened a startling window on the solar system, as do Roger Angel's multiple mirror light-gathering machines (created under the Arizona football stadium) that open the mind to a view of the structure of the universe. (For a brief summary of the impact of past, current, and likely future effects of rapid change in optical and infrared (terrestrial and space) telescopes on astronomy see Angel 2001.) The technique of tree ring dating, invented by an Arizona astronomer, has revolutionized the interpretation of archeological data from the last 5,000 years.

Yesterday's reductionisms, shunned by mainstream 'practical' scientists, create the demand for new deeper observations, and hence for the machines that can deliver answers to entirely new qsts. Each new machine – microscope, telescope, Teletype, computer, the Internet, fMRI imaging – changes the way teams of users think about their science. The host of auxiliary hypotheses needed to give meaning to theory in the context of remote and indirect observations (inferring the structure of Saturn's ring from earth-based telescopes) are suddenly made irrelevant by deep and more direct observations of the underlying phenomena (fly by computer-enhanced photos). It's the machines that drive the new theory, hypotheses, and testing programmes that take you from atoms, to protons, to quarks. Yet with each new advance comes a blizzard of auxiliary hypotheses, all handcuffed to new theory, giving expression to new controversies seeking to rescue T and reject A, or to accept A and reject T.

Experimental Economics and Computer/Communication Technology

In 1976 when Arlington Williams (1980) created the first electronic double-auction software program for market experiments, all of us thought we were simply making it easier to run experiments, collect more accurate data, observe longer time series, facilitate data analysis, and so on. What were computerized were the procedures, recording and accounting that heretofore had been done manually. No one was anticipating how this tool might impact on and change the way we thought

about the nature of doing experiments. But with each new electronic experiment we were 'learning' (affected by, but without conscious awareness of) the fact that traders could be matched at essentially zero cost, that the set of feasible rules that could be considered was no longer restricted by costly forms of implementation and monitoring, that vastly larger message spaces could be accommodated, and that optimization algorithms could now be applied to the messages to define new electronic market forms for trading energy, air emission permits, water and other network industries. In short, the transaction cost of running experimental markets became minuscule in comparison with the pre-electronic days, and this opened up new directions that previously had been unthinkable.

This quickly led to the concept of smart computer-assisted markets, which appeared in the early 1980s (Rassenti 1981; Rassenti et al. 1982), extended conceptually to electric power and gas pipelines in the late 1980s (Rassenti and Smith 1986; McCabe et al. 1989), with practical applications to electric power networks and the trading of emission permits across time and regions in the 1990s (Rassenti et al. 2002). These developments continue as major new efforts in which the laboratory is used as a test bed for measuring, modifying, and further testing the performance characteristics of new institutional forms.

What is called e-commerce has spawned a rush to reproduce on the Internet the auction, retailing and other trading systems people know about from past experience. But the new experience of being able to match traders at practically zero cost is sure to change how people think about trade and commerce, and ultimately this will change the very nature of trading institutions. In the short run, of course, efforts to protect existing institutions will spawn efforts to shield them from entry by deliberately introducing cost barriers, but in the long run these efforts will be increasingly uneconomical.

Neuroscience carries the vision of changing the experimental study of individual, two-person interactive and market decision making. The neural correlates of decision making, how it is affected by rewards, cognitive constraints, working memory, institutions, repeat experience and a host of factors that in the past we could neither control or observe can in the future be expected to become an integral part of the way we think about and model decision making. Models of decision, now driven by game and utility theory, and based on trivial, patently false, models of mind, must take account of new models of cognitive, calculation and memory properties of mental function that are accessible to more direct observational inpt. Game-theoretic models assume consciously calculating, rational mental processes, but models of mind include non-self-aware processes just as accessible to neural brain imaging as the conscious. For the first time we may be able to give some observational content to the vague and slippery idea of 'bounded rationality' (see Camerer et al. 2005).

Conclusion

In principle the D–Q problem is a barrier to any defensible notion of a rational science that selects theories by a logical process of confrontation with scientific evidence. This is cause for joy not despair. Think how dull a life of science would be if, once we were trained, all we had to do was to turn on the threshing machine of science, feed it the facts, send its output to the printer, and run it through the formulas for writing a scientific paper.

As I see it, there is no rationally constructed science of scientific method. The attempt to do it has led to important insights and understanding, and has been a valuable exercise. But all construction must ultimately pass ecological or 'fitness' tests based on the totality of our experience. Control is of course important; it is why we do laboratory and field experiments. But control is always limited in scope, and above all the rhetoric of control should not restrict the examination and reexamination of our own assumptions, both in the theory and in its testing, or limit our capacity to think outside the professional box. We do this in the reality underneath our rhetoric because we cannot help it, so much is it part of our deep human sociality and the workings of our social brains.

Experimental Economics, History of

Francesco Guala

Abstract

Contemporary experimental economics was born in the 1950s from the combination of the experimental method used in psychology and new developments in economic theory. Early experimental studies of bargaining behaviour, social dilemmas, individual decision making and market institutions were followed by a long period of underground growth, until the booming of the field in the 1980s and 1990s.

Experimental economics has experienced one of the most stunning methodological revolutions in the history of science. In just a few decades, economics has been transformed from a discipline where the experimental method was considered impractical, ineffective and largely irrelevant to

one where some of the most exciting advancements are driven by laboratory data.

Like many other new developments in the social sciences during the second half of the 20th century, experimental economics is largely a by-product of the combination of massive investments in science, a fertile intellectual culture and socio-political conditions in the 1940s and 1950s in the United States. Although it is possible in principle to identify earlier experimental or proto-experimental work being done in economics and psychology (see Roth 1995), there is hardly any direct intellectual, personal or institutional continuity between these isolated episodes and today's fully institutionalized experimental programme.

A proper history of experimental economics is yet to be written, and one challenge faced by historians of the discipline is its strikingly interdisciplinary character. The rise of experimental economics takes the form of several, partly independent and partly intertwined threads that can be brought under a single coherent narrative only with difficulty. It is partly for this reason that most of the existing historical literature consists of personal recollections or reconstructions of individual trajectories rather than of a collective enterprise. It is possible, however, to identify some key moments and achievements that have helped to establish experimentation as a legitimate method of investigation in economics.

Historical Background and Early Years

The traditional view of economics as a primarily non-experimental science was outlined in the methodological writings of 19th-century economists. Mill (1836, p. 124), for example, identifies several practical obstacles to the use of the experimental method, in particular the impossibility of controlling key economic variables and of keeping background conditions fixed so that the effect of manipulating each cause in isolation can be checked. This was Mill's main justification for adopting the so-called 'a priori deductive' method, a mix of introspection and theoretical reasoning, to determine what an idealized *homo oeconomicus* would do in given circumstances. Despite various changes in economists' methodological rhetoric and practice, it took a century and a half for philosophical scepticism towards experimentation to fade away.

Like many methodological revolutions in science, the experimental turn in economics was primarily made possible not by a change in philosophical perspective but by a number of innovations at the level of scientific practice and theoretical commitment. At a very general level, in the middle of the 20th century economics was in the process of becoming a 'tool-based' science (Morgan 2003): from the old, discursive 'moral science' of political economy, it was changing into a discipline where models, statistics and mathematics played the role both of instruments and, crucially, of *objects* of investigation. During this conceptual revolution economists came to accept that the path towards the understanding of a real-world economy might have to go through the detailed analysis of several tools that had apparently only a vague resemblance to the final target of investigation. Theoretical models and computer simulations entered the economists' toolkit first, with laboratory experiments following shortly after.

The birth of experimental economics owes much to the publication of von Neumann and Morgenstern's *Theory of Games and Economic Behavior* (1944) and to the subsequent developments of game and decision theory. Although game theory is often seen primarily as a contribution to the theoretical corpus of economics, this was not how it was perceived at the time. Von Neumann and Morgenstern's work initially found fertile ground in a community of scientists devoted to the simultaneous development of a great variety of approaches and research methods and interested in their application to solve scientific, policy, and management problems across the disciplinary boundaries – from conflict resolution in international relations to group psychology, cybernetics, and the organization of the firm, to name just a few.

'Gaming' – playing game-theoretic problems for real – was common practice in the mathematical community at Princeton in the 1940s and

1950s, and quickly spread elsewhere as game theory increased in popularity. This practice did not involve sophisticated experimental design, but was conceived mainly as a useful way of illustrating game theoretic puzzles, as well as a check on abstract speculation and a guide to the theoretician's intuitions. Traces of this attitude can be found in the writings of some pioneers in game theory in the 1950s, who explicitly advocated a combination of formal theorizing and empirical evidence of various kinds, and engaged in (mostly casual) forms of experimenting to back up their theoretical claims (see, for example, Schelling 1960; Shubik 1960).

The first event devoted specifically to 'The Design of Experiments in Decision Processes' was a 1952 two-month seminar sponsored by the Ford Foundation, organized in Santa Monica by a group of researchers at the University of Michigan. The seminar's location was intended to facilitate the participation of members of the RAND Corporation, a think tank sponsored by the US Air Force, where among others Merrill Flood was conducting game-theoretic experiments (including famously the first Prisoner's Dilemma experiments). It is difficult to assess at all precisely the role of the Santa Monica seminar in the birth of experimental economics because, apart from an important minority, most of the published papers (in Thrall et al. 1954) are theoretical rather than experimental in character. Several later protagonists, however, first became familiar with the idea of experiments in economics through the Santa Monica seminar, which therefore functioned as a catalyst in various indirect ways (see Smith 1992).

The most extensive experimental projects of the 1950s were pursued at Penn State, Michigan, and Stanford. In collaboration with Lawrence Fouraker, the psychologist Sidney Siegel conducted a systematic investigation of bargaining behaviour at Pennsylvania State University, trying to combine what he took to be the most advanced aspects of economics (the theory) and psychology (the experimental method). The project came to an abrupt end with Siegel's death in 1961, but the resulting book (Siegel and Fouraker 1960) won the American Academy of Arts and Sciences best monograph prize. Siegel and Fouraker's experiments focused on several aspects of bargaining behaviour, but are particularly significant for the systematic study of variations in the monetary payoffs and in the information made available to the subjects. Interestingly, this research project was rather disconnected from current developments in axiomatic bargaining theory, focusing instead on testing various hypotheses from the psychological literature. 'Level of aspiration theory' emerged eventually as the best predictor of bargaining behaviour.

From the point of view of experimental design, Siegel is often credited with being the first experimenter to highlight the importance of using real incentives to motivate subjects but, with hindsight, his experiments with Fouraker are also remarkable for the implementation of strict between-subjects anonymity. The latter practice would become very common in later experimental economics, usually as an attempt to implement economic theory's standard atomistic assumptions (especially the ban on other-regarding preferences). Contrary to the standard economic theory, Fouraker and Siegel recognized that interpersonal reactions do matter, but left a systematic investigation of their effects for later research.

More or less simultaneously, Ward Edwards at Michigan pioneered the experimental study of expected utility theory, as axiomatized in the second edition of von Neumann and Morgenstern's *Theory of Games* (1947). Amos Tversky, a student of Edwards and Coombs, would play a major role in the institutionalization of behavioural economics two decades later, as we shall see. In the mid-1950s an interdisciplinary group was also at work on the new theory of individual decision making, under the heading of the Stanford Value Project. Donald Davidson and Pat Suppes (both to become famous later for their contributions to philosophy) published with Siegel one of the first monographs of experimental decision theory (Davidson et al. 1957). At the centre of their research were measurement issues, in particular the implementation of learning theory and Frank Ramsey's method for measuring utilities and subjective probabilities.

Another major centre of interdisciplinary research in those years was the Carnegie group working on the psychology of organizations. Herbert Simon – working at Carnegie and the RAND Corporation, himself a participant in the Santa Monica seminar – is usually credited with being a pivotal player in this connection, although his influence on experimental economics is mostly indirect. The Carnegie group made use of a variety of methodologies, among which experimental 'role playing', 'business games', and simulations were central. In their larger projects, like the Carnegie Tech Management Game, human decision makers took managerial decisions in an environment simulated by a computer. Although primarily devised for pedagogic and illustrative purposes, such games were also used to shed light on the 'boundedly rational' processes of decision making that guide behaviour in big organizations. There is little continuity, however, between this body of work and contemporary experimental economics, with Simon playing a role more as a source of moral support and intellectual inspiration than as a direct contributor to experimental research.

The most famous experimental discovery of this period is due to a scholar who was to have little to do with later developments in experimental economics. Maurice Allais had been developing in France his own version of utility theory as a cardinal measurable quantity well before the publication of the *Theory of Games.* At a conference he organized in Paris in 1952, during a lunch break Allais presented Leonard Savage with a 'questionnaire' that was to become famous as the 'Allais paradox' experiment. When Savage gave answers that were inconsistent with the expected utility model he himself supported, Allais was encouraged to extend his questionnaire and to circulate it more widely.

The results were partially published in French in *Econometrica* (Allais 1953) but received little attention in the short term. The main immediate result of the Allais experiment was Savage's switch to a purely normative defence of expected utility (Jallais and Pradier 2005). Milton Friedman at the time was developing his methodology of positive economics which accorded no importance to the accuracy of the models of individual decision used to predict aggregate phenomena; and Allais's chauvinistic polemic against the 'American School' probably did little to attract sympathy. For about two decades Allais did not pursue research in this area any further.

The only large-scale experimental research project in Europe during this period was led by Reinhard Selten in Frankfurt, under the auspices of Heinz Sauermann. Like other early game theorists, Selten was convinced that the theory could contribute to the solution of important social science problems only if used in conjunction with empirical evidence. Indeed, even his most celebrated theoretical achievement (the concept of subgame perfection) was conceived in the context of a larger experimental project (see Selten 1995).

The last piece of the puzzle of experimental economics in the 1950s is at the same time the most important and the most idiosyncratic. Vernon Smith had been experimenting at Purdue since 1956, focusing on the properties of different market institutions and their effects on the convergence towards equilibrium (see Smith 1981). Smith had an engineering background and, unlike most experimenters at the time, did not approach experiments from a game-theoretic perspective. In the 1940s and 1950s Edward Chamberlin at Harvard had been performing little classroom experiments for illustrative purposes, to show his graduate students the falsity of the competitive theory of markets. Although the results of such experiments had been published in the *Journal of Political Economy* (1948), nobody at the time, including Chamberlin, attributed particular scientific value to them. Smith was the exception: a few years after leaving graduate school he came to question the design used by Chamberlin and to test the robustness of the 'no convergence' results to variations in the exchange institution and repetition of the task.

Overcoming several obstacles, Smith managed to publish his counter-experiments to Chamberlin (Smith 1962). For many years Smith led the only experimental project carried on fully within the boundaries of the economics discipline. In the early 1960s his work received funding from the National Science Foundation, but, apart from a brief attempt to collaborate with the Carnegie

group (see Lee 2004), his work in this phase was mostly carried out in isolation. One important exception is Smith's brief but important encounter with Sidney Siegel at Stanford in 1961. Smith perceived Siegel as much more advanced in methodological matters, and took from him several insights in experimental design that were to become the hallmark of economic experimentation (Smith 1981, 1992).

From the Underground to the Big Bang

Like other innovations of the previous two decades, experimental economics went through a period of slow, quiet growth in the 1960s. Some early contributors, like Allais, disappeared from the scene; others, like Smith, quit experimenting for some time (1967–74) and generally struggled to find an audience. Some areas, like social dilemmas and bargaining experiments, were booming in psychology but had little impact on the economics literature (see Leonard 1994). In the 1970s, however, the landscape of experimental economics changed considerably, partly thanks to the formation of a few key partnerships. During 1968–9 Amos Tversky began collaborating with Daniel Kahneman at the Hebrew University, initially on judgement and then on decision making. In Europe, by 1972, Selten had moved to Bielefeld and started a collaboration with Werner Güth, later author of the first experiments on the ultimatum game. Allais in the meantime returned to expected utility in 1974, and was persuaded to publish a full report in English of his 1952 results (in Allais and Hagen 1979). Allais's legacy would also begin to bear some fruits on the theoretical front. The late 1970s and early 1980s were characterized by a proliferation of alternative models to expected utility, mostly inspired by the experimental evidence that had been accumulated up until then.

After the happy anarchy of the earlier period, the 1970s were marked by the beginning of some controversies and the partial separation of the experimental community into sub-disciplines. In 1974 an article by Tversky and Kahneman in *Science* was widely read as a challenge to the view that human beings were rational agents, and, although it made experiments on judgement and decision making enter the intellectual debate at large, it also fed some deep cross-disciplinary misconceptions. A few years later Lichtenstein and Slovic's seminal experiments on preference reversals were introduced into the economics literature by Grether and Plott (1979), kicking off a series of theoretical and experimental papers that would fill the pages of the *American Economic Review* for years.

Charles Plott had been in close contact with Vernon Smith since the early 1960s, and started to run experiments a decade later, after his move to Caltech. Their collaboration led not only to important experimental projects but also to the creation of the Caltech laboratory and the training of the second and third generations of experimental economists. An important outcome of this period was also the attempt to systematize the methodology of experimental economics around a set of rules or 'precepts' of experimental design (Smith 1976, 1982). Smith in these papers highlighted the importance of monetary incentives to control subjects' preferences, a practice that he had borrowed from Siegel – a psychologist – but that ironically was to become the main distinguishing feature of the 'economic' way of experimenting, as opposed to the more liberal 'psychological' way. With hindsight these methodological papers are also striking for their effective use of the language and conceptual framework of mechanism design theory. In this sense they reflected Smith's (and Plott's) attitude towards the use of experiments to tackle real-world problems of institutional design and policymaking (see Guala 2005).

With the slow exhaustion of general equilibrium theory, the turmoil in macroeconomics, and an increasing disillusionment about econometrics, the 1970s created the conditions for the seeds of the 1940s and 1950s to finally blossom. Experimental economists were in a position to take advantage of this situation. By the early 1980s most of the 'paradigmatic' experiments that would inform subsequent research had already been published (Smith and Plott's experiments on auctions and markets, Lichtenstein and Slovic (1971) on preference reversals, Plott and others on public goods (Isaac et al. 1985), Güth on the

ultimatum game (Güth et al. 1982), Alvin Roth and others on bargaining (Roth and Malouf 1979)). Consolidation meant also differentiation. A persistent low-intensity conflict at the methodological and theoretical level led to the creation of so-called 'behavioural economics'. Whereas experimental economics refers primarily to a method of investigation, the work of behavioural economists is unified by a substantial project of revision of economic theory (especially the replacement of *homo oeconomicus* with a more realistic psychological model), with experimentation constituting a major but by no means exclusive source of evidence.

The history of experimental economics in the 1980s and 1990s is the story of a booming research programme, increasingly influential within the discipline and the social sciences at large, expanding in new directions – neuroscience, for example – and attracting some of the most talented graduate students. Together with game theorists, experimenters have also been increasingly involved in policymaking, notably by contributing to the design of new market institutions for the allocation of sensitive goods – from telecommunication licences to space stations, airport slots, and physicians and surgeons (see Roth 2002). In 2002 the Nobel Memorial Prize in economics awarded to Vernon Smith and Daniel Kahneman provided official acknowledgement of this remarkable revolution.

Experimental Labour Economics

Armin Falk and Simon Gächter

Abstract

Experimental labour economics uses experimental techniques to improve our understanding of labour economics issues. We start by putting experimental data into perspective with the data-sets typically used by empirical labour economists. We then discuss several examples of how experiments can inform labour economics.

Keywords

Double auction; Efficiency wages; Employment relation; Experimental labour economics; Gift exchange; Implicit incentives; Incomplete contracts; Involuntary unemployment; Laboratory experiments; Labour economics; Labour market institutions; Minimum wages; Moral hazard; Opportunistic behaviour; Performance incentives; Piece rates; Repeated games; Reservation wage; Tournaments; Wage rigidity

Scientific progress relies on testing theories. In labour economics different data sources are available for performing such tests. An important distinction is between circumstantial data and experimental or questionnaire data. Circumstantial data is the by-product of uncontrolled, naturally occurring economic activity. In contrast, experimental data is created explicitly for scientific purposes under controlled conditions. In labour economics, the data most commonly and traditionally used is circumstantial data such as unemployment rates or data on wages, education, or income, complemented by survey data. Labour economists have only recently started to use laboratory experiments.

Laboratory experiments have several important advantages in comparison with data sets typically used in labour economics. A key advantage is the unparalleled opportunity to control crucial aspects of the economic environment. This includes control over information conditions, technology, market structure, and trends in economic fundamentals. Control over the decision environment makes it possible to identify the theoretical equilibrium in an experimental labour market, which is basically impossible with field data. Knowing the equilibrium allows the study of convergence properties, stability and efficiency. Experiments are particularly useful for investigating the economic consequences of important labour market institutions, such as minimum wages or employment protection legislations. The reason is that experiments allow the exogenous changes of institutions, holding everything else constant. In the field, by contrast, institutions are always adopted endogenously. Econometric strategies such as instrumenting for policy changes with political variables can help ameliorate this problem, but do not achieve the unequivocal exogenous variation provided by a laboratory experiment. Laboratory experiments also make it

possible to observe behaviour at the level of individual economic agents. This is important given that theoretical predictions typically involve such micro behaviours. For example, it is possible to directly observe individual reservation wages or individual wage bargaining behaviour. Yet another advantage is that with laboratory experiments one can study, at relatively low cost, institutions that do not yet exist. Analogous to experimental tests of new medicines, where the medication is administered to a small subset of the population initially, laboratory experiments can be used as a first step, before experimenting with institutions in the field. Finally, experimental evidence is replicable, which is a prerequisite in establishing solid empirical knowledge.

Data-Sets and the Comparative Advantage of Laboratory Experiments

Although we believe that laboratory experiments offer important advantages for studying institutions, and should thus be exploited more often, it is important to recognize that there are also drawbacks to this method, which calls for a complementary use of different methods. A potential disadvantage is limited generalizability. Note, however, that this critique holds with respect to any data-set, given that any empirical observation is time and space contingent. Another concern is that experiments may be overly simple, missing potentially relevant aspects of the labour market. This is in fact both a problem and an advantage of experiments. Just as economic models are simpler than reality, so experiments are designed to simplify as much as possible, without losing the essentials. Thus, simplicity need not be a defect of an experiment. The key challenge, just as in the case of building economic models, is to include those features that are essential to the question at hand.

Examples

In this section we discuss a selected set of examples of experiments that were designed to shed light on important issues in labour economics. The examples concern the nature of the employment relationship and its contractual regulation, wage rigidity, performance incentives and their potentially detrimental effects, and labour market institutions.

The Employment Relation

The employment relation is an incomplete contract, which typically leaves many important aspects unspecified. This holds in particular for the content of work effort, which is unregulated and thereby non-enforceable by third parties. Contractual incompleteness gives opportunistic agents an incentive to shirk and therefore leads to an inefficiently low surplus. Thus, voluntary cooperation is necessary to ensure efficiency. Akerlof (1982) argued that many employment relationships are therefore governed by a gift exchange: the firm pays a higher wage than necessary to keep the employee, and the employee returns the gift by providing above minimum effort. Akerlof supported his arguments by a case study and casual observations.

The gift-exchange game by Fehr et al. (1993) provided the first experimental test of the existence of gift exchanges in the framework of a formal game-theoretic model designed to mimic an incomplete employment contract. In their experiment, participants assumed the roles of 'workers' and 'firms'. A firm made a wage offer that a worker could accept. If the worker accepted, he or she had then to choose a costly effort level. Parameters were such that a self-interested worker would always choose the lowest possible effort, since effort was costly. In turn, the firm had no incentive to pay an above-minimal wage, because a self-interested worker would shirk anyway. The results of numerous experiments in this framework showed, however, that wages and effort levels are positively correlated. Higher wages were reciprocated by higher effort levels, a finding which is consistent with the gift-exchange argument by Akerlof. This observation is also consistent with field evidence regarding the link between personnel policy and work morale (Bewley 1999).

In these experiments the employment relationship was modelled as a one-shot game, because this allows an unambiguous prediction under the joint

assumptions of rationality and self-interest. Yet in reality, employment relationships are long-term relationships. To test the impact of repeated interaction, Gächter and Falk (2002) conducted the gift-exchange experiment in the form of repeated games in which the same firm–worker pair interacted for ten periods. These repeated games were compared with one-shot games in which each firm was matched with ten different workers. The results showed a significantly higher effort in the repeated game than in the one-shot games. Gächter and Falk showed that the reason for this result is that in the repeated games the selfish types imitate the reciprocal types. This result provides support for theoretical arguments (for example, MacLeod and Malcomson 1998) that incomplete employment relations allow for implicit incentives for non- opportunistic behaviour.

In the experiments by Gächter and Falk (2002) the experimenter determined the duration of the employment relationship exogenously. In reality, however, the duration of employment relationships arises endogenously. Contract theory suggests that the duration might be linked to contractual incompleteness. Specifically, when contracts are incomplete, a long-term relationship provides implicit incentives that constrain opportunistic behaviour – an argument supported by the cited experimental evidence. If contracts are complete then implicit incentives are not necessary to constrain opportunism. Thus, employment relationships will tend to be short term under contractual completeness. Brown et al. (2004) tested these arguments experimentally and found strong support for them.

Efficiency Wages, Wage Rigidity, and Involuntary Unemployment

Efficiency wage theories explain why even in the absence of market interventions wages might be downwardly rigid, causing involuntary unemployment. Akerlof's (1982) gift-exchange theory is one efficiency wage theory that can explain involuntary unemployment. The main idea is simple. If gift exchanges exist, then firms have no incentive to lower wages because this would lead to low performance. Thus, paying high wages is profitable to the firm – wages are downwardly rigid and can cause involuntary unemployment. Fehr et al. (1998) demonstrated the behavioural validity of this argument experimentally.

Fehr and Falk (1999) provide the most stringent confirmation that gift exchanges can lead to downward wage rigidity. In their experiment an employment relationship was embedded in a 'double auction' market institution in which there were more workers than firms. This institution is known for its competitive properties; under complete contracts experimental double auction markets tend to clear very quickly. In the Fehr–Falk experiments both workers and firms could make wage offers. This enables us to observe whether workers underbid each other and firms therefore have the possibility of employing a worker at a low wage. There was indeed fierce competition among workers who underbid each other down to the theoretically predicted wage. Underbidding occurred in both treatments, the 'complete contract treatment' and the 'incomplete contract treatment'. In the latter, the striking finding was that firms did not take advantage of the possibility of paying low wages; instead they deliberately paid very high wages. The workers' reciprocal effort choice explains why firms had an incentive to pay high wages. In the control experiments with complete contracts gift exchanges were precluded by design and actual wages were very close to market clearing wages. Thus, incomplete contracts and gift exchange can explain wage rigidity and involuntary unemployment.

Performance Incentives (and Their Detrimental Effects)

Compensation and performance incentives have always been central topics in labour economics. Compensation may take different forms. The simplest form is a piece rate where a worker receives a certain wage for each unit she produces. Compensation may also depend on relative performance and be coupled with the possibility of moving up the career ladder. Tournament theory (Lazear and Rosen 1981) is an important theoretical framework for understanding career incentives and relative performance incentives.

Bull et al. (1987) provide the first experimental analysis of piece rate and tournament incentives.

They designed their experiments so that the incentive schemes were directly comparable, that is, the predicted effort level was the same both under piece rates and under tournament incentives. The results confirmed the theoretical predictions in both treatments. As it turned out, however, the support for tournament theory is weaker than for piece rate theory. In various treatment conditions these authors find that average effort choices converged close to the equilibrium prediction, but the variance was up to 30 times higher under tournament incentives than under the piece rate system.

The results by Bull et al. (1987) provide clear evidence that incentives influence behaviour very strongly. However, numerous experiments as well as field evidence (Bewley 1999) suggest that employment relationships are also governed by 'good will' and voluntary cooperation. This raises the question how explicit performance incentives affect voluntary cooperation – a fertile area of current research in experimental labour economics. A nice illustration of the potentially dysfunctional effects of introducing explicit incentives is the field experiment by Gneezy and Rustichini (2000). These authors studied the parents' response to the introduction of a fixed fine for picking up their children too late from kindergarten. The experiment lasted for 20 weeks and there were two conditions. In the baseline condition no fine existed. In the treatment condition the experimenters implemented a fixed fine after week four for picking up a child too late. The fine was removed after week 16. From week seven onwards, there was a steep *increase* in the number of latecomers until their number was roughly twice as high as in the baseline condition. Moreover, when the fine was removed at the end of week 16 the number of tardy parents remained roughly twice as high as in the baseline condition. This result clearly contradicts standard incentive theory, which predicts that the introduction of the fine should lower the incidence of late coming. A likely explanation of this finding is that the implicit contract that governed the employment relationship was changed from a good-will-based one to a market-like transaction, in which 'a fine is a price' and parents bought the commodity of being late.

Labour Market Institutions

A particularly important advantage of laboratory experiments concerns the possibility to test the economic effects of (labour market) institutions in a controlled way. An example of such an institutional test is the paper on minimum wages by Falk et al. (2006). In their experiment firms make wage offers to workers in labour markets either with or without minimum wages. The key insight of their study is that minimum wages may affect the reservation wages of workers in a non-trivial way: first, when minimum wages are introduced, workers stipulate reservation wages above the level of the minimum wage level, because being paid at just the level of the minimum wage is considered unfair. Second, while the introduction of a minimum wage increases reservation wages, the removal of a minimum wage legislation changes reservation wages only marginally. These findings help explain several empirical minimum wage puzzles. First, there exists an anomalously low utilization of subminimum wages in situations where employers actually could pay workers less than the minimum; second there exist so-called spillover effects, that is, wages are often increased by an amount in excess of that necessary for compliance with the minimum wage; and third, minimum wages do not always cause a decrease in employment, in particular if the minimum wage increase is modest (see also Card and Krueger 1995).

The finding that minimum wages affect workers' fairness perceptions of wages is also supported by Brandts and Charness (2004) who introduced a minimum wage in the context of an experimental labour market with worker moral hazard where workers' fairness concerns drive effort. They show that workers provide less effort for the same wage level in the presence of the minimum wage. This supports the view that the impact of minimum wages on workers' attributions of fairness intentions to firms partially shapes their effort responses.

Concluding Remarks

Experimental economics is a method of empirical investigation, not a separate subfield of

economics. Experimental methods can therefore in principle be utilized in all areas of economics. In this article we have illustrated some selected applications of experimental methods to important issues in labour economics. Further discussions of the issues raised here can be found in Fehr and Gächter (2000), Gächter and Fehr (2002), Fehr and Falk (2002), Falk and Fehr (2003) and Falk and Huffman (2007).

Experimental Macroeconomics

John Duffy

Abstract

Experimental macroeconomics is a sub-field of experimental economics that makes use of controlled laboratory methods to understand aggregate economic phenomena and to test the specific assumptions and predictions of macroeconomic models. This article reviews important contributions of experimental macroeconomics research, which include an understanding of when equilibration works, when it fails, and the means by which macro-coordination problems are resolved. It also discusses important methodological issues including the choice of market institution, the implementation of representative agent and overlapping generations models, discounting and infinite horizons, and the external validity of experimental macroeconomic findings.

Experimental macroeconomics is a subfield of experimental economics that makes use of controlled laboratory methods to understand aggregate economic phenomena and to test the specific assumptions and predictions of macroeconomic models. Surveys of experimental macroeconomics are found in Ochs (1995), Duffy (1998) and Ricciuti (2004). Macroeconomic topics that have been studied in the laboratory include convergence to Walrasian competitive equilibrium (Lian and Plott 1998), growth and development (Lei and Noussair 2002; Capra et al. 2005), specialization and trade (Noussair et al. 1995), Keynesian coordination failures (Cooper 1999; Van Huyck et al. 1990), the use of money as a medium of exchange (Brown 1996; Duffy and Ochs 1999, 2002) and as a store of value (McCabe 1989; Lim et al. 1994; Marimon and Sunder 1993, 1994), exchange rate determination (Arifovic 1996; Noussair et al. 1997), money illusion (Fehr and Tyran 2001), asset price bubbles and crashes (Smith et al. 1988; Lei et al. 2001; Hommes et al. 2005) sunspots (Marimon et al. 1993; Duffy and Fisher 2005), bank runs (Schotter and Yorulmazer 2003; Garratt and Keister 2005), contagions (Corbae and Duffy 2006), speculative currency attacks (Heinemann et al. 2004), and the economic impact of various fiscal and monetary policies (Riedl and Van Winden 2001; Arifovic and Sargent 2003; Marimon and Sunder 1994; Bernasconi and Kirchkamp 2000).

The use of laboratory experiments, involving small groups of subjects interacting with one another for short periods of time, to analyse aggregate, economy-wide phenomena or to test macroeconomic model predictions or assumptions might be met with some scepticism. However, there are many insights to be gained from controlled laboratory experimentation that cannot be obtained using standard macroeconometric approaches, namely, econometric analyses of the macroeconomic data reported by government agencies. Often the data most relevant to testing a macroeconomic model are simply unavailable. There may also be identification, endogeneity and equilibrium selection issues that cannot be satisfactorily addressed using econometric methods. Indeed, Robert Lucas (1986) was the first macroeconomist to make such observations, and he invited laboratory tests of rational expectations macroeconomic models; much of the subsequent experimental macroeconomics literature may be viewed as a response to Lucas's (1986) invitation. It is also worth noting that experimental methodologies have been improbably applied to the study of many other aggregate phenomena including astronomy, epidemiology, evolution, meteorology, political science and sociology.

Insights from Macroeconomic Experiments

To date, experimental macroeconomics research has yielded some important insights, including an understanding of when equilibration works, when it fails, and the means by which equilibrium selection or coordination problems are resolved. Equilibration, the process by which competitive equilibrium is achieved, is often ignored by modern macroeconomic modellers, who typically assume that market clearing is friction-free and instantaneous. Experimentalists, following the lead of Smith (1962), have explored mechanisms such as the double auction, the availability of information, futures markets and other means by which this equilibration

might be achieved or enhanced (see, for example, Forsythe et al. 1982; Plott and Sunder 1982; Sunder 1995 for partial equilibrium approaches; and Lian and Plott 1998 for a general equilibrium approach). A general finding is that, with enough trading experience and information feedback about transaction prices, bids, and asks, even small populations of five to ten subjects can learn to trade at prices and achieve efficiency consistent with competitive equilibrium in a large class of market environments. Indeed, the institutional rules, for instance of the double auction, may be all that is necessary to assure equilibration, as shown in the zero-intelligence trader approach of Gode and Sunder (1993).

Experimental insights regarding equilibration have enabled experimentalists to design market environments where equilibration may fail to obtain; in its place are observed price bubbles and crashes (Smith et al. 1988; Lei et al. 2001; Hommes et al. 2005). Explaining these laboratory asset price bubbles has proved challenging. Lei et al. (2001) show that speculative motives alone cannot explain bubble formation and suggest that it may have more to do with subject boredom. Duffy and Ünver (2006) suggest that anchoring effects may factor in subjects' bidding up of prices until binding budget constraints force a crash. A further puzzle is that experienced subjects in laboratory asset markets learn to avoid price bubbles and crashes, and generally price assets in line with fundamental values. An explanation for why bubbles and crashes occur among inexperienced but not experienced subjects has yet to be provided. Experiments with mixtures of experienced and inexperienced subjects show no tendency for bubbles to arise (Dufwenberg et al. 2005).

In environments with multiple equilibria, theory is typically silent as to which equilibrium agents will select or whether there will be transitions between equilibria. Understanding how agents coordinate on an equilibrium is of great interest to macroeconomists, as coordination problems are thought to play an important role in the persistence of business cycle fluctuations. Experimental evidence can and has been used to address the issue of which, among multiple equilibria, is most likely to be achieved, and why.

For instance, Van Huyck et al. (1990) have shown how minimum effort, team production payoff functions can lead to Keynes-type coordination failures – that is, coordination by groups of subjects on Pareto inferior equilibria. Such inefficiencies do not arise from conflicting objectives or from asymmetries of information; rather, they arise from individuals' *strategic uncertainty* with regard to the actions of other market participants. Similarly, Duffy and Ochs (1999, 2002) report that subjects have no difficulty coordinating on efficient monetary exchange equilibria in Kiyotaki–Wright-type money-search models when theory calls for the use of fundamental, cost-minimizing strategies, but subjects have much greater difficulty coordinating on efficient monetary equilibria that require them to employ more costly and forward-looking, speculative strategies, due perhaps to the unwillingness of other subjects to adopt those same speculative strategies.

Not all the experimental evidence points to inefficiencies in macro-coordination problems. Marimon and Sunder (1993) show that when subjects are presented with a Laffer-curve-type tradeoff between two inflation rates, the efficient, low-inflation equilibria is more likely to be selected than is the inefficient, high-inflation equilibrium. They show that the low-inflation equilibrium is stable under the adaptive learning dynamics that subjects use whereas the high-inflation equilibrium is not. Similarly, Arifovic and Sargent (2003) study behaviour in a Kydland–Prescott model of expected inflation output trade-offs and find that a majority of subjects acting in the role of central bank are able to choose policies so as to induce subjects, in the role of the public, to coordinate their expectations on the efficient but time- inconsistent Ramsey equilibrium. Still, they report occasional instances of 'backsliding' to the less efficient, time-consistent Nash equilibrium.

Finally, Duffy and Fisher (2005) explore subjects' use of non-fundamental 'sunspot' variables as coordination devices in an environment with multiple equilibria. They show that, when information is highly centralized, as in a call market, subjects use realizations of a sunspot variable as a device for coordinating on low- or high-price equilibria, but that this coordination mechanism

may break down when information is more decentralized, as in a double auction, or when the mapping from realizations of the sunspot variable to the action space is unclear.

Methodological Issues

Methodologically, macroeconomic experiments typically involve some kind of centralized market-clearing mechanism through which subjects interact with one another, for instance as buyers or sellers, or both. The double auction market mechanism (Friedman and Rust 1991) is the most commonly used market-clearing mechanism, as it allows for continuous information on bids, asks, transaction prices and volume – information which is thought to be critical to rapid equilibration and high levels of allocative efficiency (Lian and Plott 1998; Noussair et al. 1995, 1997). The simultaneous, sealed-bid 'call' market version of this mechanism has also been used by some researchers (Cason and Friedman 1997; Duffy and Fisher 2005; Capra et al. 2005).

Some less centralized market mechanisms have also been used. For instance, Brown (1996), Duffy and Ochs (1999, 2002) study a money-search model in which subjects are randomly paired and may trade goods with one another at a fixed exchange rate. In addition, game-theoretic models are also commonly employed, especially in studies of coordination failure, contagion and speculative attacks (Van Huyck et al. 1990; Corbae and Duffy 2006; Heinemann et al. 2004).

A hallmark of modern macroeconomic modelling is the characterization of the economy using recursive dynamical systems where expectations of future endogenous variables determine current outcomes. Several experimental researchers testing such models have found it useful to separate subjects' forecast decisions from market-trading decisions. For instance, Marimon and Sunder (1993, 1994, 1995) and Hommes et al. (2005) elicit subjects' forecasts of the next period's price level. Using these individual forecasts, they determine subjects' individual demands for the consumption good in the current period and, as supply is fixed, they simultaneously determine the current period price. Similarly, Adam (2007) elicits forecasts of inflation one and two periods ahead, consistent with the monetary sticky price model that he investigates; these expectations are then used to determine output and inflation in the current period. Marimon and Sunder (1994) refer to this type of experimental design as a 'learning to forecast' framework, which they contrast with a 'learning to optimize' framework. Of course, in macroeconomic models, it is assumed that agents are able to both forecast and optimize at the same time.

Many macroeconomic models have representative agents and infinite horizons or an infinity of agents and goods which pose some challenges for laboratory implementation and testing of theoretical predictions. The representative agent assumption has been examined by Noussair and Matheny (2000) and Lei and Noussair (2002). They compare consumption and investment decisions made by individual subjects operating as 'representative agent-social planners' in the standard Cass–Koopmans optimal growth framework with the decisions made by groups of subjects who first trade shares of capital via a double-auction market clearing mechanism and then allocate their income between consumption and investment. They find that the double-auction market mechanism results in allocations that are far closer to the theoretical predictions than are the decisions made by subjects in the representative agent role attempting to solve the optimization problem on their own.

To implement infinite horizons, researchers have adopted two designs. One design, used for example by Marimon and Sunder (1993), is to recruit subjects for a fixed period of time but terminate the session early, without advance notice, following the end of some period of play. As Marimon and Sunder use a forward- looking dynamic model, they use the one-step-ahead forecasts made by a subset of subjects who are paid for their forecast accuracy to determine final period allocations. A second design is to introduce a constant small probability, $1 - \delta$, that each period will be the last one played in a sequence, and allow enough time for several indefinite sequences to be played in an experimental session (Duffy and Ochs

1999, 2002; Lei and Noussair 2002; Capra et al. 2005). This design has the advantage of inducing both the stationarity associated with an infinite horizon and discounting of future payoffs at rate $(1 - \delta)/\delta$ per period (equivalently a discount *factor* of δ). Related to the infinite horizon problem, overlapping generations models, as studied by Marimon and Sunder (1993, 1994, 1995) and Marimon et al. (1993) have an infinity of agents (and goods). Marimon and Sunder cope with this difficulty by recycling subjects – allowing each subject to live several two- period lives over the course of an indefinite sequence of periods. Marimon and Sunder (1993) argue that this repeated entry and exit of subjects does not induce any strategic opportunities that are not already present in the overlapping generations model without 'rebirth'. Indeed, the need for a large number of agents to study macroeconomic behaviour is a common issue confronted by researchers. However, results from many double auction experiments suggest that competitive equilibrium can be quickly achieved with as few as three to five subjects operating on each side of the market. Similarly, while search models of money assume a continuum of agents, Duffy and Ochs (2002) argue that the strategic incentives generated by having finite subject populations do not alter the equilibrium predictions of those models under the assumption of a continuum of agents.

