E

Easterlin Hypothesis

Diane J. Macunovich and Richard A. Easterlin

Abstract

The economic and social fortunes of a birth cohort tend to vary as a function of that cohort's relative size, approximated by the crude birth rate surrounding the cohort's birth. Effects have been observed on young men's earnings and unemployment rates, college enrolment rates, marriage and divorce, fertility, crime, and suicide rates. These effects have been found to be asymmetrical about the peak of a baby boom, and the original hypothesis has been extended to suggest a wide range of effects on the economy as a whole, from GDP growth rate, through interest rates and stock market performance, to measures of productivity.

The Easterlin, or 'relative cohort size', hypothesis as originally formulated posits that, other things constant, the economic and social fortunes of a cohort (those born in a given year) tend to vary as a function of its relative size, approximated by the crude birth rate surrounding the cohort's birth (Easterlin 1987). This hypothesis has since been extended to suggest a wider range of effects on the economy as a whole (Macunovich 2002).

Although cohort size effects were originally expected to be symmetrical around the peak of the baby boom, which in the United States entered the labour market around 1980, it is now thought that they are tempered by aggregate demand effects and by feedback effects from adjustments made by young adults on the 'leading edge' of a baby boom. As a result, cohorts – and the economy generally – on the 'leading edge of a baby boom fare much better than those on the 'trailing edge', when all else is equal.

The ultimate effects of changing relative cohort size are hypothesized to fall into these three categories:

1. Direct or first-order effects of relative cohort size on male relative income (the earnings of young men relative to their aspirations); male unemployment and hours worked; men's and women's college wage premium (the extra earnings of a college graduate relative to

Macmillan Publishers Ltd (ed.), *The New Palgrave Dictionary of Economics*,
https://doi.org/10.1057/978-1-349-95189-5

those of a secondary school graduate); and levels of income inequality generally.
2. Second-order effects operating through male relative income, especially the demographic adjustments people make in response to changing relative income, such as changes in women's labour force participation and their occupational choices; men's and women's college enrolment rates; marriage and divorce; fertility; crime, drug use, and suicide rates; out-of-wedlock childbearing and the incidence of female-headed families; and living arrangements.
3. Third-order effects on the economy of changing relative cohort size and the resulting demographic adjustments, such as changes in average wage growth; the overall demand for goods and services in the economy and hence the growth rate of the economy; inflation, interest rates, and savings rates; stock market performance; industrial structure; measures of gross domestic product (GDP); and productivity measures.

The three categories of effect are discussed first in this article, followed by a consideration of feedback effects and a discussion of empirical evidence.

First-Order Effects

The linkage between higher birth rates and adverse social and economic effects arises from 'crowding mechanisms' operating within three major social institutions, the family, school and the labour market. Within the family, a sustained upsurge in the birth rate is likely to entail an increase in the average number of siblings, higher average birth order, and a shorter average birth interval, and there is a substantial literature in psychology, sociology and economics linking child development negatively to one or more of these magnitudes (Ernst and Angst 1983; Heer 1985). The negative effects that have been investigated range over a wide variety of phenomena. With regard to mental health, for example, there is evidence that problem behaviours such as fighting, breaking rules, and delinquency are associated with increased family size. Adverse effects on morbidity and mortality of children have been found to be associated with increased family size and shorter birth spacing. A negative association between IQ and number of siblings has been found in a number of studies, and, with IQ controlled for, between educational attainment and family size. The principal mechanism underlying such developments is likely to be the dilution of parental time and energy per child and family economic resources per child, associated with increased family size.

The family mechanisms just discussed imply that, on average, a larger cohort is likely to perform less well in school. But even in the absence of any adverse effects within the family, a large cohort is likely to experience crowding in schools, which reduces average educational performance (Freeman 1976). At any given time the human and physical capital stock comprising the school system tends to be either fixed in amount or to expand at a fairly constant rate, so that a surge in entrants into the school system tends to be accompanied by a reduction in physical facilities and teachers per student. In the United States, school planning decisions are divided among numerous local governments and private institutions, and expansion has tended to occur in reaction to, rather than in anticipation of, a large cohort's entry. Moreover, even when expansion occurs it is usually not accompanied by maintenance of curriculum standards, partly because of the diminishing pool of qualified teachers available to supply the needs of educational expansion.

The experience of a large cohort both in the family and in school is likely, in turn, to leave the cohort less well prepared, on reaching adulthood, for success in the labour market. But even if there were no prior effects, the entry of a large proportion of young and relatively inexperienced workers into the labour market creates a new set of crowding phenomena, because the expansion of complementary factor inputs is unlikely to be commensurate with that of the youth labour force. Additions to physical capital stock tend to be dominated by considerations other than the relative supply of younger workers, and the growth in

older, experienced, workers is largely governed by prior demographic conditions. Growth in the relative supply of younger workers results, in consequence, in a deterioration of their relative wage rates, unemployment conditions and upward job mobility (Welch 1979). The adverse effects of labour market crowding tend to reinforce those of crowding within the school and family. For example, the deterioration in relative wage rates of the young translates into lower returns to education and consequent adverse impact on school drop-out rates and college enrolment (Freeman 1976). Also, problems encountered in finding a good job may reinforce feelings of inadequacy or frustration already stirred up by some prior experiences at home or in school, and lead to lower labour force participation among young men.

Second-Order Effects

The relative economic standing of successive generations at a given point in time may be altered systematically by fluctuations in relative cohort size. If parents' living levels play an important role in setting their children's material aspirations, as socialization theory leads one to believe, then an increase in the shortfall of children's wage rates relative to parents will cause the children to feel relatively deprived and under greater pressure to keep up. The importance of relative status influences of this type in affecting attitudes or behaviour has been widely recognized in social science theory (Duesenberry 1949).

Confronted with the prospect of a deterioration in its living level relative to that of its parents, a large young adult cohort may make a number of adaptations in an attempt to preserve its comparative standing. Foremost among these are changes in behaviour related to family formation and family life (Macunovich and Easterlin 1990; McNown and Rajbhandary 2003). To avoid the financial pressures associated with family responsibilities, marriage may be deferred. If marriage occurs, wives are more likely to work and to put off childbearing. If a wife bears children, she is more likely to couple labour force participation with childrearing, and to have a smaller number of children more widely spaced (Macunovich 2002; Jeon and Shields 2005).