Perhaps the most difficult methodological issue is the external validity of macroeconomic experimental findings. While external validity is generally a problem for all experimental economists, it might be regarded as a greater problem for macroexperimentalists seeking to explain economy-wide aggregate macroeconomic phenomena using necessarily small-scale laboratory evidence. Experimental macroeconomists have several responses to this issue. First, as noted earlier, modern macroeconomic models have explicit microfoundations as to how individual agents make decisions (for example, agents recognize the relevant trade-offs, form rational expectations) which can be directly tested in the laboratory. Indeed, in the laboratory one can be more certain about micro-level *causal relationships*, that is, that an experimenter induced change in a variable is the source of any observed change in subject behaviour as opposed to some other, unaccounted-for factors. Macroeconometric analyses of field data cannot claim the same degree of *internal validity*. A second response is to make use of highly experienced subjects – those who have participated in the same experiment many times – as a means of better proxying real-world behaviour. As noted earlier, asset price bubbles and crashes seem to disappear with experienced subjects. A third response has been to use parametric forms or calibrations of macroeconomic models that are of interest to macroeconomists, or to present subjects with real macroeconomic data as part of the experimental design (for example, Bernasconi et al. 2004). Finally, many experimentalists would argue that all experimental work, including macroeconomic experiments, should be judged by the findings obtained and not by biases concerning the suitability of laboratory versus other empirical methods, all of which have their strengths and weaknesses.

Experimental Methods in Economics

C. F. Bastable

Abstract

In the mid-20th century economists became involved in the design and conduct of laboratory experiments to examine propositions implied by economic theory. This development brought new standards of rigour to the data gathering process. This article gives an account of the author's experiment in 1956 to test the hypothesis that the competitive market process yields welfare improving (and, under certain limiting ideal conditions, welfare maximizing) outcomes, provides an interpretive history of the development of experimental economics, discusses the functions of market experiments in microeconomic analysis, and classifies the application of experimental methods.

Historically, the method and subject matter of economics have presupposed that it was a non-experimental (or 'field observational') science more like astronomy or meteorology than physics or chemistry. Based on general, introspectively 'plausible', assumptions about human preferences, and about the cost and technology based supply response of producers, economists have sought to understand the functioning of economies, using observations generated by economic outcomes realized over time. The data of the astronomer is of this same type, but it would be wrong to conclude that astronomy and economics are methodologically equivalent. There are two important differences between astronomy and economics which help to illuminate some of the methodological problems of economics. First, based upon parallelism (the maintained hypothesis that the same physical laws hold everywhere), astronomy draws on all the relevant theory from classical mechanics and particle physics – theory which has evolved under rigorous laboratory tests. Traditionally, economists have not had an analogous body of tested behavioural principles that have survived controlled experimental tests, and which can be assumed to apply with insignificant error to the microeconomic behaviour that underpins the observable operations of the economy. Analogously, one might have supposed that there would have arisen an important area of common interest between economics and, say, experimental psychology, similar to that between astronomy and physics, but this has only started to develop in recent years.

Second, the data of astronomy are painstakingly gathered by professional observational astronomers for scientific purposes, and these data are taken seriously (if not always non-controversially) by astrophysicists and

cosmologists. Most of the data of economics has been collected by government or private agencies for non- scientific purposes. Hence astronomers are directly responsible for the scientific credibility of their data in a way that economists have not been. In economics, when things appear not to turn out as expected the quality of the data is more likely to be questioned than the relevance and quality of the abstract reasoning. Old theories fade away, not from the weight of falsifying evidence that catalyses theoretical creativity into developing better theory, but from lack of interest, as intellectual energy is attracted to the development of new techniques and to the solution of new puzzles that remain untested.

At approximately the mid-20th century, professional economics began to change with the introduction of the laboratory experiment into economic method. In this embryonic research programme economists (and a psychologist, Sidney Siegel) became directly involved in the design and conduct of experiments to examine propositions implied by economic theories of markets. For the first time this made it possible to introduce *demonstrable* knowledge into the economist's attempt to understand markets.

This laboratory approach to economics also brought to the economist direct responsibility for an important source of scientific data generated by controlled processes that can be replicated by other experimentalists. This development invited economic theorists to submit to a new discipline, but also brought an important new discipline and new standards of rigour to the data gathering process itself.

An untested theory is simply a hypothesis. As such it is part of our *self*- knowledge. Science seeks to expand our knowledge of *things* by a process of testing this type of self-knowledge. Much of economic theory can be called, appropriately, 'ecclesiastical theory'; it is accepted (or rejected) on the basis of authority, tradition, or opinion about assumptions, rather than on the basis of having survived a rigorous falsification process that can be replicated.

Interest in the replicability of scientific research stems from a desire to answer the question 'Do you see what I see?' Replication and control are the two primary means by which we attempt to reduce the error in our common knowledge of economic processes. However, the question 'Do you see what I see?' contains three component questions, recognition of which helps to identify three different senses in which a research study may fail to be replicable:

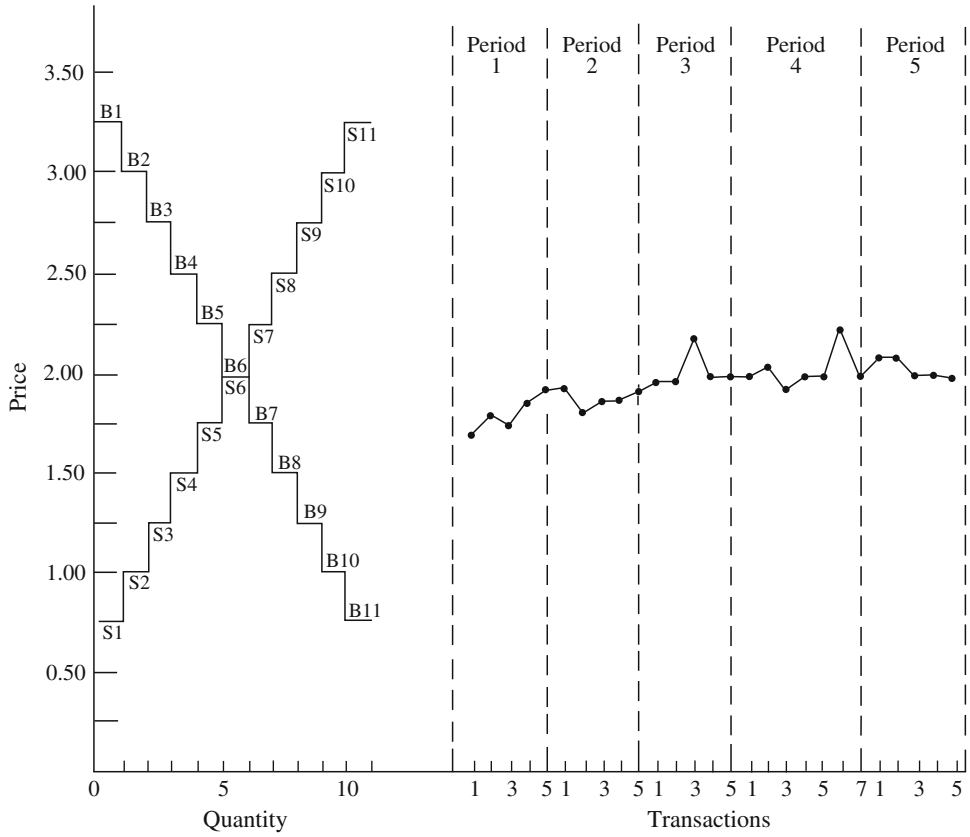
(1) *Do you observe what I observe?* Since economics has traditionally been confined to the analysis of non-experimental data, the answer to this question has been trivially, 'yes'. We observe the same thing because we use the same data. This non-replicability of our traditional data sources has helped to motivate some to turn increasingly to experimental methods. We can say that you have replicated my experiments if you are unable to reject the hypothesis that your experimental data came from the same population as mine. This means that the experimenter, his/her subjects, and/or procedures are not significant treatment variables.
(2) *Do you interpret what we observe as I interpret it?* Given that we both observe the same, or replicable data, do we put the same interpretation on these data? The interpretation of observations requires theory (either formal or informal), or at least an empirical interpretation of the theory in the context that generated the data. Theory usually requires empirical interpretation either because (i) the theory is not developed directly in terms of what can be observed (e.g. the theory may assume risk aversion which is not directly observable), or (ii) the data were not collected for the purpose of testing, or estimating the parameters of a theory. Consequently, failure to replicate may be due to differences in interpretation which result from different meanings being ascribed to the theory. Thus two researchers may apply different transformations to raw field data (e.g. different adjustments for the effect of taxes), so that the results are not replicable because their theory interpretations differ.
(3) *Do you conclude what I conclude from our interpretation?* The conclusions reached in two different research studies may be different

even though the data and their interpretation are the same. In economics this is most often due to different model specifications. This problem is inherent in non-experimental methodologies in which, at best, one usually can estimate only the parameters of a pre-specified model and cannot credibly test one model or theory against another. An example is the question of whether the Phillips' curve constitutes a behavioural trade-off between the rates of inflation and unemployment, or represents an equilibrium association without causal significance.

Markets and Market Experiments

Markets and how they function constitute the core of any economic system, whether it is highly decentralized – popularly, a 'capitalistic' system, or highly centralized – popularly, a 'planned' system. This is true for the decentralized economy because markets are the spontaneous institutions of exchange that use prices to guide resource allocation and human economic action. It is true for the centralized economy because in such economies markets always exist or arise in legal form (private agriculture in Russia) and clandestine or illegal form (barter, bribery, the trading of favours, and underground exchange in Russia, Poland and elsewhere). Markets arise spontaneously in all cultures in response to the human desire for betterment (to 'profit') through exchange. Where the commodity or service is illegal (prostitution, gambling, the sale of liquor under Prohibition or of marijuana, cocaine, etc.) the result is not to prevent exchange, but to raise the risk and therefore the costs of exchange. This is because enforcement is itself costly, and it is never economical for the authorities (whether Soviet or American) even to approximate perfect enforcement. The spontaneity with which markets arise is perhaps no better illustrated than when (1979–80) US airlines for promotional purposes issued travel vouchers to their passengers. One of these vouchers could be redeemed by the bearer as a cash substitute in the purchase of new airline tickets. Consequently vouchers were of value to future passengers. Furthermore, since (as Hayek would say) the 'circumstances of time and place' for the potential redemption of vouchers were different for different individuals, there existed the preconditions for the active voucher market that was soon observed in all busy airports. Current passengers with vouchers who were unlikely to be travelling again soon held an asset worth less to themselves than to others who were more certain of their future or impending travel plans. The resulting market established prices that were discounts from the redemption or 'face' value of vouchers. Sellers who were unlikely to be able to redeem their vouchers preferred to sell them at a discount for cash. Buyers who were reasonably sure of their travel plans could save money by purchasing vouchers at a discount. Thus the welfare of every active buyer and seller increased via this market. Without a market, many – perhaps most – vouchers would not have been exercised and would thus have been 'wasted'.

The previous paragraph illustrates a fundamental hypothesis (theorem) of economics: the ('competitive') market process yields welfare improving (and, under certain limiting ideal conditions, welfare maximizing) outcomes. But is the hypothesis 'true', or at least very probably true? (Lakatos (1978) would correctly ask 'Has it led to an empirically progressive research programme?') I think it is 'true', but how do I know this? Do you see what I see? A Marxist does not see what I see in the above interpretation of a market. The young student studying economics does not see what I see, although if they continue to study economics eventually they (predictably) come to see what I see (or, at least, they say they do). Is this because we have inadvertently brainwashed them? The gasoline consumer does not see what I see. They see themselves in a *zero* sum game with an oil company: any increase in price merely redistributes wealth from the consumer to the company, which is not 'fair' since the company is richer. What I see in a market is a *positive* sum game yielding gains from exchange, which constitutes the fundamental mechanism for creating, not merely redistributing wealth. The traditional method by which the economist gets others to see this 'true' function of markets is by



Experimental Methods in Economics, Fig. 1

logical arguments (suppose it were not true, then . . .), examples, and 'observations', such as are contained in my description of the voucher market, in which what is 'observed' is hortatively described and interpreted in terms of the hypothesis itself. But if this knowledge of the function of markets is 'true', can it be demonstrated? Experimentalists claim that laboratory experiments can provide a uniquely important technique of demonstration for supplementing the theoretical interpretation of field observations.

I conducted my first experiment in the spring of 1956. Since then hundreds of similar, as well as environmentally richer experiments have been conducted by myself and by others. In 1956, my introductory economics class consisted of 22 science and engineering students, and although this might not have been the 'large number' traditionally thought to have been necessary to yield a competitive market, I thought it was large enough for a practice run to initiate a research programme capable of falsifying the standard theory. I conducted the experiment before lecturing on the theory and 'behaviour' of markets in class so as not to 'contaminate' the sample. The 22 subjects were each assigned one card from a well-shuffled deck of 11 white and 11 yellow cards. The white cards identified the sellers, and the yellow cards identified the buyers. Each white card carried a price, known only to that seller, which represented that seller's minimum selling price for one unit, and each yellow card identified a price, known only to that buyer, representing that buyer's maximum buying price for one unit. On the left of Fig. 1 is listed these so-called 'limit' prices, identified by buyer, B1, B2 etc. (in descending order, D) and by seller, S1, S2 etc. (in ascending order, S). To keep things simple and well controlled each buyer (seller) was informed that he/she was a buyer (seller) of at most one unit of

the item in each of several trading periods. Thus demand, D (supply, S) was 'renewed' in each trading period as a steady state flow, with no carry-over in unsatisfied demand (or unsold stock), from one period to the next. In the airline voucher example, imagine the vouchers being issued, followed by trading; the vouchers then expire, new vouchers are issued, traded and so on. In the experiment, suppose real motivation is provided by promising to pay (in cash) to each buyer the difference between that buyer's assigned limit buying price and the price actually paid in each period that a unit is purchased in the market. Thus suppose seller 5 sells their unit to buyer 2 at the price 2.25. Then buyer 2 earns a 'profit' of $0.75 from this exchange. In this way we induce on each buyer a value (or hypothesized willingness-to-pay) equal to the assigned limit buy price. Similarly, suppose each seller is paid the difference between that seller's actual sales price and assigned limit price ('cost', or willingness-to-sell) in each trading period that a unit is sold. Thus in the previous exchange example, seller 5 earns $0.50 from the transaction.

This experimental procedure operationalizes the market preconditions that (1) 'the circumstances of time and place' for each economic agent are dispersed and known only to that agent (as in the above voucher market) and (2) agents have a secure property right in the objects of trade and the private gains ('profits') from trade (an airline travel voucher was transferable and redeemable by any bearer). The reader should note that 'profit' is identified as much with the act of buying as with that of selling. This is because 'profit' is the surplus earned by a buyer who buys for less than his willingness-to-pay, just as a seller's 'profit' is the surplus earned when an item is sold for more than the amount for which they are willing to sell. Willingness-to-sell need not have, and usually does not have anything to do with accounting 'cost', or production 'cost', from which one computes accounting profit. Willingness-to-sell, like willingness-to-buy, is determined by the immediate circumstances of each agent. Hence, a passenger might be prepared to pay the regular full fare premium on a first-class ticket for an emergency trip to visit a sick relative. The accountant's concept of profit cannot be applied to the passenger's decision any more than it can be applied to that of a passenger willing to sell a voucher at a deep discount. In what follows I will use the term 'buyer's surplus' or 'seller's surplus' instead of 'profit' to refer to the gains from exchange enjoyed by buyers or sellers because the term 'profit' is so strongly, exclusively and misleadingly associated with selling activities.

Now let us interpret the previously cited fundamental theorem of economics in the context of the experimental design contained in Fig. 1. We note first that the ordered set of seller (buyer) limit prices defines a supply (demand) function (Fig. 1). A supply (demand) function provides a list of the total quantities that sellers (buyers) would be willing to sell (buy) at corresponding hypothetical fixed prices. Neither of these functions is capable of being observed, scientifically, in the field. This is because the postulated limit prices are inherently private and not publicly observable. We could poll every potential seller (buyer) of vouchers in Chicago's O'Hare airport on 20 December 1979 to get each person's reported limit price, but we would have no way of validating the 'observations' thus obtained. Referring to Fig. 1, we see that in my 1956 experiment, sellers (hypothetically) were just willing to sell three units at price 1.25, nine units at 2.75 and so on. Similarly buyers (hypothetically) were just willing to buy four units at 2.50, seven units at 1.75 and so on. If seller 3 is indifferent between selling and not selling at 1.25, and if every seller (buyer) is likewise indifferent at his/her limit price, then any particular unit may not be sold (purchased) at this limit price. One means of dealing with this problem in laboratory markets is to promise to pay a small 'commission', say 5 cents, to each buyer and seller for each unit bought or sold. Thus seller 3 has a small inducement to sell at 1.25 if he can do no better, and buyer 6 has a small inducement to buy at 2.00 if she can do no better.

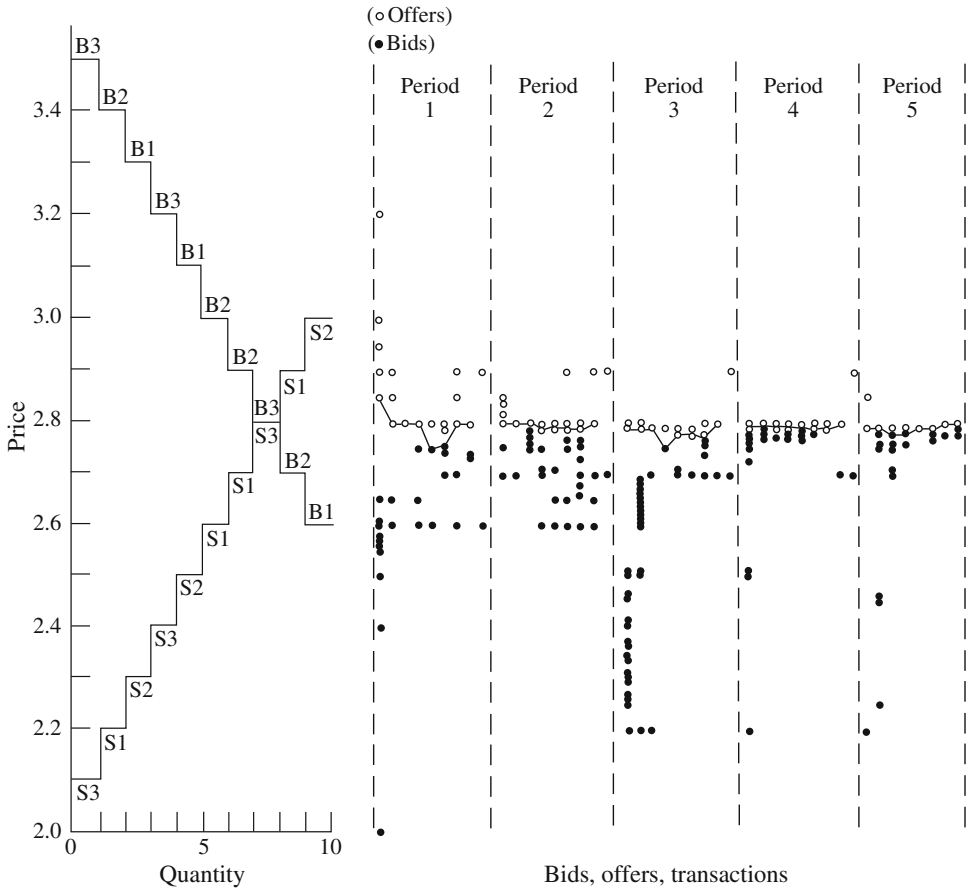
Economic theory defines the competitive equilibrium as the price and corresponding quantity that clears the market; that is, it sets the quantity that sellers are willing to sell equal to the quantity that buyers are willing to buy. This assumes that the subjective cost of transacting is zero; otherwise any units with limit prices equal to the competitive equilibrium price will not exchange.

In Fig. 1 this competitive equilibrium price is 2.00. If the 5 cent 'commission' paid to each trading buyer and seller is sufficient to compensate for any subjective cost of transacting, then buyer 6 and seller 6 will each trade and the competitive equilibrium quantity exchanged will be 6 units. At the competitive equilibrium price, buyer 1 earns a surplus of 3.25–2.00 = 1.25 (plus commission) per period and so on. Total surplus, which measures the maximum possible gains from exchange, or maximum wealth *created* by the existence of the market institution, is 7.50 per period, at the competitive equilibrium.

If by some miracle the competitive equilibrium price and exchange quantity were to prevail in this market, sellers 1–6 would sell, buyers 1–6 would buy, while sellers 7–11 would make no sales and buyers 7–11 would make no purchases. It might be thought that this is unfair – the market should permit some or all of the 'submarginal' buyers (sellers) 7–11 to trade – or that more wealth would be created if there were more than six exchanges. But these interpretations are wrong. By definition, buyer 10 is not willing to pay more than 1.00. Consequently, it is a peculiar notion of fairness to argue that buyer 10 should have as much priority as buyer 1 in obtaining a unit. In the airline voucher example, this would mean that a buyer who is unlikely to redeem a voucher should have the same priority as a buyer who is likely to redeem a voucher. One can imagine a market in which, say, buyer 1 is paired with seller 9 at price 3.00, buyer 2 with seller 8 at price 2.75, and so on with nine units traded. If this were to occur it would mean buyers 7–9, who are less likely to use vouchers, have purchased them, and sellers 7–9, who initially held vouchers, and were more likely to use them than buyers 7–9, have sold their vouchers. Furthermore, this allocation yields additional possible gains from exchange, and is thus *not sustainable*, even if it were thought to be desirable. That is, buyer 9, who bought from seller 1 at price 1.00, could resell the unit to seller 9 (who sold her unit to buyer 2), at price (say) 2.00. Why? Because, by definition a voucher is worth 2.75 to seller 9 and only 1.25 to buyer 9. Similar additional trades can be made by buyers (sellers) 7 and 8. The end result would be that buyers 1–6 and sellers 7–11 would be the terminal holders of vouchers, just as if the competitive equilibrium had been reached initially.

Hence, either the competitive equilibrium prevails, or if inefficient trades occur at dispersed prices, then further 'speculative' gains can be made by some buyers and sellers. If these gains are fully captured the end result is the same allocation as would occur at the competitive equilibrium price and quantity.

Having specified the environment (individual private values) of our experimental market, what remains is to specify an exchange institution. In my 1956 experiment I elected to use trading rules similar to those that characterize trading on the organized stock and commodity exchanges. These markets use the 'double oral auction' procedure. In this institution as soon as the market 'opens' any buyer is free to announce a bid to buy and any seller is free to announce an offer to sell. In the experimental version each bid (offer) is for a single unit. Thus a buyer might say 'buy, 1.00', while a seller might say 'sell, 5.00', and it is understood that the buyer bids 1.00 for a unit and the seller offers to sell one unit for 5.00. Bids and offers are freely announced and can be modified. A contract occurs if any seller accepts the bid of any buyer, or any buyer accepts the offer of any seller. In the simple experimental market, since each participant is a buyer or seller of at most one unit per trading period, the contracting buyer and seller drop out of the market for the remainder of the trading period, but return to the market when a new trading 'day' begins. The experimenter announces the close of each trading period and the opening of the subsequent period, with each trading period timed to extend, say, five minutes. Each contract price is plotted on the right of Fig. 1 for the five trading periods of the experiment. This result was not as expected. The conventional view among economists was that a competitive equilibrium was like a frictionless ideal state which could not be conceived as actually occurring, even approximately. It could be conceived of occurring only in the presence of an abstract 'institution' such as a Walrasian *tâtonnement* or an Edgeworth recontracting procedure. It was for teaching, not believing.



Experimental Methods in Economics, Fig. 2

From Fig. 1 it is evident that in the strict sense the competitive equilibrium was not attained in any period, but the accuracy of the competitive equilibrium theory is easily comparable to that of countless physical processes. Certainly, the data clearly do not support the monopoly, or seller collusion model. The total return to sellers is maximized when four units are sold at price 2.50. Similarly, the monopsony, or buyer collusion model requires four units to exchange at price 1.50.

Since 1956, several hundred experiments using different supply and demand conditions, experienced as well as inexperienced subjects, buyers and sellers with multiple unit trading capacity, a great variation in the numbers of buyers and sellers, and different trading institutions, have established the replicability and robustness of these results. For many years at the University of Arizona and Indiana University we have been using various computerized (the PLATO system) versions of the double 'oral' auction, developed by Arlington Williams, in which participating subjects trade with each other through computer terminals. These experiments establish that the 1956 results are robust with respect to substantial reductions in the number of buyers and sellers. Most such experiments use only four buyers and four sellers, each capable of trading several units. Some have used only two sellers, yet the competitive equilibrium model performs very well under double auction rules. Figure 2 shows the supply and demand design and the market results for a typical experiment in which subjects trade through PLATO computer terminals under computer-monitored double auction rules.

In addition to its antiquarian value, Fig. 1 illustrates the problem of monitoring the rules of a 'manual' experiment. Observe that in period 4 there were seven contracts which are recorded as occurring in the price range between $1.90 and $2.25. This is not possible since there are only six buyers with limit buy prices above $1.90. Either a buyer violated his budget constraint, or the experimenter erred in recording a price in his first experiment. In Fig. 2 there is plotted each contract (an accepted bid if the contract line passes through a 'dot'; an accepted offer if the line passes through a 'circle') and the bids ('dots') and offers ('circles') that preceded each accepted bid or offer. One of the several advantages of computerized experimental markets is that the complete data of the market (all bids, offers, and contracts at their time of execution) are recorded accurately and non-invasively, and all experimental rules are enforced perfectly. In particular the violation of a budget constraint revealed in Fig. 1, which is a perpetual problem with manually executed experiments, is not a problem when trading is perfectly computer monitored.

The rapid convergence shown in Figs. 1 and 2 has not always extended to trading institutions other than the double auction. For example, the 'posted offer' pricing mechanism (associated with most retail markets), in which sellers post take it or leave it non-negotiable prices at the beginning of each period, yields higher prices and less efficient allocations than the double auction. This difference in performance becomes smaller with experienced subjects and with longer trading sequences in a given experiment (Ketcham et al. 1984). Similarly, a comparison of double auction with a sealed bid-offer auction finds the latter to be less efficient and to deviate more from the competitive equilibrium predictions (Smith et al. 1982). Thus, institutions have been demonstrated to make a difference in what we observe. The data and analysis strongly suggest that institutions make a difference because the rules (legal environment) make a difference, and the rules make a difference because they affect individual incentives.

Brief Interpretive History of the Development of Experimental Economics

The two most influential early experimental studies represent the two most primary poles of experimental economics: the study of individual preference (choice) under uncertainty (Mosteller and Nogee 1951) and of market behaviour (Chamberlin 1948). The investigation of uncertainty and preference has focused on the testing of von Neumann–Morgenstern–Savage subjective expected utility theory. Battalio, Kagel and others have pioneered in the testing of the Slutsky–Hicks commodity demand and labour supply preferences using humans (1973) and animals (1975). A series of large-scale field experiments in the 1970s extended the experimental study of individual preference to the measurement of the effect of the negative income tax and other factors on labour supply and to the measurement of the demand for electricity, housing and medical services.

Since the human species has been observed to participate in market exchange for thousands of years, the experimental study of market behaviour is central to economics. Preferences are not directly observable, but preference theory, as an abstract construct, has been *postulated* by economists to be fundamental to the explanation and understanding of market behaviour. In this sense the experimental study of group market behaviour depends upon the study of individual preference behaviour. But this intellectual history should not obscure the fact that the study of markets and the study of preferences need not be construed as inseparable. Adam Smith clearly viewed the human 'propensity to truck, barter and exchange' (and *not* the existence of human preferences) as axiomatic to the scientific study of economic behaviour. Obversely, the work of Battalio and Kagel showing that animals behave as if they had Slutsky–Hicks preferences makes it plain that substitution behaviour is an important cross species characteristic, but that such phenomena need not be associated with market exchange.

A significant feature of Chamberlin's (1948) original work is that it concerned the study of behaviourally complete markets; that is all trades, including purchases as well as sales, were executed by active subject agents. This feature has continued in the subsequent bilateral bargaining experiments of Siegel and Fouraker (1960) and in market experiments (Smith 1962, 1982; Williams and Smith 1984) such as those discussed in section "Markets and Market Experiments". This feature was not present in the early and subsequent experimental oligopoly literature (Hoggatt 1959; Sauermann and Selten 1959; Shubik 1962; Friedman 1963), in which the demand behaviour of buyers was simulated, that is, programmed from a specified demand function conditional on the prices selected in each 'trading' period by the sellers. This simulation of demand behaviour is justified as an intermediate step in testing models of seller price behaviour that assume passive, simple maximizing, demand-revelation behaviour by buyers. But the conclusions of such experimental studies should not be assumed to be applicable, even provisionally, to any observed complete market without first showing that the experimental results are robust with respect to the substitution of subject buyers for simulated buyers.

The Functions of Market Experiments in Microeconomic Analysis

A conceptual framework for clarifying some uses and functions of experiments in microeconomics can be articulated by suitable modification and adaptation (Smith 1982) of the concepts underlying the adjustment process, as in the welfare economics literature (see references to Hurwicz and Reiter in Smith 1982). In this literature a microeconomic environment consists of a list of agents $\{1, \ldots, N\}$, a list of commodities and resources $\{1,\ldots, K\}$and certain characteristics of each agent i, such as the agent's preferences (utility) u_i technological (knowledge) endowment T^i, and commodity endowment w_i .Thus agent i is defined by the triplet of characteristics $E^i = (u^i, T^i, w^i)$ defined on the K-dimensional commodity space. A microeconomic *environment* is defined by the collection $E = (E^1, \ldots, E^N)$ of these characteristics. This collection represents a set of primitive circumstances that condition agents' interaction through institutions. The superscript i, besides identifying a particular agent, also means that these primitive circumstances are in their *nature* private: it is the individual who likes, works, knows and makes.

There can be no such thing as a credible institution-free economics. Institutions define the property right rules by which agents communicate and exchange or transform commodities within the limits and opportunities inherent in the environment, E. Since markets require communication to effect exchange, property rights in messages are as important as property rights in goods and ideas. An institution specifies a language, $M = (M^1, \ldots, M^N)$, consisting of message elements $m = (m^1, \ldots, m^N)$, where M^i is the set of messages that can be sent by agent i (for example, the range of bids that can be sent by a buyer). An institution also defines a set of allocation rules $h = (h^1(m), \ldots, h^N(m))$ and a set of cost imputation rules $c = (c^1(m), \ldots, c^N(m))$ where $h^i(m)$ is the commodity allocation to agent i and $c^i(m)$ is the payment to be made by i, each as a function of the messages sent by all agents. Finally, the institution defines a set of adjustment process rules (assumed to be common to all agents), $g(t_0, t, T)$, consisting of a starting rule, $g(t_0, \cdot, \cdot)$, a transition rule, $g(\cdot, t, \cdot)$, governing the sequencing of messages, and a stopping rule, $g(\cdot, \cdot, T)$, which terminates the exchange of messages and triggers the allocation and cost imputation rules. Each agent's property rights in communication and exchange is thus defined by $I^i = (M^i, h^i(m), c^i(m), g(t_0, t, T))$. A microeconomic *institution* is defined by the collection of these individual property right characteristics, $I = (I^1, \ldots, I^N)$.

A microeconomic *system* is defined by the conjunction of an environment and an institution, $S = (E, I)$. To illustrate a microeconomic system, consider an auction for a single indivisible object such as a painting or an antique vase. Let each of

N agents place an independent, certain, monetary value on the item v_1, . . . , v_N, with agent i knowing his own value, v_i, but having only uncertain (probability distribution) information on the values of others. Thus $E^i = (v^i; p(v), N)$. If the exchange institution is the 'first price' sealed-bid auction, the rules are that all N bidders each submit a single bid any time between the announcement of the auction offering at t_0, and the closing of bids, at T. The item is then awarded to the maker of the highest bid at a price equal to the amount bid. Thus, if the agents are numbered in descending order of the bids, the first price auction institution $I_1 = I_1^1 = \left[h^1(m) = 1, c^1(m) = b_1\right]$ and $I_1^i = \left[h^i(m) = 0, c^i(m) = 0\right], i > 1$, where $m = (b_1, \ldots, b_N)$ consists of all bids tendered. That is, the item is awarded to the high bidder, $i = 1$, who pays b_1, and all others receive and pay nothing. This contrasts with the 'second price' sealed-bid auction $I_2 = \left(I_2^1, \ldots, I_2^N\right)$ in which $I_2^1 = \left[h^1(m) = 1, c^1(m) = b_2\right]$ and $I_2^i = \left[h^i(m) = 0, c^i(m) = 0\right], i > 1$; that is, the highest bidder receives the allocation but pays a price equal to the second highest bid submitted.

Another example is the English or progressive oral auction, whose rules are discussed under the entry auctions (experiments). It should be noted that the 'double oral' auction, used extensively in stock and commodity trading and in the two experimental markets discussed in section "Markets and Market Experiments", is a two-sided generalization of the English auction.

A microeconomic system is activated by the behavioural choices of agents in the set M. In the static, or final outcome, description of an economy, agent *behaviour* can be defined as a function (or correspondence) $m^i = \beta^i(E^i|\ I)$ carrying the characteristics E^i of agent i into a message m^i, conditional upon the property right specifications of the operant institution I. If all exchange-relevant agent characteristics are included in E^i, then $\beta \equiv \beta^i$ for all i. Given the message-sending behaviour of each agent, $\beta(E|\ I)$, the institution determines the outcomes

$$h^i(m) = h^i\left[\beta\left(E^1|\ I\right), \ldots, \beta\left(E^N|\ I\right)\right]$$

and

$$c^i(m) = c^i\left[\beta\left(E^1|\ I\right), \ldots, \beta\left(E^N|\ I\right)\right].$$

Within this framework we see that agents do not choose allocations directly; agents choose messages with institutions determining allocations under the rules that carry messages into allocations. (You cannot choose to 'buy' an auctioned item; you can only choose to raise the standing bid at an English auction or submit a particular bid in a sealed bid auction.) However, the allocation and cost imputation rules may have important incentive effects on behaviour, and therefore messages will in general depend on these rules. Hence, market outcomes will result from the conjunction of institutions' and agents' behaviour.

A proper theory of agents' behaviour allows one to deduce a particular β function based on assumptions about the agent's environment and the institution, and his motivation to act. Auction theory is perhaps the only part of economic theory that is fully institution specific. For example, in the second price sealed bid auction it is a dominant strategy for each agent simply to bid his or her value; that is

$$b^i = \beta\left(E^i|\ I_2\right) = \beta(v_i|\ I_2) = v_i, i = 1, \ldots, N.$$

The resulting outcome is that $b_1 = v_1$ is the winning bid and agent 1 pays the price v_2. Similarly, in the English auction, agent 1 will eventually exclude agent 2 by raising the standing bid to v_2 (or somewhat above), and obtain the item at this price. In the first price auction Vickrey proved that if each agent maximizes expected Surplus $(v_i - b_i)$ in an environment with $P(v) = v$ (the vi are drawn from a constant density on [0, 1]), then we can deduce the noncooperative equilibrium bid function, $b_i = \beta(E^i|\ I_1) = \beta[v_i; P(v), N|\ I_1] = (N - 1)\ v_i|N$ (see the entry on auctions (experiments) for a more complete discussion).

With the above framework it is possible to explicate the roles of theory and experiment, and their relationship, in a progressive research programme (Lakatos 1978) of economic analysis. But to do this we must first ask two questions:

(1) 'Which of the elements of a microeconomic system are not observable?' The nonobservable elements are (i) preferences, (ii) knowledge endowments, and (iii) agent message behaviour, $\beta(E^i|\ I)$. Even if messages are available and recorded, we still cannot observe message behaviour functions because we cannot observe, or vary, preferences. The best we can do with field observations of outcomes is to interpret them in terms of models based on assumptions about preferences (Cobb- Douglas, constant elasticity of substitution, homothetic), knowledge (complete, incomplete, common), and behaviour (cooperative, noncooperative). Any 'tests' of such models must necessarily be joint tests of all of these unobservable elements. More often the econometric exercise is parameter estimation, which is conditional upon these same elements.

(2) 'What would we like to know?' We would like to know enough about how agents' behaviour is affected by alternative environments and institutions so that we can classify them according to the mapping they provide into outcomes. Do some institutions yield Pareto optimal outcomes, and/or stable prices, and, if so, are the results robust with respect to alternative environments?

These two questions together tell us that what we want to know is inaccessible in natural experiments (field data) because key elements of the equation are unobservable and/or cannot be controlled. If laboratory experiments are to help us learn what we want to know, certain precepts that constitute proposed sufficient conditions for a valid controlled microeconomic experiment must be satisfied:

(1) *Non-satiation* (or monotonicity of reward). Subject agents strictly prefer any increase in the reward medium, π; that is $U_i(\pi_i)$ is monotone increasing for all i.
(2) *Saliency.* Agents have the unqualified right to claim rewards that increase (decrease) in the good (bad) outcomes, x_i, in an experiment; the institution of an experiment renders these rewards salient by defining outcomes in terms of the message choices of agents.

In both the field and the laboratory it is the institution that induces value on messages, given each agent's (subjective) value of commodity outcomes. In the laboratory we use a monetary reward function to induce utility value on the abstract accounting outcomes ('commodities') of an experiment. Thus, agent i is given a concave schedule, $v_i(x_i)$, defining the 'redemption value' in dollars for x_i units purchased in an experimental market, and is assured of receiving a net payment equal to $v_i(x_i)$ less the purchase prices of the x_i units in the market. If the x_i units are all purchased at price p (which is the assumption used to derive a hypothetical demand schedule) the agent is paid $\pi_i = V_i(x_i) - px_i$, with utility $u^i(x_i) = U_i(\pi_i(x_i))$. In defining demand it is assumed that the agent directly chooses x_i (that is $x_i = m_i$). Therefore, if i maximizes $u^i(x_i) = U_i[V_i(x_i) - px_i]$, then at a maximum we have $U_i'\left[V_i'(x_i) - p\right] = 0$, giving the demand function $x_i = V_i'^{(-1)}(p)$ if $U_i' > 0$, where $V_i'^{(-1)}$ is the inverse of i's marginal redemption value of x_i units. (The same procedure for a seller using a cost function $C_j(x_j)$ and paying $px_j - C_j(x_j)$ allows one to induce a marginal cost supply of j.) This illustration generalizes easily: if the joint redemption value is $V_i(x_i, y_i)$ for two abstract commodities (x_i, y_i) , $u^i = U_i[V^i(x_i, y_i)]$ induces an indifference map given by the level curves of $V^i(x_i, y_i)$, on (x_i, y_i), with marginal rate of substitution $U_i'V_x^i/U_i'V_y^i = V_x^i/V_y^i$, if $U_i' > 0$. if $V^i(x_i, X)$ the reward function, with x_i a private and X a common (public) outcome good, we are able to control preferences in the study of public good allocation mechanisms, or if

$$X = \sum_{i=1}^{N} x_i$$

we are poised to study allocation with an 'atmospheric' externality (Coursey and Smith 1985).

The first two precepts are sufficient to allow us to assert that we have created a microeconomic system $S = (E, I)$ in the laboratory. But to assure that we have created a controlled microeconomy, we need two additional precepts:

(3) *Dominance*. Own rewards dominate any subjective costs of transacting (or other motivation) in the experimental market.

As with any person, subject agents may have variables other than money in their utility functions. In particular, if there is cognitive and kinesthetic (observe the traders on a Stock Exchange floor) disutility associated with the message-transaction process of the institution, then utility might be better written $U_i(\pi_i, m^i)$. To the extent that this is so we induce a smaller demand on i with the payoff $v_i(x_i)$ than was computed above, and we lose control over preferences. As a practical matter experimentalists think the problem can usually be finessed by using rewards that are large relative to the complexity of the task, and by adopting experimental procedures that reduce complexity (e.g. using the computer to record decisions, perform needed calculations, provide perfect recall, etc.). Another approach, as noted in section "Markets and Market Experiments", is to pay a small commission for each trade to compensate for the subjective transaction costs.

(4) *Privacy*. The subjects in an experiment each receive information only on his/ her own reward schedule.

This precept is used to provide control over interpersonal utilities (payoff externalities). Real people may experience negative or positive utilities from the rewards of others, and to the extent that this occurs we lose control over induced demand, supply and preference functions. Remember that the reward functions have the same role in an experiment that preference functions have in the economy, and the latter preferences are private and non-observable.

If our interest is confined to testing hypotheses from theory, we are done. Precepts (1)–(4) are sufficient to provide rigorous tests of the theorist's ability to model individual and market behaviour. But one naturally asks if replicable results from the laboratory are transferable to field environments. This requires:

(5) *Parallelism*. Propositions about behaviour and/or the performance of institutions that have been tested in one microeconomy (laboratory or field) apply also to other microeconomies (laboratory or field) where similar *ceteris paribus* conditions hold.

Astronomy, meteorology, biology and other sciences use the maintained hypothesis that the same physical laws hold everywhere. Economics postulates that when the environment and institution are the same, behaviour will be the same; that is, behaviour is determined by a relatively austere subset of life's parameters. Whether this is 'true' is an empirical question. Hence, when one experimentalist studies variations on the treatment variables of another it is customary to replicate the earlier work to check parallelism. Similarly, one must design field experiments, or devise econometric models using non-experimental field data, that provide tests of the transferability of experimental results to any particular market in the field. Only in this way can questions of parallelism be answered. They are not answered with speculations about alleged differences between the experimental subject's behaviour and (undefined) 'real world' behaviour. The experimental laboratory *is* a real world, with real people, real institutions, real payoffs and commodities just as real as stock certificates and airline travel vouchers, both of which have utility because of the claim rights they legally bestow on the bearer.

Classifying the Application of Experimental Methods

There are many types of experiments and many fields of economic study to which experimental methods have been applied.

The experimental study of auctions makes the most extensive use of models of individual behaviour based explicitly on the message requirements of the different institutions. This literature provides test comparisons of predicted behaviour, $m^i = \beta^i(E_i|\, I)$, with observations on individual choice, $\hat{m}^i = \beta^i\left(\hat{E}^i \,|\, I\right)$, for given realizations,

$\hat{E}^i$ (such as values, $\hat{v}^i$ where they are assigned at random). The large literature on experimental double auctions makes no such individual comparisons, because the theoretical literature had not yielded tractable models of individual bid- offer behaviour (but recent contributions by Friedman (1984), and Wilson (1984) are providing such models). Here as in most other areas of experimental research the comparisons are between the predicted price–quantity outcomes of static theory (such as competitive, monopoly, and Cournot models), and observed outcomes. But double auctions have been studied (see references in Smith 1982) in a variety of environments; for example, the effect of price floors and ceilings have been examined (see references in Plott 1982). In all cases these studies are making comparisons. In *nomotheoretical* experiments one compares theory and observation, whereas in *nomoempirical* experiments one compares the effect of different institutions and/or environments as a means of documenting replicable empirical 'laws' that may stimulate modelling energy in new directions. The idea that formal theory must precede meaningful observation does not account for most of the historical development of science. *Heuristic* or exploratory experiments that provide empirical probes of new topics and new experimental methods should not be discouraged.

In industrial organization, and antitrust economics, experimental methods have been applied to examine the effects of monopoly, conspiracy, and alleged anticompetitive practices, and to study the concept of natural monopoly and its relation to scale economics, entry cost and the contestable markets hypothesis (see references in Plott 1982; Smith 1982; Coursey et al. 1984).

An important development in the experimental study of allocation processes has been the extension of experimental market methods to majority rule (and other) committee processes, and to market-like group processes for the provision of goods which have public or common outcome characteristics (loosely, public goods). These studies have examined public good allocation under majority (and Roberts') rules for committee including the effect of the agenda (see the references to Fiorina and Plott, and Levine and Plott in Smith 1982), and under compensated unanimity processes suggested by theorists (see the references in Coursey and Smith 1985). Generally, this literature reports substantial experimental support for the theory of majority rule outcomes, the theory of agenda processes (the sequencing of issues for voting decisions), and for incentive compatible models of the provision of public goods.

Experimental Methods in Economics (ii)

Vernon L. Smith

Historically, the method and subject matter of economics have presupposed that it was a non-experimental (or 'field observational') science more like astronomy or meteorology than physics or chemistry. Based on general, introspectively 'plausible', assumptions about human preferences, and about the cost and technology based supply response of producers, economists have sought to understand the functioning of economies, using observations generated by economic outcomes realized over time. The data of the astronomer is of this same type, but it would be wrong to conclude that astronomy and economics are methodologically equivalent. There are two important differences between astronomy and economics which help to illuminate some of the methodological problems of economics. First, based upon parallelism (the maintained hypothesis that the same physical laws hold everywhere), astronomy draws on all the relevant theory from classical mechanics and particle physics – theory which has evolved under rigorous laboratory tests. Traditionally, economists have not had an analogous body of tested behavioural principles that have survived controlled experimental tests, and which can be assumed to apply with insignificant error to the microeconomic behaviour that underpins the observable operations of the economy. Analogously, one might have supposed that there would have arisen an important area of common interest between economics and, say, experimental psychology, similar to that between astronomy and physics, but this has only started to develop in recent years.

Second, the data of astronomy are painstakingly gathered by professional observational astronomers for scientific purposes, and these data are taken seriously (if not always non-controversially) by astrophysicists and cosmologists. Most of the data of economics has been collected by government or private agencies for non-scientific purposes. Hence astronomers are directly responsible for the scientific credibility of their data in a way that economists have not been. In economics, when things appear not to turn out as expected the quality of the data is more likely to be questioned than the relevance and quality of the abstract reasoning. Old theories fade away, not from the weight of falsifying evidence that catalyses theoretical creativity into developing better theory, but from lack of interest, as intellectual energy is attracted to the development of new techniques and to the solution of new puzzles that remain untested.

At approximately the mid–20th century, professional economics began to change with the introduction of the laboratory experiment into economic method. In this embryonic research programme economists (and a psychologist, Sidney Siegel) became directly involved in the design and conduct of experiments to examine propositions implied by economic theories of markets. For the first time this made it possible to introduce

demonstrable knowledge into the economist's attempt to understand markets.

This laboratory approach to economics also brought to the economist direct responsibility for an important source of scientific data generated by controlled processes that can be replicated by other experimentalists. This development invited economic theorists to submit to a new discipline, but also brought an important new discipline and new standards of rigour to the data gathering process itself.

An untested theory is simply a hypothesis. As such it is part of our *self*-knowledge. Science seeks to expand our knowledge of *things* by a process of testing this type of self-knowledge. Much of economic theory can be called, appropriately, 'ecclesiastical theory'; it is accepted (or rejected) on the basis of authority, tradition, or opinion about assumptions, rather than on the basis of having survived a rigorous falsification process that can be replicated.

Interest in the replicability of scientific research stems from a desire to answer the question 'Do you see what I see?'. Replication and control are the two primary means by which we attempt to reduce the error in our common knowledge of economic processes. However, the question 'Do you see what I see?' contains three component questions, recognition of which helps to identify three different senses in which a research study may fail to be replicable:

1. *Do you observe what I observe?* Since economics has traditionally been confined to the analysis of non-experimental data, the answer to this question has been trivially, 'yes'. We observe the same thing because we use the same data. This non-replicability of our traditional data sources has helped to motivate some to turn increasingly to experimental methods. We can say that you have replicated my experiments if you are unable to reject the hypothesis that your experimental data came from the same population as mine. This means that the experimenter, his/her subjects, and/or procedures are not significant treatment variables.
2. *Do you interpret what we observe as I interpret it?* Given that we both observe the same, or replicable data, do we put the same interpretation on these data? The interpretation of observations requires theory (either formal or informal), or at least an empirical interpretation of the theory in the context that generated the data. Theory usually requires empirical interpretation either because (i) the theory is not developed directly in terms of what can be observed (e.g. the theory may assume risk aversion which is not directly observable), or (ii) the data were not collected for the purpose of testing, or estimating the parameters of a theory. Consequently, failure to replicate may be due to differences in interpretation which result from different meanings being ascribed to the theory. Thus two researchers may apply different transformations to raw field data (e.g. different adjustments for the effect of taxes), so that the results are not replicable because their theory interpretations differ.
3. *Do you conclude what I conclude from our interpretation?* The conclusions reached in two different research studies may be different even though the data and their interpretation are the same. In economics this is most often due to different model specifications. This problem is inherent in non-experimental methodologies in which, at best, one usually can estimate only the parameters of a prespecified model and cannot credibly test one model or theory against another. An example is the question of whether the Phillips' curve constitutes a behavioural trade-off between the rates of inflation and unemployment, or represents an equilibrium association without causal significance.

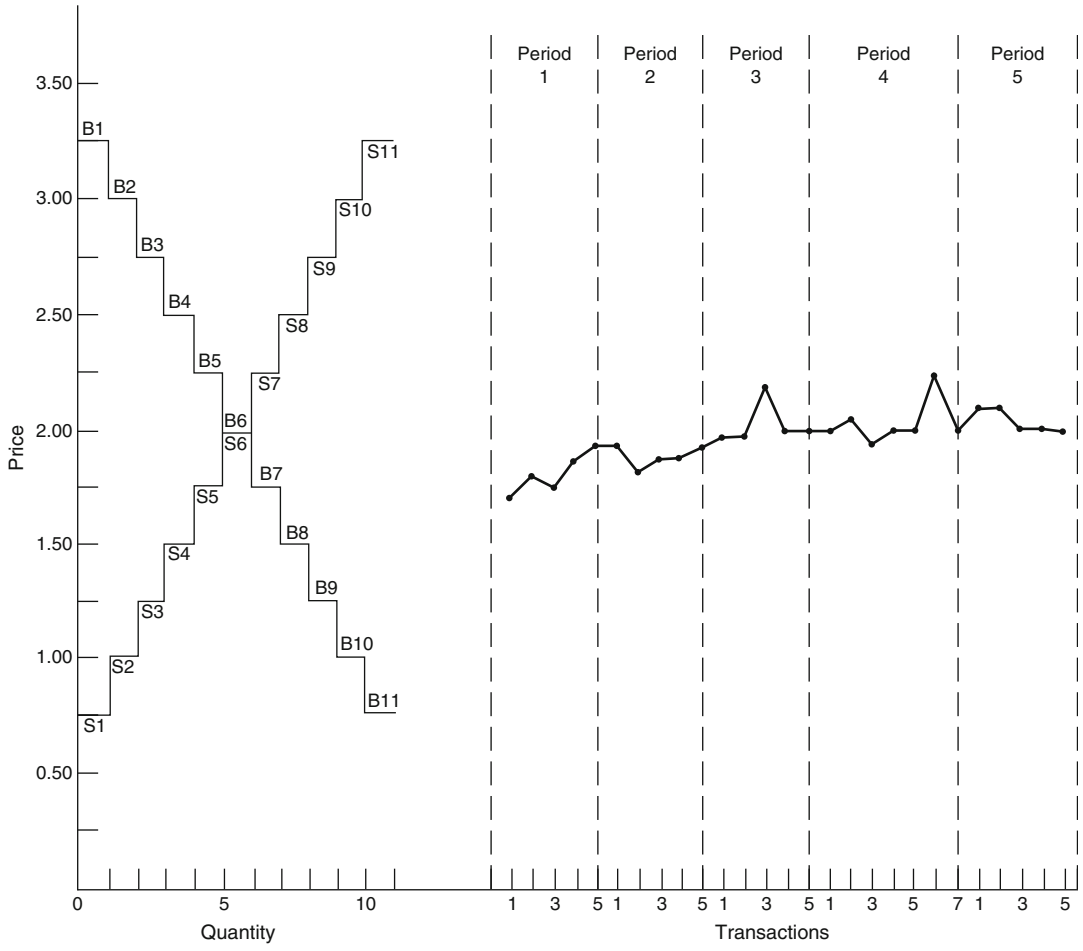
Markets and Market Experiments

Markets and how they function constitute the core of any economic system, whether it is highly decentralized – popularly, a 'capitalistic' system, or highly centralized – popularly, a 'planned' system. This is true for the decentralized economy because markets are the spontaneous institutions of exchange that use prices to guide resource allocation and human economic action. It is true for the centralized economy because in such

economies markets always exist or arise in legal form (private agriculture in Russia) and clandestine or illegal form (barter, bribery, the trading of favours, and underground exchange in Russia, Poland and elsewhere). Markets arise spontaneously in all cultures in response to the human desire for betterment (to 'profit') through exchange. Where the commodity or service is illegal (prostitution, gambling, the sale of liquor under Prohibition or of marijuana, cocaine, etc.) the result is not to prevent exchange, but to raise the risk and therefore the costs of exchange. This is because enforcement is itself costly, and it is never economical for the authorities (whether Soviet or American) even to approximate perfect enforcement. The spontaneity with which markets arise is perhaps no better illustrated than when (1979–1980) US airlines for promotional purposes issued travel vouchers to their passengers. One of these vouchers could be redeemed by the bearer as a cash substitute in the purchase of new airline tickets. Consequently vouchers were of value to future passengers. Furthermore, since (as Hayek would say) the 'circumstances of time and place' for the potential redemption of vouchers were different for different individuals, there existed the preconditions for the active voucher market that was soon observed in all busy airports. Current passengers with vouchers who were unlikely to be travelling again soon held an asset worth less to themselves than to others who were more certain of their future or impending travel plans. The resulting market established prices that were discounts from the redemption or 'face' value of vouchers. Sellers who were unlikely to be able to redeem their vouchers preferred to sell them at a discount for cash. Buyers who were reasonably sure of their travel plans could save money by purchasing vouchers at a discount. Thus the welfare of every active buyer and seller increased via this market. Without a market, many – perhaps most – vouchers would not have been exercised and would thus have been 'wasted'.

The previous paragraph illustrates a fundamental hypothesis (theorem) of economics: the ('competitive') market process yields welfare improving (and, under certain limiting ideal conditions, welfare maximizing) outcomes. But is the hypothesis 'true', or at least very probably true? (Lakatos (1978) would correctly ask 'Has it led to an empirically progressive research programme?') I think it is 'true', but how do I know this? Do you see what I see? A Marxist does not see what I see in the above interpretation of a market. The young student studying economics does not see what I see, although if they continue to study economics eventually they (predictably) come to see what I see (or, at least, they say they do). Is this because we have inadvertently brainwashed them? The gasoline consumer does not see what I see. They see themselves in a *zero* sum game with an oil company: any increase in price merely redistributes wealth from the consumer to the company, which is not 'fair' since the company is richer. What I see in a market is a *positive* sum game yielding gains from exchange, which constitutes the fundamental mechanism for creating, not merely redistributing wealth. The traditional method by which the economist gets others to see this 'true' function of markets is by logical arguments (suppose it were not true, then . . .), examples, and 'observations', such as are contained in my description of the voucher market, in which what is 'observed' is hortatively described and interpreted in terms of the hypothesis itself. But if this knowledge of the function of markets is 'true', can it be demonstrated? Experimentalists claim that laboratory experiments can provide a uniquely important technique of demonstration for supplementing the theoretical interpretation of field observations.

I conducted my first experiment in the spring of 1956. Since then hundreds of similar, as well as environmentally richer experiments have been conducted by myself and by others. In 1956, my introductory economics class consisted of 22 science and engineering students, and although this might not have been the 'large number' traditionally thought to have been necessary to yield a competitive market, I though it was large enough for a practice run to initiate a research programme capable of falsifying the standard theory. I conducted the experiment before lecturing on the theory and 'behaviour' of markets in class so as not to 'contaminate' the sample. The 22 subjects



Experimental Methods in Economics (ii), Fig. 1

were each assigned one card from a well-shuffled deck of 11 white and 11 yellow cards. The white cards identified the sellers, and the yellow cards identified the buyers. Each white card carried a price, known only to that seller, which represented that seller's minimum selling price for one unit, and each yellow card identified a price, known only to that buyer, representing that buyer's maximum buying price for one unit. On the left of Fig. 1 is listed these so-called 'limit' prices, identified by buyer, B1, B2 etc. (in descending order, D) and by seller, S1, S2 etc. (in ascending order, S). To keep things simple and well controlled each buyer (seller) was informed that he/she was a buyer (seller) of at most one unit of the item in each of several trading periods. Thus demand, D(supply, S) was 'renewed' in each trading period as a steady state flow, with no carry-over in unsatisfied demand (or unsold stock), from one period to the next. In the airline voucher example, imagine the vouchers being issued, followed by trading; the vouchers then expire, new vouchers are issued, traded and so on. In the experiment, suppose real motivation is provided by promising to pay (in cash) to each buyer the difference between that buyer's assigned limit buying price and the price actually paid in each period that a unit is purchased in the market. Thus suppose seller 5 sells their unit to buyer 2 at the price 2.25. Then buyer 2 earns a 'profit' of $0.75 from this exchange. In this way we induce on each buyer a value (or hypothesized

willingness-to-pay) equal to the assigned limit buy price. Similarly, suppose each seller is paid the difference between that seller's actual sales price and assigned limit price ('cost', or willingness-to-sell) in each trading period that a unit is sold. Thus in the previous exchange example, seller 5 earns \$0.50 from the transaction.

This experimental procedure operationalizes the market preconditions that (1) 'the circumstances of time and place' for each economic agent are dispersed and known only to that agent (as in the above voucher market) and (2) agents have a secure property right in the objects of trade and the private gains ('profits') from trade (an airline travel voucher was transferable and redeemable by any bearer). The reader should note that 'profit' is identified as much with the act of buying as with that of selling. This is because 'profit' is the surplus earned by a buyer who buys for less than his willingness-to-pay, just as a seller's 'profit' is the surplus earned when an item is sold for more than the amount for which they are willing to sell. Willingness-to-sell need not have, and usually does not have anything to do with accounting 'cost', or production 'cost', from which one computes accounting profit. Willingness-to-sell, like willingness-to-buy, is determined by the immediate circumstances of each agent. Hence, a passenger might be prepared to pay the regular full fare premium on a first-class ticket for an emergency trip to visit a sick relative. The accountant's concept of profit cannot be applied to the passenger's decision any more than it can be applied to that of a passenger willing to sell a voucher at a deep discount. In what follows I will use the term 'buyer's surplus' or 'seller's surplus' instead of 'profit' to refer to the gains from exchange enjoyed by buyers or sellers because the term 'profit' is so strongly, exclusively and misleadingly associated with selling activities.

Now let us interpret the previously cited fundamental theorem of economics in the context of the experimental design contained in Fig. 1. We note first that the ordered set of seller (buyer) limit prices defines a supply (demand) function (Fig. 1). A supply (demand) function provides a list of the total quantities that sellers (buyers) would be willing to sell (buy) at corresponding hypothetical fixed prices. Neither of these functions is capable of being observed, scientifically, in the field. This is because the postulated limit prices are inherently private and not publicly observable. We could poll every potential seller (buyer) of vouchers in Chicago's O'Hare airport on 20 December 1979 to get each person's reported limit price, but we would have no way of validating the 'observations' thus obtained. Referring to Fig. 1, we see that in my 1956 experiment, sellers (hypothetically) were just willing to sell three units at price 1.25, nine units at 2.75 and so on. Similarly buyers (hypothetically) were just willing to buy four units at 2.50, seven units at 1.75 and so on. If seller 3 is indifferent between selling and not selling at 1.25, and if every seller (buyer) is likewise indifferent at his/her limit price, then any particular unit may not be sold (purchased) at this limit price. One means of dealing with this problem in laboratory markets is to promise to pay a small 'commission', say 5 cents, to each buyer and seller for each unit bought or sold. Thus seller 3 has a small inducement to sell at 1.25 if he can do no better, and buyer 6 has a small inducement to buy at 2.00 if she can do no better.

Economic theory defines the competitive equilibrium as the price and corresponding quantity that clears the market; that is, it sets the quantity that sellers are willing to sell equal to the quantity that buyers are willing to buy. This assumes that the subjective cost of transacting is zero; otherwise any units with limit prices equal to the competitive equilibrium price will not exchange. In Fig. 1 this competitive equilibrium price is 2.00. If the 5 cent 'commission' paid to each trading buyer and seller is sufficient to compensate for any subjective cost of transacting, then buyer 6 and seller 6 will each trade and the competitive equilibrium quantity exchanged will be 6 units. At the competitive equilibrium price, buyer 1 earns a surplus of $3.25 - 2.00 = 1.25$ (plus commission) per period and so on. Total surplus, which measures the maximum possible gains from exchange, or maximum wealth *created* by the existence of the market institution, is 7.50 per period, at the competitive equilibrium.

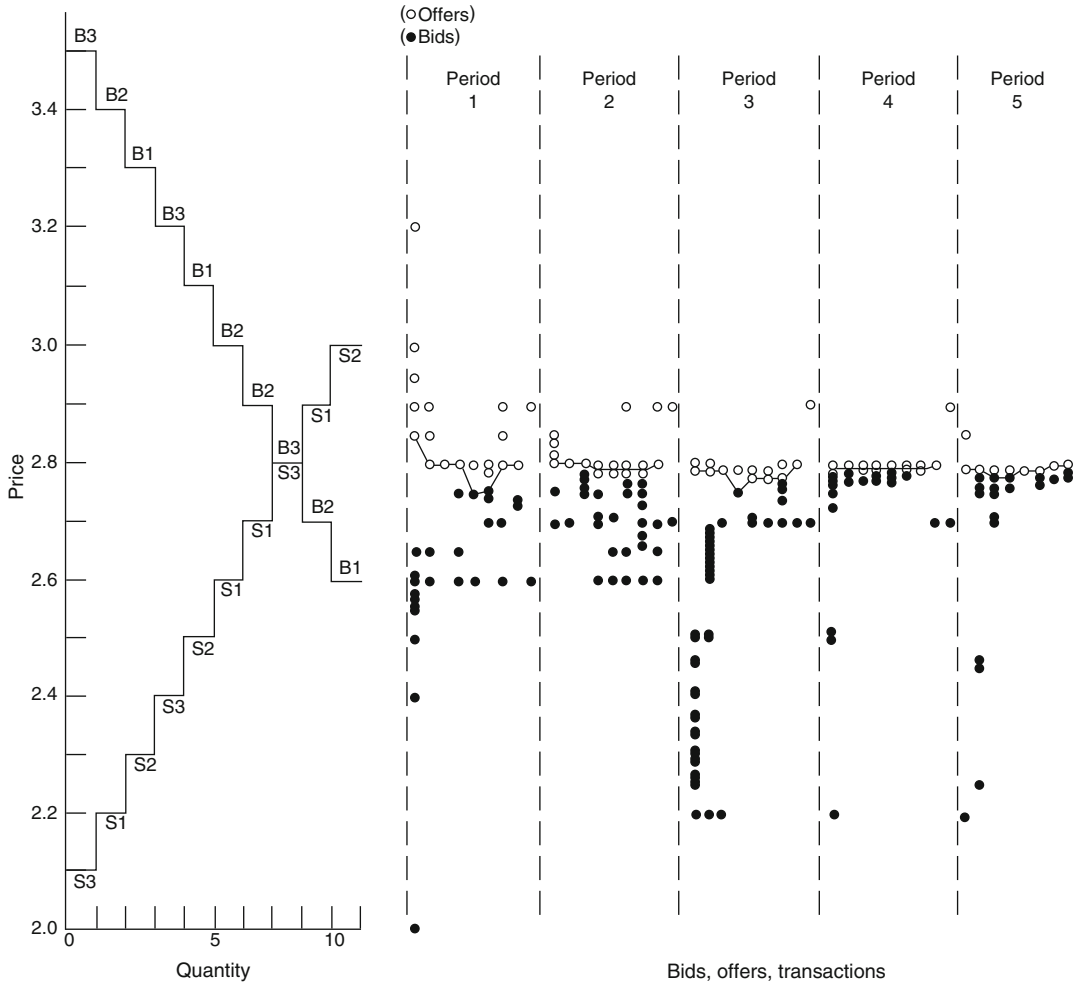
If by some miracle the competitive equilibrium price and exchange quantity were to prevail in this market, sellers 1–6 would sell, buyers 1–6 would buy, while sellers 7–11 would make no sales and buyers 7–11 would make no purchases. It might be thought that this is unfair – the market should permit some or all of the 'submarginal' buyers (sellers) 7–11 to trade – or that more wealth would be created if there were more than six exchanges. But these interpretations are wrong. By definition, buyer 10 is not willing to pay more than 1.00. Consequently, it is a peculiar notion of fairness to argue that buyer 10 should have as much priority as buyer 1 in obtaining a unit. In the airline voucher example, this would mean that a buyer who is unlikely to redeem a voucher should have the same priority as a buyer who is likely to redeem a voucher. One can imagine a market in which, say, buyer 1 is paired with seller 9 at price 3.00, buyer 2 with seller 8 at price 2.75, and so on with nine units traded. If this were to occur it would mean buyers 7–9, who are less likely to use vouchers, have purchased them, and sellers 7–9, who initially held vouchers, and were more likely to use them than buyers 7–9, have sold their vouchers. Furthermore, this allocation yields additional possible gains from exchange, and is thus *not sustainable*, even if it were thought to be desirable. That is, buyer 9, who bought from seller 1 at price 1.00, could resell the unit to seller 9 (who sold her unit to buyer 2), at price (say) 2.00. Why? Because, by definition a voucher is worth 2.75 to seller 9 and only 1.25 to buyer 9. Similar additional trades can be made by buyers (sellers) 7 and 8. The end result would be that buyers 1–6 and sellers 7–11 would be the terminal holders of vouchers, just as if the competitive equilibrium had been reached initially.

Hence, either the competitive equilibrium prevails, or if inefficient trades occur at dispersed prices, then further 'speculative' gains can be made by some buyers and sellers. If these gains are fully captured the end result is the same allocation as would occur at the competitive equilibrium price and quantity.

Having specified the environment (individual private values) of our experimental market, what remains is to specify an exchange institution. In my 1956 experiment I elected to use trading rules similar to those that characterize trading on the organized stock and commodity exchanges. These markets use the 'double oral auction' procedure. In this institution as soon as the market 'opens' any buyer is free to announce a bid to buy and any seller is free to announce an offer to sell. In the experimental version each bid (offer) is for a single unit. Thus a buyer might say 'buy, 1.00', while a seller might say 'sell, 5.00', and it is understood that the buyer bids 1.00 for a unit and the seller offers to sell one unit for 5.00. Bids and offers are freely announced and can be modified. A contract occurs if any seller accepts the bid of any buyer, or any buyer accepts the offer of any seller. In the simple experimental market, since each participant is a buyer or seller of at most one unit per trading period, the contracting buyer and seller drop out of the market for the remainder of the trading period, but return to the market when a new trading 'day' begins. The experimenter announces the close of each trading period and the opening of the subsequent period, with each trading period timed to extend, say, five minutes. Each contract price is plotted on the right of Fig. 1 for the five trading periods of the experiment. This result was not as expected. The conventional view among economists was that a competitive equilibrium was like a frictionless ideal state which could not be conceived as actually occurring, even approximately. It could be conceived of occurring only in the presence of an abstract 'institution' such as a Walrasian *tâtonnement* or an Edgeworth recontracting procedure. It was for teaching, not believing.

From Fig. 1 it is evident that in the strict sense the competitive equilibrium was not attained in any period, but the accuracy of the competitive equilibrium theory is easily comparable to that of countless physical processes. Certainly, the data clearly do not support the monopoly, or seller collusion model. The total return to sellers is maximized when four units are sold at price 2.50. Similarly, the monopsony, or buyer collusion model requires four units to exchange at price 1.50.

Since 1956, several hundred experiments using different supply and demand conditions,



Experimental Methods in Economics (ii), Fig. 2

experienced as well as inexperienced subjects, buyers and sellers with multiple unit trading capacity, a great variation in the numbers of buyers and sellers, and different trading institutions, have established the replicability and robustness of these results. For many years at the University of Arizona and Indiana University we have been using various computerized (the PLATO system) versions of the double 'oral' auction, developed by Arlington Williams, in which participating subjects trade with each other through computer terminals. These experiments establish that the 1956 results are robust with respect to substantial reductions in the number of buyers and sellers. Most such experiments use only four buyers and four sellers, each capable of trading several units. Some have used only two sellers, yet the competitive equilibrium model performs very well under double auction rules. Figure 2 shows the supply and demand design and the market results for a typical experiment in which subjects trade through PLATO computer terminals under computer-monitored double auction rules.

In addition to its antiquarian value, Fig. 1 illustrates the problem of monitoring the rules of a 'manual' experiment. Observe that in period 4 there were seven contracts which are recorded as occurring in the price range between $1.90 and $2.25. This is not possible since there are only six

buyers with limit buy prices above $1.90. Either a buyer violated his budget constraint, or the experimenter erred in recording a price in his first experiment. In Fig. 2 there is plotted each contract (an accepted bid if the contract line passes through a 'dot'; an accepted offer if the line passes through a 'circle') and the bids ('dots') and offers ('circles') that preceded each accepted bid or offer. One of the several advantages of computerized experimental markets is that the complete data of the market (all bids, offers, and contracts at their time of execution) are recorded accurately and non-invasively, and all experimental rules are enforced perfectly. In particular the violation of a budget constraint revealed in Fig. 1, which is a perpetual problem with manually executed experiments, is not a problem when trading is perfectly computer monitored.

The rapid convergence shown in Figs. 1 and 2 has not always extended to trading institutions other than the double auction. For example, the 'posted offer' pricing mechanism (associated with most retail markets), in which sellers post take it or leave it non-negotiable prices at the beginning of each period, yields higher prices and less efficient allocations than the double auction. This difference in performance becomes smaller with experienced subjects and with longer trading sequences in a given experiment (Ketcham et al. 1984). Similarly, a comparison of double auction with a sealed bid-offer auction finds the latter to be less efficient and to deviate more from the competitive equilibrium predictions (Smith et al. 1982). Thus, institutions have been demonstrated to make a difference in what we observe. The data and analysis strongly suggest that institutions make a difference because the rules (legal environment) make a difference, and the rules make a difference because they affect individual incentives.

Brief Interpretive History of the Development of Experimental Economics

The two most influential early experimental studies represent the two most primary poles of experimental economics: the study of individual preference (choice) under uncertainty (Mosteller and Nogee 1951) and of market behaviour (Chamberlin 1948). The investigation of uncertainty and preference has focused on the testing of von Neumann–Morgenstern–Savage subjective expected utility theory. Battalio, Kagel and others have pioneered in the testing of the Slutsky–Hicks commodity demand and labour supply preferences using humans (1973) and animals (1975). A series of large-scale field experiments in the 1970s extended the experimental study of individual preference to the measurement of the effect of the negative income tax and other factors on labour supply and to the measurement of the demand for electricity, housing and medical services.

Since the human species has been observed to participate in market exchange for thousands of years, the experimental study of market behaviour is central to economics. Preferences are not directly observable, but preference theory, as an abstract construct, has been *postulated* by economists to be fundamental to the explanation and understanding of market behaviour. In this sense the experimental study of group market behaviour depends upon the study of individual preference behaviour. But this intellectual history should not obscure the fact that the study of markets and the study of preferences need not be construed as inseparable. Adam Smith clearly viewed the human 'propensity to truck, barter and exchange' (and *not* the existence of human preferences) as axiomatic to the scientific study of economic behaviour. Obversely, the work of Battalio and Kagel showing that animals behave as if they had Slutsky–Hicks preferences makes it plain that substitution behaviour is an important cross species characteristic, but that such phenomena need not be associated with market exchange.

A significant feature of Chamberlin's (1948) original work is that it concerned the study of behaviourally complete markets; that is all trades, including purchases as well as sales, were executed by active subject agents. This feature has continued in the subsequent bilateral bargaining experiments of Siegel and Fouraker (1960) and in market experiments (Smith 1962, 1982; Williams and Smith 1984) such as those discussed in

section, "Markets and Market Experiments". This feature was not present in the early and subsequent experimental oligopoly literature (Hoggatt 1959; Sauermann and Selten 1959; Shubik 1962; Friedman 1963), in which the demand behaviour of buyers was simulated, that is, programmed from a specified demand function conditional on the prices selected in each 'trading' period by the sellers. This simulation of demand behaviour is justified as an intermediate step in testing models of seller price behaviour that assume passive, simple maximizing, demand-revelation behaviour by buyers. But the conclusions of such experimental studies should not be assumed to be applicable, even provisionally, to any observed complete market without first showing that the experimental results are robust with respect to the substitution of subject buyers for simulated buyers.

The Functions of Market Experiments in Microeconomic Analysis

A conceptual framework for clarifying some uses and functions of experiments in microeconomics can be articulated by suitable modification and adaptation (Smith 1982) of the concepts underlying the adjustment process, as in the welfare economics literature (see references to Hurwicz and Reiter in Smith 1982). In this literature a microeconomic environment consists of a list of agents $\{1, \ldots, N\}$, a list of commodities and resources $\{1, \ldots, K\}$, and certain characteristics of each agent i, such as the agent's preferences (utility) u_i, technological (knowledge) endowment T^i, and commodity endowment w_i. Thus agent i is defined by the triplet of characteristics $E^i = (u^i, T^i, w^i)$ defined on the K-dimensional commodity space. A microeconomic *environment* is defined by the collection $E = (E^1, \ldots, E^N)$ of these characteristics. This collection represents a set of primitive circumstances that condition agents' interaction through institutions. The superscript i, besides identifying a particular agent, also means that these primitive circumstances are in their *nature* private: it is the individual who likes, works, knows and makes.

There can be no such thing as a credible institution-free economics. Institutions define the property right rules by which agents communicate and exchange or transform commodities within the limits and opportunities inherent in the environment, E. Since markets require communication to effect exchange, property rights in messages are as important as property rights in goods and ideas. An institution specifies a language, $M = (M^1, \ldots, M^N)$, consisting of message elements $m = (m^1, \ldots, m^N)$, where M^i is the set of messages that can be sent by agent i (for example, the range of bids that can be sent by a buyer). An institution also defines a set of allocation rules $h = (h^1(m),\ldots, h^N(m))$ and a set of cost imputation rules $c = (c^1(m), \ldots, c^N(m))$, where h^i(m) is the commodity allocation to agent i and $c^i(m)$ is the payment to be made by i, each as a function of the messages sent by all agents. Finally, the institution defines a set of adjustment process rules (assumed to be common to all agents), $g(t_0, t, T)$, consisting of a starting rule, $g(t_0, \cdot, \cdot)$, a transition rule, $g(\cdot, t, \cdot)$, governing the sequencing of messages, and a stopping rule, $g(\cdot, \cdot, T)$, which terminates the exchange of messages and triggers the allocation and cost imputation rules. Each agent's property rights in communication and exchange is thus defined by $I^i = (M^i, h^i(m), c^i(m), g(t_0, t, T))$. A microeconomic *institution* is defined by the collection of these individual property right characteristics, $I = (I^1,\ldots,I^N)$.

A microeconomic *system* is defined by the conjunction of an environment and an institution, $S = (E, I)$. To illustrate a microeconomic system, consider an auction for a single indivisible object such as a painting or an antique vase. Let each of N agents place an independent, certain, monetary value on the item $v_1, \ldots, v_N$, with agent i knowing his own value, v_i, but having only uncertain (probability distribution) information on the values of others. Thus $E^i = (v^i; P(v), N)$. If the exchange institution is the 'first price' sealed-bid auction, the rules are that all N bidders each submit a single bid any time between the announcement of the auction offering at t_0, and the closing of bids, at T. The item is then awarded to the maker of the highest bid at a price equal to the amount bid. Thus, if the agents are numbered in

descending order of the bids, the first price auction institution $I_1 = (I_1^1 = [h^1(m) = 1, c^1(m) = b_1]$ and $I_1^i = [h^i(m) = 0, c^i(m) = 0], i > 1$, where $m = (b_1, \ldots, b_N)$ consists of all bids tendered. That is, the item is awarded to the high bidder, $i = 1$, who pays b_1, and all others receive and pay nothing. This contrasts with the 'second price' sealed-bid auction $I_2 = (I_2^1, \ldots, I_2^N)$ in which $I_2^1 = [h^i(m) = 1, c^i(m) = b_2]$ and $I_2^2 = [h^i(m) = 0, c^i(m) = 0], i > 1$; that is, the highest bidder receives the allocation but pays a price equal to the second highest bid submitted.

Another example is the English or progressive oral auction, whose rules are discussed under the entry AUCTIONS. It should be noted that the 'double oral' auction, used extensively in stock and commodity trading and in the two experimental markets discussed in section, "Markets and Market Experiments", is a two-sided generalization of the English auction.

A microeconomic system is activated by the behavioural choices of agents in the set M. In the static, or final outcome, description of an economy, agent *behaviour* can be defined as a function (or correspondence) $m^i = \beta^i(E^i|I)$ carrying the characteristics E^i of agent i into a message m^i, conditional upon the property right specifications of the operant institution I. If all exchange-relevant agent characteristics are included in E^i, then $\beta \equiv \beta^i$ for all i. Given the message-sending behaviour of each agent, $\beta(E \mid I)$, the institution determines the outcomes

$$h^i(m) = h^i[\beta E^1 I), \ldots, \beta(E^N I)]$$

and

$$c^i(m) = c^i[\beta E^1|I), \ldots, \beta(E^N|I)].$$

Within this framework we see that agents do not choose allocations directly; agents choose messages with institutions determining allocations under the rules that carry messages into allocations. (You cannot choose to 'buy' an auctioned item; you can only choose to raise the standing bid at an English auction or submit a particular bid in a sealed bid auction.) However, the allocation and cost imputation rules may have important incentive effects on behaviour, and therefore messages will in general depend on these rules. Hence, market outcomes will result from the conjunction of institutions' and agents' behaviour.

A proper theory of agents' behaviour allows one to deduce a particular β function based on assumptions about the agent's environment and the institution, and his motivation to act. Auction theory is perhaps the only part of economic theory that is fully institution specific. For example, in the second price sealed bid auction it is a dominant strategy for each agent simply to bid his or her value; that is

$$b^i = \beta[E^i|I_2) = \beta(v_i|I_2) = v_i, \quad i = 1, \ldots, N.$$

The resulting outcome is that $b_1 = v_1$ is the winning bid and agent 1 pays the price v_2. Similarly, in the English auction, agent 1 will eventually exclude agent 2 by raising the standing bid to v_2 (or somewhat above), and obtain the item at this price. In the first price auction Vickrey proved that if each agent maximizes expected surplus $(v_i - b_i)$ in an environment with $P(v) = v$ (the v_i are drawn from a constant density on [0, 1]), then we can deduce the noncooperative equilibrium bid function, $b_i = \beta(E^i \mid I_1) = \beta[v_i; P(v), N| I_1] = (N - 1)\, v_i|N$ (see the entry on AUCTIONS for a more complete discussion).

With the above framework it is possible to explicate the roles of theory and experiment, and their relationship, in a progressive research programme (Lakatos 1978) of economic analysis. But to do this we must first ask two questions:

1. 'Which of the elements of a microeconomic system are not observable?' The non-observable elements are (i) preferences, (ii) knowledge endowments, and (iii) agent message behaviour, $\beta(E^i|I)$. Even if messages are available and recorded, we still cannot observe message behaviour functions because we cannot observe, or vary, preferences. The best we can do with field observations of outcomes is to interpret them in terms of models

based on assumptions about preferences (Cobb-Douglas, constant elasticity of substitution, homothetic), knowledge (complete, incomplete, common), and behaviour (cooperative, noncooperative). Any 'tests' of such models must necessarily be joint tests of all of these unobservable elements. More often the econometric exercise is parameter estimation, which is conditional upon these same elements.

2. 'What would we like to know?' We would like to know enough about how agents' behaviour is affected by alternative environments and institutions so that we can classify them according to the mapping they provide into outcomes. Do some institutions yield Pareto optimal outcomes, and/or stable prices, and, if so, are the results robust with respect to alternative environments?

These two questions together tell us that what we want to know is inaccessible in natural experiments (field data) because key elements of the equation are unobservable and/or cannot be controlled. If laboratory experiments are to help us learn what we want to know, certain precepts that constitute proposed sufficient conditions for a valid controlled microeconomic experiment must be satisfied:

1. *Non-satiation* (or monotonicity of reward). Subject agents strictly prefer any increase in the reward medium, π ; that is U_i (π_i) is monotone increasing for all i.
2. *Saliency.* Agents have the unqualified right to claim rewards that increase (decrease) in the good (bad) outcomes, x_i, in an experiment; the institution of an experiment renders these rewards salient by defining outcomes in terms of the message choices of agents.

In both the field and the laboratory it is the institution that induces value on messages, given each agent's (subjective) value of commodity outcomes. In the laboratory we use a monetary reward function to induce utility value on the abstract accounting outcomes ('commodities') of an experiment. Thus, agent i is given a concave schedule, $V_i(x_i)$, defining the 'redemption value' in dollars for x_i units purchased in an experimental market, and is assured of receiving a net payment equal to $V_i(x_i)$ less the purchase prices of the x_i units in the market. If the x_i units are all purchased at price p (which is the assumption used to derive a hypothetical demand schedule) the agent is paid $\pi_i = V_i(x_i) - px_i$, with utility $u^i(x) = U(\pi(x_i))$. In defining demand it is assumed that the agent directly chooses x_i (that is $x_i = m_i$). Therefore, if i maximizes $u^i(x_i) = U_i[V_i(x_i) - px]$, then at a maximum we have $U_i' \cdot [V_i'(x_i) - p] = 0$, giving the demand function $x_i = V_i^{'(-1)}(p)$ *if* $U_i' > 0$, where $V_i^{'(-1)}$ is the inverse of i's marginal redemption value of x_i units. (The same procedure for a seller using a cost function $C_j(x_j)$ and paying $px_j - C_j(x_j)$ allows one to induce a marginal cost supply of j.) This illustration generalizes easily: if the joint redemption value is $V_i(x_i, y_i)$ for two abstract commodities (x_i, y_i), $u^i = U_i[V^i(x_i, y_i)]$ induces an indifference map given by the level curves of $V^i(x_i, y_i)$, on (x_i, y_i), with marginal rate of substitution $U_i'V_x^i/U_i'V_y^i = V_x^i/V_y^i$, if $U_i' > 0$. If $Vi(x_i, X)$ the reward function, with x_i a private and X a common (public) outcome good, we are able to control preferences in the study of public good allocation mechanisms, or if

$$X = \sum_{i=1}^{N} x_i$$

we are poised to study allocation with an 'atmospheric' externality (Coursey and Smith 1985).

The first two precepts are sufficient to allow us to assert that we have created a microeconomic sysem $S = (E, I)$ in the laboratory. But to assure that we have created a controlled microeconomy, we need two additional precepts:

3. *Dominance*. Own rewards dominate any subjective costs of transacting (or other motivation) in the experimental market.

As with any person, subject agents may have variables other than money in their utility functions. In particular, if there is cognitive and kinesthetic (observe the traders on a Stock Exchange

floor) disutility associated with the message-transaction process of the institution, then utility might be better written $U_i(\pi_i, m_i)$. To the extent that this is so we induce a smaller demand on i with the payoff $V_i(x_i)$ than was computed above, and we lose control over preferences. As a practical matter experimentalists think the problem can usually be finessed by using rewards that are large relative to the complexity of the task, and by adopting experimental procedures that reduce complexity (e.g. using the computer to record decisions, perform needed calculations, provide perfect recall, etc.). Another approach, as noted in section, "Markets and Market Experiments", is to pay a small commission for each trade to compensate for the subjective transaction costs.

4. *Privacy.* The subjects in an experiment each receive information only on his/her own reward schedule.

This precept is used to provide control over interpersonal utilities (payoff externalities). Real people may experience negative or positive utilities from the rewards of others, and to the extent that this occurs we lose control over induced demand, supply and preference functions. Remember that the reward functions have the same role in an experiment that preference functions have in the economy, and the latter preferences are private and non-observable.

If our interest is confined to testing hypotheses from theory, we are done. Precepts (1)–(4) are sufficient to provide rigorous tests of the theorist's ability to model individual and market behaviour. But one naturally asks if replicable results from the laboratory are transferable to field environments. This requires.

5. *Parallelism*. Propositions about behaviour and/or the performance of institutions that have been tested in one microeconomy (laboratory or field) apply also to other microeconomies (laboratory or field) where similar *ceteris paribus* conditions hold.