The process of demographic adjustment to changing relative income can best be thought of in terms of *ex ante* and *ex post* income; that is, the disposable per capita income of individuals prior to and then following the adjustments. Analyses of baby boom cohorts in the United States have found that a cohort's male relative income – individual earning potential of baby boomers relative to that of their parents – was significantly lower than the individual earning potential of *pre-boom* cohorts relative to *their* parents. But after making the type of demographic adjustments indicated above, the boomers managed to bring their per capita disposable income on a par with that of their parents (Easterlin et al. 1990).

Other reactions to the psychological stresses induced by large cohort size may be viewed as socially dysfunctional. Feelings of inadequacy and frustration, for example, may lead to disproportionate consumption of alcohol and drugs, to mental depression, and, at the extreme, to a higher rate of suicide (Pampel 2001; Stockard and O'Brien 2002). Feelings of bitterness, disappointment and rage may induce a higher incidence of crime (O'Brien et al. 1999). Within marriage, the stresses of conflicting work and motherhood roles for women, and feelings of inadequacy as a breadwinner for men, are likely to result in a higher incidence of divorce (Macunovich 2002). In the political sphere, the disaffection felt by a large cohort because of its lack of success may make it more responsive to the appeals of those who are politically alienated (O'Brien and Gwartney-Gibbs 1989).

Third-Order Effects

The second-order effects described in the previous section will, through reduced marriage rates and increased divorce and female labour force participation rates, reduce the proportion of households with stay-at-home spouses, which increases the tendency to purchase market replacements for the goods and services traditionally produced by

women in the home. The result is a 'commoditization' of many goods and services that used to be produced in the home. They are now exchanged in the market – and thus counted in official measures of GDP and productivity – whereas previously they were part of the excluded 'non-market' economy.

This commoditization of goods and services causes measures of industrial structure to skew strongly toward services and retail, away from agriculture and manufacturing, creating low-wage service jobs. In addition, the influx of inexperienced young workers as members of a large birth cohort – both men and women – into the labour market exacerbates any decline in productivity growth by changing the composition of the workforce to one dominated by inexperienced and therefore lower-productivity workers. This decline in relative wages of younger workers resulting from their oversupply would lead employers to substitute cheaper labour for more expensive capital, thus lowering the young workers' productivity still further by providing those low-wage workers with less productivity-enhancing machinery and technology.

Although some analysts maintain that the potential age structure effect of the baby boomers on personal savings is not large enough to explain the full drop in US national savings rates since the 1980s, studies of this phenomenon to date have focused only on the behaviour of the baby boomers themselves. However, one might argue that the baby boomers have affected the propensity to save in age groups other than their own. For example, because boomers' earnings were depressed and they experienced an inflated housing market when they went to buy homes (both the effects of their own large cohort size), many parents of baby boomers drew on their own savings in order to help with down payments.

When the age structure of children is permitted to affect consumption and savings, a very strong age-related pattern of expenditures and saving can be identified. Children induce savings on the part of their parents between the ages of five and 16, possibly in anticipation of later educational expenses. When the relationships identified in this way are combined with the changing age distribution in the US population during the 20th century, they produce a savings rate that fluctuates by plus or minus 25 per cent around the mean, simply as a result of changing age structure (Macunovich 2002).

Similarly, a strong effect has been identified of changing age structure (measured simply as the proportion of young to old in the population) on real interest rates and inflation, because of differential patterns of savings and consumption with age (McMillan and Baesel 1990). A higher proportion of young adults in a population will produce lower aggregate savings levels – and hence higher interest rates. In this model, today's lower interest and inflation rates are the result of the ageing of the baby boomers, as they begin to acquire assets for their retirement years. The converse of this phenomenon – the potential 'meltdown' effect of a retiring baby boom on financial markets, asset values and interest rates – has been described as well (Schieber and Shoven 1994).

Some research has estimated a strong effect of age structure on housing prices in the United States, with the entry of the baby boom into the housing market causing the severe house price inflation of the 1970s and 1980s, and the entry of the baby bust causing house price deflation (Mankiw and Weil 1989). Although some have disputed the magnitude of the effect estimated there, most researchers have confirmed its existence. A later study, for example, found significant effects of detailed (single year) age structure in the adult population on all forms of consumption, including housing demand, and on money demand (Fair and Dominguez 1991).

These potential effects on aggregate demand, savings rates, interest rates and inflation suggest that there might have been a connection between changing age structure and macroeconomic fluctuations in the United States and elsewhere during the 20th century. When the population of young adults is expanding, the resultant growth in demand for durable goods creates confidence in investors, while an unexpected slowdown in the growth rate of young adults could cause cutbacks in production and investment in response to inventory buildups, with a snowball effect throughout the economy. There was a close

correspondence in the United States in the 20th century between 'turnaround points' of growth in the key age group of 15–24, and significant economic dislocations in 1908, 1929, 1938 and 1974. Similarly, there was a correlation between age structure and economic performance in industrialized nations in the 1930s, and in both industrialized and developing nations since the 1980s, with the 'Asian Tigers' some of the most recent examples (Macunovich 2002).

Feedback Effects on the Relationship Between Relative Cohort Size and Relative Income

Easterlin's original statements recognized the potential effects of outside influences on the relative cohort size mechanism (Easterlin 1987). However, the dynamic nature of the mechanism – the fact that many of these other factors would, in fact, be secondary and tertiary results of changing relative cohort size, and thus endogenous in any empirical application – has not been fully appreciated in most analyses to date. As a result, it is often concluded that the hypothesis may have been relevant in the post-Second World War period up to about 1980, but that it fails to extend beyond one full cycle to apply to the period since 1980.

The aggregate demand effect of changing relative cohort size, discussed in the previous section, is hypothesized to contribute significantly to the observed asymmetry in relative cohort size effects on male relative income. Although cohorts on the leading edge of a baby boom experience declining wages relative to those of older workers, they do so in an economy experiencing strong growth in aggregate demand resulting from the increasing relative cohort size among young adults. Cohorts on the lagging edge of a baby boom, however, enter a labour market weakened by the economic slump resulting from a transition from expanding to contracting relative cohort size.

Similarly, as one of the secondary effects of changing relative cohort size discussed earlier, female labour force participation is hypothesized to have increased in response to declining male relative income as the leading edge of the baby boom entered the labour market. If, as hypothesized, these young women also increased their levels of educational attainment in anticipation of future labour market participation, they would have in many cases competed directly with the male members of their cohort and exacerbated the effects of relative cohort size on male relative income. This effect would have been greatest for cohorts on the lagging edge of the boom – those who should have benefited from declining relative cohort size. It is important in empirical analyses to recognize the potential endogeneity of these other factors, rather than treat relative cohort size effects as 'contingent' on exogenous changes in female labour force participation, educational attainment and wages. Wage analyses based on relative cohort size which control for a cohort's position in the US baby boom – and thus allow for aggregate demand and female labour force changes – can explain most of the observed change in young men's entry level wages and in their returns to experience and education (Macunovich 2002).