Astronomy, meteorology, biology and other sciences use the maintained hypothesis that the same physical laws hold everywhere. Economics postulates that when the environment and institution are the same, behaviour will be the same; that is, behaviour is determined by a relatively austere subset of life's parameters. Whether this is 'true' is an empirical question. Hence, when one experimentalist studies variations on the treatment variables of another it is customary to replicate the earlier work to check parallelism. Similarly, one must design field experiments, or devise econometric models using non-experimental field data, that provide tests of the transferability of experimental results to any particular market in the field. Only in this way can questions of parallelism be answered. They are not answered with speculations about alleged differences between the experimental subject's behaviour and (undefined) 'real world' behaviour. The experimental laboratory *is* a real world, with real people, real institutions, real payoffs and commodities just as real as stock certificates and airline travel vouchers, both of which have utility because of the claim rights they legally bestow on the bearer.

Classifying the Application of Experimental Methods

There are many types of experiments and many fields of economic study to which experimental methods have been applied.

The experimental study of auctions makes the most extensive use of models of individual behaviour based explicitly on the message requirements of the different institutions. This literature provides test comparisons of predicted behaviour, $m^i = \beta(E^i|I)$, with observations on individual choice, $\widehat{m}_i = \beta\left(\widehat{E}_i|I\right)$ for given realizations, $\hat{E}_i$ (such as values, $\widehat{v}_i$, where they are assigned at random). The large literature on experimental double auctions makes no such individual comparisons, because the theoretical literature had not yielded tractable models of individual bid-offer behaviour (but recent contributions by Friedman (1984), and Wilson (1984) are providing such models). Here as in most other areas of experimental research the comparisons are between the

predicted price–quantity outcomes of static theory (such as competitive, monopoly, and Cournot models), and observed outcomes. But double auctions have been studied (see references in Smith 1982) in a variety of environments; for example, the effect of price floors and ceilings have been examined (see references in Plott 1982). In all cases these studies are making comparisons. In *nomotheoretical* experiments one compares theory and observation, whereas in *nomoempirical* experiments one compares the effect of different institutions and/or environments as a means of documenting replicable empirical 'laws' that may stimulate modelling energy in new directions. The idea that formal theory must precede meaningful observation does not account for most of the historical development of science. *Heuristic* or exploratory experiments that provide empirical probes of new topics and new experimental methods should not be discouraged.

In industrial organization, and antitrust economics, experimental methods have been applied to examine the effects of monopoly, conspiracy, and alleged anticompetitive practices, and to study the concept of natural monopoly and its relation to scale economics, entry cost and the contestable markets hypothesis (see references in Plott 1982; Smith 1982; Coursey et al. 1984).

An important development in the experimental study of allocation processes has been the extension of experimental market methods to majority rule (and other) committee processes, and to market-like group processes for the provision of goods which have public or common outcome characteristics (loosely, public goods). These studies have examined public good allocation under majority (and Roberts') rules for committee including the effect of the agenda (see the references to Fiorina and Plott, and Levine and Plott in Smith 1982), and under compensated unanimity processes suggested by theorists (see the references in Coursey and Smith 1985). Generally, this literature reports substantial experimental support for the theory of majority rule outcomes, the theory of agenda processes (the sequencing of issues for voting decisions), and for incentive compatible models of the provision of public goods.

Experimental Methods in Environmental Economics

Jason F. Shogren

Abstract

Experimental methods have long played a role in environmental economics. The strong link emerged due to the need to make decisions within the complex confluences of markets, missing markets, and no markets. Two broad areas of experimental work are discussed, institutional and valuation. Institutional experiments help reveal how good ideas for environmental protection can go badly with poorly understood rules and incentives; valuation experiments help illustrate how values for environmental protection depend on the socialization created, directly or indirectly, by the exchange institutions in operation.

Environmental policy is designed within the confluence of markets, missing markets, and no markets. Within this mixture, economists offer working rules to help make outcomes more efficient, usually based on ideas formed by rational choice theory. The rules ask decision-makers to compare benefits in relation to costs, to account for the risks and gains across time and space for winners and losers, to facilitate the movement of resources from low-value uses to high-value uses, and to equate incremental gains per cost across policy actions. The environmental economic challenge is to find effective decision rules that will help move an economy towards efficient resource allocation in the face of market failure, for example, externalities, non-rival consumption, non-excludable net benefits, nonconvexities and asymmetric information (see Hanley, Shogren and White 2007).

Experimental methods have proven to be a useful tool in addressing this challenge. Environmental economists used experimental methods relatively early on, following the lead of Vernon Smith, Charles Plott and other pioneers. Experimental methods began to take hold in the 1980s, primarily in the area of non-market valuation (see Bohm 1972; Bennett 1983; Knetsch and Sinden 1984; Coursey et al. 1987). Today, experimental economic research is commonplace in environmental economic discussions and research programmes, with data being generated both in the laboratory and field (see for example the research in Cherry et al. 2007). Experiments in this area can be grouped broadly into two categories, *institutional* and *valuation*. Institutional experiments test-bed new institutions such as marketable pollution permits and ambient non-point pollution taxes prior to implementation; valuation experiments use the laboratory or field to study how people value goods and services that are not otherwise bought and sold in markets.

Institutional experiments build on traditional designs to test the efficiency of alternative exchange mechanisms under different economic circumstances. Usually the institutions under examination are those theoretically argued to correct for some market failure. Benefits and costs in these institutional experiments are *induced* by the experimenter – buyers have pre-assigned resale values; sellers have designated induced costs; and the goal is to measure the efficiency of a set of alternative incentive schemes.

In contrast, valuation experiments flip the institutional experiment on its head, using experimental methods to elicit preferences for some particular private or public good given alternative market and non-market circumstances. Here eliciting *homegrown* preferences or values – those residing within the minds of people – is of ultimate interest. Research in value elicitation has been environmental economics' most unique contribution to experimental economics. The work has produced insight into how the framing of a question affects values, how different demand-revealing incentives elicit different values, and how unintentional cues affect a person's value for a good. Consider now a few examples of institutional and valuation experiments used in environmental economics.

Institutional Experiments

Institutional experiments focus on evaluating market and non-market solutions to environmental problems. The key to these institutional experiments rests in the dialogue between the laboratory and potential or actual applications to environmental policy. For decades, environmental policy around the globe has been proposed and implemented in the real world with minimal input from insight gathered using experimental economics methods. Today, however, this is changing. Researchers are now using experiments to help understand and affect policy development, and this link between the laboratory and policy is probably more rigorously explored in environmental economics than any other area (Bohm 2003).

Institutional environmental economic experiments can be categorized as three broad areas – institutions to provide incentives to control externality problems that arise from pollution or land use; institutions to increase the voluntary provision of public goods, such as climate change, or to manage effectively common property, such as fishing zones; and institutions designed to manage resources through negotiation and cooperation, that is, the Coase theorem. We now briefly consider each in turn, starting with early work, moving to current applications, and general principles.

First, experiments examining economic solutions to externality problems began in earnest with Plott's (1983) work on Pigovian taxation. Plott designed a competitive market of buyers and sellers who trade a valuable good. After first establishing that traders ignored negative social costs in a competitive market, he explored whether Pigovian taxes or tradable permits could equate private incentives with social costs. Both increased efficiency with repeated trading periods and quickly hit 100% efficiency. Since then there has been an explosion of work examining incentive systems in a variety of settings, producing a growing and positive dialogue between policy proposals and insight from experimental studies.

Probably the most active area today remains the experimental work that tests the efficiency of tradable permit systems. Experimental methods have evaluated the efficacy of different trading rules in a variety of settings (for example, Bohm and Carlén 1999). An important early example is the US Environmental Protection Agency's Acid Rain emission trading. This work revealed a basic flaw in the original design of the permit auction run by the Environmental Protection Agency (EPA) (see Cason 1995; Cason and Plott 1996). The laboratory results revealed how the EPA could increase the efficiency of the auction by changing how permits were allocated. Originally, buyers and sellers submitted bids and offers for emission permits, and the EPA set the market price discriminatively off the demand curve by first matching the seller with the lowest offer to the buyer with the highest bid. The matching then

continued with the second lowest offer to the second highest bid, and so on, until the equilibrium quantity is reached. Rational sellers should see through this auction, and begin capturing rents by understating their true offer so they would be matched with a high bidder. Cason's laboratory results confirmed this intuition – sellers undercut each other to get into the high end of the market. The end result was an inefficient auction. Such lessons can be profitable, but insight like this should be made available before the regulatory tool is already in place, thus avoiding wasting resources due to inefficient design features. (For another important example comparing alternative trading institutions, see the tests of the RECLAIM market for the Los Angeles Basin by Ishikida et al. 2000).

Land conservation is a second area in which experimentally informed market designs have improved policy implementation. The Bush Tender auctions were designed to conserve land in Australia by creating a market where landowners bid to set aside specific units of land. Cason and Gangadharan (2004) examine how information about environmental benefits and a market clearing auction mechanism affect efficiency. Their results reveal an interesting pattern: people who did not know the environmental benefits provided by their private land were less likely to bid strategically in a conservation auction. Private ignorance reduces public expenditures. Based on this they suggest a provocative policy – a regulator might restrict the biological information publicly provided to landowners prior to running the auction. Another example of test-bedding is Parkhurst et al. (2002) agglomeration-bonus and smart-subsidy coordination game experiments, which illustrate an incentive scheme that can induce private landowners to create contiguous protected areas voluntarily. They compare a *smart subsidy* proposal, which creates an explicit link between neighbouring landowners with adjacent parcels, in relation to two standard policy options, compulsion and a standard fixed-fee subsidy. Their results show that a no-bonus mechanism always created fragmented habitat, whereas with the bonus, players found the first-best habitat reserve.

Second, environmental policy has long confronted the inherent efficiency issues associated with public goods and common property resources. These experimental games capture the elemental economic problem that drives many environmental goods: non-rival and non-exclusive consumption lead to free riding and inefficient production levels. Experimental evidence reveals neither complete free riding nor full cooperation (Ledyard 1995). As noted by Ostrom (2000), three types of people commonly inhabit public-good and common-property experiments: the standard rational egoists, the conditional cooperators, and the willing punishers. Conditional cooperators cooperate when they expect others to reciprocate; otherwise they do not. Within the standard game (see public goods experiments) rules can be manipulated to induce more or less cooperation depending on the mix of subject types, marginal payoffs, group size, communication, and voting with third-party enforcement.

For global environmental goods like climate change, a key policy issue is the impact on efficiency when a collective agreement has costly third-party enforcement. Punishment of free riders is a second-order public good; cooperation means bearing some private cost to sanction others. One relevant policy question is whether an institution based on a voting rule with a punishment mechanism can work to increase contributions to a public good. Kroll, Cherry and Shogren (2007) examined this in the laboratory and observed that voting alone does not increase cooperation; rather, if voters can pay to punish violators, contributions increase significantly. Overall efficiency for a voting-with-punishment rule exceeds the level observed for a voting-without-punishment rule. This result has implications for how policymakers think about institutions such as International Environmental Agreements (IEA), which are more likely to be successful if one nation is willing to act like the 'global police', and pay the costs of punishing violators (Barrett 2003).

Another real-world policy issue is whether policymakers can use economic incentive devices in real-world applications to reveal public good

demand (Bohm 1972). Any proposed system has to 'work' – to provide the good when benefits exceed the provision costs – and has to be straightforward enough to be implemented in the field, characteristics that can be tested in the laboratory. One such mechanism is the *provision point* mechanism: if contributions meet or exceed a targeted provision cost, the public good is supplied to the group; otherwise, it is not. In a design that mimics field conditions, Rondeau, Schulze and Poe (1999) explored a mechanism in which contributions are returned if costs were not met. Their results suggest the provision point mechanism was 'demand revealing in aggregate' for a large group with heterogeneous preferences, suggesting that a relatively simple mechanism could be used in the field to elicit preferences, leading to the efficient provision of a public good.

Third, many observers and policymakers see place-based collaboration and bargaining as the future of environmental policy – arguing for more local control through negotiation and accountability (for example, Sabel et al. 2000). Collaborative decision-making groups have begun to flourish in rural settings such as the western United States, and now number in the hundreds, ranging from informal grass-roots gatherings to government-mandated advisory councils. To an economist, this is the direct application of the Coase theorem – parties in dispute negotiating on a jointly acceptable agreement over resource use. Starting with Hoffman and Spitzer (1982), researchers have used experimental methods to test the robustness of collaborative decision-making underlying the Coase theorem. Hoffman and Spitzer's initial results supported the Coase theorem in that bargains were highly efficient. Harrison and McKee (1985) confirmed that Coasean bargaining under unilateral and joint property rights regimes can be efficient. Both experiments assumed the transaction costs of bargaining were zero. Recent experimental work has explored how bargaining efficiency is affected by positive transaction costs and addition friction due to large numbers of bargainers, property right insecurity, delay costs, imperfect contract enforcement, asymmetric information, and uncertain final authority. The lesson from over two decades of Coase bargaining research is that people have to address the nature of transaction costs and friction.

We illustrate using Rhoads and Shogren's (2003) policy-driven Coasean bargaining experiment. Experts see two elements of consensus-based environmental protection as crucial for effective regulatory outcomes: *final authority*, so that a collaborative agreement is binding; and *information symmetry*, in which bargainers create a common information pool about player payoffs. Their results are consistent with the findings of the experts: final authority and information symmetry were necessary conditions for efficient Coasean bargaining. Without final authority, efficiency falls by two-thirds, and falls further with asymmetric information. If the policy objective is to make a negotiated agreement efficient, the policy challenge is to understand the trade-offs associated with granting or denying final authority to the local bargainers.

In summary, the general principle in institutional environmental economics experiments that has emerged over the years is that the germ of a good idea can be codified into a bad one if the rules of implementation trigger unintended incentives that undercut the efficiency of the system. Experimental methods can be used to reveal which good ideas are actually beneficial to control externalities, provide public goods, and facilitate collaboration – and which ideas are ultimately counterproductive.

Valuation Experiments

Economists also use experimental methods to understand better the behavioural underpinnings of environmental valuation. Experiments can be used to address incentive and contextual questions that arise in assessing values through direct statements of preferences. Three general areas have emerged: rational valuation, direct elicitation of values, and exploring the effectiveness of hypothetical non-market valuation surveys (see Shogren 2006).

First, economists assume people can provide rational statements of their preferences and values

towards the environment. Rather than assume that people make rational choices and reveal consistent values for environmental protection, environmental economists use experiments to examine whether people's choices and stated values meet these criteria. Enough evidence of behavioural anomalies now exists to undercut this presumption (Kahneman and Tversky 2000). Without an exchange institution to arbitrage his or her irrational choices, the unsocialized person can engage in behaviours inconsistent with rational choice theory (see Akerlof 1997).

The key behavioural regularity that potentially undercuts all valuation work is the WTP–WTA gap. Rational choice theory suggests that with small income effects and many available substitutes, the willingness to pay (WTP) for a commodity and the willingness to accept (WTA) compensation to sell the same commodity should be about equal. But evidence suggests that WTA exceeds WTP by up to tenfold. The experimental WTP–WTA work can be divided into two camps: research that suggests the gap is based on a psychological *endowment effect* and that which points to weak market institutions. A person who assigns greater value to a good he or she already owns exhibits the endowment effect, which leads to higher WTA to sell the good than WTP to buy the identical good (Kahneman et al. 1990). The market experience explanation says that people have naive expectations about what they can sell the good for outside an active market place. This experimental work showed that market-like experience can remove the gap (see Shogren et al. 1994, 2001).

Second, valuation experiments are used to measure actual values for public and private goods (Lusk and Shogren 2007). Direct valuation experiments are designed so that people buy and sell actual goods to elicit real values, in which researchers test how alternative exchange institutions affect these values. They entail real payments and binding budget constraints, and use auctions to sell goods for money, albeit within a stylized setting. Experimental designs are used to understand the balance between laboratory control and natural context, enabling researchers to learn things about behaviour that would have been impossible to discover from alternative tools. Subtle changes in experimental procedure affect behaviour, such as paying people before as opposed to after bidding, reporting the market-clearing price, and the novelty of the good.

Third, in the 1980s, Coursey and Schulze (1986) hoped the laboratory would be used more to test-bed field surveys. Today, in 2007, experiments are commonly employed to address problems in stated preference surveys such as hypothetical bias, calibration, surrogate bidding, and incentive compatibility. For instance, experiments have revealed time and again that *hypothetical bias* is real – people frequently promise more than they actually deliver. Experimental work has focused on trying to measure the degree of bias and what methods can be used to eliminate or reduce it in survey work. A good example is Cummings and Taylor (1999) who find that they can remove the hypothetical bias by telling a respondent about it.

In summary, choices and economic values emerge in the social context of an active exchange institution, and thus the measurement of value should not be separated from the interactive experience provided by an exchange institution. Institutions and the institutional context matter because experience can make rational choice more transparent to a person. Institutions also dictate the rules under which exchange occurs, and these rules can differ across settings. People can interpret differently the information conveyed by such settings. The reality is that most people make allocation decisions in several institutional settings each day – markets, missing markets, and unidentified markets. How does this institutional mix affect how people make their choices and form or state their preferences for environmental protection? This question is fundamental because it gives a reason for the purposeful actions underlying all valuation work.

Experimental work like the *rationality spillover* treatments in Cherry, Crocker and Shogren (2003) reveal that exposure to competition and discipline is needed to achieve rationality. In becoming rational, people refine their statements of value to better match their preferences. The contact with others who are making similar

decisions in an exchange institution puts in context the economic maxim that choices have consequences and stated values have meaning for environmental valuation. Relying on rational theory to guide environmental valuation and policy makes more sense if people make, or act as if they make, consistent and systematic choices about certain and risky events. Valuation work in the laboratory needs to continue to address the economic conditions under which the presumption of rationality is supported and when it is not, which in turn has implications for the values we directly elicit.

Concluding Remarks

Through the use of experimental methods, environmental economists now understand better how people learn about and react to incentives, institutions and information. They can compare how decisions are made with and without real economic commitments, within and without active exchange institutions, and with and without signals of value. They can then delve into what the results suggest for *ex ante* questionnaire design, *ex post* statistical evaluation, and, more importantly perhaps, economic theory itself. The environmental economics literature continues to follow the classic experimental strategy: start simply and add complexity slowly so as to understand which factors matter, and why.

In addition, all experiments in environmental economics reveal the perpetual tension between *control* and *context*. At the core, the experimental method is about *control*. One controls the experimental circumstances by trying to change only one variable at a time, which will reduce problems of confounding. Without control, it is unclear whether unpredicted behaviour is due to a poor theory or experimental design, or both. In contrast, others argue that *context* is desirable to avoid a setting that is too sterile and too removed from reality for something so real as environmental policy. Context affects participants' motivation.

Finally, as evidence continues to accumulate, a clearer and more definitive picture will emerge of how our institutions affect the efficiency and perceived value of environmental policies. The future of experimental work will be to design institutions that address the combination of market failure and behavioural anomalies. Otherwise we could find environmental economics falling into a new second-best problem: if we correct market failure without addressing behavioural biases, we might actually reduce overall social welfare.

Experiments and Econometrics

Daniel E. Houser

Abstract

'Experimetrics' refers to formal procedures used in designed investigations of economic hypotheses. Fundamental experimetric contributions by Ronald A. Fisher provided the foundation for a rich literature informing the design and analysis of economics experiments. Key components of this foundation include the concepts of randomization, independence and blocking. Experimetric analysis plays a central role in advancing economic models, and will gain further importance as scholars adopt increasingly sophisticated designed research programmes to illuminate positive economic theory.

Introduction

'Experimetrics' refers to formal procedures used in designed investigations of economic hypotheses. A series of pathbreaking experimetric contributions by Ronald A. Fisher, written largely during the 1920s and early 1930s, elucidated fundamental concepts in the design and analysis of experiments (see, for example, Box 1980, for a survey). He was first to obtain rigorous experimetric results on the importance of randomization, independence and blocking, and he created many powerful analysis tools that remain widely used, including Fisher's nonparametric Exact Test (Fisher 1926; see also Fisher 1935).

Controlled experiments allow compelling scientific inferences with respect to hypotheses of interest. Many economic experiments inform hypotheses regarding primitives assumed to be constant within an experiment (for example, preferences or decision strategies), or the effects on economic outcomes of changes in institutions (for example, comparing different auction rules or unemployment regulations; see experimental economics). One conducts controlled experiments to inform economic hypotheses because relevant naturally occurring data typically include noise of unknown form and magnitude outside the investigator's control. Econometric procedures can go some distance towards solving this problem, but even sophisticated approaches often allow only limited conclusions.

For example, suppose one wanted to investigate the (causal) effect of caffeine on heart rhythms. One approach is to obtain a random sample of 'heavy' coffee drinkers and compare them with a random sample of people who do not use caffeine. Because it is not possible with naturally occurring data to control the reason a person falls into a category, discovering that people with greater caffeine consumption have more cardiac episodes need not imply a causal caffeine effect. The reason is that a preference for coffee may stem from a biological characteristic that is itself causally tied to irregular cardiac events.

An advantage of designed investigations is that they allow cogent inference regarding causal effects through the appropriate use of randomization, independence and blocking.

Randomization

Experiments with randomized designs allow compelling causal inference. The reason is that randomly assigning participants to treatments, and randomly assigning treatments to dates and times, minimizes the possibility of systematic error. In the caffeine example, intentionally assigning heavy caffeine drinkers exclusively to a caffeine treatment generates a systematic error and invalidates causal inference. However, an experiment where subjects are randomly assigned to caffeine and no-caffeine treatments independent of their typical caffeine use allows one to draw appropriate inferences regarding causal relationships.

Independence

Randomization also helps to ensure independence both within and between treatments' observations. Loosely speaking, observations are independent if information about one observation does not provide information about another. Independence is critical for many experimetric analyses, and its failure can lead to misleading conclusions. An objective randomization procedure for treatment assignments insures against the possibility that participants in one treatment might unintentionally systematically vary from other treatments' participants.

Blocking

Causal relationships can be assessed with greater precision through 'blocking'. Blocking is a design procedure with which an experimenter can separate treatment effects from nuisance sources of data variation. In the above, heart rhythms might be affected by both caffeine and anxiety over the process of measuring heart rhythms. Especially because it is expected to

differ between participants, anxiety is a source of nuisance variation that clouds inferences regarding caffeine effects. To address this one could 'block' by participant. This involves measuring each subject both with and without caffeine (in separate, randomly ordered trials). Caffeine effects are measured as the difference between trials, thus mitigating noise due to individual anxiety effects.

Experimetrics Toolbox

Although many specialized experimetric tools have been developed, the experimetrics toolbox also includes a large number of general purpose procedures that have become standard in the experimental economics literature. A regular concern is that independence is not satisfied. The failure of independence can occur because of 'session' effects, meaning that there is less behavioural variation within than between sessions. Violations of independence can also occur if repeated measurements are taken on the same individual due to individual effects. Standard procedures can address this. Sessions can be treated as fixed effects, and random effects can be used to control for individual differences. The resulting 'mixed effect' model can be analysed using standard parametric, panel-data procedures (see, for example, Frechette 2005).

Also in the toolbox is the McKelvey and Palfrey (1995) 'quantal response equilibrium' (QRE) framework (see quantal response equilibria). QRE is a parametric procedure for analysing data from finite games. The key idea is to incorporate errors into players' best response functions, thus creating 'quantal response' functions. This results in an extremely flexible model that can rationalize a wide variety of behaviours. Haile et al. (2006) point out that this flexibility comes at a cost: in general QRE can rationalize any distribution of behaviour in any normal form game, and imposes no falsifiable restrictions without additional assumptions on the stochastic components of the model. Thus, those who wish to implement QRE analyses face the experimetric challenge of creating designs within which such assumptions are defensible.

For reasons including sample size and robustness, the experimetrics toolbox includes many nonparametric procedures (see Siegel and Castellan 1988, for a user- friendly textbook treatment of popular nonparametric approaches). For example, Mann–Whitney tests, and their k-sample generalization due to Jonckheere (1954), are frequently used to compare medians among treatments' data. Also common is Fisher's Exact Test, which uses all the information in the data and is the most powerful nonparametric approach to inference with respect to differences among treatments. Its use is limited by the fact that it can be computationally cumbersome to implement when the numbers of treatments or observations are large.

External Validity

An experiment's conclusions are 'externally valid' if they can be extrapolated to other environments. To rigorously address external validity requires that the source of treatment effects can be identified, which in turn implies a fundamental rule of experiment design: within any good experiment, any treatment can be matched with another that differs from it in exactly one way.

External validity is both important and subtle. For example, consider the well- known 'dictator game' where one participant is assigned the role of 'dictator', and the other 'receiver'. The dictator is given $20, and the receiver nothing. The dictator is told to split the $20 between herself and her receiver in any way she likes, after which the experiment ends. A widely replicated result is that a large fraction of dictators send half ($10) to an anonymous stranger, and one might question whether this finding is externally valid. In particular, there is no evidence that this behaviour is prevalent among winners of naturally occurring lotteries.

There are clear similarities between the situations of lottery winners and dictators. Still, the fact that actions of dictators in laboratory games do not match actions of lottery winners does not

necessarily mean that dictator games lack external validity. The reason is that identical decision strategies can imply different decisions in different environments. For example, recent research provides compelling evidence that dictators' decisions are tightly connected to their beliefs regarding the decisions of others who have faced this same situation: dictators give because they believe other dictators give (Bicchieri and Xiao 2007). This mechanism plausibly guides decisions in naturally occurring environments. In particular, lottery winners do not give because they believe other lottery winners do not give large fractions of their winnings to anonymous strangers. Thus, external validity does not require that one be able to match actions in an experiment to actions in another environment. Rather, an experiment is externally valid if one can extrapolate to novel contexts its conclusions with respect to individual or strategic decision processes.

Applied Experimetrics Research

An important application of experimetrics is to discriminate between many competing theories of learning that have emerged (see individual learning in games). Doing this includes significant experimetric challenges, as it requires one to account for heterogeneity in the way subjects learn. The reason is that not doing so will tend to bias fit statistics in favour of reinforcement (and hybrid) models. Wilcox (2006) shows the reason is that reinforcement models condition behaviour on informative functions of past choices, and in the presence of learning heterogeneity these choices will carry idiosyncratic parameter information not otherwise incorporated into the specification. Having said this, it is also the case that many data-sets from typical learning experiments can be roughly equally well described by many different learning models (Salmon 2001). Consequently, the 'best' model can be highly sensitive to the particular criterion one uses for model selection, as well as the particular experiment under consideration (Feltovich 2000). As a result, in-sample fit is often good, but this does not necessarily imply that much has been learned about the way in which people actually learn and make choices (Salmon 2001).

Knowing how people make choices is critical to advance both economic theory and institution design. Consequently, a significant experimetric literature explores how people make decisions in complex environments, with a focus on characterizing the nature and number of different 'decision rules' at use in a population. Most approaches to accomplishing this require pre-specifying the decision rules the researcher believes people could follow, and then using choice data to assign one of those rules to each member of the population (see, for example, El-Gamal and Grether 1995). However, in some cases one might be unwilling or unable to pre-specify the decision rules, and it turns out that doing so is not necessary. In particular, Houser et al. (2004) detail a Bayesian experimetric procedure that uses individual choice data to determine endogenously the nature and number of decision rules in a population. The approach requires only that one specify the information relevant to individuals' decisions.

Substantive experimetric advances have been obtained in far too many areas to detail here. Although no general survey is available, Houser et al. (2004), Ashley et al. (2005), and Loomes (2005), include excellent summaries of experimetric contributions to a variety of widely-studied games and decision problems.

Conclusion

Experimetrics continues to evolve as scholars adopt highly sophisticated design and analysis procedures to inform new questions. A ready example is the rapidly expanding research in neuroeconomics (see neuroeconomics). The massive spatial- panel data structure that characterizes brain images poses unique inferential problems. Progress on these problems requires significant complementary innovations to both design and analysis strategies. The resulting experimetric advances are sure to have significant impact on economic theory and policy analysis.

Explanation

Julian Reiss

Abstract

Explaining socio-economic phenomena is one important aim of economics. There is very little agreement, however, on what precisely constitutes an adequate economic explanation. Starting from the very influential but defective 'deductive-nomological model' of explanation, this article describes and criticizes the major contemporary competitors for such an account (the probabilistic–causal, the mechanistic–causal and the unificationist models) and argues that none of them can by itself capture all aspects of a good explanation. When seeking to explain a socio-economic phenomenon it should therefore be borne in mind that different types of explanation serve different purposes.

In the early 1950s Milton Friedman famously declared that the 'ultimate goal of a positive science is the development of a 'theory' or 'hypothesis' that yields valid and meaningful (that is, not truistic) predictions about phenomena not yet observed' (Friedman 1953, p. 7). Today, after the demise of logical positivism in philosophy and positivistic trends in economics, economists tend to regard the explanation of phenomena as one legitimate aim of economics besides the more directly policy-oriented aims of prediction and control. Perhaps, following Friedman, explaining

a phenomenon is primarily of instrumental value for the preparation and guidance of policy. But perhaps economists seek to explain in order to increase our understanding of the economic world, for purely cognitive reasons. Whether derivative or fundamental, explanation is a major goal that economists pursue and understanding what exactly is sought is an important task for economic methodology.

An adequate account of explanation in economics should satisfy at least three desiderata:

(a) it should be *descriptively adequate*; that is, it should be consistent with economic practice;
(b) it should be *epistemically adequate*; that is, it should give reason to believe that that which it identifies as an explanation is indeed explanatory; and
(c) it should be *empirically adequate*; that is, it should not identify something as an explanation unless it is based on sufficient evidence.

The so-called deductive–nomological or DN model of explanation (Hempel and Oppenheim 1948) can rightly be regarded as the received view of scientific explanation. Although the theory is now generally regarded as untenable, it is it is useful to consider its guiding ideas as a starting point because its flaws motivate the alternative, more satisfactory accounts.

The Deductive–Nomological Model

According to the DN model, an explanation is an argument whose premises constitute the so-called explanans (or 'that which explains') and whose conclusion constitutes the so-called explanandum (or 'that which is to be explained'). The explanandum will usually be a description of a noteworthy singular event (such as 'Black Monday', 'the rise of the dot.com industry' or 'the collapse of the Tiger economies') or a repeated pattern of events, which may be called a 'phenomenon' (such as 'hyperinflations', 'the J-curve effect' or 'the price drop of cars that have just left the showroom').

The adjectives 'deductive' and 'nomological' indicate that the argument must meet at least two criteria in order to count as an explanation. First, the argument must be deductively valid, that is, the explanandum must follow logically from the explanans. Second, among the premises of the explanans there must be at least one law of nature (the Greek word *nómos* means habit or law). Typically, it is also demanded that the premises of the explanans be true or at least verified. However, none of these criteria is individually necessary nor are the criteria jointly sufficient.

In many cases explanations are probabilistic rather than deterministic and thus the explanandum does not always logically follow from the explanans. John Doe's exposure to asbestos explains his contraction of lung cancer but the statement 'John contracted lung cancer' is not entailed by the statement 'John was exposed to asbestos'. Second, and related, laws of nature in the sense of universal regularities are few and far between, especially in non-fundamental sciences such as economics. All so-called 'laws' in economics, such as the law of supply and demand, the iron law of wages, Okun's law, Say's Law and so forth are, at best, true *ceteris paribus*, that is, if nothing intervenes and relative to a specific institutional structure. For example, we can use the law of supply and demand to predict that demand for a good will decrease when a tax is imposed. However, depending on what else happens in the economy actual demand may or may not decrease. If disposable incomes rise sufficiently or if preferences change in the right way, demand may in fact increase.

Third, it is not clear whether laws in the sense used by proponents of the DN model are explanatory at all. Suppose that it is a law – a universal regularity – that economic expansions follow monetary expansions. Economists no doubt regard knowledge of this kind as very valuable, but unless more is told about the relationship it would hardly count as explanatory. The DN model is therefore neither descriptively nor epistemically adequate.

In response to these and other difficulties of the DN model (for a valuable discussion of many of the

criticisms, see van Fraassen 1980, pp. 103–29) philosophers have developed alternative accounts of explanation. One tradition holds that to explain a phenomenon means to cite the causes of the phenomenon. It therefore roughly agrees with the 'nomological' part of the DN model but replaces the notion of law with that of cause. Another tradition holds that to explain a phenomenon means to show how it fits into a systematization of our beliefs about the world. It agrees with the 'deductive' part of the DN model and insists that good explanations are those that unify diverse sets of beliefs. Both traditions can be found in economics, and both come in two variants.

The Probabilistic–Causal Model

The chief difficulty for the causalist, who maintains that to explain a phenomenon is to provide information about its causes, is to elucidate the notion of cause. We believe that a tightening of the money stock explains the subsequent increase in interest rates; a change in minimum wages explains changes in the employment rate; veteran status explains earnings. In none of these cases is there a universal regularity between event-types; rather, earlier events appear to be probabilistic causes in the sense that they are *statistically relevant*.

One view thus held that event X explains event Y if the probability of Y in some population described by Z is different when X is present from when it is absent: $P(Y|\ X,\ Z) \neq P(Y|Z)$ (cf. Salmon 1971). In econometrics this idea is akin to the notion of a multiple regression:

$$Y = \alpha X + \boldsymbol{\beta}\mathbf{Z} + \varepsilon,$$

where Y is the explained variable, X is the explanatory variable and $\mathbf{Z}$ is a vector of background variables. X is statistically relevant to Y if and only α is different from zero, and can thus be used to explain Y.

Not all statistically relevant events appear to be explanatorily relevant, however. A drop in the barometer reading raises the probability of a storm but the barometer reading does not explain the storm. It is a common cause – the change in atmospheric pressure – that explains its joint effects, the barometer reading and the storm.

This suggests that X plus the set of background factors must constitute the full set of causes of the explained variable (cf. Cartwright 1983, Essay 1): in any population that is homogenous with respect to atmospheric pressure, the barometer reading is statistically irrelevant to the occurrence of the storm. An obvious drawback of this account is that it asks for immense amounts of background knowledge for identifying explanatory factors from statistics. It requires that all other causes of a phenomenon (that is, all confounding factors) to be known or known to be distributed equally between a treatment and a control group, as in a randomized trial. Given the complexities of the social world, one can expect this requirement to be met only exceptionally.

There are also more principled difficulties. One problem arises because some factors may act differently depending on what other causes are present. An increase in the money stock may have different effects on the economy depending on the interest rate and investor behaviour. In extreme situations increasing money may have no effects on the economy at all, and so the government's ability to conduct monetary policy is thus incapacitated. It therefore seems exaggerated to demand that explanatory factors raise the probability of the explained variable in *all* causally homogeneous populations (which is presupposed by the linear models favoured by econometricians). But is it enough for a factor to raise the probability of the effect in one single population or should it raise its probability on average (cf. Dupré 1984)? Moreover, when factors act genuinely probabilistically, factors can be statistically relevant despite the fact that they are not explanatorily relevant, even when all other causes have been included. Suppose that in some causally homogeneous background Z, money M is a probabilistic cause of both nominal income Y as well as the level of prices L. Let $P(Y|M, Z) = P(L|M, Z) = 0.8$. Now, let money cause income on precisely those occasions that it causes prices and vice versa. Then, $1 = P(Y|L, M, Z) > P(Y|M, Z) = 0.8$ even though the change in prices does

not explain the change in nominal income – it is a mere correlate (cf. Cartwright 1999, ch. 5).

But it is important to keep practical and epistemic issues apart. *If* one knows that *C* is a probabilistic cause of a phenomenon of interest *E*, then there is no reason to deny that one can use *C* in an explanation of *E*. The epistemic adequacy of the probabilistic–causal model derives from the general acceptance of causes as explanatory factors. However, finding out if *C* is a probabilistic cause of *E* will often face insurmountable practical difficulties.

The Mechanistic–Causal Model

In philosophy of science, the mechanistic–causal model has been mostly associated with the name Wesley Salmon (see for instance Salmon 1984). It attempts to improve upon the probabilistic model on two counts. On the one hand, for practical purposes it may be easier to find out whether *C* causes *E* by investigating whether or not there is a mechanism running from *C* to *E* than by statistical inference. For instance, Milton Friedman and Anna Schwartz (1963, p. 59) write:

> However consistent may be the [statistical] relation between monetary change and economic change, and however strong the evidence for the autonomy of the monetary changes, we shall not be persuaded that the monetary changes are the source [that is, cause] of the economic changes unless we can specify in some detail the mechanism that connects the one with the other.

Indeed, if *C* causes *E* we expect there to be a mechanism running from *C* to *E*. Evidence about a mechanism from *C* to *E* can thus provide evidence for a causal connection. In turn, according to this view, the mechanism can be used to explain *E*.

On the other hand, causal explanations that are based on statistical inferences often cite relationships among aggregate factors such as the money stock, the unemployment rate, inflation and so on, and can arguably be said to be somewhat shallow. Perhaps a monetary expansion can be used to explain a subsequent economic expansion because there is statistical evidence that the former is the cause of the latter. In this way one learns at best *that* the monetary change causes the economic change. Describing the transmission mechanism one further learns *how* the monetary change causes the economic change. The explanation is thus arguably more detailed, deeper.

It cannot be said, however, that the mechanistic account wins unequivocally over the probabilistic account on both fronts. In order to meet the empirical adequacy desideratum, a mechanistic explanation must be based on evidence no less than a probabilistic-causal explanation. A mere 'sketch' of a mechanism (such as the sketch of the transmission mechanism that follows above quotation by Friedman and Schwartz) does not explain anything. Usually, mechanistic explanations cite relationships among individuals, their preferences and external constraints. The argument that such hypotheses are more readily verifiable (for instance, because they may be verifiable by introspection) goes back at least to the writings of John Stuart Mill (1830). But it is not clear whether it is always easier to provide evidence for causal mechanisms that run at the micro level than for aggregate causal relationships. For instance, the problem of confounding factors is in no way confined to statistical inferences among aggregate variables, and, at the micro level, can only seemingly be alleviated by assuming away the operation of confounders a priori.

Moreover, although with some justification it can be said that mechanistic explanations are deeper than aggregate explanations, there are situations in which information about exactly how some variable influences another is entirely irrelevant. A policymaker, for instance, may be more interested in what is common among expansion episodes rather than in the exact processes that made them happen – which may be different on each occasion.

How Models Explain: Unificationism

Let us now move from the applied side to the more theoretical side of economics. Consider the following quotation (Akerlof 1970):

> From time to time one hears either mention of or surprise at the large price difference between new

> cars and those which have just left the showroom. The usual lunch table justification for this phenomenon is the pure joy of owning a 'new' car. We offer a different explanation.

Akerlof then describes an asymmetric-information model in which low-quality second-hand cars drive higher-quality cars out of the market, which leads to a decrease in average quality and prices. One way to interpret what Akerlof does is to regard the explanatory power of models such as his as consisting in an ability to suggest *schemas* that allow the description of a wide variety of different and seemingly unconnected phenomena. In Akerlof's original article, for instance, the model of the second-hand car market is regarded as a mere 'finger exercise' for further application in markets as diverse as insurance, labour, other goods and credit markets. Other economists invoke transaction costs to explain the existence of firms, intergovernmental collaboration, why crime rates are higher among the poor and 'fair use' doctrines about the use of copyrighted material among many other phenomena. Many other salient theoretical concepts in economics play a similar unifying role.

Philip Kitcher developed the idea that to explain a phenomenon means to derive a description of the phenomenon from an instance of an argument pattern, instances of which can be used for deriving descriptions of many different kinds of phenomena into a formal account (Kitcher 1989). Despite its intuitive appeal, however, it is quite clear that unification cannot be all there is to explanation. How could we tell whether those factors that are salient in a model are the ones that drive the results in the real world? This is a particular problem in economics as many of the concepts that do the alleged explanatory work in models such as Akerlof's are not very discriminatory. There is hardly any market transaction that is not characterized by asymmetric information because it is virtually always the case that one party knows more or something different about a contractually relevant property. Similar observations can be made about other concepts such as human capital or transaction costs or imperfect information. In some situations such factors will be the ones that drive the result, in others they will merely provide a background against which other factors operate. But this is a dominantly qualitative question that should be decided by empirical means, not by means of models alone. Moreover, it seems unlikely that unification is necessary for explanation. Many economic events will be explained with reference to very local and idiosyncratic processes such as wars, innovations and individuals' decisions that lack the power to unify whole classes of events (for further criticism of the unification model, see Woodward 2003, ch. 8).

Nevertheless, unification plays at least two important roles in economic explanation. First, models such as Akerlof's suggest factors that may be causes of real phenomena. Unifying model schemas thus have an important heuristic role. Second, unifying explanations are in some sense desirable explanations. Even though the causal role a factor plays in bringing about a phenomenon is that which makes a model that describes the operation of this factor explanatory, it is its ability to systematize our beliefs and to reduce the number of 'brute facts' we have to accept as given that makes the explanation attractive to economists.

Equilibrium Explanation

Economics is full of equilibrium notions such as the Nash equilibrium, evolutionarily stable equilibrium, sunspot equilibrium, partial and general equilibrium theories. For a variety of reasons, economists tend to downplay explanatory accounts if these accounts do not have a bearing on theory (Heckman 2000, p. 85):

> Applications of this approach [that aims at the statistically analysis of 'natural experiments'] often run the risk of producing estimates of causal parameters that are difficult to interpret. Like the evidence produced in VAR [vector autoregression] accounting exercises, the evidence produced by this school is difficult to relate to the body of evidence about the basic behavioural elasticities of economics. The lack of a theoretical framework makes it difficult to cumulate findings across studies, or to compare the findings of one study with another. Many applications of this approach produce estimates very similar to biostatistical 'treatment effects' without any clear economic interpretation.

Equilibrium explanations, of course, have exactly this virtue: they show how some phenomenon can be systematized in a theoretical framework. Equilibrium explanations obtain at a level in between aggregate probabilistic explanations and causal-mechanical explanations. Unlike aggregate explanations, they are always formulated in terms of micro entities such as preferences, production possibilities and so forth. But, unlike causal–mechanical explanations, they rarely specify the exact details of how an equilibrium is reached or how an economy moves from one equilibrium to another. Equilibrium explanations abstract from the causal dynamics and focus on static end-points. Elliott Sober therefore argues (Sober 1983, p. 204, emphasis in original):

> Equilibrium explanations present *disjunctions* of possible causal scenarios; the actual cause is given by one of the disjuncts, but the explanation doesn't say which.

Because of this, equilibrium explanations are more unifying than explanations that describe the actual causal mechanism that lead to the equilibrium. Nevertheless, equilibrium explanations (at least in economics) tend to cite a lot of information about causes such as preferences, productivity growth, technology and so on. Although abstracting from *some* causal detail, equilibrium explanations can thus safely be regarded as a species of causal explanation.