Empirical Analyses

Empirically, the most important application of the hypothesis has been to explain the varying experience of young adults in the United States since the Second World War. There is, however, some evidence of its relevance to the experience of developed countries more generally in this period (Korenman and Neumark 2000; Pampel 2001; Stockard and O'Brien 2002; Jeon and Shields 2005), and perhaps as a mechanism leading to fertility decline during the demographic transition in developing countries (Macunovich 2002).

Overall, however, empirical analyses testing various aspects of the Easterlin hypothesis have produced fairly mixed results. By 2007 there have been two comprehensive analyses of the literature on the Easterlin hypothesis, and one meta-analysis of 19 studies completed between 1976 and 2002. The meta-analysis (Waldorf and Byun 2005) focused on the age structure–fertility link, and concluded that analytical problems contribute to

an apparent lack of empirical support for the Easterlin hypothesis. Most significant among these were the failure to recognize the endogeneity of an income variable when combined with a relative cohort size variable, and the use of very broad age groups in defining relative cohort size.

The first of the literature reviews considered a broad range of topics, including labour market experience and education; marriage, fertility and divorce; and crime, suicide and alienation. It concluded:

> [T]he evidence for the Easterlin effect proves mixed at best and plain wrong at worst... Aggregate data support the hypothesis more than individual level data, period-specific or time-series data support the hypothesis more than cohort-specific data, experiences from 1945–1980 support the hypothesis more than the years since 1980, and trends in the United States support the hypothesis more than trends in European nations. (Pampel and Peters 1995, p. 189.

The second literature review evaluated 76 published analyses focused solely on fertility, and concluded:

> With an equal number of micro- and macro-level analyses using North American data (twenty-two), the 'track record' of the hypothesis is the same in both venues, with fifteen providing significant support in each case. The literature suggests unequivocal support for the relativity of the income concept in fertility but is less clear regarding the source(s) of differences in material aspirations, and suggests that the observed relationship between fertility and cohort size has varied across countries and time periods due to the effects of additional factors not included in most models. (Macunovich 1998, p. 53)

This review suggests that, because of data limitations and idiosyncratic interpretations of the hypothesis by individual researchers, many of the studies with unfavourable findings have been only peripherally related to the Easterlin hypothesis.

Conclusion

Since the early 1980s, demographic concepts have encroached modestly on economic theory, as evidenced by the appearance of life cycle, overlapping generations and vintage models. The cohort size hypothesis might be viewed as another in this sequence. Its roots, however, extend beyond economics, reaching out into sociology, demography and psychology, and it seeks to encompass a wider range of attitudinal and behavioural phenomena than is traditionally considered economic.

East-West Economic Relations

Marie Lavigne

The decade 1966–1975 is usually considered as the golden age of East-West economic relations. Already during the previous decade, i.e. since the end of the cold war, the USSR and the Eastern European countries had increased their trade with the West at an annual rate of growth slightly higher than their total trade. But after 1966 the expansion of trade and cooperation was sustained both by a favourable political climate and by strong economic complementarities between the West (here equated to the OECD countries) and the East (the USSR and the six European countries that are members of the CMEA, or Council for Mutual Economic Assistance; hereafter we shall mention them as CPEs or centrally planned economies, for the sake of brevity).

These years were marked by *détente*, initiated in 1966 with the triumphal visit to the USSR of the French President General de Gaulle. This was not only a bilateral event, but it set the stage for diversified and institutionalized links between Eastern and Western European economies. Later on, in 1972, US President Nixon's visit to Moscow opened the shorter phase of bright USUSSR economic relations which ended in 1975. At the beginning of that year, the Soviet Union unilaterally repudiated the Soviet-American treaty of commerce, as a retaliation for the deprivation of the most favoured nation clause; according to the American legislation just introduced, the clause could not be granted to a country restricting the rights for its citizens to emigrate. Before *détente* came altogether to its end, it was symbolically magnified in the final Act of the Conference for Security and Co-operation in Europe, signed in Helsinki in August 1975. The economic 'basket' of this text was meant to appear as the Charter of East-West mutually profitable relations.

From the economic point of view, the 1966–1975 decade was indeed a time of converging interests. The USSR and Eastern European countries had just engaged in economic reforms. They needed to modernize their industries. The Western firms found new markets for selling equipment and turnkey plants. High rates of economic growth, both in the West and in the East, sustained the prospects for increased exports from the East to the West, once the new capacities acquired from the West were put into operation. An era of deepening industrial cooperation, based upon technology imports and reverse flows of manufactured goods, seemed to open.

It was then almost forgotten that even in such a favourable context, East-West trade accounted for less then 3% of world trade. While in 1975 it amounted to slightly under 30% of total trade for the CPEs (slightly more for the USSR and less for the six smaller CPEs taken together), it never

exceeded 5% of total trade for the Western countries, except for some non-typical cases (such as Austria or Finland).

The following decade, ending in 1985, has witnessed a general shrinking of East-West trade. There was a conspicuous deterioration of the political climate with the invasion of Afghanistan by the Soviet troops in December 1979 and, 2 years later, martial law in Poland. The world economic crisis exerted some adverse effects as well. True, it benefited the USSR as an oil exporter. But the Western recession hampered the export drive of the smaller CPEs. The manufactured goods which they intended to export so as to repay their imports of equipment became less saleable in the East. Thus the imbalance between imports and exports, which had been steadily growing since 1970, could not be corrected through expanded sales. An easier way out was to borrow on Western financial markets. The CPEs were still creditworthy, and the level of international liquidity was high as a result of the inflow of petro-dollars. The total indebtedness of the CPEs culminated in 1981. The subsequent adjustments conducted in 1981–1983 (though a decrease in imports and domestic investment) ended up with a marked improvement in the CPEs external financial position and with a decrease in their foreign debt (except for Poland). But the general slowdown of growth in the East, partly due to these adjustments, does not allow for a steep upward trend in East-West trade.

The outlook for East-West economic relations is to be evaluated through the combination of two opposed sets of factors. On the one hand, there are strong interests on both sides pressing for the expansion of trade and cooperation. On the other, equally strong obstacles are hindering such a development. The outcome is probably to be seen in a stabilization of those relations, below the level reached during the 'golden age' decade.

Economic Interests

East-West trade is sometimes said to be a one-way street. As the magnitudes of shares in total trade show, these relations are several times more important for the East than for the West. However, dependencies are to be found on both sides, with an uneven distribution.

In the West, European countries are the main group of partners. They account for roughly 75% of sales to the East and 90% of imports from the East (figures of 1983). This pattern has been stable since the end of the 1970s. In 1970 the share of Western Europe was very similar on the import side, but larger on the export side (about 10 points more). Since then, two major exporters have emerged outside Europe, Japan (for technology) and the United States (for grain, mainly to the USSR).

In the East, the USSR gained a growing share of East-West trade after 1970. From twofifths of the total trade of the European CPEs with the West, it reached 50% in the mid-1970s and over 60% in the 1980s. This is mainly due to the increase in oil prices after 1973; it allowed the Soviet Union to secure a higher rate of growth of its trade with the West compared with the other CPEs up to 1980, and to avoid the decrease in trade which the other CPEs experienced in the beginning of the 1980s.

This growing concentration of East-West trade on the Soviet Union is an expression of stronger interdependences.

For Western Europe, especially for the large industrial corporations, the USSR emerged in the 1970s as a major purchaser of heavy equipment, whose orders helped to sustain the level of activities and jobs during the recession years. The controversial multi-billion dollars gas pipeline deal concluded in 1981 is a clear demonstration of such interests. When in 1982 the US government tried to oppose the supply of tubes and other equipment for the pipeline, as a retaliation for the Soviet role in the Polish crisis, and also as an attempt to reduce the export capacities of natural gas of the USSR, the European governments backed their firms. Even though the Soviet orders for equipment substantially declined after then, the Soviet Union remains a huge market.

On the other side, the Soviet Union has become a significant supplier of energy to Western Europe. Fuels now account for about 80% of its sales to the West, from about half that share in the

beginning of the 1970s. The major Western European energy importers (Germany, France, Italy) are now dependent for 6–7% of their total energy imports on the Soviet Union. For natural gas alone, their dependence may be above the 30% mark at the end of the 1980s, from about 15% to 20% a decade earlier. The Soviet market is a means of achieving a diversification in energy imports; it is a cheaper supplier for oil and gas because of the distance factor, and may be considered as a more reliable one, than the Third World.

Regarding trade with the United States, the major link is grain. The Soviet Union began to buy large quantities of American grain in 1975–1976 and has been the largest single customer of the United States since then. US sales never again reached the 70% share of Soviet grain imports which they formed in 1979. However, the strength of economic versus political interests is clearly demonstrated by the failure of the grain embargo, which had to be lifted under the pressure of American farmers. The long-term grain sales agreement linking the two countries, first signed in 1975, has not only been renewed but also supplemented with an anti-embargo clause (in 1983).

The Western trade of Eastern Europe lacks these powerful interdependences. The smaller CPEs taken together are on average less involved in trade with the West than the USSR. In 1984, the share of Western trade in their total trade was about 25% (against 30% for the USSR) and had been declining since 1980. But while Bulgaria and Czechoslovakia, much more oriented toward trade within CMEA, have a very low share of their total trade with the West (12–15%), Hungary (35%), Poland, GDR and Romania (30%) are potentially interested in expanding their trade with the West. However, opportunities for that are low. Their supply is made of sensitive goods (steel, chemicals, textiles, manufactured goods, agricultural products), the demand for which is sluggish in the West – and they complain of growing protectionism. For these goods competition is growing on Western markets from the new industrializing countries of the Third World, which in addition are more advanced in some high technology fields (electronics). They can hardly expect concessions from Western countries, for which they provide less promising markets than the USSR. The development of compensation deals is only a marginal way of securing outlets for their goods.

Obstacles

In the background of these differentiated economic interests, specific obstacles hinder East-West trade, in the political, institutional (systemic) and financial fields, to which must be added the 1986 developments on the world oil market.

Is East-West trade *political* in essence? In Western Europe, politics and economic relations are regarded as distinct by governments and firms. The lasting failure to find an agreement between EEC and the CMEA, since the beginning of official talks in 1976, is mainly due to the lack of institutional competence of the CMEA in matters of trade as appraised by the EC Commission (even if on the side of the Commission there is a political concern to avoid strengthening the Soviet-dominated CMEA as an organization). The major involvement of politics in East-West economic relations is related to US policy. The 'linkage' concept of tying economic advantages to Soviet concessions in the political sphere was associated in the 1970s with commercial policies (the granting of the MFN clause) or financial conditions (for access to bank credits). Since the end of that decade it has evolved into a policy of sanctions, first as a retaliation for the Soviet invasion of Afghanistan in 1979 (the grain embargo against the USSR, which was lifted in April 1981, and a tighter control of high technology sales); then as a response to the martial law imposed in December 1981 in Poland. In this last case the sanctions hit Poland (though credit and export restrictions, a suspension of the MFN clause), and the USSR (through attempts to stop the Eurosiberian pipeline deal by preventing the Western European countries from selling equipment to the USSR and from concluding the agreements for the purchases of gas). They were also

extended to the other CPEs through a very severe credit squeeze. All these measures culminated in 1982. They proved largely ineffective but generated conflicts within the Western Alliance. The major and lasting field of political pressure is to be found in the embargo on high technology sales to the CPEs, conducted through the Cocom (Coordinating Committee), an informal organization set up in 1949 and including the NATO countries plus Japan. Very active during the years of the cold war, it seemed to be withering in the late 1970s but regained momentum from 1980 on. The present rationale of the Cocom restrictions is threefold: to impose sanctions; to prevent the Soviet bloc from acquiring dual-use technologies (for military as well as civilian ends); to enlarge the scope of controls by restricting high-technology exports of non-Cocom members (Sweden, Switzerland, Austria, and even some Third World countries such as India).

The *systemic* obstacles in trade are related to the specific organization of state trading in the CPEs. The monopoly of foreign trade and the related planning of trade flows remain very rigid in the Soviet Union. Increased flexibility has been introduced in the trade mechanisms of all the other CPEs, where enterprises are gaining easier access to foreign trade transactions. Direct interfirm contacts have been stimulated through industrial cooperation. In all these countries except for GDR, it is now possible to create joint enterprises with foreign equity capital (the experiences remain limited). The state trading system, however reformed, still prevents the CPEs from successfully adjusting to the market requirements in the West.