The greatest challenge for equilibrium explanations is, however, to meet the desideratum of empirical adequacy. In order to derive any results in an equilibrium model, usually a large number of highly distorting idealizations have to be made: consumers maximize utilities and producers their profits; they operate under perfect information; markets clear instantaneously; goods are infinitely divisible and so on and so forth. Furthermore, results derived from a model making such idealizations tend to be very sensitive to specification changes. There is therefore little reason to believe that those forces that drive the equilibrium results obtain also outside the model. Hence, unless it can be shown that this is the case, equilibrium models should be regarded as mere potential explanations.

Conclusion: The Variety of Causal Explanations

The different types of explanation perform different epistemological roles. Very detailed causal–mechanistic explanations can be contrastive: they can provide information about what is special about the way in which a phenomenon came about, the way in which its causal history differs from the causal histories of other, similar phenomena. Aggregate and unifying explanations, by contrast, are comparative: they provide information about what similar or different phenomena have in common (cf. Pettit 1993, pp. 253–7). For those who are interested in explanation mostly for the practical goals of prediction and policy, aggregate explanations will often be the relevant type. However, mechanistic knowledge can be used to improve predictions, for instance, because it may provide information about the ways in which aggregate relationships sometimes fail to hold. Those with more purely cognitive goals will often prefer explanations that unify.

Exploitation

Gilbert L. Skillman

Abstract

This term 'exploitation' is used to characterize social relationships in which one party takes advantage of the attributes or position of another. Used normatively, it conveys the stronger sense that the exploiter takes *inappropriate* or *unfair* advantage of another's condition. While the concept has been invoked in a number of economic contexts, it has been treated most extensively in Marxist analysis of class relations in market economies, featuring in particular *orthodox, neo-Ricardian,* and *rational-choice Marxist* approaches to the phenomenon. There is ongoing debate concerning both the systemic basis and the normative significance of exploitation.

As applied to social settings, 'exploitation' characterizes relationships in which one party takes advantage of the attributes or situation of another. A complete positive account of a given instance of exploitation would include, in addition to the identities of the parties to the relationship, three elements: the process by which one party exploits the other, the nature of advantage taken, and the conditions that make exploitation possible.

Used normatively, the term conveys the stronger connotation that the exploiter takes *inappropriate* or *unfair* advantage of another's condition. Understood in this latter sense, exploitation theory thus provides an alternative to the Pareto–utilitarian principle as a basis for assessing social outcomes, inasmuch as a given relationship may be deemed exploitative even if it improves the welfare of the exploited party.

The concept of exploitation has been invoked across a range of distinct economic contexts and paradigms. It has been applied, for example, in mainstream economic analysis of monopsonistic wage practices, and in feminist economics to characterize gender relations within households. The term has been treated most extensively, however, in Marxist political economy, which treatment is therefore the focus of the remaining discussion.

Marxian economic theorizing with respect to this phenomenon can, at some risk of oversimplification, be traced through three stages of development corresponding to distinct systems of analysis brought successively to bear on the question: *orthodox Marxist* analysis grounded in Karl Marx's reformulation of the classical labour theory of value; *Sraffian* or *neo-Ricardian* analysis

based on the mathematical properties of linear production systems; and *rational-choice Marxist* analysis utilizing formal methods of optimization and equilibrium analysis. The ensuing clash in perspectives both within the Marxian framework and between the latter and the liberal tradition undergirding the mainstream paradigm has generated a lively debate on the positive and normative significance of exploitation.

Marx's Account of Capitalist Exploitation

Karl Marx analysed societies in terms of relations between *classes*, defined in terms of ownership and control of alienable productive assets or *means of production.* In class systems such as feudalism or slavery, Marx held, those who controlled the means of production directly exploited workers by compelling them to expend more labour than that necessary to meet their own consumption needs. Capitalism, in Marx's account, is a specific historical form of class society in which antagonistic class relations are mediated by market transactions. The central analytical problem, in Marx's view, is thus to explain how exploitation of labour might arise in individually voluntary exchanges between traders with formally equal property rights.

Marx's solution to this problem, developed in the first volume of *Capital* (1867), is grounded in the postulate, previously advanced by David Ricardo, that a commodity's *value* is determined by the labour time necessary to produce it under average production conditions. On the basis of this value framework, Marx advanced three propositions: (*a*) capitalist profit is based on the extraction of surplus labour, and thus the exploitation of workers; (*b*) in industrial capitalism, the locus of exploitation is the capitalist-directed production process rather than the marketplace, although exchange relations are the necessary pretext for exploitation to occur; and (*c*) the systemic basis for exploitation under capitalism is that workers are 'free in the double sense' , that is, both legally able to offer their services in the labour market and 'free' of owning any substantial means of production themselves – a condition Marx saw as the outcome of historical processes of expropriation such as the enclosure movement in pre-industrial Great Britain.

Marx argued the first proposition, which in later formulations has been termed the 'fundamental Marxian theorem' (FMT), on the heuristic premise that commodity prices are proportional to their respective labour values. The key to Marx's demonstration is his distinction between *labour power*, that is, the capacity for productive effort, sold as a commodity in capitalist labour markets, and *labour*, the exercise of that capacity. If commodities exchange at their respective values, then positive profit is possible if and only if the labour expended by workers in capitalist production exceeds the value of their labour power – that is, workers perform surplus labour for capitalist firm owners.

Marx acknowledged that commodities typically do not exchange at their values, but maintained that prices were nonetheless 'regulated' by values, and attempted in the third volume of *Capital* (edited and published in 1894 after Marx's death by his collaborator Frederick Engels) to demonstrate the aggregate correspondence of profit and surplus labour given competitive market valuation of commodities resulting in economy-wide equalization of profit rates. His treatment of this *transformation problem* is suspect, however, due to an evidently inconsistent 'transformation' of value magnitudes in his expressions determining market prices.

Marx's second proposition emerged as a corollary of his distinction between labour power and labour. Marx argued that what capitalists purchase in the market is not a specified amount of labour time or bundle of labour services, but rather just individuals' capacity to work for a given period of time. The use value of this capacity must therefore be realized by extracting surplus labour in the process of capitalist-controlled production. It should be noted, however, that Marx did not insist as a matter of *definition* that capitalist exploitation occurs in the arena of production. In earlier drafts of *Capital* (including that which provided the basis for Engels's edition of the third volume), he frequently alluded to instances of exploitation arising from transactions involving the finance of

commodity production without direct capitalist supervision.

With respect to the third proposition, Marx argued in his theory of economic colonization that workers would be unwilling to provide capitalists with surplus value on a regular basis if they were able to produce independently to meet their own needs. Thus, capitalist profit could not in his assessment be systematic unless workers were on the whole divested of substantial ownership in the means of production, such that their livelihoods would be significantly compromised if they chose not to work for wages.

Neo-Ricardian Refinements of the FMT

The calculation of commodity labour values, necessary for the determination of exploitation status in an exchange economy, is most straightforward in the case of *Leontief* production processes, characterized by fixed input coefficients and the absence of jointly produced goods, a scenario consistent with Marx's account in the first volume of *Capital* and his treatment of the transformation problem in the third volume. However, even with this basic representation of production conditions, competitively determined commodity prices are typically disproportionate to their values. In light of his problematic 'transformation' procedure, Marx's account raises a question concerning the generality of the FMT.

Beginning in the 1960s, this question was taken up by a number of economists who, following a mode of inquiry introduced by Sraffa (1960), applied mathematical results characterizing the formal properties of linear systems understood to represent unit input requirements in a capitalist economy based on Leontief production. This literature is informed by an important theorem due independently to Frobenius and Perron (see Kurz and Salvadori 1995) which states in effect that, if it is possible to produce a surplus net of physical input requirements and real wages, and if all commodities require the direct or indirect input of other commodities, then there exists a competitive price vector supporting a strictly positive rate of profit. On the basis of this result, one can establish the FMT, framed as the formal equivalence of positive profit and the exploitation of labour given any vector of positive competitively determined commodity prices. This equivalence was subsequently extended to scenarios involving joint production and the presence of multiple alternative Leontief techniques for producing each commodity, subject to a reformulation of labour values, to be discussed below.

The Sraffian approach prompted a number of debates in the Marxian literature. An overriding concern is methodological in nature, as orthodox Marxists have questioned the relevance of ahistorical mathematical models to Marx's analytical methods and insights. There are, moreover, substantive correlates of their methodological concerns. On the one hand, the neo-Ricardian approach is silent with respect to Marx's second proposition, as the formal representation of production conditions central to the new framework simply takes as given the quantitative translation of labour capacity into productive labour expenditures. Similarly, the question of the systemic conditions enabling the extraction of surplus labour is necessarily begged in this analysis. Consequently, the equivalence between profit and capitalist exploitation established in the new versions of the FMT does not lend itself readily to an assessment of the causal connection between surplus labour and profit; the asserted equivalence might, for example, simply be a reflection of some unspecified underlying condition.

On the other hand, the Sraffian approach challenges the explanatory primacy of labour values, in so far as competitive prices are seen to be calculable directly from production and distribution conditions without any intermediate derivation of labour values. Furthermore, generalization to the case of multiple techniques and joint production introduces an element of ambiguity in the standard calculation of individual commodity values because multiple imputations of labour expenditure are then possible for each individual commodity. Morishima (Morishima and Catephores 1978) addressed the latter problem by redefining labour values in terms of the minimum possible direct labour required to produce a given bundle of net outputs. This procedure

preserves the FMT, but at a potential cost of empirical relevance, as it is at best not obvious that actual capitalists would pursue this objective in selecting among alternative techniques.

While thus casting doubt on Marx's hypothesis that individual commodity prices are somehow regulated by their respective labour values, the Sraffian approach does not directly challenge Marx's labour-based definition of exploitation. Although it provides a basis for calculating economic surplus without reference to labour values, and indicates that the operation of a viable competitive economy is consistent with a range of class distributions of that surplus, this framework establishes no independent basis for judging any such distributive outcome to be the consequence of exploitation.

Rational-choice Marxism and the Systemic Basis of Exploitation

Although the orthodox Marxian account of capitalist exploitation is clearly not methodologically individualist in nature, presumably its exponents understand it to be consistent with the interactions of self-seeking individuals responding intelligently to their available options. Granting the latter possibility raises plausible questions as to why, on the one hand, workers allow themselves to be persistently exploited by capitalists, or on the other, why capitalists choose to exercise direct control over production rather than using simple contractual means for extracting surplus labour. The corresponding normative concern asks how exploitation might be considered morally objectionable if understood to occur in voluntary transactions between rational individuals.

These and similar questions motivate a body of inquiry that has come to be termed 'rational-choice Marxism', which utilizes mainstream tools of optimization and equilibrium analysis in investigating the systemic basis and features of exploitation in market economies. A central point of reference for this stage of the Marxian literature is Roemer's *General Theory of Exploitation and Class* (1982), which poses a cogent and fundamental challenge to the canonical Marxian account. Roemer proposes a re-conceptualization of economic exploitation that dispenses entirely with labour value calculations and makes explicit the systemic basis for moral objections to its existence.

Roemer investigates the traditional labour value-based approach to exploitation in the context of both subsistence and accumulating exchange economies, initially maintaining the standard Leontief specification of production conditions and calculation of commodity values in terms of direct and indirect unit labour requirements. In this sense, his analysis commences where the Sraffian approach leaves off, embedding its representation of production conditions in a general equilibrium framework with optimizing agents.

Roemer expands this framework in two ways. First, in the scenario of subsistence exchange economies, markets for produced commodities are alternatively combined with labour and credit markets facilitating the organization of production activity. Second, in the context of accumulating market economies, he allows for unequal endowments of labour capacity and a more general representation of production possibilities.

Roemer's argument is chiefly organized around three analytical results roughly corresponding to Marx's original propositions. First, the *class-exploitation correspondence principle* (CECP) reflects Marx's fundamental assessment of the class basis of exploitation: 'capitalists', that is, those who hire or extend credit to workers, exploit, while those who work for wages or borrow to finance production activities are exploited. In the strong version of this theorem, class status is furthermore consistently linked to the market value of alienable endowments, such that the sufficiently wealthy become exploiting capitalists and the relatively indigent become exploited workers in market equilibrium.

The CECP deepens and extends the sense of the FMT by linking exploitation status to class position. Roemer demonstrates that the CECP obtains for both subsistence and accumulating economies given Leontief technology and identical preferences and labour endowments, subject only to modifications in the labour-based index of

exploitation status to accommodate the distinction between subsistence and surplus economies.

Second, Roemer argues that neither the degree nor the structure of equilibrium exploitation depend in general on whether production activities are supported by labour or credit markets. At first glance, this *isomorphism theorem* appears to rebut Marx's identification of production as the primary locus of exploitation. However, as in the Sraffian approach, Roemer's framework abstracts from the problem of translating labour capacity into labour performed. Thus the implied rebuttal of Marx's second proposition is contingent: on the assumption that capitalists face no significant obstacles in contracting for given labour services or loan repayments with interest, exchange rather than production relations provide the essential framework for capitalist exploitation. This qualified refutation nonetheless carries theoretical force, in so far as Marx's value-theoretic account of capitalist exploitation in the first volume of *Capital* does not explicitly feature conditions that would in contemporary terms be described as contracting failures.

Third, Roemer's general equilibrium framework affords a characterization of the systemic conditions for exploitation to occur in either subsistence or accumulating exchange economies. Roemer identifies *differential ownership of scarce productive assets* (DOSPA) as the necessary and (absent significant contracting failures) sufficient basis for the existence of exploitation. Differential ownership refers to inequality in the market value of individuals' endowments of productive assets, specifically (given the assumption of identical labour capacities) their endowments of *alienable* productive assets, that is, 'capital'. Significantly, the sense of *capital scarcity* in Roemer's framework is that of *absolute* scarcity, such that the market demand for capital assets (either direct or imputed) is positive at the level of total available capital supply. Otherwise, since Roemer's actors don't discount future payoffs or demand risk premia, capital goods would not command a positive rate of return.

It is readily seen why wealth inequality and capital scarcity are jointly necessary for exploitation to arise. If productive assets are equally distributed, then even if capital is scarce no agent wishes to supply it because of the resulting sacrifice in increased labour expenditure. If capital is not scarce in the absolute sense, then no agent demands it even if others enjoy greater wealth. This result presumes that individuals are identical except in their endowments of alienable assets.

Realistic generalizations of production and endowment conditions, Roemer argues, undermine the sense and scope of Marx's labour-based theory of exploitation. First, representing production possibilities as a convex cone, which maintains the assumption of constant returns to scale but allows for such practical features as factor substitution, fixed capital and joint production, introduces a tension between the labour-based conceptions of commodity value and capitalist exploitation: even if Morishima's revised valuation procedure were adopted to accommodate these more inclusive production conditions, the CECP no longer obtains in general.

To address this problem, Roemer suggests a plausible reformulation of labour value in which capitalists, rather than adopting the labour-minimizing technique for given net outputs, are instead understood to choose techniques which minimize costs at going market prices. As he demonstrates, this modification preserves the CECP, but at the necessary cost of rendering commodity values strictly dependent on commodity prices, thus reversing the causal connection asserted by Marx.

The CECP is more fundamentally compromised by quantitative and qualitative variations in individuals' inalienable endowments of labour capacity. Merely quantitative variations in labour endowments, corresponding for example to the case that some workers are able to work harder or faster than others, weakly preserve the CECP, but eliminate the monotonic relationship between class status and alienable wealth. Thus, from the standpoint of Marx's canonical account, perversities can arise such as rich but exploited wage workers or poor but exploiting capital suppliers. (A similar difficulty arises, it might be noted, given additional non-produced factors such as 'land,' which further disrupt the connection between embodied labour times and individual wealth.)

Heterogeneous labour endowments, reflecting differential abilities across distinct production tasks, raise an even more fundamental problem with respect to defining embodied labour magnitudes, as qualitatively distinct labour expenditures must somehow be aggregated before individuals' exploitation status can be assessed. But, even if a consistent procedure for aggregating heterogeneous labour inputs were identified, such as weighting them with their respective wage rates, no meaningful and consistent relationship among wealth, class position and exploitation status can thereby be established in general. Thus, the labour value-based conception of exploitation appears to break down entirely in this realistic scenario.

The Normative Significance of Exploitation

These anomalies prompt Roemer to advance a new conception of exploitation that assesses economic outcomes through comparison with some alternative property rights regime reflecting a given distributional norm. Besides sidestepping the inconsistencies arising in the labour-based approach to exploitation, this formulation offers the advantage of making explicit the grounds for judging given relationships as exploitative. As such it has potential applications beyond the scope of Marxian analysis.

Roemer's approach can be represented in terms of a cooperative game with transferable payoffs. Let N denote a set of economic actors with representative subset C, called a *coalition.* Let (C_i, C_j) designate disjoint subsets of N representing distinct coalitions in the larger society. (In Roemer's account, these coalitions are defined more specifically as complements, so that $C_j = N - C_i$.) Suppose that coalitional payoffs in this game are determined by the function $u(C)$, and define a withdrawal rule $\pi(C)$ for the game, interpreted as the payoff to coalition C should it choose to reject the allocation $u(C)$ and freely withdraw with the resources permitted it by the game's rules.

Then, given the payoff allocation rule $u(C)$, coalition C_i is said to be exploited by coalition C_j relative to withdrawal rule $\pi(C)$ if (*i*) $u(C_i) < \pi(C)$ (C_i would be made better off by withdrawing), (*ii*) $u(C_j) > \pi(Cj)$ (C_j would be made worse off by withdrawing), and (*iii*) C_j *dominates* C_i. Roemer doesn't specify the meaning of 'domination' in the *General Theory,* and offers alternative formulations in subsequent work without settling on a definitive statement of the condition. A plausible interpretation is that the payoffs $(u(C_i), u(C_j))$are somehow imposed by C_j in lieu of a feasible alternative payoff rule $\tilde{u}(C)$ such that $\tilde{u}(C_i) \geq \pi(C_i)$(coalition C_i isn't made better off by withdrawing, given $\tilde{u}$) and $u(C_j) > \tilde{u}(C_j)$ (coalition C_j benefits by choosing u over $\tilde{u}$).

An allocation $u(C)$ is then called 'non-exploitative' (NE) relative to the game characterized by $\pi(C)$ if no coalition $C \subset N$ is exploited. NE allocations are thus related to the well-known concept of the *core* of a game characterized by $\pi(C)$. All allocations in the core are NE, but not necessarily vice versa, since an allocation may be NE yet Pareto-inefficient.

The normative significance of this formulation clearly depends in part on the specification and justification of the withdrawal rule $\pi(C)$. Roemer posits three forms or levels of exploitation corresponding to different types of economic organization. *Feudal* exploitation is defined relative to a rule allowing individuals to withdraw with the free use of their existing endowments, the interpretation being that this form of exploitation involves coercive or strategic strictures on others' utilization of their property. *Capitalist* exploitation is said to exist in the context of a rule allowing actors to withdraw with the per capita share of the economy's alienable productive assets, reflecting the assessment that wealth inequality is a prerequisite for Marxian exploitation in private ownership economies. Finally, *socialist* exploitation is defined relative to a rule allowing individuals to withdraw with the per capita share of both *alienable* and *inalienable* productive assets, including skills and innate abilities.

In subsequent work (for example, Roemer 1985), Roemer has argued that moral objections to exploitation are most appropriately understood as normative demands for the provision of equal

economic opportunities to all. This is a plausible inference, and one that may in any case be compelling to those who characterize capitalist economic relations as exploitative. However, in light of the dominance condition in Roemer's three-part definition, one might with equal justification condemn the *relational* aspect of exploitation, specifically the acts by which exploiters take advantage of the vulnerable position of others, whatever the material conditions that created this asymmetry.

This point can be illustrated with reference to two strands in the rational-choice Marxist literature subsequent to Roemer's *General Theory.* One involves the criticism that Roemer's use of the competitive general equilibrium framework abstracts from contracting failures and thus ignores crucial aspects of the process by which workers are exploited in capitalist economies. In their influential treatment of this issue, Bowles and Gintis (1990) argue that the strategic response of capital suppliers to contracting failures in labour markets creates a situation of *contested exchange* in which a form of unilateral economic power is exercised over workers in capital-owned firms. They argue for the institution of democratically organized firms as a safeguard against the exercise of such power, without qualifications as to the distributional basis for this form of exchange.

A second line of criticism concerns Roemer's use of a static analytical framework in treating the essentially dynamic phenomenon of capital accumulation. This point is developed by Veneziani (2006), who argues that the condition of absolute capital scarcity, necessary for the existence of exploitation in Roemer's models, becomes extremely fragile once embedded in a genuinely intertemporal equilibrium context. On this basis, Veneziani suggests that the competitive model premised on perfect contracting arrangements is not a suitable vehicle for illuminating the Marxian theory of exploitation.

The validity of this claim, and more generally the systemic basis for capital scarcity and profit, remain open theoretical and empirical questions that stand at the boundary distinguishing Marxian and mainstream economic perspectives. In any case, there are distinct senses in which enduring capital scarcity might be deemed consistent with the manifestation of exploitative economic relationships. One possibility is that capital scarcity is somehow preserved by unequal material conditions. If, for example, time or risk preferences were income elastic, then persistent capital scarcity might arise from inequalities of the sort targeted in Roemer's account. However, even if such preferences were innate and generally uncorrelated with wealth, consistent with the standard neoclassical account, exploitation might still be said to arise if capital suppliers used inappropriate means (such as those criticized by Bowles and Gintis) to maximize the advantage derived from their unique position.

Extended Family

Olivia Harris

It has long been assumed that extended families are typical of pre-capitalist or non-capitalist societies, while the nuclear family form is the product of industrialization and urbanization. Modernization theories, deriving ultimately from nineteenth-century thinkers such as the French social reformer Frédéric Le Play (e.g., 1871), and finding different forms of expression in the Chicago School of urban sociology (e.g., Wirth 1938) and Parsonian functionalism (e.g., Parsons and Bales 1955), was articulated in a moderate form by W. Goode:

> Whenever the economic system expands through industrialisation, family patterns change. Extended kinship ties weaken, lineage patterns dissolve, and a trend toward some form of the conjugal system generally begins to appear -that is, the nuclear family becomes a more independent kinship unit (1963, p. 6).

While Goode himself recognizes that the conjugal family was prevalent in Western Europe long before the Industrial Revolution and limits himself to stating how functionally suited it is to the industrial system, it has long been assumed that the nuclear family emerged as a result of the development of capitalism (e.g., Tawney 1912). How this supposed transformation is interpreted depends on ideological positions: for those critical of the effects of capitalism the extended family evokes a world of solidarity and human values, while for the opposite tradition which finds its decisive expression in liberalism as a political doctrine, the extended family serves to maintain dependency between kin and to prevent the development of the entrepreneurial spirit.

What is meant by the extended family? The terms is ambiguous in the same way as the concept of the family itself: that is, it can refer either to a *co-resident group*, consisting of a wider group of kin than the single nuclear family, or to a network of genealogically and affinally related kin who cooperate and interact closely. However, in either case it is used especially to contrast with the dissolving of kin ties and their replacement by various types of voluntary association and contractual ties, which are said to be typical of capitalist society.

The extended family is frequently defined by the criterion of co-residence, not only because large residential groupings contrast so strikingly with the small units of Western capitalist society, but also because there is a normative assumption contained within the word 'family' that close kin *should* share their resources and if possible live together.

However, even the criterion of co-residence is not as clear-cut as might at first appear (Goody 1972). Available historical and anthropological evidence reveals that there are many different ways in which kin can share domestic space, from maintaining virtually independent budgets, to operating as a close-knit single economic unit with a strong head (usually known as a 'patriarch'). Moreover, while most authors try to maintain a distinction between the terms family and household, the terms frequently become elided or confused. The word family of course derives from the Latin *familia*, which referred to a whole complex household enterprise, including slaves. This broader definition of 'family' was only restricted to genealogical kin from the beginning of the nineteenth century (Flandrin 1976, pp. 4–10). The ambiguity arises from the contemporary ideology that co-resident domestic groups (i.e. households) *should* be based on close kin relationships, and that the intimacy, cooperation and pooling of resources found within a household are only appropriate between close kin. More specifically, Western familial ideology assumes that the co-resident kin group is the social unit within which sharing and pooling take place, while exchange takes place *between* households (Harris 1982).

Such assumptions have two problems: first, that they render us blind to the presence within households of people who are not related to the household core, that is, servants, lodgers and others. This has had damaging consequences for European family history, which only in recent years has begun to appreciate the significance of what is clearly a major pattern of European family

organization and domestic life (Macfarlane 1970; Harris 1982; Smith 1984). Secondly, such assumptions place undue emphasis on the individual household unit, at the expense of adequate consideration of movement and cooperation *between* households or their members.

Apart from methodological problems, the view that extended families are 'pre-capitalist' while the nuclear family is typical of capitalism has turned out to be inaccurate even for English history and the early development of capitalism. Macfarlane has recently summarized a large body of historical research to argue that the English peasant economy was not based on extended families from at least the thirteenth century. English rural society was mobile, with a developed market in land and labour; children were as likely to work as servants for a wage and buy land when they reached maturity, as to inherit a family farm (Macfarlane 1978). Moreover, a study of nineteenth-century Lancashire proposed that industrialization actually *increased* the number of extended (i.e. three-generation) households (Anderson 1971; see also Tilly and Scott 1978; Hareven 1982).

On a more general level, the work of Laslett and his associates has used extensive historical demographic research to argue that 'the nuclear family predominates numerically almost everywhere, even in underdeveloped parts of the world' (Laslett 1972, p. 9). Laslett's arguments were particularly directed against the orthodoxy established by Le Play that the three-generational 'stem family' *(famille souche)* was the dominant family form of the European peasantry, derived from factors such as the inalienability of the land belonging to a particular house and patriline, the buying out of siblings by a chosen successor, and extensive provisions for retirement.

Certain difficulties can be found with Laslett's influential and important arguments; in particular, Berkner (1972) has demonstrated the existence of stem families in eighteenth-century Austria by emphasizing an essential feature of households ignored by Laslett, namely that they change over time in accordance with individual life cycles and mortality rates. Thus, even in areas where the 'stem family' is the basic principle of organization, only a minority of actual households will conform to this type. This approach has been extended by Wolf (1984) to include the notion of 'family cycle' in a discussion of rural Taiwan in the twentieth century. Others have argued that Laslett's use of the 'community' as his basic unit of analysis is inappropriate, since there are significant variations between households according to class and socio-economic position. Overall there is a problem in assessing how far majority household forms in terms of *statistical frequency* reflect what each society considers to be the ideal. The discrepancy can be illustrated by contemporary industrial Britain, where research has revealed that a surprisingly large percentage of households do not conform to the ideal nuclear family type, for all that it is enshrined in legislation, welfare policies and religious belief (McIntosh 1979). The problems are obviously magnified when we turn to scanty historical data.

In recent years, detailed historical research on European families has revealed a complexity and variation that modifies Laslett's early argument but also refuses any simple correlation of family types with particular modes of production, economic stages, or even countries. Even regarding England, opinions differ as to how far and in what circumstances the nuclear family was the dominant type; taking a broader European perspective, Anderson summarizes the debate as follows:

> the European pre-industrial household was a regionally diverse one with England, northern France, North America and possibly the Low Countries . . . being unique in both their low proportion of complex households and their overall homogeneity of household patterns. By contrast, areas of much greater complexity predominated in the east and south . . . while in Northern Europe a more locally diverse pattern was found (1980, p. 29).

Various explanations have been proposed for variation in household and family forms; the influence of different systems of distributing productive property has rightly been considered of major importance. Goody (1976) offers a global theory of the formation of domestic groups in terms of land distribution which in turn he derives from agricultural technology (see also Goody et al. 1976). However, it is too general to be applicable to the understanding of local variations; a recent

exhaustive discussion of the evidence from English history from 1250 to 1800 concludes that it would be hard to maintain that the relationship between landed property and the family's development cycle was the sole or even the most important determinant of rural family forms (Smith 1984, p. 86).

In modernization theories, one of the structural explanations for the replacement of the extended family by the nuclear or conjugal family was precisely the shift away from agrarian production with land as the basic means of subsistence, to an industrial system in which the majority owned no means of production except their own labour power. However, some have argued that the organization of labour can be a major determinant of household size in peasant societies. Conversely, studies of proto-industrialization and factory production show how family ties can be strengthened and household size increased in order to maximize cooperation and the pooling of labour (Anderson 1971; Medick 1976). The same pattern can be documented outside of Europe in different contexts: some of the classic examples of large extended family households, for example, the Indian joint family, or the Japanese *dozuku*, have shown remarkable resilience in adapting to the various processes of urbanization and industrialization (Yanagisako 1979; see also Smith et al. 1984).

Large, extended family households, although not as generally found in pre-capitalist societies as was once supposed, do occur in many different contexts. However, there are major problems of definition. Is it really appropriate to include within a single category an Amazonian longhouse (*maloca*) inhabited by a variety of agnatically related families who cooperate in consumption, and the famous Balkan *zadruga*, where an older man might run a unit consisting of up to fifty people all his direct descendants, who operate as a single production unit?

Thus the whole notion of the extended family household needs substantial modification, whether one considers its historical distribution, its determinants, or its status as an individual unit.

In the broader sense of extended family as a network of kin, too, debates centre on how far such kin ties are typical of 'pre-capitalist' societies, and how far they disintegrate with the development of capitalism. Shorter (1975) presents a provocative version of the modernization thesis, arguing that the 'modern family' is private and more independent of wider kin and social ties than the 'traditional' family. But there is substantial disagreement: students of European history cite evidence to argue that neighbourhood ties have long been more significant in everyday life than kin ties (e.g., Macfarlane 1970). Goody (1983) argues that European family structures are unusual in this respect, because of policies of the early Church to proscribe marriage between close kin. Conversely, case studies from the nations of the economic periphery, and of non-European migrant groups in metropolitan regions, indicate how suited extended family networks are to business success (e.g., the classic studies for West Africa of Cohen, 1969, and Okali, 1983). Overall, the emphasis of modernization theories on linear change determined by the economy cannot be sustained, both because the pattern supposed to be typical of industrial society is found much earlier in European history, and because it is tied too closely to a supposed functional fit with industrial production. With the current restructuring of the world economy away from industry, we can expect extended family forms to thrive in many economic situations.

Extensive and Intensive Rent

Guido Montani

The distinction between extensive and intensive rent appears clearly in the history of economic thought with Ricardo, even though a number of economists discussed these concepts previously on various occasions (e.g. Anderson 1777). After Ricardo, until the end of the century, every economist understood the concept of rent to mean the possibility of obtaining an income from the ownership of scarce natural resources, such as land and mines. But that notion of rent changed progressively and substantially after the so-called 'marginalist revolution'. It may be, therefore, useful to examine the transformation of the notion of rent from classical to marginalist economics.

To understand the concept of rent in classical political economy proper, it is essential to relate it to the notion of surplus, that is the quantity of commodities which at the end of the production cycle (usually the year) are left for consumption, net investment (or waste) after the means of production are replaced so that the new production cycle can begin again on at least the same scale. Quesnay was the first to show clearly that rent is a component of surplus. In the *Tableau économique* (1758) rent appears as a share of the agricultural product – agriculture is the only productive sector – which is paid every year by farmers to landlords. In the same way, Adam Smith spoke of rent as a revenue belonging to landlords as a surplus. As soon as land becomes private property [says Smith] the landlord demands a share of almost all the produce which the labourer can either raise, or collect from it. His rent makes the first deduction from the produce of the labour which is employed upon land (Smith 1776, p. 58). But neither Quesnay, nor Smith gave a satisfactory explanation of the causes affecting the level of the rates of rent. For Quesnay, landlords had a feudal right to ask farmers for a rent. And Smith considered rent as a 'monopoly price'.

Only with Ricardo, who published in 1815, at the same time as Malthus's and West's works on the same subject, *An Essay on the Influence of a Low Price of Corn on the Profits of Stock*, does the classical theory of rent take on a clear and precise shape. In a certain sense, the *Principles*, published two years later, can be considered, as far as rent is concerned, only as an application of the labour theory of value of the specific case already worked on in the *Essay*. 'Rent', says Ricardo, 'is that portion of the produce of the earth, which is paid to the landlord for the use of the original and indestructible powers of the soil' (Ricardo 1817, p. 67). The landlord can raise a rent only when land becomes scarce, that is when the demand for agricultural produce cannot be satisfied without putting into cultivation lands of inferior quality.

> When in the progress of society [says Ricardo] land of the second degree of fertility is taken into cultivation, rent immediately commences on that of the first quality, and the amount of that rent will depend on the difference in the quality of these two portions of land. (Ricardo 1817, p. 70)

This is extensive rent.

But Ricardo recognized a second kind of rent. Before inferior land is cultivated, 'capital can be employed more productively on those lands which are already in cultivation'. This is intensive rent, 'for rent is always the difference between the produce obtained by the employment of two equal quantities of capital and labour' (Ricardo 1817, p. 71).

This viewpoint changed considerably in the marginalist theory of value and distribution. The distinction between extensive and intensive rent was maintained, but progressively the notion of rent as a surplus disappeared and a new explanation of the law of decreasing returns was introduced into economic theory. In Jevons, for instance, rent is again a surplus, even if its explanation is founded on the new mathematical marginalist techniques. 'The accepted theory of rent', says Jevons, referring to Ricardo's and J.S. Mill's doctrine, 'needs little or no alteration to adapt it to expression in mathematical symbols'. And supposing that a worker is employed on a given area of land, rent will be 'the excess of produce which can be exacted from him… if he be not himself the owner of the land' (Jevons 1871, pp. 220, 223). A few years later, Walras protested over such a treatment of rent. Lesson 39 of his *Eléments d'économie politique pure* (1874) is devoted to an 'Exposition and refutation of the English theory of rent'. His starting point is Ricardo's and Mill's distinction between extensive and intensive rent on which he is in agreement, but after a mathematical restatement of these theories, he asks himself 'why this school does not try to formulate a unified general theory to determine the prices of all productive services in the same way'. Walras' aim is to include rent theory in a system of general economic equilibrium in which all prices of commodities and services are interdependent.

> All that remains of Ricardo's theory after a rigorous analysis is that rent is not a component part, but a result, of the price of products. But the same thing can be said of wages and interest. Hence, rent, wages, interest, the prices of products, and the coefficients of production are all unknowns within the same problem; they must always be determined together and not independently of one another. (Walras 1874, p. 416, 418)

Marshall considerably extended the concept of rent. 'The rent of land', affirms Marshall, 'is no unique fact, but simply the chief species of a large genus of economic phenomena' (Marshall 1890, p. 523). All income can include an element of rent. 'There is an element of true rent in the composite product that is commonly called wages, an element of true earnings in what is commonly called rent and so on' (Marshall 1890, p. 350). If the supply of a certain factor is scarce, and cannot increase in a certain period of time, then it is possible to gain an income which may be properly called rent. We can imagine cases of 'pure rent' and cases of 'quasi-rent'. An example of quasi-rent is that of incomes gained on old investments of capital. There is no sharp line of division between pure rent and quasi-rent. Commodities which are in short supply in the short run can be produced in a greater quantity in the long run, so that any possibility of obtaining rent disappears.

Moreover, Marshall softened the distinction between extensive and intensive rent, which he calls differential and scarcity rent. 'In a sense',

says Marshall, 'all rents are scarcity rents, and all rents are differential rents'. We can say that differential rent arises because the land of a single quality comes to be, at a certain point in time, in short supply.

> In this connection [concludes Marshall], it may be noted that the opinion that the existence of inferior land, or other agents of production, tends to raise the rents of the better agents is not merely untrue. It is the reverse of the truth. For, if the bad land were to be flooded and rendered incapable of producing anything at all, the cultivation of other land would need to be more intensive; and therefore the price of the product would be higher, and rents generally would be higher, than if that land had been a poor contributor to the total stock of produce. (Marshall 1890, pp. 351–2)

If Marshall was the economist who gave the greatest contribution to the extension of the concept of rent, Wicksteed was the one who gave it a precise and probably definitive arrangement inside the marginalist theory of distribution. According the Wicksteed the marginalist, or as he calls it, the differential theory of distribution, when fully grasped 'must destroy the very conception of separate laws of distribution such as the law of rent, the law of interest, or the law of wages' (Wicksteed 1914, p. 789). The possibility of coordinating the distribution shares, in order that their sum amounts to the total net product, rests on the fact that the differential service to production of every factor is always the same, even if the way may differ from factor to factor. For example, for land the quality which is relevant is extension, for labour skill and dexterity, etc. 'The law of distribution', affirms Wicksteed, 'is one, and is governed not by the differences of nature in the factors, but by the identity of their differential effect' (Wicksteed 1914, p. 789). In other words, what is important for the marginalist theory is not the heterogeneity of factors, but the differential effect of a different quantity of a factor of the same quality.

The consequences of this observation are quite radical.

> Ricardo's celebrated law of rent really asserts nothing except that the superior article fetches the superior price, in proportion to its superiority; and it is obvious that all 'superiorities' in land, whether arising from 'inalienable' properties or from expenditure of capital, tell in exactly the same way upon the rent. (Wicksteed 1914, p. 790)

When we consider the usual diagram in which different qualities of land are represented on the abscissas and the different fertilities obtained form a given 'dose' of labour and capital on the ordinate we must be aware of the fact that that curve is not a *functional curve*. We simply arranged the different kinds of land in a descending order according to their fertility. On the contrary, if we increase the quantity of a certain factor in relation to a fixed quantity of another factor we may construct a curve which shows a *functional* relation between the 'doses' of the factor and the marginal product, which has a behaviour depending on the quantity of the variable factor employed. In the first case considered, there is no law of rent at all 'but the tacit assumption that the differential theory of distribution is true of every factor of production except land, and that rent is what is left after everything that is not rent is taken away'. Only with a functional curve do we have a true theory of rent and distribution, but in such a case 'we must understand that when the differential distribution is affected there is no surplus or residuum at all' (Wicksteed 1914, pp. 791–2). All the product is therefore distributed to the production factors according to their marginal product.

To conclude our short description of the place of rent in the marginalist theory of distribution, it is clear that with Wicksteed rent is no longer a share of the annual surplus, but an income, the nature of which is perfectly symmetrical with that of capital and labour: they are all paid according to their marginal product. But to reach that result it was essential to reduce the classical law of decreasing returns to the 'law of variable proportions'. As Wicksteed states firmly, only the expansion or contraction of a homogeneous factor in relation to a given quantity of another one gives rise to a marginal product.

The marginalist theory of rent and, more generally, of distribution were widely accepted until recent times. Only with the publication in 1960 of *Production of Commodities by Means of Commodities* by Piero Sraffa were increasing doubts

raised by economists on the reasonableness of its assumptions. Sraffa resumed the classical point of view of the problem of value and distribution, placing the notion of surplus at the centre of his inquiry. Inside that theoretical framework it is again quite natural to consider rent as a surplus, that is, a share of the net income distributed to landlords (or other owners of scarce natural resources). Indeed, Sraffa states that 'it is hardly necessary to dwell on the doctrine that 'taxes on rent fall wholly on landlords and thus cannot affect the prices of commodities or the rate of profits' (Sraffa 1960 p. 74), which was precisely the point of view defended by Ricardo.

Sraffa draws a clear-cut distinction between extensive and intensive rent. If we consider a system of production equations, we can take into consideration two sectors: industry and agriculture. The equations of the industrial sector enable us to determine the rate of profits, given the wage rate, and all industrial prices. In the agricultural sector only corn is produced (which is not utilized as a means of production in the industrial sector). Let us suppose now that n different qualities of land are disposable. If the quantity of corn required can be raised on the more fertile land, land will be redundant and there will be no rent. The price of corn is determined by its production equation, since the costs of its means of production (reckoned on the basis of the industrial prices) are known and the rate of profits and wages are equally known. Only when the need arises to put less fertile lands into cultivation will a rent be possible for the owners of the more fertile farms. But the marginal land will pay no rent.

Intensive rent is possible when land of a single quality is in short supply. In such a case, two different processes or methods of cultivation can be used side by side determining a uniform rent per acre. The existence of two methods adopted simultaneously on the same land should be considered as the result of a process of intensive diminishing returns.

> The existence side by side, of two methods can be regarded as a phase in the course of a progressive increase of production on the land. The increase takes place through the gradual extension of the method that produces more corn at a higher unit cost, at the expense of the method that produces less. (Sraffa 1960, p. 76)

It is worthwhile here noticing that Sraffa's analysis is based on the assumption that the quantities of commodities which should be produced and brought to the market are given. Any inquiry regarding the factors affecting these magnitudes should be undertaken at a further stage: here relative prices, the levels of personal income, consumption habits, and so on should be considered as independent variables affecting the quantities of commodities required. But if it is agreed, as a first step, to consider the quantities to be produced as given, some interesting results will emerge:

(a) In the case of extensive rent, the extension of production from a more fertile to a less fertile land, owing to the need to produce more agricultural products, will cause a lowering of the general rate of profits (if corn is a means of production), an increase in the price of the agricultural commodity in relation the industrial ones and a consequent rise in rents on the more fertile lands. In a similar way, in the case of intensive rent, an increase in the quantity produced of a certain agricultural good will cause a change in the methods of production – the old pair of techniques will give place to a new more efficient one – with a consequent increase in the agricultural price and rent, and the reduction of the general rate of profits. Both results (Montani 1972) are perfectly in agreement with the Ricardian doctrine of rent.

(b) The order of fertility of the various kinds of land is not given, once and for all, by nature. The more fertile lands (i.e. lands which are put into cultivation first because of the rate of profits they give to the agricultural entrepreneur) do not coincide with the lands paying higher rents. Ricardo's opinion is not correct on this point:

> When land of the third quality is taken into cultivation, rent immediately commences on the second. At the same time, the rent of the first quality will rise, for that must always be above the rent of the second, by the difference between the produce

> which they yield with a given quantity of capital and labour (Ricardo, p. 70; our italics).

Generally speaking, if lands 1, 2 and 3 are already cultivated and rent on land 1 is higher than rent on land 2, it may happen that when land 4 is put into cultivation the rate of rent on land 2 may become greater than the rate of rent on land 1. The reversal of the order of rents is possible both for the rate of rent per unit of land and for rate of rent per unit of product (Montani 1972).