The *financial* problems of East-West relations are less dramatic than in 1980–1981, when the total indebtedness of the USSR and Eastern Europe combined exceeded $80 billion, more than four times its level of the end of 1974. Two countries, Poland and Romania, entered in 1981 a process of rescheduling, which is still going on for Poland. Two others, GDR and Hungary, successfully managed to restore their external accounts in 1982–1984. Since then, the Western banks have again been ready to expand their loans not only to the Soviet Union, which has always remained a good risk, but also to the other CPEs, which by all accounts seem more creditworthy than the Third World.

East-West economic relations are finally to be replaced in the broader context of the CPEs' foreign economic relations, including intra-CMEA trade. The move toward closer integration, advocated by the Soviet Union at the Summit meeting of the CMEA in June 1984 and based upon the heavy requirements of the USSR regarding its imports from its partners, might well appear as an additional constraint to the expansion of East-West relations for the smaller CPEs.

The fall in oil prices, since the end of 1985, may have strong adverse effects on East-West trade. If the average price for oil is for some time stabilized at half its 1985 level, the Soviet Union will lose at least one third of its export gains in its trade with the West. These losses may be compensated for, in the short run, by cuts in imports and increased borrowing, together with a stronger pressure on the smaller CMEA countries. The latter will thus have to divert to the Soviet market goods exportable to the West. In addition, they too will lose as sellers of refined oil products, with the same consequences as for the USSR. The 'golden age' of East-West trade is definitely not to be renewed.

Eckstein was an entrepreneur who moved a whole technology from the research community into the marketplace. Until he founded Data Resources, Inc., macroeconometric models were research vehicles and not vehicles for aiding business decision making. Under his direction Data Resources came to dominate the marketplace for this type of information, but more importantly it changed the nature of the game. To be taken seriously after his innovation, all economic forecasts had to be buttressed with econometric equations and no large firm would attempt to begin its decision-making processes without an understanding of the national and international economic forecasts emanating from such models.

Born in Ulm, Germany, in 1927, Dr. Eckstein fled to England in 1938 and came to the United States in 1939. He graduated from Stuyvesant High School in New York City and served in the United States Army Signal Corps from 1946 to 1947. He received an AB degree from Princeton University in 1951 and a Ph.D. from Harvard University in 1955.

In 1968, he and Donald B. Marron founded Data Resources, Inc., which has grown into the largest economic information company in the world. The firm became a subsidiary of McGraw-Hill, Inc. in 1979. He directed the development of the Data Resources Model of the US economy, and was responsible for its forecasting operations.

As an immigrant to the United States from Nazi Germany, Otto Eckstein wanted to contribute something to America's future success. Better economic policies that would lead to a higher American standard of living were not an abstraction to him. They were the centre of his professional life.

His professional career began with the analysis of large scale multi-year water resources projects and how one might better allocate national resources in such projects. In the late 1950s he was the principal intellectual director of a Joint Economic Committee study on how the United States might break out of what was then seen as the stagnation of the mid-1950s. His study on growth, full employment and price stability laid the basis for the successful economic policies that were followed in the first two-thirds of the 1960s. But he went on to implement those intellectual foundations as a member of the President's Council of Economic Advisers under President Johnson.

No one who knew the enthusiasm of Otto Eckstein for studying, teaching, and practising economics could thereafter think of economics as the dismal science.

Ecole Nationale des Ponts et Chaussées

Robert B. Ekelund Jr and Robert F. Hébert

French School of Civil Engineering, located at 28 rue des Saint-Pères, Paris. Established in 1747 by Daniel Trudaine, Finance Minister to Louis XV, the Ecole has traditionally produced economists of exceptional talent and originality. Isnard, Dupuit and Cheysson were students there and at various times its faculty included the likes of Henri Navier, Joseph Minard, Joseph Garnier, Henri Baudrillart, Charles Gide, Clément Colson and François Divisia.

The idea of an institution dedicated to the professionalization of French engineers had its roots in the 17th century. In 1690 Vauban created the Corps of Military Engineers, which was to serve as a model for future public bodies of this sort. He even went so far as to propose a public examination to test the scientific knowledge of young people aspiring to become engineers. After an inauspicious beginning, the Ecole slowly acquired more scholarly aspirations. It was directed in its formative years by J.R. Perronet, who established the high standards and pedagogical technique responsible for the ultimate success of the school, so much so that French engineers became the envy of the world. Although a formal course in economics was not established until 1847 (receiving impetus from Dupuit's pioneer researches in 1844), engineers were 'officially' exhorted to study economics as early as 1792.

The Revolution of 1789 brought sweeping changes to higher education in France. For a time it seemed as though the Ecole would be swept away as a vestige of the *ancien régime,* but Mirabeau successfully defended its existence, and by the time Napoleon came to power, a major expansion of faculty, students and curriculum was under way. With the establishment of the Ecole Polytechnique in 1794, the nature of the Ecole des Ponts et Chaussées changed from an undergraduate to a postgraduate institution, offering admission by competitive examination and specialized training for polytechnicians seeking to become civil engineers. These civil engineers became problem-solvers in the areas of flood control, municipal water distribution and sewage disposal, canal building, railway construction, road building and myriad other matters of concern to engineers.

The 19th century was the 'golden age' of the Ecole, a time when the faculty was upgraded and the curriculum was stretched to include stereotomy (1799), modern languages (1806), mineralogy and geology (1826), administrative law (1831), political economy (1847), thermodynamics (1851), and applied chemistry (1864). The role of the Ecole was pivotal and international in both engineering and economics. Henri Navier, for example, was sent in 1821 and in 1823 by the Director General of the Corps to study British achievements in suspension bridge design and construction. Upon his return Navier, who wrote a number of essays on the economic value of public works, offered a *Mémoire sur les ponts suspendus* which brought the French to the forefront of such technology for much of the 19th century. Jules Dupuit entered the Ecole in 1824, where he reacted to both Navier's engineering and

economic studies, later producing a theory of marginal utility and a full scale welfare analysis of markets and market structure. In 1830 an American student, Charles Ellet, Jr., entered the Ecole, returning home as the premier suspension bridge builder and designer of his age *and* as one of the most creative American economic theorists of the century. In short, the 19th century is the period when economic inquiry at the Ecole burgeoned, easily outdistancing the policy squabbles that occupied French academic economists at the universities and in academic journals. It was the era of Dupuit, Cheysson and Colson, the unrecognized giants of 19th century French economics.

Today the Ecole des Ponts et Chaussées stands as the oldest of France's *grandes écoles*. Perched at the top of a rigid and highly centralized educational system, it persists in admitting the country's intellectual elite and in providing them with solid training in economics.

Ecological Economics

Anastasios Xepapadeas

Abstract

Ecological economics is the study of the interactions and co-evolution in time and space of human economies and the ecosystems in which human economies are embedded. It uncovers the links and feedbacks between human economies and ecosystems, and so provides a unified picture of ecology and economy. The link between ecology and human economies has been manifested in the development of resource management or bio-economic models, in which the main focus has been on fishery or forestry management where the impact of humans on ecosystems is realized through harvesting. More closed links have been developed, however, as both disciplines evolve.

Ecology can be regarded as the study of living species such as animals, plants and microorganisms, and the relations among them and their natural environment. In this context, an ecosystem includes these species and their non-living environment, their interactions, and their evolution in time and space (see, for example, Roughgarden et al. 1989). Economics, meanwhile, is the study of how human societies use scarce resources to produce commodities and to distribute them among their members.

The need for an interdisciplinary approach – 'ecological economics' – stems from the fact that natural ecosystems and human economies are closely linked. In the process of production and consumption, human beings use ecosystems and their services, influence their evolution, and are the recipients of feedbacks originating from their actions upon ecosystems. As Kenneth Boulding (1965) notes in his classic paper 'Earth as a space ship', which can be regarded as a landmark in the emergence of ecological economics, 'Man is finally going to have to face the fact that he is a biological system living in an ecological system, and that his survival

power is going to depend on his developing symbiotic relationships of a closed-cycle character with all the other elements and populations of the world of ecological systems.'

Thus, ecological economics can be regarded as the study of the interactions and co-evolution in time and space of human economies and the ecosystems in which human economies are embedded. This implies that the task of ecological economics is to bridge the gap between economy and ecology by uncovering the links and the feedbacks between human economies and ecosystems, and by using these links and feedbacks to provide a unified picture of ecology and economy and their interactions and co-evolution. In a sense, ecological economics aims at linking ecological models and economic models in order to provide insights into complex and interrelated phenomena stemming from and affecting both ecosystems and human economies.

The natural link between ecology and human economies has been manifested in the traditional development of resource management or bio-economic models (for example, Clark 1990), in which the main focus has been on fishery or forestry management where the impact of humans on ecosystems is realized through harvesting. More close links have been developed, however, as both disciplines evolve.

Common methodological approaches may also be encountered in ecology and economics. Optimality behaviour, which is fundamental in economics, has also been used to provide insights into the structure of ecological systems, in the context of optimal foraging behaviour, species competition, or net energy maximization by organisms (for example, Tschirhart 2000; Tilman et al. 2005) with the purpose of founding macrobehaviours in ecosystems – such as those emerging from population dynamics – on microfoundations.

In the same context, the classical phenomenological-descriptive approach to species competition based on Lotka–Volterra systems has recently been complemented by mechanistic resource-based models of species competition for limiting resources (Tilman 1982, 1988). This approach has obvious links to competition among economic agents for limited resources. Furthermore, by linking the functioning of natural ecosystems with the provision of useful services to humans, or by using concepts such as ecosystems productivity, insurance from the genetic diversity of ecological systems against catastrophic events, or development of new products using genetic resources existing in natural ecosystems (Heal 2000), new insights into the fundamental issues of the valuation of ecosystems or the valuation of biodiversity have been derived. (Examples of useful services to humans include provisioning services, such as food, water, fuel, genetic material; regulation services, such as climate regulation, disease regulation; and cultural services and supporting services, such as soil formation, nutrient cycling; see Millennium Ecosystem Assessment 2005.)

Ecological Models

The traditional bio-economic models (Clark 1990), which describe the evolution of the population or the biomass of species when harvesting takes place, have formed the building blocks of ecological-economic modelling. These models can be extended along various lines to provide a more realistic picture of ecosystems (for a detailed analysis, see Murray 2003) and help build meaningful ecological-economic models. To start with, let $x(t)$ denote the biomass of a certain species at time t. Then evolution of the biomass is described by an ordinary differential equation

$$\frac{dx(t)}{dt} = \text{birth} - \text{naturaldeath} + \text{migration} - \text{harvesting}. \quad (1)$$

In the analysis of population models it is common, unless it is a specific case, to set the migration rate at zero, and to represent the natural rate of population growth (birth-natural death) by a function $F(x)$. The most common specification of this function is the famous *logistic function*, which is

$F(x) = rx(1-x/K)$. In this function r is a positive constant called *intrinsic growth rate* and K is the *carrying capacity* of the environment which depends on factors such as resource availability or environmental pollution. If we denote by $h(t)$ the rate of harvesting of the species biomass by humans, the population model becomes:

$$\frac{dx(t)}{dt} = F(x) - h(t), x(0) = x_0. \quad (2)$$

If $h(t) \equiv F(x)$, the population remains constant and the harvesting rate corresponds to *sustainable yield*. Harvesting rate is usually modelled as population dependent or $h = qEx$, where q is a positive constant, referred to as a *catchability coefficient* in fishery models, and E is *harvesting effort*. Human activities can affect the species population, in addition to harvesting, by affecting parameters such as the intrinsic growth rates or the carrying capacity. For example, if the stock of environmental pollution of a certain pollutant (such as phosphorus in a lake) in a natural ecosystem is denoted by P, with dynamics described by

$$\frac{dP(t)}{dt} = g(s(t), P(t)), P(0) = P_0, \quad (3)$$

where $s(t)$ is the rate of emissions (such as phosphorus loadings), and the pollutant affects parameters of the population model, then the combined model will be (3) along with

$$\frac{dx(t)}{dt} = r(P)x\left[1 - \frac{x}{K(P)}\right] - qEx, r'(P) < 0, K'(P) < 0. \quad (4)$$

If the catchability coefficient is affected by technical change, then it can be expressed by a function of time as $q(t)$. In this case (4) is not autonomous. Alternatively q can be a function of technological variables like R&D evolving in the economic module.