> (a) The scarcity of land does not depend only on the quantity of the agricultural product to be produced, but on the distribution of income between profits and wages too. Given certain methods of production, some natural resources, as land, mineral deposits, etc, become 'scarce' or 'redundant' according to the quantity produced of a given commodity and to the relative level of the rate of profits in relation to wages. This may happen both for extensive and intensive rent. Therefore, since no change in the proportions of the 'production factors' occurs when the natural resource becomes scarce or redundant owing to the change in distribution, it is obvious that the meaning of 'decreasing returns' inside the classical theory of rent (and distribution) is different from that connected with the 'law of variable proportions.' (Montani 1975)

The vicissitudes of the theory of rent in the history of economic thought are, therefore, strictly connected to the meaning of the law of decreasing returns; this can be appreciated from what has been said above about how the content of this law changed considerably during the transition from the classical to the marginalist paradigm. Marshall was well aware of the diversity of the two points of view, and stated quite clearly that

> the diminishing return which arises from an ill-proportioned application of the various agents of production into a particular task has little in common with that broad tendency to the pressure of a crowded and growing population on the means of subsistence. The great classical Law of Diminishing Return has its chief application, not to any one particular crop, but to all the chief food crops. (Marshall, p. 338)

This classical meaning of the law was progressively forgotten by the economists owing to the over-narrow view imposed by the marginalist theory of distribution.

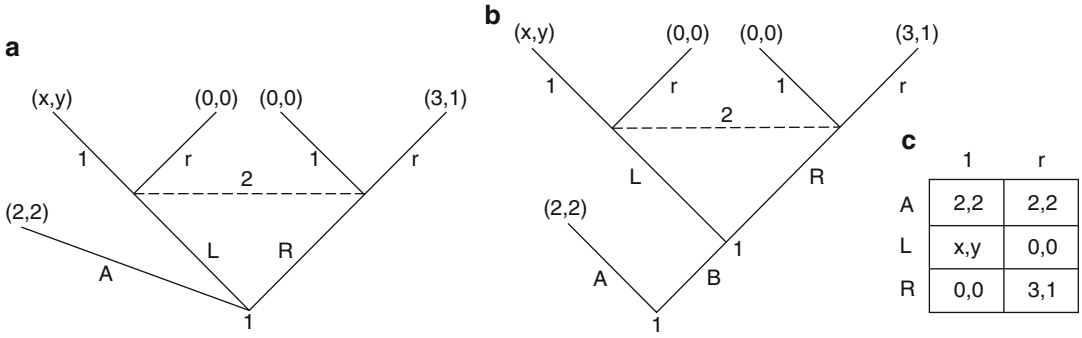
Extensive Form Games

Eric Van Damme

The most general model used to describe conflict situations is the extensive form model, which specifies in detail the dynamic evolution of each situation and thus provides an exact description of 'who knows what when' and 'what is the



Extensive Form Games, Fig. 1

consequence of which'. The model should contain all relevant aspects of the situation; in particular, any possibility of (pre)commitment should be explicitly included. This implies that the game should be analysed by solution concepts from noncooperative game theory, that is, refinements of Nash equilibria. The term extensive form game was coined in von Neumann and Morgenstern (1944) in which a set theoretic approach was used. We will describe the graph theoretical representation proposed in Kuhn (1953) that has become the standard model. For convenience, attention will be restricted to finite games.

The basic element in the Kuhn representation of an n-person extensive form game is a rooted tree, that is, a directed acyclic graph with a distinguished vertex. The game starts at the root of the tree. The tree's terminal nodes correspond to the endpoints of the game and associated with each of these there is an n-vector of real numbers specifying the payoff to each player (in von Neumann–Morgenstern utilities) that results from that play. The nonterminal nodes represent the decision points in the game. Each such point is labelled with an index $i (i \in \{0, 1, \ldots, n\})$ indicating which player has to move at that point.

Player O is the chance player who performs the moves of nature. A maximal set of decision points that a player cannot distinguish between is called an information set. A choice at an information set associates a unique successor to every decision point in this set, hence, a choice consists of a set of edges, exactly one edge emanating from each point in the set. Information sets of the chance player are singletons and the probability of each choice of chance is specified. Formally then, an extensive form game is a sixtuple $\Gamma = (K, P, U, C, p, h)$ which respectively specify the underlying tree, the player labelling, the information sets, the choices, the probabilities of chance choices and the payoffs.

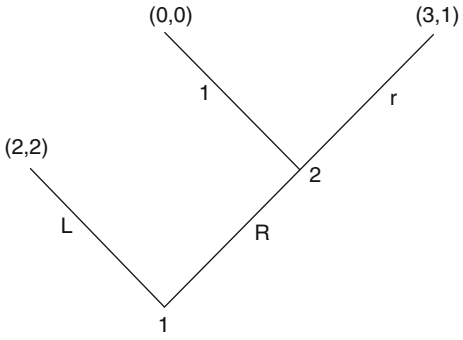
As an example, consider the 2-person game of Fig. 1a. First player 1 has to move. If he chooses A, the game terminates with both players receiving 2. If he chooses L or R, player 2 has to move and, when he is called to move, this player does not know whether L or R has been chosen. Hence, the 2 decision points of player 2 constitute an information set and this is indicated by a dashed line connecting the points. If the choices L and ℓ are taken, then player 1 receives x, while player 2 gets y. The payoff vectors at the other endpoints are listed similarly, that is, with player l's payoff first. The game of Fig. 1b differs from that in Fig. 1a only in the fact that now player 1 has to choose between L and R only after he has decided not to choose A. In this case, the game admits a proper subgame starting at the second decision point of player 1. This subgame can also be interpreted as the players making their choices simultaneously.

A strategy is a complete specification of how a player intends to play in every contingency that might arise. It can be planned in advance and can be given to an agent (or a computing machine) who can then play on behalf of the player. A pure strategy specifies a single choice at each information set, a behaviour strategy prescribes local randomization among choices at information sets and a mixed strategy requires a player to randomize

several pure strategies at the beginning of the game. The normal form of an extensive game is a table listing all pure strategy combinations and the payoff vectors resulting from them. Figure 1c displays the normal form of Fig. 1a, and, up to inessential details, this also represents the game of Fig. 1b. The normal form suppresses the dynamic structure of the extensive game and condenses all decision-making into one stage. This normalization offers a major conceptual simplification, at the expense of computational complexity: the set of strategies may be so large that normalization is not practical. Below we return to the question of whether essential information is destroyed when a game is normalized.

A game is said to be of perfect recall if each player always remembers what he has previously known or done, that is, if information is increasing over time. A game may fail to have perfect recall when a player is a team such as in bridge and in this case behaviour strategies may be inferior to mixed strategies since the latter allow for complete correlation between different agents of the team. However, by modelling different agents as different players with the same payoff function one can restore perfect recall, hence, in the literature attention is usually restricted to this class of games. In Kuhn (1953) and Aumann (1964) is has been shown that, if there is perfect recall, the restriction to behaviour strategies is justified.

A game is said to be of perfect information if all information sets are singletons, that is, if there are no simultaneous moves and if each player always is perfectly informed about anything that happened in the past. In this case, there is no need to randomize and the game can be solved by working backwards from the end (as already observed in Zermelo 1913). For generic games, this procedure yields a unique solution which is also the solution obtained by iterative elimination of dominated strategies in the normal form. The assumption of the model that there are no external commitment possibilities implies that only this dynamic programming solution is viable; however, this generally is not the unique Nash equilibrium. In the game of Fig. 2, the roll-back procedure yields (R, r), but a second equilibrium is (L, ℓ). The latter is a Nash equilibrium since



Extensive Form Games, Fig. 2

player 2 does not have to execute the threat when it is believed. However, the threat is not credible: player 2 has to move only when 1 has chosen R and facing the *fait accompli* that R has been chosen, player 2 is better off choosing r. Note that it is essential that 2 cannot commit himself: If he could we would have a different game of which the outcome could perfectly well be (2, 2).

A major part of noncooperative game theory is concerned with how to extend the backwards induction principle to games with imperfect information, that is how to exclude intuitively unreasonable Nash equilibria in general. This research originates with Selten (1965) in which the concept of subgame perfect equilibria was introduced, that is, of strategies that constitute an equilibrium in every subgame. If $y < 0$, then the unique equilibrium of the subgame in Fig. 1b is (R, r) and, consequently, (BR, r) is the unique subgame perfect equilibrium in that case. If $x < 2$, however, then (AL, ℓ) is an equilibrium that is not subgame perfect. The game of Fig. 1a does not admit any proper subgames; hence, any equilibrium is subgame perfect, in particular (A, ℓ) is subgame perfect if $x > 2$. This shows that the set of subgame perfect equilibria depends on the details of the tree and that the criterion of subgame perfection does not eliminate all intuitively unreasonable equilibria.

To remedy the latter drawback, the concept of (trembling hand) perfectness was introduced in Selten (1975). The idea behind this concept is that with a small probability players make mistakes, so that each choice is taken with an infinitesimal probability and, hence, each information

set can be reached. If $y \leq 0$, then the unique perfect equilibrium outcome in Fig. 1a, b is (1, 3): player 2 is forced to choose r since L and R occur with positive probability.

The perfectness concept is closely related to the sequential equilibrium concept proposed in Kreps and Wilson (1982). The latter is based on the idea of 'Bayesian' players who construct subjective beliefs about where they are in the tree when an information set is reached unexpectedly and who maximize expected payoffs associated with such beliefs. The requirements that beliefs be shared by players and that they be consistent with the strategies being played (Bayesian updating) imply that the difference from perfection is only marginal. In Fig. 1a, only (R, r) is sequential when $y < 0$. When $y = 0$, then (A, ℓ) is sequential, but not perfect: choosing ℓ is justified if one assigns probability 1 to the mistake L, but according to perfectness R also occurs with a positive probability.

Unfortunately, the great freedom that one has in constructing beliefs implies that many intuitively unreasonable equilibria are sequential. In Fig. 1a, if $y > 0$, then player 2 can justify playing ℓ by assigning probability 1 to the 'mistake' L, hence, (A, ℓ) is a sequential equilibrium if $x \leq 2$. However, if $x < 0$, then L is dominated by both A and R and thinking that 1 has chosen L is certainly nonsensical. (Note that, if $x < 0$, then (AL, ℓ) is not a sequential equilibrium of the game of Fig. 1b, hence, the set of sequential (perfect) equilibrium outcomes depends on the details of the tree.) By assuming that a player will make more costly mistakes with a much smaller probability than less costly ones (as in Myerson's (1978) concept of proper equilibria) one can eliminate the equilibrium (A, ℓ) when $x \leq 0$ (since then L is dominated by R), but this does not work if $x > 0$. Still, the equilibrium (A, ℓ) is nonsensical if $x < 2$: If player 2 is reached, he should conclude that player 1 has passed off a payoff of 2 and, hence, that he aims for the payoff of 3 and has chosen R. Consequently, player 2 should respond by r: only the equilibrium (R, r) is viable.

What distinguishes the equilibrium (R, r) in Fig. 1 is that this is the only one that is stable against all small perturbations of the equilibrium strategies, and the above discussion suggests that such equilibria might be the proper objects to study. An investigation of these stable equilibria has been performed in Kohlberg and Mertens (1984) and they have shown that whether an equilibrium outcome is stable or not can already be detected in the normal form. This brings us back to the question of whether an extensive form is adequately represented by its normal form, that is, whether two extensive games with the same normal form are equivalent. One answer is that this depends on the solution concept employed: it is affirmative for Nash equilibria, for proper equilibria (van Damme 1983, 1984) and for stable equilibria, i.e. for the strongest and the weakest concepts, but it is negative for the intermediate concepts of (subgame) perfect and sequential equilibria. A more satisfactory answer is provided by a theorem of Thompson (1952) (see Kohlberg and Mertens 1984) that completely characterizes the class of transformations that can be applied to an extensive form game without changing its (reduced) normal form: The normal form is an adequate representation if and only if these transformations are inessential. Nevertheless, the normal form should be used with care, especially in games with incomplete information (cf. Harsanyi 1967–8; Aumann and Maschler 1972), or when communication is possible (cf. Myerson 1986).

External Debt

Peter M. Oppenheimer

The term ‘external debt’ refers to financial obligations incurred by individuals or, more commonly, institutions resident in one country vis-à-vis those resident in another. In other words, the obligations cross the borders of sovereign states. Usually different nationalities or citizenships are involved, as well as different residencies, but this is not strictly necessary. For instance, a US corporation in the United States may borrow from a US bank branch on London, which in turn funds the loan by taking deposits from American residents of the United States. The involvement of a financial intermediary in London means that this chain of transactions among American nationals is governed in part by English law and regulations rather than, or as well as, US law (and of course the laws may conflict). In fact, legal or regulatory differences are likely to be the reason why such all-American transactions move ‘off-shore’ in the first place. For example, reserve or liquidity requirements applying to US banks in London may be less severe than those applying in New York, thus enabling the London branch to offer more attractive terms than its New York counterpart to depositors and borrowers alike.

In the above example US residents have both a debt and a claim vis-à-vis non-residents. So the net external asset position of the United States is the same as it would be if neither of these particular transactions had taken place. The same would apply if the bank in London were British or Japanese rather than American, and if US residents had placed their overseas assets not with this bank but with some other institution in a third country. Nonetheless, with countries as with individuals or firms, it is not only the net (external) financial position which matters. A country (or a firm) may have substantial net (external) assets and still face financial difficulties – a liquidity crisis or a run on the currency – if its liabilities are more liquid than its assets, and external creditors demand repayment; or if domestic residents wish to send more capital abroad and foreign creditors refuse to grant additional loans. Conversely, insofar as a debtor country is readily able to meet the interest due on its foreign debt from export proceeds or other normal receipts, its net debtor position is not a source of embarrassment.

These considerations point the way to theoretical and practical criteria for external borrowing and lending by a country; but a number of other points have first to be clarified. Aside from debts, external liabilities (and assets) may take the form of claims on real property (ordinary shares, land, buildings, etc). Unlike such claims, debts carry

legal obligations to pay interest and/or amortization over some stated period; but, unless specifically indexed, these obligations are in nominal money terms, not in real terms. The rate of interest may be either fixed or fluctuating according to some formula, but will normally depend in large measure upon the currency denomination of the loan. The faster the real-terms purchasing power of a currency is expected to depreciate in the future, the higher the interest rate that it will carry. Creditors therefore lose, and debtors gain, to the extent that the currency in question loses real value during the period of the loan at a faster pace than financial markets had anticipated at the time the loan was made; and conversely when it loses real value more slowly. Monetary authorities in countries with longer-term borrowings denominated in their own currency are accordingly exposed to a degree of temptation (moral hazard) to encourage faster depreciation of their currencies in order to reduce the burden of such debts; and conversely for monetary authorities of countries with longer-term external lending in their own currency (though this has not been viewed as a significant risk in practice).

External debt may take the form either of securities that are in principle marketable (bonds or bills) or of non-marketable claims such as bank loans, trade credit between firms or government-to-government loans. Before 1914, international lending was conducted overwhelmingly by way of securities; subsequently other claims have played a larger role, most especially so in the 1970s, which saw a huge wave of lending to less developed countries (notably in Latin America) in the form of medium-term credits, denominated mainly in US dollars, put together by syndicates of major commercial banks.

External Borrowing and the Macroeconomy

Starting with a clean sheet, a country acquires *net* external liabilities (assets) by spending abroad out of current income more (less) than it is currently earning abroad – in other words, by running a deficit (surplus) on the current account of its balance of payments. Once external assets and liabilities exist, the net position is also affected by valuation changes, i.e. appreciation and depreciation, of the various items. Another way of looking at a current payments deficit is to say that it represents external dis-saving by the country in question, and comes about as a result of the combined saving and spending decisions of all the country's residents. Macroeconomic policies exercise a crucial influence, both directly (the government being a major spending unit) and indirectly (through the impact of fiscal, monetary and exchange-rate policies upon private-sector outlays). It is important to distinguish between external saving and total saving. Most of a country's total saving is matched by expenditure on domestic capital formation, i.e. investment in buildings, machinery, etc., whether by the private or public sectors. External dis-saving and hence the current payments deficit equals the *excess* of domestic investment over national saving (and conversely for external saving and a current payments surplus). In symbols $X - M = S - I$, where X is export receipts, including earnings on overseas assets as well as sales of goods and services, M is import payments, S is national saving and I is domestic investment. Clearly the net decline in the external asset/liability position which matches a current account deficit may take many different forms – such as acquisition of domestic factories by foreign firms, sale of overseas assets by domestic residents, drawing down of official foreign-exchange reserves, etc. – and need not involve external borrowing in the strict sense of the term.

Criteria

Some external borrowing is undertaken in emergency or disequilibrium situations, as an alternative to depletion of foreign exchange reserves or, beyond that, to rapid elimination of a current account deficit by means of restraint on domestic expenditure which would cause significant disruption or hardship. Thus, a domestic investment boom may be sustained and allowed to run its course rather than be cut short by balance-of-payments pressures. Or the impact of an

unwelcome event, such as a sudden and unexpected drop in export receipts in a primary-product-exporting country, may be cushioned. In this instance the argument for emergency borrowing is most evident when the drop in export income is expected for good reason to be short-lived. When it is expected to be of long duration, some external borrowing may still be appropriate, so that the country may adapt to its new circumstances gradually. In sum, borrowing is rational whenever the discounted present value of its cost is judged to be less than that of the expenditures which would be foregone if the borrowing did not take place.

Analogous criteria apply to external borrowing along an equilibrium growth path. Assume for simplicity that there is a single world-wide interest rate at which funds can be both lent and borrowed. A country should undertake all domestic investment projects expected to be profitable in foreign-currency terms at this interest rate, arranging the structure and timing of its investment programme so as to maximize the present-value difference between total return and total cost. At the same time the country's total saving will depend on population size, income level, income distribution and thriftiness or time preference. The country will be a net borrower or net lender abroad in any particular phase of its development, depending on whether domestic investment is running ahead of or behind national saving. More explicit and precise formulations of this principle can be derived in the context of the mathematical theory of optimum growth (see Shell 1967).

Uncertainty, Default Risk and the Banking System

The principles outlined so far largely abstract from problems of imperfect foresight and information. Any credit market has to cope with such problems, but special issues arise in relation to international lending.

Although a borrower promises to service his debt, circumstances or dishonesty may lead him to default on or repudiate the obligation. In the face of this possibility, various kinds of safeguard are available to actual or potential creditors. First, private creditors should not merely lend to one or a few borrowers, but should spread risks by holding a market portfolio of claims. Secondly, the market itself will generate differential pricing of loans, with debtors judged riskier having to pay higher interest rates and/or being rationed in the amounts that they can borrow at any price. The role of rationing is emphasised by the theory of adverse selection (Stiglitz and Weiss 1981), which suggests that higher interest rates tend to drive away the prudent and good-quality borrowers, leaving mainly the more doubtful prospects still in the market. Thirdly, borrowers who default on their obligations are liable to forfeit property either automatically or after legal proceedings. Such proceedings may, however, be costly and troublesome to pursue, especially in the international context, where action may be required in more than one country. Fourthly, default or bankruptcy carries a stigma which will prevent or hamper the possessor's access to credit and other markets for a greater or lesser period of time. By the same token, creditors may be able to enforce prudent policies of their choosing upon debtors as a condition of prolonging credit rather than declaring the debtor in default. In practice such power can be exercised only by banks or other financial institutions; and in the case of government ('sovereign') borrowers mostly only by other governments or supranational institutions such as the International Monetary Fund (IMF).

The point about continued access to international markets has to carry a lot of weight in the case of sovereign borrowers, where the mechanism of foreclosure (property forfeiture) is inapplicable. With a commercial (non-sovereign) loan, lenders will wish to ensure that the market value of the assets available as security in the event of default or insolvency is at least equal to the discounted present value of the lost interest and repayments. The nearest comparable condition in the case of a sovereign loan is to ensure that the borrower believes his self-interest to lie in maintaining debt service, because default would bring him more losses than gains. If his losses are defined simply in terms of denial of

future loan inflows (a plausible albeit somewhat narrow definition), then the incentive to default arises if and only if the discounted present value of the potential future inflows is less than that of the interest and amortization payments avoided by defaulting. To prevent this condition being met, lenders must put appropriate limits on the growth of their loans to sovereign borrowers, the limits depending at any one time on the existing level of debt, the real rate of interest and the debtor economy's growth rate (see, for instance, Niehans 1986; Eaton and Gersovitz 1981).

Suppose, however, that lenders miscalculate and allow external debt to build up to a point where sovereign borrowers are seriously tempted to default. To lure them away from this option, lenders must then continue to re-lend debt service payments as they fall due and, in addition, ensure that the real interest rate being charged is at least no higher, and probably somewhat lower, than the borrower's long-term economic growth rate. Depending on circumstances, lenders may prefer to cut their losses by accepting default; and some may have no effective choice in the matter – for instance, widely scattered small bondholders with no practical means of influencing the scale or terms of new lending.

The foregoing optimal lending strategies to sovereign borrowers may not be achievable by competitive private lenders acting on their own. Financial markets, being characterized by incompleteness of information about the creditworthiness of borrowers and about future economic trends, are prone to be heavily influenced by herd instinct and fashion, even if decisions are rationalized in analytical terms. When circumstances look favourable, it is difficultto prevent excessive growth of lending to favoured sectors or customers, including sovereign borrowers – especially with financial institutions also competing for positions of market leadership and size. Then, when the climate turns sour, private lenders left to themselves may precipitate a financial crash by recalling loans when debtors are in no position to repay. Observing these tendencies at work in 19th-century British credit markets, Walter Bagehot (1873; see also Hirsch 1977) argued that stabilization of the financial system requires a degree of restraint on competition through some mixture of oligopolistic market structure and central-bank guidance or approval, the latter as a *quid pro quo* for protecting banks against runs by means of last-resort lending facilities.

A similar lesson emerged from global lending developments in the 1970s and 1980s. When less developed countries in Latin America and elsewhere became major international borrowers after 1970, and especially after the quadrupling of oil prices in 1973–4, most of the sovereign lending was handled by the commercial bank network of the major industrial countries, which was far more flexible than official credit channels centred on the IMF in intermediating to new patterns of international capital flows. In the process, however, lending banks, especially in the United States, made themselves vulnerable by lending amounts greatly in excess of their capital and reserves to a handful of sovereign borrowers. From 1979 onwards monetary restraint imposed by the US Federal Reserve System triggered a shift in the world financial climate whose extent and duration could scarcely have been foreseen. In particular, international real interest rates rose from a negative figure to around 7 per cent, and the terms of trade moved heavily against primary producers. After two-to-three years the burden of debt service had become unsustainable in relation to borrowers' export receipts. During 1982–3 some 35 countries were obliged to seek rescheduling of their external debts. The fact that this happened in an orderly manner, and without involving a serious chain of bank failures, was due to the action of the principal OECD-country central banks, led by the Federal Reserve, in conjunction with the IMF and the Bank for International Settlements. They buttressed commercial bank lending with official credits and, more important, exercised moral suasion to induce the banks to renew sovereign loans as they fell due, rather than seek a large-scale withdrawal of funds which would not have been feasible. This cooperative 'crisis management' was the international

equivalent of last-resort lending in a domestic banking system.

External Economies

Peter Bohm

Abstract

External economies and diseconomies nowadays generally mean unpaid side effects of one producer's output or inputs on other producers. External economies in this sense imply as a rule that market prices in a competitive market economy will not reflect marginal social costs of production, giving rise to a 'market failure'. But, with technological external economies and diseconomies now most often replaced by the well-defined concept of externality, and with pecuniary external economies and diseconomies being synonymous with general market interdependence, external economies no longer have much of a role to play in economic analysis.

'The concept of external economies is one of the most elusive in economic literature.' This is how Tibor Scitovsky began his article 'Two Concepts of External Economies' (1954). His statement is still true, and it may be added that there are at least two such concepts.

The meaning of external economies and its counterpart, external diseconomies, has changed over time. Nowadays, it is essentially synonymous with externality or external effects in the sphere of production. That is, external economies (diseconomies) or positive (negative) external effects in production are unpaid side effects of one producer's output or inputs on other producers. (As an illustrative example, we can take the case where a dam constructed by a hydroelectric power plant eliminates flooding of farmers' crop fields – external economy – or reduces the catches of fishermen downstream – external diseconomies; a producer's pollution which increases the costs of, *inter alia,* other producers is perhaps the most important case of externalities.) Sometimes, external economies also refer to unpaid side effects of or on consumption activities, but this meaning is disregarded here.

External economies in this modern sense imply as a rule that market prices in a competitive market economy will not reflect marginal social costs of production. Hence, a 'market failure' arises,

meaning that the market economy cannot attain a state of efficiency on its own. Specifically, in an otherwise 'perfect' market economy, a producer who has external economies (positive external effects) on other producers would not extend his externality generating activity, say, his output, to the point where marginal cost of production equals marginal social benefits of production, which amounts to the market value of his marginal output plus the market value of the side effect on the output of other producers.

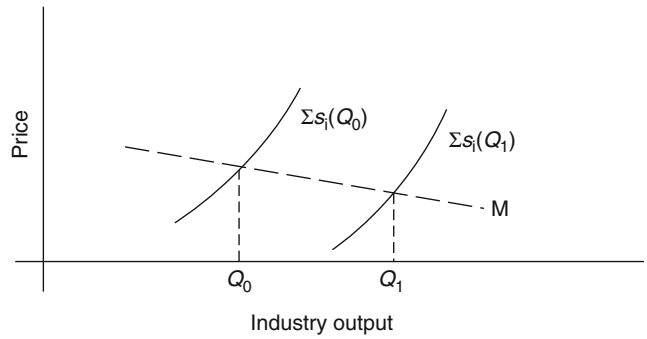
At an earlier stage, external economies in the meaning now given were called *technological external economies,* reflecting the fact that the effects were transmitted outside the market mechanism and altered the technological relationship between the recipient firm's output and the inputs under its control. Formally, we have that the output q_i, of the ith producer is affected not only by changes in his control variables, a vector x_i, but also by e_j, a variable controlled by some other producer j. This gives us the following production function:

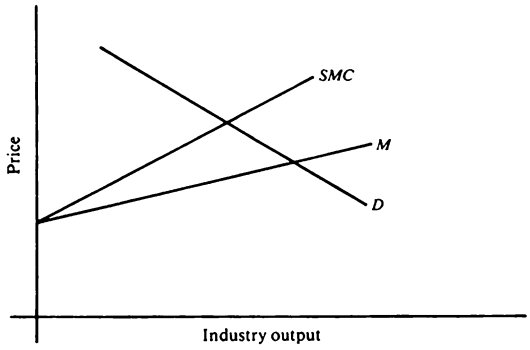
$$q_i = f_i(x_i; e_j).$$

The reason for specifying such effects as technological is that the concept of 'external economies' has been given a broad meaning ever since its introduction. During the early part of the 20th century, external economies (diseconomies) were defined so as to include beneficial (detrimental) *price effects* of producer activities. Thus, in principle, the concept included cases where increases in factor inputs by one firm lowered or raised input prices for other firms. However, much of the discussion centred on the case where increases in *industry* output lowered or raised input prices for the individual member firm. The case of reduced input prices presupposes that the supply side of the market for inputs is characterized either by imperfect competition (say, a profit-maximizing monopoly producing at decreasing marginal costs, decreasing at a rate sufficient for an increase in demand to lower price) or by a competitive industry having a downward-sloping 'supply' curve, which in turn reflects external economies in this industry. Supply conditions in the original industry, as well as in the industry producing inputs for the first industry, are shown in Fig. 1. Here, $\sum s_i(Q_0)$ is the aggregate supply of the firms in the industry when actual industry output is Q_0. When industry output increases to Q_1, input prices drop (or technological external economies arise), causing a downward shift in individual cost and supply curves and hence in the aggregate supply ($\sum s_i(Q_1)$). The curve *M,* the downward-sloping 'supply' curve, is actually a market equilibrium curve showing the equilibrium price/output combinations at different levels of demand (see Bohm 1967).

The price effects between firms or between industry and its firms were termed *pecuniary external economies* (*diseconomies*) by Viner (1931). Before him, A.C. Pigou (1920) had argued (although he phrased it differently) that

External Economies, Fig. 1





External Economies, Fig. 2

external economies and diseconomies, both technological and pecuniary, would call for government intervention in order for the industry to attain a socially efficient level of output. Specifically, Pigou argued that, if expansion of a competitive industry would increase prices of inputs sold to the industry, thus creating pecuniary external diseconomies for the individual firms in the industry, the aggregate 'supply' (or market equilibrium) curve would not reflect social marginal costs.

Pigou's argument can be illustrated in Fig. 2, where *M* is the upward-sloping long-run 'supply' curve for the industry due to rising input prices as a consequence of increasing industry output. *SMC* is the curve showing the total marginal outlay on inputs, where the difference to *M* is the increased outlay for *infra-marginal* inputs. Pigou contended (but later rescinded this position) that the *SMC* curve indicated the true social marginal costs and hence, that the price/output combination attained by the market, as shown by the intersection of market 'supply' *M* and market demand *D,* was suboptimal. He argued that the optimal level could not be attained unless a tax were levied on this industry so that, in equilibrium, price and output would be those shown by the intersection of *SMC* and *D*. (Similarly, a bounty would be required in the case of pecuniary external economies (see Fig. 1), where *SMC* would be downward-sloping and steeper than the *M* curve.)

It was demonstrated by F.H. Knight (1924) and D.H. Robertson (1924) and further elaborated by Ellis and Fellner (1943) that the total marginal outlay is irrelevant as an indicator of marginal social costs. The effect on outlay for intramarginal units of inputs represents an increment to rent on these units and hence, it is not part of the real costs of increased output; the real marginal costs are only those which have to be paid for the required marginal inputs. In other words, the rising costs for marginal inputs are those shown by the industry 'supply' curve *M*. Hence, pecuniary external economies or diseconomies would not call for government intervention. The case is different, however, for technological economies and diseconomies. Assume, for example, that output of a geographically concentrated industry pollutes the area where it is located and hence reduces the productivity of labour inputs of the individual firms in the industry. Here, all effects on input productivity, for marginal as well as intramarginal units, constitute real costs. So if the rising *M* and *SMC* reflect such effects only, Pigou's argument holds.

When the debate had arrived at this point, pecuniary external economies could be dropped as a cause of market failure and, hence, the concept lost its specific economic interest. But, now, what do the *technological* external economies and diseconomies of industry output on the individual firms in the industry actually represent? Alfred Marshall introduced the term external economies when analysing industry production costs as a function of output:

> We may divide the economies arising from an increase in the scale of production of any kind of goods, into two classes – firstly, those dependent on the general development of the industry; and secondly, those dependent on the resources of individual houses of business engaged in it, on their organization and the efficiency of their management. We may call the former *external economies,* and the latter *internal economies.* (Marshall 1920, p. 266)

The latter concept is now recognized as economies of scale in the individual firm. Marshall elaborated the meaning of the former concept using scattered examples, the most explicit of which is perhaps the increased knowledge accompanying the expansion of industry output

materialized in the publication of trade journals and other forms of improved information about markets and technology in the industry. But, in addition, he argued that industry growth, especially when concentrated to a particular region, might create a market for skilled labour, advance subsidiary industries or give rise to specialized service industries as well as improve railway communication and other infrastructure.

Thus, external economies emerged here essentially as cost reductions for individual firms as a consequence of industry growth, that is, as economies external to the firm but internal to the industry. To remain firmly within the framework of static analysis, these economies should be thought of as being reversible. But some of Marshall's examples alluded to irreversible phenomena and to dynamic effects of industry growth. This was particularly obvious when he at times referred to external economies as being dependent on the 'general progress of industrial environment'.

Marshall's claim that external economies were important in the long run – in fact, more important than internal economies – seemed to have little immediate impact on the thinking of his fellow economists. For example, the discussion of 'empty economic boxes' in the early 1920s (Clapham 1922; Pigou 1922; Robertson 1924) centred on questioning the relevance of external economies and diseconomies, the latter concept deriving from issues raised by Pigou (1920). Actually, the significance of technological external economies and diseconomies in the *static* analysis of an industry or among producers in general escaped most economists all the way up to the post-war years when traffic congestion (although already mentioned by Pigou) and the common pool problem of interdependent producers in an oil field or a fishing area became the leading examples of the industry case and environmental pollution the leading example of the general case. Eventually, diseconomies emerged as the important case and economies as the exceptional case, whereas earlier hardly any importance was attached to technological diseconomies (see, for example, Robertson 1924).

If static external effects turned out to be the most important legacy of Marshall's original contribution, external economies as a *dynamic* concept, which seems closer to Marshall's own ideas, also came to play a role in economic analysis. Dynamic external economies refer to increased division of labour resulting from industry growth, the emergence of firms specializing in new activities, some of which aim at developing capital equipment for, or servicing, other firms. An early elaboration of these ideas was made by Young (1928). Later, the concept of external economies came to play a prominent role in development planning, primarily for underdeveloped countries or regions. The general idea here was hardly at all related to the non-market interdependence of technological external economies, but rather to the market interdependence of which pecuniary external economies were part, now on an economy-wide basis. It was argued, in particular by Rosenstein-Rodan (1943) and – with a somewhat different focus – by Scitovsky (1954), that development must be planned so that supply and demand relationships among different sectors of the economy are taken into account. Specifically, it was pointed out that major investments in industrial capacity in a poor economy risk being a failure unless a required increase in the supply of inputs to meet the need of the expanding industry, as well as a sufficient stimulus of demand for the output of the expanding industry, occur at the same time. This doctrine of 'balanced growth' called for a simultaneous expansion of investment in several sectors of the economy, a 'Big Push' (Rosenstein-Rodan 1943) determined by input–output relations or general market interdependence. Scitovsky argued specifically that indivisibilities in capital formation may call for investment criteria, which – in contrast to those of individual firms – take into account the indirect supply and demand effects on profitability elsewhere in the economy.

Here, external economies came to be synonymous with what was later called linkage effects (Hirschman 1958), where backward linkages refer to the supply to the investing sector and forward linkages to the demand for the output of the investing sector. Hirschman's own analysis led

him to recommend a strategy for economic development in poor countries that was opposite to that of a 'balanced growth'. Focusing on the shortage of entrepreneurial capacity and the small impact of subtle market signals in backward areas, he advocated a strategy of 'unbalanced growth', according to which investments should be undertaken so as to reinforce market signals and create pressure for investments in sectors related to the original investments via strong linkage effects.

That linkage effects offered a more precise terminology than dynamic external economies is one reason why the latter concept now has lost ground. Another is, of course, that this meaning of external economies referred only or primarily to market interdependence, which is a general economic phenomenon. Thus, with technological external economies and diseconomies now most often replaced by the well-defined concept of external effects, and with pecuniary external economies and diseconomies being synonymous with general market interdependence, external economies no longer have much of a role to play in economic analysis. Aside from occasional use as a synonym for external effects, the concept now stands for interdependence that does not clearly fall into any of the categories mentioned here. That is, when firms affect one another in a way not covered by static equilibrium analysis or by interdependence among existing markets in the context of the dynamic analysis of economic development, external economies are still used by economists as a convenient catchall.

Again, one may ask – as did economists in the interwar period – what do these external economies actually stand for? At least some examples can be given. Growth of an industry may create a supply of new skills which turn out to provide a starting point for an altogether new line of business. Or, growth of a technologically advanced industry in a particular region leading to the location of a school of higher learning to this region may in turn stimulate – or reduce – growth of other activities. These cases are awkward to handle in traditional, well-structured economic analysis. So the main characteristic of these external economies, very much like most of those suggested by Marshall, is that we cannot yet say in any systematic way exactly what they represent.

Externalities

J. J. Laffont

Abstract

Externalities are *indirect* effects of consumption or production activity, that is, effects on agents other than the originator of such activity which do not work through the price system. In a private competitive economy, equilibria will not be in general Pareto optimal since they will reflect only *private* (direct) effects and not *social* (direct plus indirect) effects of economic activity. This article explains how this outcome arises and considers the policy responses that have been advanced to remedy the market failures stemming from externalities.

Competitive equilibria are Pareto optimal when they exist if preferences are locally non-satiated and if externalities are not present in the economy. Why externalities upset the first fundamental theorem of welfare economics and which economic policies can remedy this failure are the major questions addressed below.

Technological Externalities

Let us call technological externality the indirect effect of a consumption activity or a production activity on the consumption set of a consumer, the utility function of a consumer or the production function of a producer. By 'indirect' we mean that the effect concerns an agent other than the one exerting this economic activity and that this effect does not work through the price system.

Externalities may be positive or negative and are quite diverse. Major examples include pollution activities (air pollution, water pollution, noise pollution . . .), malevolence and benevolence, positive interaction of production activities. From a practical point of view the most significant are negative pollution activities, so that we can say that the theory of technological externalities is essentially the foundation of environmental economics.

The formalization of technological externalities is achieved in microeconomics by making production sets, utility functions and production sets (or functions) affected by externalities functionally dependent on the activities of the other agents creating these indirect effects.

For example, the utility function of a consumer is made dependent on the level of production of a firm polluting the air breathed by the consumer. This modelling option that we will implicitly adopt here is right as long as the link between production and air pollution is not alterable.

If de-polluting activities are possible the link between the level of pollution and the economic activities generating them must be made explicit. An important difficulty in analysing these activities is due to the non-convexities which they usually introduce.

Pecuniary Externalities

During the 1930s, a confused debate occurred between economists on the relevance of pecuniary externalities, that is, on externalities which work through the price system. A quite general consensus was that pecuniary externalities are irrelevant for welfare economics: the fact that by increasing my consumption of whisky I affect your welfare through the consequent increase in price does not jeopardize the Pareto optimality of competitive equilibria.

This is true when all the assumptions required for the competitive equilibria to be Pareto optimal are satisfied. In such a framework prices only equate supply and demand and pecuniary externalities do not matter. As soon as we move away from this set of assumptions prices generally play additional roles. For example, in economies with incomplete contingent markets, prices span the subspace in which consumption plans can be chosen. In economies with asymmetric information, prices transmit information. When agents affect prices, they affect the welfare of the other agents by altering their feasible consumption sets or their information structures. Pecuniary externalities matter for welfare economics.

In what follows we focus only on technological externalities.

Competitive Equilibrium with Externalities

How is the characterization of Pareto optima in convex economies affected by externalities? Very simply, as Pigou early understood. The classical equality of marginal rates of substitution and marginal rates of transformation must now be expressed using *social* marginal rates and not only *private* marginal rates as in an economy without externalities. Social marginal rates must be computed taking into account direct *and* indirect effects of economic activities. For example, the marginal cost of a polluting activity must include not only the direct marginal cost of production, but also the marginal cost imposed on the environment.

Note that Pareto optima do not exclude polluting activities, but set them at levels such that their social marginal benefit equates their social marginal cost well computed.

It is now easy to understand that in a private competitive economy, equilibria will not be in general Pareto optimal since the private decentralized optimizations of economic agents lead them to the equalization of *private and not social* marginal rates through the price system.

Markets for Pollution Rights

Consider for concreteness a firm polluting a consumer. One potential solution is to create a market for this externality. Before producing, the firm must buy from the consumer the right to pollute. If both actors were behaving competitively with respect to the price of this right, the competitive equilibrium in the economy with an extended price system would be Pareto optimal, since there is no externality left.

A number of difficulties exist with this approach. In general we cannot expect agents to behave competitively unless we are in the special case of impersonal externalities. Then, there is a fundamental non-convexity in the case of negative externalities since as a negative externality increases the production set shrinks, but there is a limit to this effect which is the zero production level. Competitive equilibria cannot then exist unless bounds are set on supplies of pollution rights. (For a positive price, a firm would like to offer an infinite amount of pollution rights and close down.)

In the above set-up, the implicit status quo was the absence of externalities. The initial rights are a clean environment: 'Polluters must pay.' We can instead give to the polluting firm the right to pollute and then ask the consumer to buy from the firm a decrease of his pollution. This different allocation of initial rights does not upset the Pareto optimality of the competitive equilibrium, but of course has distributional effects.

Taxation of Externalities

The likely strategic behaviour by agents on markets of pollution rights makes taxation of externalities the most common policy tool. The polluter must then pay for each unit of a polluting activity a tax which equals the marginal cost imposed by this activity on the other agents. The polluter then internalizes the externality and Pareto optimality is restored. If the externality is positive he must be similarly subsidized.

Note that nothing is said about the amount of taxes so obtained by the government. There is no

presumption that it is given to the polluters. In fact, the implicit assumption is that it is redistributed through lump-sum transfers which do not affect agents' behaviours (in the sense of their first-order conditions). From the point of view of Pareto optimality, the important goal is to modify polluters' behaviours.

If lump-sum transfers are not available, the budget of the government must be balanced and then goods different from the polluting activities must be taxed or subsidized to solve the ensuing second-best problem.

The major difficulty with this solution is informational.

Imperfect Information

The traditional theory of externalities has proceeded as if the regulators had complete knowledge of the economy and were therefore able to compute optimal taxes, or as if agents were not behaving strategically with respect to their private information. Very often this is not the case and the problem is to elicit this private information and use it to compute taxes, a more difficult problem.

Intuitively, the solution of what is now a second-best problem is to have taxes which depend nonlinearly on polluting activities. This nonlinearity may sometimes take the extreme form of a zero tax up to a given amount and a very large tax above, a mechanism which is equivalent to a quota.

Planning and Externalities

Externalities are not only a problem of market economies with an insufficient number of markets. One way to suppress an externality between two agents is to have them integrate into a single agent. All externalities would be internalized if the whole economy was integrated.

If we leave aside imperfect information and the associated strategic behaviours, the planning problem of these integrated agents is more complicated than if externalities were not present. Planning procedures appropriated to externalities have been provided.

Externalities and Cooperative Game Theory

Suppose we attempt to represent the outcome of cooperation in an economy with externalities by the core. The core is the set of allocations which are not blocked by any coalition. A coalition blocks an allocation if it can do better for all its members than this allocation.

Externalities introduce a difficulty in the definition of a blocking coalition.

When a group of agents envision forming a coalition they must conjecture what will be the behaviour of the complementary coalition since it is affected by the externalities of this complementary coalition.

Two extreme notions have been proposed. In the a-core a coalition is said to block an allocation if it can do better, whatever the actions of the complementary coalition. This is extremely prudent. In the β-core a coalition is said to block an allocation if, for any action of the complementary coalition, it can do better. The β-core is of course included in the α-core.

Results depends a lot on these conjectures about the actions of the complementary coalition, an unsatisfactory feature. One lesson, however, is that the core may be empty, that is, that externalities introduce an element of instability in economic games.

Historical Note

Following the pioneering work by Sidgwick (1887) and Marshall (1890), Pigou (1920) has provided the basic theory of static technological externalities. Coase (1960) has explained how initial rights could be assigned in various ways. Arrow (1969) has explained how externalities could be internalized by the creation of additional markets. Starrett (1972) has pointed out the associated problem of nonconvexity. The first theorem

of existence of an equilibrium with externalities has been provided by McKenzie (1955). Shapley and Shubik (1969) studied the core with externalities. A large number of authors have studied various second-best problems associated with externalities (Buchanan 1969; Plott 1966; Diamond 1973; Sandmo 1975).

Extremal Quantiles and Value-at-Risk

Victor Chernozhukov and Songzi Du

Abstract

This article examines the theory and empirics of extremal quantiles in economics, in particular value-at-risk. The theory of extremes has gone through remarkable developments and produced valuable empirical findings since the late 1980s. We emphasize conditional extremal quantile models and methods, which have applications in many areas of economic analysis. Examples of applications include the analysis of factors of high risk in finance and risk management, the analysis of socio-economic factors that contribute to extremely low infant birthweights, efficiency analysis in industrial organization, the analysis of reservation rules in economic decisions, and inference in structural auction models.

Introduction

Some Basics

Let a real random variable Y have a continuous distribution function $F_Y(y) = \text{Prob}[Y \leq y]$. A τ-quantile of Y is the number $F_Y^{-1}(\tau)$ such that $\text{Prob}\left[Y \leq F_Y^{-1}(\tau)\right] = \tau$ for some $\tau \in (0,1)$ (More generally, let $F_Y^{-1}(\tau) = \inf\{y : F_Y(y) > \tau\}$). The quantile function $F_Y^{-1}(\tau)$, viewed as a function of

probability index τ, is the inverse of the distribution function $F_Y(y)$. The quantile function is therefore a complete description of the distribution.

Let X be a vector of regressor variables. Let $F_Y(y|x) = \text{Prob}[Y \leq y|x]$ denote the conditional distribution function of Y given $X = x$. The conditional τ-quantile of a random variable Y with a continuous conditional distribution function is the number $F_Y^{-1}(\tau|x)$ such that $\text{Prob}\left[Y \leq F_Y^{-1}(\tau|x)|X = x\right] = \tau$. The conditional quantile function $F_Y^{-1}(\tau|x)$ viewed as a function of x is called the τ-quantile regression function. The main use of the quantile regression function $F_Y^{-1}(\tau|x)$ is to measure the effect of covariates on outcomes, both in the centre and in the upper and lower tails of an outcome distribution. To this effect, a quantile or a conditional τ-quantile will be referred to as *extremal* whenever the probability index τ is either low, $\tau \leq 0.15$, or high, $\tau \geq 0.85$. Without loss of generality, we focus the discussion on the low quantiles.

Examples as a Motivation

There are many applications of extremal quantiles in economics, particularly of extremal conditional quantiles. Here we give a sample of these applications as a motivation for what follows.

Example 1 Conditional Value-at-Risk Value-at-risk analysis seeks to forecast or explain very low conditional quantiles $F_Y^{-1}(\tau|X)$ of an institution's portfolio return, Y, tomorrow, using today's available information, X (Chernozhukov and Umantsev 2001). Typically, extremal quantiles $F_Y^{-1}(\tau|X)$ with $\tau = 0.01$ and $\tau = 0.05$ are of interest. Value-at-risk analysis is a daily activity for banking and other financial institutions, as required by the Securities and Exchange Commission and the Basle Committee on Banking Supervision. As a risk measure, value-at-risk is motivated by the safety-first decision principle formalized by Roy (1952), in which one makes optimal decisions subject to the constraint that the probability of the risk of a large loss is kept small. This and similar measures are commonly used in real-life financial management, insurance, and actuarial science (Embrechts et al. 1997).

Example 2 Determinants of Very Low Birthweights In the analysis of infant birthweights, we may be interested in how smoking, absence of prenatal care, and other types of maternal behaviour affect various birthweights (Abrevaya 2001). Of special interest, however, are the very low quantiles, since low birthweights have been linked to subsequent health problems. Chernozhukov (2006) provides an empirical study of extreme birthweights.

Example 3 Probabilistic Production Frontiers An important form of efficiency analysis in the economics industrial organization and regulation is the determination of efficiency or production frontiers (Timmer 1971). Given cost of production and possibly other factors, X, we are interested in the highest production levels that only a small fraction of firms, the most efficient firms, can attain. These (nearly) efficient production levels can be formally described by extremal quantile regression function, $F_Y^{-1}(\tau|X)$ for $\tau \in [1-\varepsilon, 1]$ and $\varepsilon > 0$; so only an ε-fraction of firms produce $F_Y^{-1}(\tau|X)$ or more. The models and methods discussed in this article are highly pertinent for inference on the probabilistic frontiers.

Example 4 (S,s)-Rules and Other Approximate Reservation Rules in Economic Decisions A related example is that of (S,s)-adjustment models, which arise as optimal policies in many economic models (Arrow et al. 1951). For example, the capital stock Z is adjusted up to the level S once it has depreciated to some low level s. In terms of an econometric specification, we may think that the observed capital stock satisfies the equation $Z_i = s(X_i) + v_i$, where X_i are covariates, and v_i is a disturbance that is positive most of the time, that is, Prob $(v_i \geq 0)$ is close to 1. Once the capital stock Z_i reaches the critical level, that is $Z_i \leq s(X_i)$, it is adjusted in the next period. We assume, as in Caballero and Engel (1999), that when the disturbance $v_i = Z_i - s(X_i)$ is negative, it captures unobserved heterogeneity and small decision mistakes that are independent of observed covariates X_i. (In this example, Z_i

could be any monotone transformation of the stock variable. For instance, the log transformation gives an accelerated failure time model for the capital stock. Caballero and Engel 1999, explore such specifications for empirical (S,s) models in detail). In a given cross-section or time series, adjustment will occur infrequently, so in fact data at or below the lower adjustment band $s(X_i)$ will be observed with a small probability Prob $(v_i \leq 0)$; hence $F_Z^{-1}(\tau|X) = s(X) + F_v^{-1}(\tau)$ for $\tau \in (0, \text{Prob}\ (v \leq 0))$. The lower-band function $s(X)$ therefore coincides with the lower conditional quantile function up to an additive constant. A similar argument works for the upper-band function $S(X)$.

Example 5 Structural Auction Models In the standard specification of the first-price procurement auction where bidders hold independent valuations, the winning bid, B_i, satisfies the equation $B_i = c(X_i)\beta(n_i))\ \varepsilon_i$, $\varepsilon_i \geq 0$, where $c(X_i)$ is the efficient cost function and $\beta(n_i) \geq 1$ is a mark-up that approaches 1 as the number of bidders, n_i, approaches infinity (Donald and Paarsch 2002). By construction, $c(X_i)\beta(n_i)$ is the extreme conditional quantile function. In empirical analysis, it is realistic to let the disturbance ε_i take some small negative value so that, when negative, these disturbances capture small decision mistakes that are independent of included explanatory variables. In this case the quantile function satisfies $F_B^{-1}(\tau|X, n) = C(X)\beta(n) + F_\varepsilon^{-1}(\tau)$, for $\tau \in (0, P[\varepsilon \leq 0])$. Quantile regression methods can be employed to make inference on $c(X)$ and $\beta(n)$.

Organization of the Article

The rest of the article is organized as follows. Section "Basic Models of Extremal Quantiles" describes the basic model of extremal quantiles and extremal conditional quantiles. Section "Basic Estimation Methods" describes basic estimation theory and inference theory. Section "Empirical Applications: An Overview and an Illustration" reviews the key empirical applications and provides an illustrative example. Section "Conclusion" concludes.

Basic Models of Extremal Quantiles

A Basic Model of Extremal Quantiles

Towards discussing inference methods, assume that the distribution function of the response variable Y has Pareto-type tails, which means that tails behave approximately like power functions. Such tails are prevalent in economic data, as discovered by the prominent Italian econonometrician Vilfredo Pareto in 1895 (see Pareto 1964). Pareto-type tails encompass or approximate a rich variety of tail behaviour, including that of thick-tailed and thin-tailed distributions, having either bounded or unbounded support, and their mathematical theory in connection to extreme value theory has been developed by Gnedenko (1943) and de Haan (1970).

Consider a random variable Y and define a random variable U as $U \equiv Y$, if the lower end-point of the support of Y is $-\infty$, and $U \equiv Y - F_Y^{-1}(0)$, if the lower end-point of the support of Y is $F_Y^{-1}(0) > -\infty$. The distribution function of U, denoted by F_U then has the lower end-point $F_U^{-1}(0) > -\infty$ or $F_U^{-1}(0) = 0$. The assumption that the distribution function F_U and its quantile function F_U^{-1} exhibit Pareto-type behaviour in the tails can be formally stated as the following two equivalent conditions (the notation $a \sim b$ means that $a/b \to 1$ as appropriate limits are taken):

$$F_U(u) \sim \overline{L}(u) \cdot u^{-1/\xi} \text{ as } u \searrow F_U^{-1}(0), \qquad (1)$$

$$F_U^{-1}(\tau) \sim L(\tau) \cdot \tau^{-\xi} \text{ as } \tau \searrow 0, \qquad (2)$$

for some real number $\xi \neq 0$, where $\overline{L}(u)$ is a nonparametric, slowly varying function at $F^{-1}(0)$, and $L(\tau)$ is a nonparametric slowly varying function at 0 (A function $u \mapsto L(u)$ is said to be slowly varying at 0 if $\lim_{l \searrow s}[L(l)/L(ml)] = 1$ for any $m > 0$). The prime examples of slowly varying functions are the constant function $L(y) = L$ and the logarithmic function. The number ξ defined in (1) and (2) is called the extreme value (EV) index.

The absolute value $|\xi|$ of the EV index ξ measures heavy tailedness of distributions. A distribution F_Y with Pareto-type tails

necessarily has a finite lower support point if $\xi < 0$ and an infinite lower support point if $\xi > 0$. Distributions with $\xi > 0$ include stable distributions, Pareto distributions, t distributions, and many others. For example, the t distribution with v degrees of freedom has the EV index $\xi = 1/v$ and exhibits a wide range of tail behaviour. In particular, setting $v = 1$ yields the Cauchy distribution which has heavy tails (with $\xi = 1$), while setting $v = 30$ yields approximately the normal distribution which has light tails (with $\xi = 1/30$). On the other hand, distributions with $\xi < 0$ include the uniform, exponential, Weibull distributions, and others.

The assumption of Pareto-type tails can be equivalently cast in terms of the regular variation assumption, as is commonly done in EV theory. Distribution function F_U is said to be *regularly varying* at $F_U^{-1}(0)$ with index of regular variation $-1/\xi$ if $\lim_{y \searrow F_U^{-1}(0)} (F_U(ym)/F_U(y) = m^{-1/\xi}$, for any $m > 0$. This condition is equivalent to the regular variation of quantile function F_U^{-1} at 0 with index $-\xi$:

$$\lim_{\tau \searrow 0} (F_U^{-1}(\tau m)/F_U^{-1}(\tau) = m^{-\xi}, \text{for any } m > 0.$$

It should be mentioned that the case of $\xi = 0$ corresponds to the class of rapidly varying distribution functions. These distribution functions have exponentially light tails, with the normal and exponential distributions being the chief examples. To simplify exposition, we do not discuss this case explicitly. However, since the limit distribution of main statistics are continuous in ξ, including at $\xi = 0$, inference theory for the case of $\xi = 0$ can be adequately approximated by the case of $\xi \approx 0$.

A Basic Model of Extremal Conditional Quantiles

Consider the classical linear functional form for the conditional quantile function of Y given $X = x$:

$$\begin{aligned} F_U^{-1}(\tau | x) &= x' \beta(\tau), \text{for all } \tau \in \mathcal{I} \\ &= (0, \eta], \text{some } \eta \in (0, 1], \end{aligned} \tag{3}$$

and for every x in the support of X. This linear functional form is flexible in the sense that it has good approximation properties. Given the original regressor X^*, the final set of regressors X to be used in estimation can be formed as a vector of approximating functions. For example, X may include power functions, splines, and other transformations of X^*. The linear functional form also provides computational convenience.

The following model for the tails and its generalizations were developed in Chernozhukov (2005). The main assumption is that the response variable Y, transformed by some auxiliary regression line, has regularly varying tails with EV index ξ. Indeed, in addition to (3), suppose there exists an auxiliary parameter β_e such that the disturbance $U \equiv Y - X'\beta_e$ has conditional end-point 0 or $-\infty$ a.s. and its conditional quantile function $F_U^{-1}(\tau | x)$ satisfies the following tail-equivalence relationship as $\tau \searrow 0$, uniformly for x in the support of X:

$$F_U^{-1}(\tau | x) = F_Y^{-1}(\tau | x) - x' \beta_e \sim F_u^{-1}(\tau), \tag{4}$$

where F_u^{-1} is a quantile function such that

$$F_u^{-1}(\tau) \sim L(\tau) \tau^{-\xi}, \tag{5}$$

where $L(\tau)$ is a non-parametric slowly varying function at 0. Equation (5) imposes Pareto-type behaviour on the conditional law, while Eq. (4) requires this behaviour to hold uniformly across conditioning values. Since this assumption only affects the tails, it allows covariates to impact the extremal quantiles and the central quantiles very differently; the impact of covariates on extremal quantiles is approximated by β_e, which could differ sharply from, for example, the impact on the median given by $\beta(1/2)$. Chernozhukov (2005) provides further generalizations of this model.

Basic Estimation Methods

Estimates Based on Sample Quantiles

Given T observations $\{Y_t, t = 1, \ldots, T\}$, the τ-sample quantile can be obtained by solving the following optimization problem:

$$\hat{F}_Y^{-1}(\tau) \in \arg\min_{\beta \in R^d} \sum_{t=1}^{T} \rho_\tau(Y_t - \beta), \qquad (6)$$

where $\rho_\tau(u) = (\tau - 1(u < 0))u$ is the asymmetric absolute deviation function of Fox and Rubin (1964).

Sample quantiles are also order statistics, and we will refer to τT as the *order* of τ-quantile. The sequence of quantile index-sample size pairs (τ, T) will be said to be an *extreme order* sequence if $\tau \searrow 0$ and $\tau T \to k > 0$, an *intermediate order* sequence if $\tau \searrow 0$ and $\tau T \to \infty$, and a *central order* sequence if τ is fixed and $T \to \infty$. Each different type of the sequence leads to different asymptotic approximations to the finite-sample distributions of sample quantiles. Extreme order sequences lead to non-normal (extreme-value) distributions (EV) that approximate the finite sample distributions of extremal (high and low) quantiles much better than the normal distributions do. In particular, EV distributions work much better than the normal distribution if $\tau T \leq 30$.

Extreme Order Quantiles

Consider an extreme-order sequence. The following is the classical result on the limit distribution of order statistics: for any integer $k \geq 1$ and $\tau = k/T$, as $T \to \infty$,

$$A_T\left(\hat{F}_Y^{-1}(\tau) - F_Y^{-1}(\tau)\right) \to {}_d\Gamma_k^{-\xi} - k^{-\xi} \qquad (7)$$

where

$$A_T = 1/F_U^{-1}(1/T), \quad \Gamma_k = \mathscr{E}_1 + \cdots + \mathscr{E}_k \qquad (8)$$

and $(\mathscr{E}_1, \mathscr{E}_2, \ldots)$ is an independent and identically distributed sequence of standard exponential variables.

Result (7) was obtained by Gnedenko (1943) under the assumption that $Y_1, Y_2, \ldots$ is a sequence of independently and identically distributed (i.i.d.) random variables. Result (7) continues to hold for stationary weakly dependent series, provided the probability of extreme events occurring in clusters is negligible relative to the probability of a single extreme event (Meyer 1973). The results have been generalized to more general time series processes (Leadbetter et al. 1983).

Result (7) gives an EV distribution as an approximation to the finite-sample distribution of $\hat{F}_Y^{-1}(\tau)$ The EV distribution is characterized by the EV index ξ, which can be estimated by one of the methods described below. Variables Γ_k, entering the definition of the EV distribution, are known as *gamma* random variables. The limit distribution of the kth-order statistic is therefore a transformation of a gamma variable. The EV distribution is not symmetric and may have significant (median) bias. The EV distribution has finite moments if $\xi < 0$ and has finite moments of up to order $1/\xi$ if $\xi > 0$.

The classical result is not feasible for purposes of inference on $F_Y^{-1}(\tau)$, since the scaling constant A_T is not easily estimable consistently. One way to overcome this problem is to make additional strong assumptions in order to estimate A_T consistently. For instance, suppose that $F_U^{-1}(\tau) \sim L\tau^{-\xi}$, then one can estimate ξ using methods described below and L by $\hat{L} = \left(\hat{F}_Y^{-1}(2\tau) - \hat{F}_Y^{-1}(\tau)\right) / \left(2^{-\hat{\xi}} - 1\right)\tau^{-\hat{\xi}}$.

Another way to overcome the aforementioned infeasibility is to consider the asymptotics of self-normalized extreme order quantiles, as in Chernozhukov (2006):

$$Z_T(\tau) = \mathcal{A}_T\left(\hat{F}_Y^{-1}(\tau) - F_Y^{-1}(\tau)\right) \to d\frac{\sqrt{k}\left(\Gamma_k^{-\xi} - k^{-\xi}\right)}{\Gamma_{mk}^{-\xi} - \Gamma_k^{-\xi}} \qquad (9)$$

where for $m > 1$ such that mk is an integer,

$$\mathcal{A}_T = \frac{\sqrt{\tau T}}{\hat{F}_Y^{-1}(m\tau) - \hat{F}_Y^{-1}(\tau)}. \qquad (10)$$

Here, the scaling factor A_T is feasible in that it is completely a function of data. The limit distribution only depends on the EV index ξ, and its quantiles can be easily calculated analytically or by simulation.

E

Intermediate Order Quantiles

Consider next an intermediate order sequence. As $\tau \searrow 0$ and $\tau T \to \infty$, under further regularity conditions,

$$Z_T(\tau) = \mathcal{A}_T\left(F_Y^{-1}(\tau) - F_Y^{-1}(\tau)\right) \to_d \mathcal{N}\left(0, \frac{\xi^2}{(m^\xi - 1)^2}\right), \qquad (11)$$

where A_T is defined as in (10). This result, obtained by Dekkers and de Haan (1989), gives a normal asymptotic approximation to the finite-sample distribution of sample quantile $F_Y^{-1}(\tau)$ The main condition for application of this distribution is that $\tau T \to \infty$. In finite samples, we may interpret this as requiring that $\tau T \geq 30$ at the minimum.

The normal approximation (11) is convenient, but extreme approximation (9) is always better, because it does not fail when $\tau T \to k < \infty$ and it coincides with the normal approximation (11) once k is large.

Extremal Bootstrap

In many cases it is convenient to implement inference using the following approach. Consider the sample of i.i.d. variables:

$$(Y_1, \ldots, Y_T) = \left(\frac{\mathscr{E}_1^{-\xi} - 1}{-\xi}, \ldots, \frac{\mathscr{E}_T^{-\xi} - 1}{-\xi}\right), \qquad (12)$$

where $(\mathscr{E}_1, \ldots, \mathscr{E}_T)$ is an i.i.d. sequence of standard exponential variables. (Y_t, defined in this way, follows generalized extreme value distribution, which nests the Frechet, Weibull, and Gumbell distributions. There are other possibilities, for example, $(\mathscr{E}_1, \ldots, \mathscr{E}_T)$ in (13) can be replaced by uniform variables $(U_1, \ldots, U_T)$, in which case Y_t follows the generalized Pareto distribution.) Variables generated in this way have the quantile function:

$$F_Y^{-1}(\tau) = \frac{[-\ln(1-\tau)]^{-\tau} - 1}{-\xi} \qquad (13)$$

Observe that $F_Y^{-1}(\tau) - 1/\xi \sim \tau^{-\xi}/\xi$, so condition (1) is satisfied. We propose to estimate the finite-sample distributions of $Z_T(\tau) = \mathscr{A}_T\left(F_Y^{-1}(\tau) - F_Y^{-1}(\tau)\right)$ by the finite-sample distribution of $Z_T(\tau)$ for the case when the data follow (13). In this way, we reproduce both the EV limit (9) and the normal limit (11) under extreme and intermediate sequences, and also guarantee good finite-sample performance for the case when (13) holds exactly. The simulation can be done using the following algorithm:

1. For each $i \leq B$, draw $(Y_1, \ldots, Y_T)$ as i.i.d. according to (13), replacing ξ with a suitable estimate $\hat{\xi}$. Compute the statistic $Z_{T,i}(\tau) = \mathcal{A}_T\left(F_Y^{-1}(\tau) - F_Y^{-1}(\tau)\right)$.
2. Use quantiles of the simulated sample $(Z_{T,i}(\tau), i \leq B)$ for inference purposes.

This scheme could be used to estimate distributions of other statistics, including estimators of the EV index and extrapolation estimators.

Another method, developed in Chernozhukov (2006), is based on subsampling the self-normalized quantile statistic. This method is less accurate than the extremal bootstrap. However, it applies under more general conditions. It should be noted that the canonical (nonparametric) bootstrap does not work in these settings (Bickel and Freedman 1981).

Confidence Intervals for $F_Y^{-1}(\tau)$ and Bias Correction for $F_Y^{-1}(\tau)$

Let the α-quantile of $Z_T(\tau)$ be denoted by $c(\alpha)$. The estimates of $c(\alpha)$ can be obtained using either EV approximation, normal approximation, or the extremal bootstrap, also having replaced ξ with a suitable estimate. Denote the resulting estimates by $\hat{c}(\alpha)$. Then, the median bias-corrected estimate and α%-confidence region for $F_Y^{-1}(\tau)$ can be constructed as

$$F_Y^{-1}(\tau) - \frac{\hat{c}(1/2)}{\mathcal{A}_T} \quad \text{and} \quad \left[\hat{F}_Y^{-1}(\tau) - \frac{\hat{c}(1-\alpha/2)}{\mathcal{A}_T}, \hat{F}_Y^{-1}(\tau) - \frac{\hat{c}(\alpha/2)}{\mathcal{A}_T}\right]. \qquad (14)$$

Estimators of the EV Index ξ

There are two principal estimators. The first estimator, due to Pickands (1975), relies on the ratio of sample quantile spacings:

$$\hat{\xi} = -\ln\left[\frac{\hat{F}_Y^{-1}(4\tau) - \hat{F}_Y^{-1}(2\tau)}{\hat{F}_Y^{-1}(2\tau) - \hat{F}_Y^{-1}(\tau)}\right]/\ln 2, \qquad (15)$$

such that $\tau \to 0$ and $\tau T \to \infty$ as $T \to \infty$. Under further regularity conditions,

$$\sqrt{\tau T}\left(\hat{\xi} - \xi\right) \to_d \mathcal{N}^d\left(0, \frac{\xi^2\left(2^{2\xi+1}+1\right)}{\left(2\left(2^{\xi}-1\right)\ln 2\right)^2}\right) \qquad (16)$$

Another estimator, developed by Hill (1975), is a moments estimator (notation $(x)_-$ means $(x)_- = -x$ if $x < 0$ and $(x)_- = 0$ if $x \geq 0$):

$$\hat{\xi} = \frac{\sum_{t=1}^{T} \ln\left(Y_t/\hat{F}_Y^{-1}(\tau)\right)_-}{T\tau} \qquad (17)$$

such that $\tau \to 0$ and $\tau T \to \infty$ as $T \to \infty$. This estimator is applicable only for the case of $\xi > 0$. The estimator can be motivated by a maximum likelihood method that fits an exact power law to the tail data. Under further regularity conditions,

$$\sqrt{\tau T}\left(\hat{\xi} - \xi\right) \to_d \mathcal{N}\left(0, \xi^2\right). \qquad (18)$$

The methods for choosing τ are described in Embrechts et al. (1997). The variance of estimators decreases as τ increases, but the bias (relative to the true ξ) goes up. Another view on the choice of τ is the following: statistical models are approximations, not literal descriptions of the data. In practice, dependence of $\hat{\xi}$ on the threshold τ reflects that power laws with different values of ξ fit better different tail regions. Therefore, if the interest lies in making inference on $\hat{F}_Y^{-1}(\tau)$ for a particular τ, it seems reasonable to use ξ constructed using the same τ or most similar τ' subject to the condition that $\tau' T \geq 30$ (The latter condition requires that a sufficient sample be available to estimate ξ).

The limit results above can be used for the construction of confidence regions. As an alternative, we can apply extremal bootstrap to statistic $Z_T = \sqrt{\tau T}\left(\hat{\xi} - \xi\right)$. To estimate the quantiles of Z_T. Given the estimated α-quantiles $\hat{c}(\alpha)$, we can construct the median bias-corrected estimate and α%-confidence regions for ξ.

Extrapolation Estimators

When very extreme quantiles cannot be estimated precisely, the following strategy is sensible: estimate less extreme quantiles reliably, and then extrapolate these estimates using the assumptions on tail behaviour stated earlier. Dekkers and de Haan (1989) developed the following extrapolation estimator:

$$\hat{F}_Y^{-1}(\tau_e) = \frac{(\tau_e/\tau)^{-\hat{\xi}} - 1}{2^{-\hat{\xi}} - 1}\left[\hat{F}_Y^{-1}(2\tau) - \hat{F}_Y^{-1}(\tau)\right] + \hat{F}_Y^{-1}(\tau), \qquad (19)$$

where $\tau_e \ll \tau$. Another useful estimator, which is valid only for the case of $\xi > 0$, is the following:

$$\hat{F}_Y^{-1}(\tau_e) = (\tau_e/\tau)^{-\hat{\xi}} \cdot \hat{F}_Y^{-1}(\tau), \qquad (20)$$

where $\tau_e \ll \tau$. The above estimators have good properties provided the quantities on the right-hand side of (19) and (20) are well estimated, which requires that τT be large, and that the tail model be a good approximation of the underlying true tail.

Estimates Based on Sample Regression Quantiles

Given T observations $\{Y_t, X_t, t = 1, \ldots, T\}$, the quantile regression estimate of $F_Y^{-1}(\tau|x)$ is given by:

$$\hat{F}_Y^{-1}(\tau|x) = x'\hat{\beta}(\tau), \hat{\beta}(\tau) = \arg\min_{\beta \in \mathbb{R}^d} \sum_{t=1}^{T} \rho_\tau\left(Y_t - X_t'\beta\right), \qquad (21)$$

where $\rho_\tau(u) = (\tau - 1(u < 0))u$. Quantile regression was introduced by Laplace (1818) for the

median case. Koenker and Bassett (1978) extended this formulation to other quantiles.

Extreme Order Asymptotics

Chernozhukov (2005) derives asymptotic distributions of regression quantiles under extreme-order sequences. Consider the canonically normalized QR statistic

$$\hat{Z}_T(k) = A_T\left(\hat{\beta}(\tau) - \beta(\tau)\right), \text{where } A_T = 1/F_u^{-1}(1/T), \tag{22}$$

and the self-normalized QR statistic

$$Z_T(k) = \mathcal{A}_T\left(\hat{\beta}(\tau) - \beta(\tau)\right), \text{where } \mathcal{A}_T = \frac{\sqrt{\tau T}}{\overline{X}'\left(\hat{\beta}(m\tau) - \hat{\beta}(\tau)\right)}, \tag{23}$$

where $\tau T(m-1) > d$. The first statistic uses an infeasible canonical normalization, while the second statistic uses a feasible normalization. Then as $\tau T \to k > 0$ and $T \to \infty$

$$\begin{aligned}\hat{Z}_T(\tau) &\to_d Z^d\infty(k) - k^{-\xi}, Z_\infty(k) \\ &= \text{argmin}_{z\in\mathbb{R}^d}\left[-kE[X]'z + \sum_{i=1}^{\infty}\left[X_i'z - \Gamma_i^{-\xi}\right]_+\right] \\ &\quad \times (\xi < 0)\, Z_\infty(k) = \text{argmin}_{z\in\mathbb{R}^d} \\ &\left[-kE[X]'z + \sum_{i=1}^{\infty}\left[X_i'z - \Gamma_i^{-\xi}\right]_+\right] \\ &\quad \times (\xi > 0)\end{aligned} \tag{24}$$

where $\{\Gamma_1, \Gamma_2, \ldots\} := \{\mathscr{E}_1, \mathscr{E}_1 + \mathscr{E}_2, \ldots\}$ and $\{\mathscr{E}_1, \mathscr{E}_1, \ldots\}$ is an i.i.d. sequence of exponential variables that is independent of $\{X_1, X_2, \ldots\}$. Further, for any m such that $k(m-1) > d$,

$$Z_T(\tau) \to_d \frac{\sqrt{k}Z_\infty(k)}{E[X]'(Z_\infty(mk) - Z_\infty(k))}. \tag{25}$$

The results hold under the assumption that the data come from either an i.i.d. sequence or a stationary weakly dependent sequence with extreme events satisfying a non-clustering condition.

Related results for canonically normalized statistics for the case where $\tau T \to 0$ as $T \to \infty$ have been obtained by Knight (2001) and Portnoy and Jurečková (1999).

Intermediate Order Asymptotics

Chernozhukov (2005) shows that under intermediate order sequences, as $\tau \searrow 0$ and $\tau T \to \infty$,

$$\begin{aligned}Z_T(\tau) &= \mathcal{A}_T\left(\hat{\beta}(\tau) - \beta(\tau)\right) \\ &\to_d \mathcal{N}^d\left(0, [E(XX')]^{-1}\frac{\xi^2}{(m^{-\xi}-1)^2}\right),\end{aligned} \tag{26}$$

where $\mathscr{A}_T$ is defined as in (28). Like the result under extreme order sequences, this result holds under the assumption that the data come either from an i.i.d. sequence or from a stationary weakly dependent sequence with extreme events satisfying a non-clustering condition.

Extremal Bootstrap

In practice, it is convenient to implement inference by constructing a bootstrap model that approximates the tail features of the true conditional quantile model under the assumptions of Sect. "A Basic Model of Extremal Conditional Quantiles"; then using this model to simulate the distributions of estimators of extreme quantiles and tail parameters.

Consider the sample

$$\begin{aligned}&((Y_1, X_1), \ldots, (Y_T, X_T)) \\ &= \left(\left(\frac{\mathscr{E}_1^{-\xi} - 1}{-\xi}, X_1\right), \ldots, \left(\frac{\mathscr{E}_T^{-\xi} - 1}{-\xi}, X_T\right)\right),\end{aligned} \tag{27}$$

where $(\mathscr{E}_1, \ldots, \mathscr{E}_T)$ is an i.i.d. sequence of standard exponential variables and $(X_1, \ldots, X_T)$ is a fixed set of observations on regressors that we have. Variable Y_t generated in this way has the conditional quantile function

$$\begin{aligned}&F_{Y_t}^{-1}(\tau|X_t) = X_t'\beta(\tau) = \frac{[-\ln(1-\tau)]^{-\xi} - 1}{-\xi}, \\ &\text{where } \beta(\tau) = \left(\frac{[-\ln(1-\tau)]^{-\xi} - 1}{-\xi}, 0, \ldots, 0\right)'.\end{aligned} \tag{28}$$

Observe that $F_{Y_t}^{-1}(\tau|X_t) - 1/\xi \sim \tau^{-\xi}/\xi$, so the model satisfies conditions (4) and (5), as does the true conditional quantile model under our assumptions. Hence we can estimate the finite-sample distributions of $Z_T(\tau) = \mathcal{A}_T\left(\hat{\beta}(\tau) - \beta(\tau)\right)$ by the finite-sample distribution of $Z_T(\tau)$ in the case when data follows (32). In this simple way, we can replicate both the EV approximation (31) and the normal approximation (24) and also guarantee good finite-sample performance for the case when the model (32) holds. The simulation can be done using the following algorithm:

1. For each $i \leq B$, draw data according to (32), replacing ξ with a suitable estimate $\hat{\xi}$. Compute the statistic $Z_{T,i}(\tau) = \mathcal{A}_T\left(\hat{\beta}(\tau) - \beta(\tau)\right)$.
2. Use the empirical distribution of the simulated sample $(Z_{T,i}(\tau), i \leq B)$ for inference.

This method can also be used to estimate distributions of estimators of the EV index and extrapolation estimators described below.

As mentioned before, there is another inference method proposed by Chernozhukov (2006) which uses subsampling to estimate the distribution of the self-normalized statistic $Z_T(\tau)$. This method is less accurate than the extremal bootstrap, but it applies under more general conditions.

Confidence Intervals and Bias Corrected Estimates

Suppose we are interested in the parameter $\psi'\beta(\tau)$ for some non-zero vector ψ. Let the α-quantile of $\psi' Z_T(\tau)$ be denoted by $c(\alpha)$. Having replaced ξ with a suitable estimate, the estimates of $c(\alpha)$ can be obtained using either the EV approximation, normal approximation or the extremal bootstrap. Denote the resulting estimates by $\hat{c}(\alpha)$. The median-bias corrected estimator and the α%-confidence interval for $\psi'\beta(\tau)$ can be constructed as

$$\psi'\hat{\beta}(\tau) - \frac{\hat{c}(1/2)}{\mathcal{A}_T} \text{ and } \left[\psi'\hat{\beta}(\tau) - \frac{\hat{c}(\alpha/2)}{\mathcal{A}_T}, \psi'\hat{\beta}(\tau) - \frac{\hat{c}(1-\alpha/2)}{\mathcal{A}_T}\right]. \tag{29}$$

Estimators of the EV Index ξ

The following estimators are regression analogs of the Pickands and Hill estimators. The first estimator takes the form

$$\hat{\xi} = -\ln\left[\frac{\hat{F}_Y^{-1}(4\tau\overline{X}) - \hat{F}_Y^{-1}(2\tau\overline{X})}{\hat{F}_Y^{-1}(2\tau\overline{X}) - \hat{F}_Y^{-1}(\tau\overline{X})}\right]/\ln 2, \tag{30}$$

where $\overline{X}$ is the average value of X_t. Under additional regularity conditions, as $\tau \searrow 0$ and $\tau T \to \infty$

$$\sqrt{\tau T}\left(\hat{\xi} - \xi\right) \to_d \mathcal{N}\left(0, \frac{\xi^2\left(2^{2\xi+1}+1\right)}{\left(2\left(2^{\xi}-1\right)\ln 2\right)^2}\right). \tag{31}$$

The second estimator, which is applicable when $\xi > 0$, takes the form:

$$\hat{\xi} = -\frac{\sum_{t=1}^{T} \ln\left(Y_t/\hat{F}_Y^{-1}(\tau|X_t)\right)}{T\tau}. \tag{32}$$

Under additional regularity conditions, as $\tau \searrow 0$ and $\tau T \to \infty$

$$\sqrt{\tau T}\left(\hat{\xi} - \xi\right) \to_d \mathcal{N}\left(0, \xi^2\right). \tag{33}$$

The limit results above can be used for the construction of confidence regions. An alternative approach is to apply the extremal bootstrap to statistic $Z_T = \sqrt{\tau T}\left(\hat{\xi} - \xi\right)$ to estimate the quantiles of this statistic. Then we can use estimated α-quantiles $\hat{c}(\alpha)$ for constructing the median bias-corrected estimate and α%-confidence regions for ξ:

$$\hat{\xi} - \frac{\hat{c}(1/2)}{\sqrt{\tau T}} \text{ and } \left[\hat{\xi} - \frac{\hat{c}(1-\alpha/2)}{\sqrt{\tau T}}, \hat{\xi} - \frac{\hat{c}(\alpha/2)}{\sqrt{\tau T}}\right]. \tag{34}$$

Extrapolation Estimators

By analogy with the unconditional case, the extrapolation estimators for $\hat{F}_Y^{-1}(\tau_e\overline{X})$, where τ_e is a very low value, can be constructed as

$$\hat{F}_Y^{-1}(\tau_e|x) = \frac{(\tau_e/\tau)^{-\hat{\xi}} - 1}{m^{-\hat{\xi}} - 1} \left[\hat{F}_Y^{-1}(m\tau|x) - \hat{F}_Y^{-1}(\tau|x)\right] + \hat{F}_Y^{-1}(\tau|x), \quad (35)$$

$$\hat{F}_Y^{-1}(\tau_e|x) = (\tau_e/\tau)^{-\hat{\xi}} \hat{F}_Y^{-1}(\tau|x)(\xi > 0), \quad (36)$$

where $\tau_e \ll \tau$. Note that the estimator (41) is valid only in the case $\xi > 0$. The comments given for the unconditional case apply here as well. Also, we can construct confidence regions for $F_Y^{-1}(\tau_e|x)$ based on extrapolation estimators. This can be done by applying the extremal bootstrap to statistic $Z_T = \mathcal{A}_T\left(\hat{F}_Y^{-1}(\tau_e|x) - \hat{F}_Y^{-1}(\tau_e|x)\right)$ where $\mathcal{A}_T = \sqrt{\tau T}/\overline{X}'\left(\hat{\beta}(2\tau) - \hat{\beta}(\tau)\right)$.

Empirical Applications: An Overview and an Illustration

A Simple Overview

The following review is not exhaustive by any means; it aims to provide only a few quintessential references.

Extremal Unconditional Quantiles

As mentioned in Sect. "Basic Models of Extremal Quantiles", Pareto analysed income and wealth data in 1895 and suggested that power laws accurately describe the tail data. Pareto's discovery, although rmkably simple, had a profound effect on both empirics and the theory of extremes. Zipf (1949), Mandelbrot (1963), Fama (1965), Praetz (1972), Sen (1973), Jansen and de Vries (1991), and Longin (1996), among others, gave further empirical evidence on the nature and prevalence of Pareto-type laws in economic data, including city sizes, incomes, and financial returns.

It should be mentioned that many of the early studies were highly informal in nature. The theoretical work in extreme value theory has opened paths for better analysis. From this aspect, the study of Jansen and de Vries (1991) can be singled out as it gave, to our knowledge, the first highly rigorous analysis of the tail properties of financial returns. Jansen and de Vries (1991) estimate the EV indices for various primary US stocks to be between $\xi = 1/5$ and $\xi = 1/3$. Using quantile extrapolation estimators to estimate value-at-risk, they also conclude that the 1987 market crash was not an outlier. Rather it was a rare event, the magnitude of which could have been predicted using prior data. This study stimulated numerous other studies that rigorously document the tail properties of economic data (Embrechts et al. 1997).

Extremal Conditional Quantiles

There has been considerably less work on conditional methods. However, following recent theoretical advances we expect that this area will see active development in the near future. In what follows, we merely highlight some of the topics and directions.

In what might be the earliest example of conditional quantile analysis, Quetelet (1871) fitted various conditional quantile curves to age–height data. Remarkably, Quetelet's work included tabulations of very high and very low quantiles of heights as a function of age. There is a great potential for the applications of extremal quantile regression methods in similar problems. In a recent study, Chernozhukov (2006) estimates the impact of smoking and maternal behaviour on extremely low birthweights in the United States, focusing on black mothers. He finds that the impact of these variables on birthweights in the ranges between 250 and 1500 g sharply differs from their impact on the central birthweights. For instance, smoking is not correlated with extremal birthweights, while quality of prenatal medical care is strongly linked to extremal birthweights.

Aigner and Chu (1968), Timmer (1971), and Aigner et al. (1976) pioneered a large empirical literature on production frontiers. A major problem of the subsequent empirical literature has been the lack of statistical methods for construction of reliable estimates and confidence regions. The new methods discussed in Sect. "Basic Estimation Methods" solve the problem, and should improve the rigour of the empirical work in this area.

There is a considerable appeal for the use of extremal conditional quantile methods in auction models. An important study that illustrates the potential is by Donald and Paarsch (2002), who analyse an empirical structural auction model.

They estimate the conditional support function of bids using extreme order statistics for each covariate cell, then project the estimated function onto a lower dimensional structural function implied by the model via a minimum-distance method. A generalization of this approach is to employ extremal quantile regression for estimation of the (approximate) support function in the first stage (The use of near-extreme quantile regression for estimation of approximate support functions allows the researcher to discard some outliers that do not conform the model, in the spirit of the discussion given in Sect. "Introduction").

Value-at-risk is another potentially important area of applications of the extremal quantile regression. Chernozhukov and Umantsev (2001) apply these methods to the problem of forecasting value-at-risk of a major US oil company. They estimate extremal conditional quantiles, using both ordinary and extrapolation methods, and implement confidence regions, using subsampling methods described in Chernozhukov (2006). The section below briefly revisits some of the main qsts of this study.

An Illustrative Example

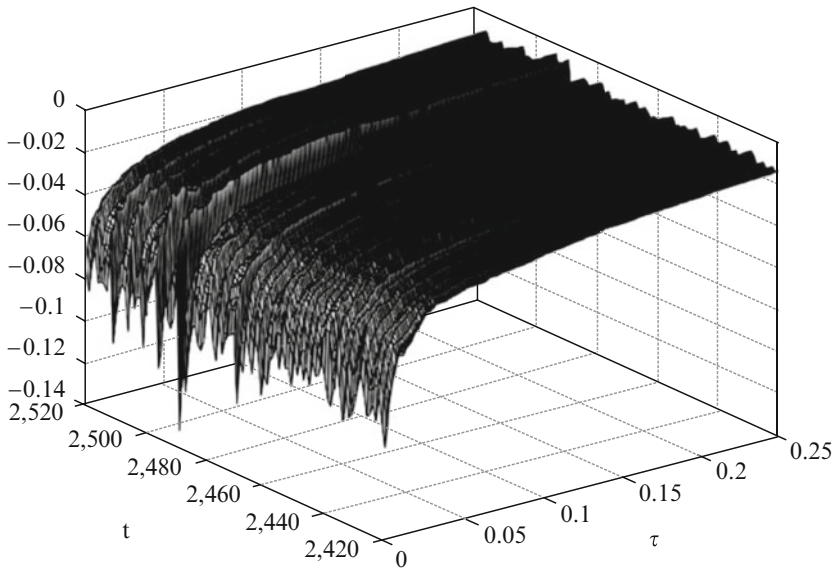
Here we consider a problem of forecasting conditional value-at-risk. We revisit some of the qsts asked in Chernozhukov and Umantsev (2001) with an improved methodology. To implement the analysis, we use algorithms written in R language that rely on Koenker's (2006) quantreg package as the basic platform. The algorithms as well as the data-set can be downloaded from http://www.mit.edu/~vchern/EQR (accessed 23 April 2007). A detailed description of the data-set is given in Chernozhukov and Umantsev (2001).