The population model (2) can be generalized to age-structured populations and multi-species populations. In multi-species populations the Lotka–Volterra predator–prey models are classic. If we denote the prey population by $x(t)$ and the predator population by $y(t)$ and ignore harvesting for the moment to simplify things, the model can be written as

$$\frac{dx(t)}{dt} = x\left[r\left(1 - \frac{x}{K}\right) - yR(x)\right], x(0) = x_0 \quad (5)$$

$$\frac{dy(t)}{dt} = ym\left(1 - \frac{ny}{x}\right), y(0) = y_0 m, n > 0 \quad (6)$$

where $R(x)$ is a function called the *predation term*, which can be specified as $\gamma x/(x^2+\delta^2)$, γ, $\delta > 0$. A more general multi-species model with J prey and J predators can be written, for $i = 1,\ldots,J$, as

$$\frac{dx_i(t)}{dt} = x_i\left[a_i - \sum_{j=1}^{J}\beta_{ij}y_i\right], x_i(0) = x_{i0} \quad (7)$$

$$\frac{dy_i(t)}{dt} = y_i\left[\sum_{j=1}^{J}\gamma_{ij}x_j - \delta_i\right], y_i(0) = y_{i0} \quad (8)$$

where all parameters are positive constants. An even more general model of interacting populations can be obtained by the generalized Kolmogorov model where the evolution of each species biomass is described by:

$$\frac{dx_i(t)}{dt} = x_i F_i(x_1, x_2, x_3, \ldots) i = 1, 2, 3, \ldots \quad (9)$$

In the mechanistic resource-based models of species competition emerging from the work of Tilman (for example, Tilman 1982, 1988), species compete for limiting resources. (For the use of this model in ecological-economic modelling, see Brock and Xepapadeas 2002; Tilman et al. 2005.) In these models the growth of a species depends on the limiting resource, and interactions among species take place through the species' effects on the limiting resource. Let $\mathbf{x} = (x_1,\ldots,x_n)$ be the vector of species biomasses and R the amount of the available limiting resource. Then a mechanistic resource-based model with a single limiting factor in a given

area and $i = 1,\ldots,n$ species can be described by the following equations:

$$\frac{\dot{x}_i}{x_i} = g_i(R) - d_i, x_i(0) = x_{i0} \tag{10}$$

$$\dot{R} = S - aR - \sum_{i=1}^{n} w_i x_i g_i(R) \tag{11}$$

where $g_i(R)$ is resource-related growth, d_i is the species' natural death rate, S is the amount of resource supplied, a is the natural resource removal rate (leaching rate), and w_i is specific resource consumption by species i. The main result in this framework relates to an exclusion principle stating that, in a landscape free of disturbances, the species with the lowest resource requirement in equilibrium will competitively displace all other species, driving the system to a monoculture. Species coexistence and polycultures in equilibrium can be supported in a system with more than one limiting resource, or even in single resource systems if there is temperaturedependent growth and temperature variation in the ecosystem, spatial or temporal variations in resource ratios, differences in local palatabilities and local abundance of herbivores.

In addition to the temporal variation captured by the models described above an important characteristic of ecosystems is that of spatial variation. Biological resources tend to disperse in space under forces promoting 'spreading' or 'concentrating' (Okubo 2001); these processes, along with intra- and inter-species interactions, induce the formation of spatial patterns for species. A central concept in modelling the dispersal of biological resources is that of *diffusion*. Diffusion is defined as a process whereby the microscopic irregular movement of particles such as cells, bacteria, chemicals, or animals results in some macroscopic regular motion of the group. Biological diffusion is based on random walk models which, when coupled with population growth equations, lead to general reaction-diffusion systems (see, for example, Okubo and Levin 2001; Murray 2003). When only one species is examined, the coupling of classical diffusion with a logistic growth function leads to the so-called Fisher–Kolmogorov equation, which can be written as

$$\frac{\partial x(z,t)}{\partial t} = F(x(z,t)) + D_x \frac{\partial^2 x(z,t)}{\partial z^2} \tag{12}$$

where $x(z,t)$ denotes the concentration of the biomass at spatial point z at time t. The biomass grows according to a standard growth function $F(x)$ which determines the resource's kinetics but also disperses in space with a constant diffusion coefficient D_x. (Nonlinear reaction diffusion equations are associated with propagating wave solutions.) In general, a diffusion process in an ecosystem tends to produce a uniform population density, that is, spatial homogeneity. Thus it might be expected that diffusion would 'stabilize' ecosystems where species disperse and humans intervene through harvesting.

There, is however, one exception, known as 'diffusion induced instability' or 'diffusive instability'. It was Alan Turing (1952) who suggested that under certain conditions reaction-diffusion systems can generate spatially heterogeneous patterns. This is the so-called 'Turing mechanism' for generating diffusion instability. With two interacting species evolving according to

$$\frac{\partial x(z,t)}{\partial t} = F(x,y) + D_x \frac{\partial^2 x(z,t)}{\partial z^2} \tag{13}$$

$$\frac{\partial y(z,t)}{\partial t} = G(x,y) + D_y \frac{\partial^2 y(z,t)}{\partial z^2}, \tag{14}$$

if in the absence of diffusion ($D_x = D_y = 0$) the system tends to a spatially uniform stable steady state, then under certain conditions, depending on the relationship D_x/D_y, spatially heterogeneous patterns can emerge due to diffusion-induced instability.

Spatial variations in ecological systems can also be analysed in terms of meta-population models. A meta-population is a set of local populations occupying isolated patches which are connected by migrating individuals. Meta-population dynamics can be developed for single

or many species (Levin 1974). For the single species case the dynamics become

$$\frac{d\mathbf{x}}{dt} = \mathrm{F}(\mathbf{x})\mathbf{x} + \mathbf{D}\mathbf{x} \tag{15}$$

where $\mathbf{x}=(x_1,\ldots,x_J)$ is a column vector of species densities, $\mathbf{F}$ has its ith row depending on the ith row of $\mathbf{x}$, and $\mathbf{D} = [d_{ij}]$ is a connectivity matrix, where d_{ij} is the rate of movement from patch j to patch i ($j \neq i$). Thus dynamics are local with the exception of movements from one patch to the other.

A more general model encompassing $i = 1,\ldots,n$ species competing for $j = 1,\ldots, J$ limiting resources, with density-dependent growth and interactions across patches $c = 1,\ldots, C$ in a given landscape, can be written as

$$\frac{\dot{x}_{ci}}{x_{ci}} = F_{ic}(\mathbf{x}_c, \mathbf{x}_{-c}) g i_c(\mathbf{R}_c, d_{ic}), \forall i, c \tag{16}$$

$$\dot{R}_{jc} = S_{jc}(\mathbf{R}_c, \mathbf{R}_{-c}) - D_{jc}(\mathbf{x}_c, \mathbf{x}_{-c}, \mathbf{R}_c, \mathbf{R}_{-c}), \forall j, c \tag{17}$$

where $\mathbf{R}_{-c}$, $\mathbf{x}_{-c}$ are respectively vectors of resources and species outside patch c.