We estimate the following conditional quantile function for various low values of τ:

$$\begin{aligned}\hat{F}_Y^{-1}(\tau|X_t) &= X_t'\beta(\tau)\\ &= \beta_0(\tau)+\beta_1(\tau)X_{t,1}\\ &\quad +\beta_2(\tau)X_{t,2}+\beta_3(\tau)X_{t,3},\end{aligned} \quad (37)$$

where Y_t is the daily (log) return on the stock of Occidental Petroleum, $X_{t,1}$ is the lagged return on spot oil price, $X_{t,2}=Y_{t-1}$ is the lagged own return, and $X_{t,3}$ is the lagged return on the Dow Jones Industrial Index. There are 2527 observations in the sample.

We first estimate and plot the function $(\tau,t)\mapsto X_t'\beta(\tau)$ in (τ,t) space, with $\tau\le 0.25$. The graph of this function, shown in Fig. 1, gives a good picture of the evolution of risk over time, indicating dates



Extremal Quantiles and Value-at-Risk, Fig. 1 The fit $X_t'\beta(\tau)$ as a function of time t and τ (*Source*: Chernozhukov and Umantsev (2001))

where the predicted risk is especially high. Let us next determine what causes these risk fluctuations.

Table 1 reports the estimates of the coefficients of the model (37). The table also reports median bias-corrected estimates and 90% confidence regions, which were obtained using the extremal bootstrap approach described in Sect. "Basic Estimation Methods". The results show that the primary determinant of the high-risk levels is the market. The further in the tail we go, the larger is the magnitude of the point estimate of the coefficient on the DJI return. Moreover, the confidence region for this coefficient excludes zero even at $\tau = 0.001$.

We next characterize the tail properties of the conditional quantile model. Table 2 reports the estimates of the EV index ξ obtained using estimator (37). The table also reports median bias-corrected estimates, and 90% confidence regions, which were obtained using the nested approach described in Sects. "Extremal Bootstrap" and "Estimators of the EV Index ξ". The bias-corrected estimates tend to be stable with respect to the start of the tail determined by probability index τ. On the basis of Table 2, we take $\hat{\xi} \approx 1/4$ to be the estimate of the EV index.

Having characterized the EV index, we can now estimate very extreme quantiles using extrapolation methods. We set the risk level at $\tau = 0.0001$, so that the return falls below $F^{-1}_{Y_t}(0.0001|X_t)$ only once per about 30 years, a very

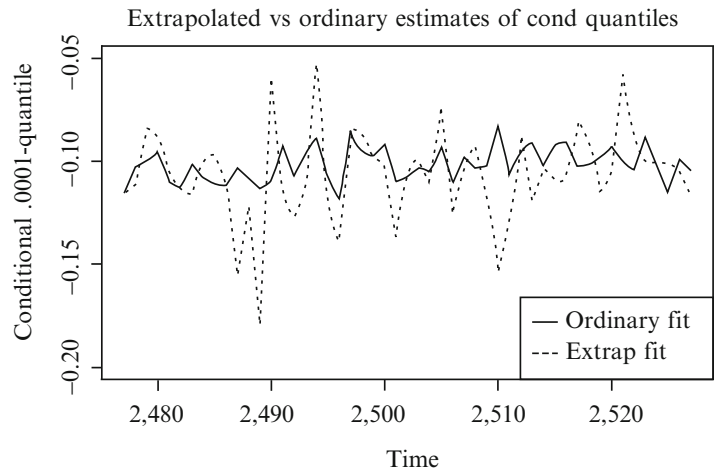
Extremal Quantiles and Value-at-Risk, Table 2 Estimation results for the EV index ξ

	Estimate	Bias-corrected	Estimate 90% conf. region
$\tau = 0.005$	0.24	0.22	[0.08, 0.34]
$\tau = 0.01$	0.23	0.17	[0.05, 0.25]
$\tau = 0.025$	0.32	0.24	[0.14, 0.30]
$\tau = 0.05$	0.35	0.23	[0.16, 0.27]



Extremal Quantiles and Value-at-Risk, Fig. 2 Extrapolated and ordinary estimates of the conditional 0.0001-quantile

rare, extreme event. The extrapolated estimates of 0.0001-quantile are obtained using Eq. (41) with $\tau = 0.05$ and $\hat{\xi} = 1/4$. The resulting extrapolation fit $\hat{F}^{-1}_{Y_t}(0.0001|X_t)$ sharply differs from the ordinary fit $X_t\hat{\beta}(\tau)$ obtained by quantile regression. The reason for this is simple: the ordinary fit uses sample data that likely contains no observations on the extreme events defined above. In sharp contrast, the extrapolated fit uses the tail model and a reliably estimated conditional 0.05-quantile to predict the magnitude of such events. The quality of this prediction clearly depends on whether the tail model is accurate (Fig. 2).

Conclusion

This article examines the theory and empirics of extremal quantiles in economics. The theory of extremes provides a set of applicable methods that have generated numerous valuable empirical findings. There is equally promising scope for the use of the extremal conditional quantile methods. The latter methods are new – there are great opportunities for further empirical and theoretical developments.

Extreme Bounds Analysis

Edward E. Leamer

Abstract

Extreme bounds analysis is a global sensitivity analysis that applies to the choice of variables in a linear regression. Rather than a discrete search over models that include or exclude subsets of the variables, this sensitivity analysis answers the question: how extreme can the estimates be if any linear homogenous restrictions on a selected subset of the coefficients are allowed? When these bounds are too wide to be useful, narrower bounds can be found by restricting the set of prior distributions that underlie the sensitivity analysis.

The analysis of economic data necessarily depends on assumptions that our weak data-sets do not allow us to test. We are forced to choose a limited number of variables in a multivariate analysis, to restrict the functional form, to limit the considered interdependence among observations to special forms, and to make special distributional assumptions. We make these assumptions, not because we believe them, but because we have to. Absent assumptions, our data-sets are utterly useless.

We sometimes put aside the discomfort that our choice of assumptions entails by doing what is conventional, like using a normal distribution, a linear functional form and the same limited set of variables studied by almost everyone else.

We sometimes pretend to treat the problem of choice of assumptions by using 'nonparametric' methods that masquerade as assumption-free. These methods are assumption-free only in Asymptopia, the land where all data-sets are unlimited. To get to the happy land of Asymptopia, we need only let the number of tested assumptions grow in the future more slowly than the number of observations. Then we can be sure to test all assumptions during our journey into the future. But here on Earth we have limited data-sets, and inevitably the way we analyse these data works well for some sets of assumptions and not so well for others. We cannot really know what we are doing unless we can draw some kind of line between the assumptions for which our inferences are valid and the assumptions for which our inferences are not valid. Thus, for example, 'heteroscedasticity-consistent' standard errors are now commonly deployed as if they were corrections for any form of heteroscedasticity. But these corrections of the standard errors, which leave the point estimates unchanged, are an appropriate treatment given the actual limited data only for some forms of heteroscedasticity, not for all. Unfortunately, with these 'nonparametric' methods, the border between the dealt-with assumptions for which the method works and the not-dealt-with assumptions is impossible to draw. Incidentally, these 'heteroscedasticity-consistent' standard errors are often called White-corrected standard errors, to which I respond rhetorically by calling the method 'White-washing'.

If conventions and nonparametric methods are not enough to soften the discomfort with the

assumptions we make, we can always fantasize that the choice of assumptions doesn't really matter. We 'know' the methods we use work well under conditions that are 'close' to the assumptions that underlie them but not well if the departures are great. We hope that the neighbourhood in which the assumptions work is wide enough to encompass the problem at hand. For example, we don't really think the distribution is normal, but how much could that matter for linear regression? Isn't it enough to have symmetric unimodal distributions, shaped 'sort of like' a normal distribution?

Neither conventions, nor nonparametric sleight-of-hand, nor hope that it doesn't really matter form an adequate scientific response to doubt about the assumptions that underlie a data analysis. The correct way to deal with ambiguity in the choice of assumptions that are beyond the range of statistical tests is a sensitivity analysis that demonstrates that our assumptions do not in fact matter much. The most common sensitivity analysis involves the choice of variables in linear regression. Rather than reporting just one regression, many researchers offer a table of results, all based on different subsets of the variables. Typically, all the reported regressions have a common set of 'core' variables but differ depending on whether or not the regressions include selected 'doubtful' variables.

Although it can be comforting to discover that the coefficients of the core variables do not change much when doubtful variables are excluded, this kind of sensitivity analysis leaves open the possibility that there is some combination of doubtful variables that would radically change the result. Has the analyst worked hard enough to find the oddball estimates that these data allow? 'Extreme bounds analysis' answers this question. In an extreme bounds analysis, the computer chooses the linear combinations of doubtful variables that, when included in the regressions along with the core variables, produce the most extreme (minimum and maximum) estimates for the coefficient on a selected core variable. There is no way of fiddling with the doubtful variables that can produce an estimate outside the extreme bounds.

If the extreme bounds interval is small enough to be useful, that is the end of the story, and the result is reported to be 'sturdy'. This would occur, for example, when the core variables and the doubtful variables are 'independent', in which case the coefficients of the core variables don't change at all when doubtful variables are excluded. But quite often with highly correlated economics data these extreme bounds can be uncomfortably wide, and we are forced either to retreat in dismay or to seek some way to make the bounds narrower.

One way of restricting the range of alternative models is to allow only inclusion/exclusion options, not the all linear combinations embodied in the extreme bounds. These inclusion/exclusion restrictions are the basis for the tables of alternative results that are commonly offered as evidence of inferential sturdiness, and the set of alternative estimates thus presented is smaller than the extreme bounds set.

But why? Why restrict to inclusion/exclusion options? Classical inference is not well suited to respond to this 'why?' question since the answer depends on the state of mind of the analyst and since classical inference presumes a researcher and an audience with a 'blank slate'. Moreover, the effect on the inferences of setting a regression coefficient to zero depends on the coordinate system for defining the parameters. (If you use x and z as explanatory variables, and I use $x + z$ and $x - z$, we get different answers.) Indeed, the extreme bounds are formed by setting coefficients to zero in an appropriately defined coordinate system, and therefore restriction to inclusion/exclusion restrictions is a meaningless restriction absent advice on how to define the coordinate system.

A Bayesian analysis can help to choose a coordinate system and can be a basis for a sensitivity analysis with a set of models that is sensibly smaller than the set of models underlying the extreme bounds. Bayesians allow the state of mind to influence the analysis by letting a researcher act as if the vector of regression coefficients on the doubtful variables, $\boldsymbol{\theta}$, comes from a normal distribution with a mean vector $\mathbf{0}$ and covariance matrix $\mathbf{V}_0$, selected by the researcher.

The smaller is the covariance matrix $\mathbf{V}_0$, the more likely are the coefficients $\boldsymbol{\theta}$ to hug close to zero and the more doubtful are the doubtful variables.

To parallel the decision always to include the core variables in the equation, it is natural to deploy a prior probability distribution for the core coefficients with an infinite variance – the blank-slate initial-ignorance option. Then, corresponding to each choice of covariance matrix for the coefficients of the doubtful variables are estimates of the coefficients of the core variables, $\hat{\beta}(\mathbf{V}_0)$. If, for example, the covariance matrix $\mathbf{V}_0$ is set to zero, this is equivalent to assuming the coefficients of the doubtful variables are all zero, and we should be running the regression with all these doubtful variables omitted. Conversely, if the covariance matrix $\mathbf{V}_0$ is set to an 'infinitely large' matrix (unlimited variances), then this is the ignorance option for the doubtful variables, and the way to do the estimation is simply to include all the doubtful variables along with the core variables in the regression.

A 'global' sensitivity analysis in this setting is carried out by building a correspondence between sets of prior covariance matrices for the doubtful variables, V_0, and the corresponding sets of estimates of the coefficients on the core variables, $\hat{\beta}(\mathbf{V}_0)$.

Three possibilities are discussed in Leamer (1978) and Leamer and Chamberlain (1976): (*a*) $\mathbf{V}_0$ unrestricted, (*b*) $\mathbf{V}_0$ diagonal, (*c*) $\mathbf{V}_0$ diagonal with all diagonal elements the same.

1. The extreme bounds apply when the covariance $\mathbf{V}_0$ is any positive semi-definite matrix.
2. The 2^p regressions, found by including different subsets of the p doubtful variables, define the bound when $\mathbf{V}_0$ is a (non-negative) *diagonal* matrix. (Thus the 'right' coordinate system is the one in which the regression coefficients are a priori independent of each other in the sense that knowledge about one doesn't affect your thinking about the others.)
3. A still narrower set of bounds is found by estimating the p + 1 'principal component' regressions with the principal component restrictions ordered by their eigenvalues. This applies when $\mathbf{V}_0$ is proportional to the identity matrix.

Each of these three sets of prior covariance matrices includes the dogmatic priors that set certain linear combinations of the coefficients exactly to zero and also complete ignorance priors that allow certain linear combinations to be completely free. Neither of these two extremes is sensible in practice, since in the first case the data evidence is completely ignored (the restriction is imposed without testing) and in the second case the prior information is completely ignored. These can be excluded to restricting the prior covariance matrix from above and below:

$\mathbf{V}_L < \mathbf{V}_0 < \mathbf{V}_U$ where $\mathbf{A} < \mathbf{B}$ means that the matrix $\mathbf{B} - \mathbf{A}$ is positive definite. The theorem that then applies comes from Leamer (1981, 1982) as is reported below. First, a statement about the posterior mean of the regression coefficient vector.

Theorem (Bayes Estimate) If, conditional on the observable matrix $\mathbf{X}$, and the unobservable parameters β, and σ^2, an observable vector $\mathbf{y}$ is normally distributed with mean $\mathbf{X}\beta$ and covariance matrix $\sigma^2\mathbf{I}$, and if the coefficient vector β comes from a normal distribution with mean $\mathbf{b}_0$ and covariance matrix $\mathbf{V}_0$, then the conditional mean of β given $\mathbf{y}$ is approximately

$$\mathbf{b}_2 = \left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_0^{-1}\right)\left(\mathbf{X}'\mathbf{X}\mathbf{b}/s^2 + \mathbf{V}_0^{-1}\mathbf{b}_0\right)$$

where s^2 is the sample estimate of $\sigma^2 : s^2 = \mathbf{y}'(\mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}')\mathbf{y}/(n-k)$, where n is the number of observations and k is the number or regression coefficients and where $\mathbf{b}$ is the ordinary least squares estimator (a solution to the normal Equations $\mathbf{X}'\mathbf{X}\mathbf{b} = \mathbf{X}'\mathbf{y}) : \mathbf{b} = (\mathbf{X}'\mathrm{X})^{-1}\mathbf{X}'\mathbf{y}$.

Theorem (Posterior Bounds) Given $\mathbf{V}_L < \mathbf{V}_0 < \mathbf{V}_U$ with $\mathbf{V}_L$ and $\mathbf{V}_U$ positive definite and with $\mathbf{V}_L < \mathbf{V}_0$ signifying that $\mathbf{V}_0 - \mathbf{V}_L$ is positive definite, then the posterior mean $\mathbf{b}_2$ lies in the ellipsoid

$$(\mathbf{b}_2 - \mathbf{f})'\mathbf{H}(\mathbf{b}_2 - \mathbf{f}) < \mathbf{c}$$

where

$$\begin{aligned}\mathbf{H} &= \left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_U^{-1}\right) \\ &+ \left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_U^{-1}\right)\left(\mathbf{V}_L^{-1} - \mathbf{V}_U^{-1}\right)^{-1}\left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_U^{-1}\right)\mathbf{f} \\ &= \left[\left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_L^{-1}\right)\right]^{-1}\left[\mathbf{X}'\mathbf{X}\mathbf{b}/s^2 + \left(\mathbf{V}_L^{-1} - \mathbf{V}_U^{-1}\right)\left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_U^{-1}\right)^{-1}\mathbf{X}'\mathbf{X}\mathbf{b}/2s^2\right]c \\ &= \left(\mathbf{b}'\mathbf{X}'\mathbf{X}\mathbf{b}/s^2\right)\left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_U^{-1}\right)^{-1}\left(\mathbf{V}_L^{-1} - \mathbf{V}_U^{-1}\right)\left(\mathbf{X}'\mathbf{X}/s^2 + \mathbf{V}_L^{-1}\right)^{-1}\mathbf{X}'\mathbf{X}\mathbf{b}/4s^2\end{aligned}$$

Extreme Poverty

Jeffrey D. Sachs and Gordon C. McCord

Abstract

Households living in extreme poverty face deprivations that cost millions of lives annually. Ending extreme poverty requires an understanding of poverty traps, including the effects of adverse biophysical and geographical factors, a lack of resources required for the investments needed to escape poverty, and poor governance. Policies must focus both on promoting market-oriented economic growth and on directly addressing the needs of the poor. Foreign aid will be required to finance interventions that poor countries cannot finance themselves, and aid to well-governed poor countries should be increased, consistent with the rich-country promise of 0.7% of GNP as official development assistance.

There are many definitions of poverty, as well as intense debates about the exact numbers of the poor, where they live and how their numbers are changing over time. As a matter of definition, it is useful to distinguish between three degrees of poverty. Extreme (or absolute) poverty, moderate

poverty and relative poverty. Extreme poverty can be thought of as 'poverty that kills', meaning that households cannot reliably meet basic needs for survival. Households living in extreme poverty are chronically undernourished, unable to access health care, lacking the amenities of safe drinking water and sanitation, unable to afford education for some or all of the children, and perhaps lacking rudimentary shelter – a roof to keep the rain out of the hut, a chimney to remove the smoke from the cooking stove – and basic articles of clothing such as shoes. Such deprivations cost lives, by the millions, every year. Life expectancy is considerably lower and mortality rates are considerably higher in countries in which large proportions of the population live in extreme poverty.

Unlike moderate and relative poverty, extreme poverty currently occurs only in developing countries. Moderate poverty generally refers to the conditions of life in which basic needs are met, but only barely. Relative poverty is generally construed as a household income level below a given proportion of average national income. The relatively poor, in high-income countries, lack access to cultural goods, entertainment, recreation, and to quality health care, education, and other perquisites of social mobility. They may also live outside of the 'mainstream' of social life, and thus without dignity and social respect.

In order to estimate the number of extreme poor, most analysts use a poverty line – a level of income below which the person is 'extremely poor' by some definition. Most countries set their own poverty lines, based on the per capita cost of a consumption basket that attempts to measure basic needs. Since the poorest people in poor countries spend most of their money on food, most of the basket used for national poverty lines consists of food, usually in terms of meeting a minimum intake of 2000 calories (Deaton 2004). These poverty lines are surely imperfect: they suffer from the measurement error inherent in household surveys; they are rarely updated with regards to spending on nutrition; they do not account for differences in rural versus urban calorie consumption; and they do not capture all dimensions of extreme poverty (for example, access to health care, safe water, sanitation, education or political voice).

Moreover, they can lead to undesirable policy results (a person just below the poverty lines could be treated very differently from someone just above the line, despite having almost equal incomes). Governments judged solely according to the number of people below the poverty line could choose to focus only on those closest to the line and ignore the poorest of the poor. Finally, as Nobel Laureate Amartya Sen has emphasized, poverty should be defined more broadly than having a low income; rather, it is the absence of basic capabilities to function in society. This could include not only income poverty (involving a lack of food, clothing, or shelter), but also lack of access to public goods, social standing, and political participation. Despite these shortcomings, most dimensions of extreme poverty that people would like to improve are correlated with household income, thus making a poverty line a helpful, though rough, first approximation of poverty rates. Measures that combined household income with provisions of public goods (disease control, public health, primary education) would surely be preferable.

In the late 1980s, and especially with the 1990 *World Development Report,* the World Bank introduced a single measure of extreme poverty – an income of one dollar per day or less (in 1985 purchasing power parity, PPP, dollars) – in order to compare rates of extreme poverty across countries and to track extreme poverty over time. The one dollar per day number was chosen since it corresponds roughly to the highest national poverty rate among low-income countries (around 360 dollars per year). In 2000, the World Bank used improved PPP estimates to adjust its global poverty line to 1.08 dollars per person per day (in 1993 PPP dollars). This global extreme poverty line has been criticized by some for not being high enough and thus undervaluing the needs of the poor (Pritchett 2003) and by others for being too arbitrary and detached from the country-specific needs of the poor (Srinivasan 2004). Nevertheless, it provides a useful, albeit highly imperfect, measuring tool to look at extreme poverty around the world.

Extreme Poverty, Table 1 Number of poor people by region, 1981–2001

	$ 1.08 per day (million) 1987							
	1981	1984	1990		1993	1996	1999	2001
East Asia	795.6	562.2	425.6	472.2	415.4	286.7	281.7	271.3
Of which China	633.7	425.0	308.4	374.8	334.2	211.6	222.8	211.6
Eastern Europe and Central Asia	3.1	2.4	1.7	2.3	17.4	19.8	29.8	17.6
Latin America and Caribbean	35.6	46.0	45.1	49.3	52.0	52.2	53.6	49.8
Middle East and North Africa	9.1	7.6	6.9	5.5	4.0	5.5	7.7	7.1
South Asia	474.8	460.3	473.3	462.3	476.2	461.3	428.5	431.1
Of which India	382.4	373.5	369.8	357.4	380.0	399.5	352.4	358.6
Sub-Saharan Africa	163.6	198.3	218.6	226.8	242.3	271.4	294.0	315.8
Total	1481.8	1276.8	1171.2	1218.5	1207.5	1096.9	1095.1	1092.7

Another important indicator for poverty is the Human Development Index (HDI), published by the United Nations Development Programme (UNDP) since 1990. The UNDP sought to incorporate the multidimensional aspects of poverty into a new indicator, and to emphasize that development should expand human capabilities, particularly those that are universally valued and basic to life: the capability to lead a long and healthy life, to be knowledgeable, and to have access to the resources needed for a decent standard of living (UNDP 2004). The result was the HDI, which averages normalized 0–1 indexes for income per capita, life expectancy, and education school enrolment and literacy. Countries classified as 'low human development' have a very strong overlap with those countries that have a high proportion of the population living under one dollar per day according to the World Bank.

Where Are the Poor?

The most recent estimates of extreme poverty around the world (using the one dollar per day estimate) were made by Shaohua Chen and Martin Ravallion at the World Bank (see Table 1). They estimated that roughly 1.1 billion people were living in extreme poverty in 2001, down from 1.5 billion in 1981 (Chen and Ravallion 2004). The overwhelming share of the world's extreme poor, 93% in 2001, live in three regions, East Asia, South Asia and Sub-Saharan Africa. Since 1981, the absolute numbers of extreme poor have risen in Sub-Saharan Africa, but have fallen in East Asia and South Asia. In terms of proportions, nearly half Africa's population is judged to live in extreme poverty, and that proportion has risen slightly over the period. The proportion of the extreme poor in East Asia has plummeted, from 58% in 1981 to 15% in 2001; in South Asia the progress has also been marked, although slightly less dramatically, from 52 to 31%. Latin America's extreme poverty rate is around 10%, and relatively unchanged; Eastern Europe's rose from a negligible level in 1981 to around 4% in 2001, the results of the upheavals of Communist collapse and economic transition to a market economy. It is worth noting that these numbers are debated heatedly; other researchers have relied on national income accounts, which tend to show somewhat faster progress in the reduction of Asian poverty, and sometimes very different estimates for the total amount of people living in extreme poverty (Sala-i-Martin 2002; Bhalla 2002). The general picture, however, remains true in all these studies: extreme poverty is concentrated in East Asia, South Asia and Sub-Saharan Africa. It is rising in Africa in absolute numbers and as a share of the population, while it is falling both in absolute numbers and as a proportion of the population in the Asian regions.

There are some defining circumstances specific to the poorest of the poor. They are found mainly in rural areas (though with a growing proportion in the cities); the rural poor tend to have fewer opportunities to earn income, have less access to education and health care, and are often more vulnerable to the forces of nature. The extreme

poor face challenges almost unknown in the rich world today – malaria, famines, lack of roads and motor vehicles, great distances to regional and world markets, lack of electricity and modern cooking fuels. Women tend to be at a disadvantage compared with men, since they often have less access to property rights (land ownership, inheritance), and since they bear the physical burden of lack of infrastructure (collecting water and fuel wood at great distances). Girls have historically received less primary and secondary education than boys. Labour markets often discriminate against women, and women tend to work longer when one counts unpaid labour at home. Domestic violence continues to burden the lives of millions of women around the world (World Bank 2001). Finally, large pockets of poverty exist within many countries due to racial and ethnic discrimination, or low social (for example, caste) status.

Consequences of Extreme Poverty

When individuals suffer from extreme poverty and lack the meagre income needed to cover even basic needs, a single episode of disease, a drought, or a pest that destroys a harvest can be the difference between life and death. In households suffering from extreme poverty, life expectancy is often around half that in the high- income world, 40 years instead of 80 years. It is common that, in the poorest countries of Sub-Saharan Africa, of every 1000 children born more than 100 die before their fifth birthday, compared with fewer than ten in the high-income world. An infant born in Sub-Saharan Africa today has only a one-in-three chance of surviving to age 65.

At the most basic level, the poorest of the poor lack the minimum amount of capital necessary to get a foothold on the first rung of the ladder of economic development. The extreme poor tend to lack six major kinds of capital:

- Human capital: health, nutrition, and skills – education – needed for each person to be economically productive.
- Business capital: the machinery, facilities, motorized transport used in agriculture, industry and services.
- Infrastructure: roads, power, water and sanitation, airport and seaports, and telecommunications systems, which are critical inputs into business productivity.
- Natural capital: arable land, healthy soils, biodiversity, and well-functioning ecosystems that provide the environmental services needed by human society.
- Public institutional capital: commercial law, judicial systems, government services and policing that underpin the peaceful and prosperous division of labour.
- Knowledge capital: the scientific and technological know-how that raises productivity in business output and the promotion of physical and natural capital.

Importantly, the poorest of the poor tend to have higher fertility rates, for several reasons. Infant mortality rates are high when there are inadequate health services, so high fertility provides 'insurance' to parents that they will succeed in raising a child who will survive to adulthood. In rural areas, children are often perceived as economic assets who provide supplementary labour for the farm household. Poor and illiterate women have few job opportunities away from the farm, and so may place a low value on the opportunity (time) costs of bringing up children. In addition, women are frequently unaware of their reproductive rights (including the right to plan their families) and lack access to reproductive health information, services, and facilities, leading to high unmet demands for contraception in low-income countries and among poorer members of all developing countries. Finally, poor households lack the income to purchase contraceptives and family planning, even when they are available. For these reasons, high fertility rates are prevalent among families living in extreme poverty, resulting in very low investments in the health and education of each child (what is known as the quantity–quality trade-off).

Poor and hungry societies are much more likely than high-income societies to fall into

violent conflicts over scarce vital resources, such as watering holes and arable land – and over scarce natural resources, such as oil, diamonds and timber (United Nations, 2004). This relationship between violence and high rates of extreme poverty holds with a high degree of statistical significance. A country with a civil war within its borders typically has only one-third of the per capita income of a country with similar characteristics but at peace. Moreover, poor countries – even those not in conflict – risk conflict in the future. A country with a per capita income of 500 dollars is about twice as likely to have a major conflict within 5 years as a country with an income of about 4000 dollars per capita (UN Millennium Project 2005). In addition, low economic growth rates are associated with higher risks of new conflict; one study finds that a negative growth shock of 5% increases the risk of civil war by 50% in the following year, and that economic conditions are probably the most important determinants of civil conflict in Sub- Saharan Africa (Miguel et al. 2004). The most comprehensive study of state failure, carried out by the State Failure Task Force established by the Central Intelligence Agency in 1994, confirms the importance of the economic roots of state failure (defined as revolutionary war, ethnic war, genocide, politicide, or adverse or disruptive regime change). The Task Force studied all 113 cases of state failure between 1957 and 1994 in countries of half a million people or more, and found that the most significant variables explaining these conflicts were the infant mortality rate (suggesting that overall low levels of material well-being are a significant contributor to state failure), openness of the economy (more economic linkages with the rest of the world diminish the chances of state failure), and democracy (democratic countries show less propensity to state failure than authoritarian regimes). The linkage to democracy also has a strong economic dimension, however, because research has shown repeatedly that the probability of a country's being democratic rises significantly with its per capita income level. In refinements of the basic study, the Task Force found that in Sub-Saharan Africa, where many societies live on the edge of subsistence, temporary economic setbacks (measured as a decline in gross domestic product per capita) were significant predictors of state failure (State Failure Task Force 1999). Similar conclusions have been reached in studies on African conflict, which find that poverty and slow economic growth raise the probability of conflict.

Theories of Extreme Poverty

For decades, observers have tried to explain why extreme poverty persists. Many theories have looked for single-factor explanations for a lack of economic growth, often grounded in racist beliefs (poor countries do not grow because their cultures, races, or religions fail to promote economic growth). The increasing number of success stories of growth proved all these theories to be wrong. However, despite the complexity of an economy and the number of things that can go wrong, single-factor explanations persist. The most common is that poverty is a result of corrupt leadership, which impedes modern development.

Governance is indeed important: economic development stalls when governments do not uphold the rule of law, pursue sound economic policy, make appropriate public investments, manage a public administration, protect basic human rights, and support civil society organizations – including those representing poor people – in national decision-making. Importantly, long-term poverty reduction in developing countries will not happen without sustained economic growth, which requires a vibrant private sector. Government, therefore, needs to provide the economic policy framework and the support that the private sector needs to grow.

However, many well-governed poor countries may be too poor to help themselves out of extreme poverty. Many well-intentioned governments lack the fiscal resources to invest in infrastructure, social services, environmental management, and even the public administration necessary to improve governance. Further, dozens of heavily indebted poor and middle-income countries have been forced by creditor governments to spend large proportions of their limited tax receipts on

debt service, undermining their ability to finance vital investments in human capital and infrastructure. The reason these poor countries cannot grow is not poor governance, but a poverty trap. They lack the basic infrastructure, human capital, and public administration – the foundations for economic development and private sector-led growth. Without roads, soil nutrients, electricity, safe cooking fuels, clinics, schools, and adequate and affordable shelter, people are chronically hungry, burdened by disease and unable to save. As mentioned above, fertility rates tend to be high, preventing families from investing enough in each child. Without adequate public sector salaries and information technologies, public management is chronically weak. For all of these interlocking reasons, these countries are then unable to attract private investment flows or retain their skilled workers, and can therefore find themselves with low or negative growth. In short, they are stuck in a poverty trap.

The concept of a low-level poverty trap is a long-standing hypothesis in the theories of economic growth and development. The earliest mathematical formalization was by Nelson (1956), who put emphasis on demography. The theoretical possibility of poverty traps in the neoclassical growth model is covered briefly in the economic growth textbook by Barro and Sala-i-Martin (1998), which also discusses briefly the possible case for large-scale development assistance to overcome such traps. The connection of a low-level trap to subsistence consumption needs is spelled out in Ben-David (1998), and connections to agriculture and education are described in the *World Economic and Social Survey* (UN 2000). Two recent empirical studies claiming that such poverty traps exist in poor countries are UNCTAD (2002) and Bloom et al. (2003). A close look at a poverty trap in Sub-Saharan Africa is in Sachs et al. (2004).

An often overlooked characteristic of poverty is that some countries and regions are clearly more vulnerable than others to falling into a poverty trap. While a history of violence of colonial rule or poor governance can leave any country bereft of basic infrastructure and human capital, physical geography plays special havoc with certain regions. Some regions need more basic infrastructure than others simply to compensate for a difficult physical environment. Some of the barriers that must be offset by investments include adverse transport conditions (landlocked economies, small island economies far from major markets, inland populations far from coasts and navigable rivers, populations living in mountains, long distances from major world markets, very low population densities); adverse agro-climatic conditions (low and highly variable rainfall, lack of suitable conditions for irrigation, nutrient-poor and nutrient-depleted soils, vulnerability to pests and other post-harvest losses, susceptibility to the effects of climate change); adverse health conditions (high ecological vulnerability to malaria and other tropical diseases, high AIDS prevalence); and other adverse conditions (lack of domestic energy sources, small internal market and lack of regional integration, vulnerability to natural hazards, artificial borders that cut across cultural and ethnic groups, proximity to countries in conflict). Adam Smith was acutely aware of the role of geography in hindering economic development. He stressed, in particular, the advantages of proximity to low-cost, sea-based trade as critical, noting that remote economies would be the last regions to achieve economic development. More recent studies have found statistical significance of these relationships between geography and economic outcome (Gallup et al. 1999a, b; Mellinger et al. 2000; Sachs and Gallup 2001).

In the rich countries of North America, Western Europe and East Asia, the process of massive investment in research and development, leading to sales of patent-protected products to a large market, stands at the core of economic growth. Advanced countries are typically investing 2% or more of their gross national product directly into the research and development process, and sometimes more than 3%. That investment is very sizeable, with hundreds of billions of dollars invested each year in research and development activities. Moreover, these investments are not simply left to the market. Governments invest heavily, especially in the early stages of R&D. In most poor countries, especially smaller ones, the innovation process usually never gets started.

Potential inventors do not invent because they know that they will not be able to recoup the large, fixed costs of developing a new product. Impoverished governments cannot afford to back the basic sciences in government laboratories and in universities. The result is an inequality of innovative activity that magnifies the inequality of global incomes. While the innovation gap is reduced in the case of some poor countries through technological diffusion, even diffusion is limited in the poorest countries, because they face distinctive ecological problems not addressed by 'rich-world science' (for example, tropical diseases and tropical farming systems), because they cannot afford high-tech capital goods and because they fail to attract foreign businesses that would bring the technology with them.

Policy Responses

Theories on how to tackle extreme poverty are varied and controversial. For the most part, they can be divided into two camps: strategies that focus on promoting market- oriented economic growth, and strategies that focus on directly addressing the needs of the poor. Of course the two approaches can be combined. The Washington Consensus, a set of policy recommendations especially prevalent from 1980 to the late 1990s, embodies the first type, with its focus on macroeconomic stability, greater economic openness to trade and investment, and improved environment for private business. The idea was that these policies would lead growth of the private sector, thus increasing demand for labour and thereby improving the welfare of the poor.

A second set of strategies focuses instead on providing what the poor need in order to increase their productivity. These investments in 'human development' argued for directing health and education investments towards the poor, and providing social safety nets. Many of these strategies became popular in the 1990s as a reaction to the Washington Consensus. There were three kinds of critiques. One held that growth would not be achieved with market reforms alone, because of the poverty trap. A second held that growth must in any event be combined with increased public investments, for example for health and education. A third, and more extreme position, held that growth per se would have adverse effects on the poorest of the poor. For example, the 1996 *Human Development Report* warned that in some cases growth can fail to create jobs and provide benefits, and can even increase empowerment of the rich, wreck cultural identities and destroy the environment (UNDP, 1996).

Numerous studies have shown that growth *does*, in fact, tend to be good for the poor (Dollar and Kraay 2002; Roemer and Gugerty 1997; Gallup et al. 1999a, b). Yet growth may not be achievable for countries trapped in poverty, and growth may not be sufficient to enable the poorest of the poor to meet their basic needs. The emerging consensus is that *both* economic growth and direct investments for the poor are necessary, in order to break the poverty trap and to provide vital public goods. International institutions are paying more attention than before to the possibility of poverty traps, and to the non-income dimensions of extreme poverty (for example, health and education). Five of the eight Millennium Development Goals (the world's time-bound and quantified targets for addressing extreme poverty, discussed below) are about promoting health and education, and individual countries are giving more priority to these broader measures than ever before.

Another dimension of the fight against extreme poverty is referred to as the rights-based approach. The guarantee that all people can live in dignity and meet their basic needs is also a basic human right – the right of each person on the planet to health, education, shelter and security as pledged in the Universal Declaration of Human Rights and various UN covenants, treaties and intergovernmental documents (such as the UN Millennium Declaration). The human rights approach seeks to use national and international human rights accountability mechanisms to monitor action on behalf of a human right rather than a development target. Economic evaluations often measure whether a given policy action contributes to reaching a target. Conceived in terms of rights, the same evaluation would measure not only those

reached by a given action, but several other considerations as well: (*a*) the numbers not being reached; (*b*) the empowerment of the poor to achieve their rights; (*c*) the protection of these rights in legislation; and so forth. To date, there has been insufficient effort to integrate development planning with a human rights framework, even though such integration has tremendous potential and relevance.

Since the creation of the United Nations in 1945, the international system has been working to reduce poverty around the world, but often with results that fall short of laudable rhetoric. In January 1961, the United Nations resolved that the decade of the 1960s would be the Decade of Development. US President Kennedy launched the decade at the UN in New York. Earlier, in his inaugural address as President, he had signalled a new sense of purpose in international affairs. He declared: 'To those peoples in the huts and villages of half the globe struggling to break the bonds of mass misery, we pledge our best efforts to help them help themselves' (History Place 2007). The second Development Decade resolved to emphasize measures deliberately targeted at the poor – to help them meet their basic needs for food, water, housing, health and education. The UN held a series of international conferences: on environment (Stockholm, 1972); population (Bucharest, 1974); food (Rome, 1974); women (Mexico City, 1975); human settlements (Vancouver, 1976); employment (Geneva, 1976); water (Mar del Plata, 1977); and desertification (Nairobi, 1977). In 1978, the governments of the world came together to sign the Alma Ata Declaration that promised 'Health for All by 2000', a promise the world failed miserably in delivering. The 1980s – the third Development Decade – were very difficult for developing countries as they suffered from a worldwide recession that hit the developing world and debtor countries with special force. Nevertheless, important improvements were made in some areas, such as nutrition, access to safe drinking water, and reductions in child mortality. One result was the international conference held in 1990 under the auspices of UNDP, UNESCO, UNICEF and the World Bank in Jomtien (Thailand), which set the target of 'Education for All by the Year 2000', another goal not met.

The 1990s also became a decade in which the response of the UN system to the flagging development movement was to embark on a series of global conferences. The UN Conference on Environment and Development (Rio de Janeiro, 1992) was followed by conferences on nutrition (Rome, 1992); human rights (Vienna, 1993); population and development (Cairo, 1994); social development (Copenhagen, 1995); women (Beijing, 1995), human settlements (Istanbul, 1996). The decade ended with the landmark Millennium Summit in 2000, which resulted in the Millennium Development Goals (MDGs), and the Financing for Development Conference in Monterrey in 2002, where rich countries renewed their pledge to provide 0.7% of their GDP in foreign aid. Also relevant was the Brussels Programme of Action for the Least Developed Countries, which suggests that they require greatly increased official development assistance, since private capital flows will not finance needed public investments. The programme outlines several priority areas for cooperation including human and institutional resource development, removing supply side constraints and enhancing productive capacity, protecting the environment, and attaining food security and reducing malnutrition.

As the UN Millennium Project has pointed out, the Millennium Development Goals are the most broadly supported, comprehensive, and specific poverty reduction targets the world has ever established, so their importance is manifold. For the international political system, they are the fulcrum on which development policy is currently based. For the billion-plus people living in extreme poverty, they represent the means to a productive life (UN Millennium Project 2005). Besides aiming to reduce the 1990 proportion of people in extreme poverty by half by 2015, the MDGs tackle poverty in its many dimensions – income poverty, hunger, disease, lack of adequate shelter, and exclusion – while promoting gender equality, education and environmental sustainability. Thus, while supporting the need for economic growth, the MDGs emphasize that the growth needs to be pro-poor. In 2005, the UN

Millennium Project presented the Secretary General with 'A Practical Plan to Achieve the Millennium Development Goals', which outlined specific interventions to address the multiple causes of poverty traps in poor countries around the world (UN Millennium Project 2005). Moreover, it emphasized that foreign aid will be needed to finance the interventions that the poor countries cannot finance themselves. In the case of well-governed poor countries, the report recommended that foreign assistance should be scaled up immediately, significantly, and on a sustained basis, consistent with the promise of 0.7% of GNP as official development assistance.

Prospects

There are reasons to be optimistic about the elimination of extreme poverty on the planet. Economic development has lifted more than 100 million people out of extreme poverty since the mid-1990s, and the pace is probably accelerating in Asia. While the population of developing countries rose from about 4 billion people to about 5 billion, average per capita incomes rose by more than 21%. With 130 million fewer people in extreme poverty in 2001 than a decade before, the proportion of people living on less than 1 dollar a day declined by 7% points, from 28 to 21%.

Despite the good news, however, Africa remains mired in seemingly intractable extreme poverty. Africa faces difficult structural challenges (very high transport costs and small markets, low-productivity agriculture, very high disease burden, a history of adverse geopolitics, and slow diffusion of technology from abroad), but, in countries where governments are committed, these challenges can be overcome if addressed through an intensive programme that directly confronts them (Sachs et al. 2004). Ending the poverty trap in Africa and meeting the MDGs will require a comprehensive strategy for public investment in conjunction with improved governance. The good news is that the amount of investment required, although out of reach of African governments alone, is within the amount already promised in foreign aid by the rich countries (UN Millennium Project 2005).

One final point is that a sustained reduction in extreme poverty requires tackling long-term challenges that the human family faces, in particular environmental challenges. Raising the incomes of billions of people around the world is surely desirable. Nevertheless, the increased income will come with increased demand for food, energy, and consumer goods, which may push our planet's already stressed ecosystems beyond what they can support. As the world works towards eliminating extreme poverty, it must do so with a conscious plan to limit the environmental burden that humanity places on the planet. Moreover, in many cases, the environmental challenges (such as water stress) may prove to be the biggest barriers to poverty reduction even in the short term.