(For a detailed analysis, see Brock and Xepapadeas 2002.) A more general setup can be obtained in the context of co-evolutionary models which describe the interactions between population (or biomass) dynamics and mutation (or trait dynamics). Antagonistic co-evolution of species on the one hand and pests or parasites or the other can be described by the so-called Red Queen hypothesis (see, for example, Van Valen 1973, and Kawecki 1998). According to this hypothesis, parasites evolve ceaselessly in response to perpetual evolution of species' (or hosts') resistance. The co-evolution of the parasites' ability to attack (virulence) and the hosts' resistance is expected to indicate persistent fluctuations of resistance and virulence. In this context the Red Queen hypothesis generates a continuous need for variation, resulting in a limit cycle or other non-point attractor in trait space dynamics, which are called Red Queen races. Red Queen cycles are observed in a slow time scale, since trait dynamics are assumed to evolve slowly, in contrast to the population, host-parasite, dynamics which are assumed to evolve fast (see Dieckmann and Law 1996).

A simple co-evolutionary model can be developed in a system with one harvested ('useful') species or host species whose biomass is denoted by x and a parasite denoted by y, where the abundance of x and y depends on the evolution of two characteristics or traits denoted by d and γ (see, for example, the Red Queen dynamic models developed by Krakauer and Jansen 2002), where d affects the fitness of x and γ affects the fitness of y.

Let the growth rates of x and the pathogen y be given by

$$g_x = \frac{\dot{x}}{x} = (s - rx - yQ(d,\gamma)) \tag{18}$$

$$g_y = \frac{\dot{y}}{y} = (xQ(d,\gamma) - \delta). \tag{19}$$

If we measure fitness by growth rates, then $\frac{\partial Q(d,\gamma)}{\partial d} < 0$, so that an increase in d increases fitness of x. In the same way, $\frac{\partial Q(d,\gamma)}{\partial \gamma} > 0$ for an increase in γ to increase fitness of y. In equilibrium of the fast population system where $\dot{x} = \dot{y} = 0$, it holds that

$$\hat{x} = \frac{\delta}{Q(d,\gamma)}, \hat{y} = \frac{s - r\hat{x}}{Q(d,\gamma)}, s \geq r\hat{x}. \tag{20}$$

that On the assumption of constant mutation rates μ_d and μ_γ, the evolutionary dynamics for the traits d and γ, when population dynamics have reached the asymptotically stable steady state, are given by

$$\dot{d} = -\mu_d \hat{x}\hat{y} \frac{\partial Q(d,\gamma)}{\partial d} \tag{21}$$

$$\dot{\gamma} = \mu_\gamma \hat{x}\hat{y} \frac{\partial Q(d,\gamma)}{\partial \gamma}. \tag{22}$$

See Krakauer and Jansen (2002) who, by considering the slow time scale trait dynamics, show that the equilibrium point $(d^*, \gamma^*) : \dot{d} = \dot{\gamma} = 0$ is not attracting; the dynamics spiral away from this

point. This behaviour is the oscillatory, Red Queen dynamics.

Ecological-Economic Modelling

The ecological models developed above are the cornerstones of the development of meaningful ecological-economic models. The impact of humans on the population of species can be realized through direct harvesting h as described in (1) and (2). This type of impact can be easily incorporated into the more general population dynamic models by selecting the harvested species. Human influence can also be realized in an indirect way by having the environmental carrying capacity affected by environmental pollution generated in the non-harvesting sector of the economy, as in (3) and (4), or by having technological considerations affecting catchability coefficients. It is also possible that external environmental conditions which are anthropogenic, such as global warming, can make some parameters associated with population dynamics or mutation dynamics change slowly. This can be modelled in (21) and (22) by considering μ_d and μ_γ as slow varying parameters, defined as $\mu_d(\varepsilon t)$ and $\mu_\gamma(\varepsilon t)$, where $0 < \varepsilon \ll 1$ is the *adiabatic parameter*. This slowly varying system could be used to model slow anthropogenic impacts on ecosystem structure.

However, the size and the severity of the impact of human economies in ecosystems depend on the way in which variables, such as harvesting or other variables which can be chosen by humans (such as emissions, investment in harvesting capacity) and which influence the evolution of ecosystems, are actually chosen. These variables can be regarded as *control variables*, and the way in which they are chosen affects the evolution of ecological variables, such as species biomasses or traits, which can be considered as the *state variables* of the problem.

The typical approach in economics is to associate the choice of the control variables with *optimizing behaviour*. Thus, the control variables are chosen so that a criterion function is optimized, and the economic problem of ecosystem management – where management means choice of control variables – is defined as a formal optimal control problem. In this problem the objective is the optimization of the criterion function subject to the constraints imposed by the structure of the ecosystem. These constraints, which provide the transition equations of the optimal control problem, are the dynamic equations of the ecological models described in the previous section.

The solution of the ecological-economic model, provided it exists, will determine the paths of the state and the control variables and the steady state of the system, which will determine the long-run equilibrium values of the ecological populations as well as the approach dynamics to the steady state. In this context, managed ecological systems which are predominantly nonlinear could exhibit dynamic behaviour characterized by multiple, locally stable and unstable steady states, limit cycles, or the emergence of hysteresis, bifurcations or irreversibilities.

The way in which the objective function is set up and the ecological constraints which are taken into account determine the solution of the ecological-economic model. In principle, a *socially optimal solution* can be distinguished from a *privately optimal solution*. The socially optimal solution corresponds to the so-called problem of the *social planner*, where the objective function takes into account not only benefits from harvesting certain resources of the ecological system, which corresponds to harvesting commercially valuable biomass, but in addition a wide spectrum of flows of services generated by the whole ecosystem. These include, as described above, regulation, cultural or supporting services, existence values, or benefits associated with productivity or insurance gains. If $V(\mathbf{h}(t))$ denotes harvesting benefits at time t associated with harvesting vector $\mathbf{h}$, and $U(\mathbf{x}(t))$ denotes the flow of benefits associated with ecosystem service generated by species biomasses existing in the ecosystem and not removed by harvesting, then the total flow of benefit is $V(\mathbf{h}(t)) + U(\mathbf{x}(t))$. In this formulation, the $V(\,)$ and $U(\,)$ functions are usually assumed to be monotonically increasing and concave. In a more general setup, the total benefit function can be non-separable, defined as $u(\mathbf{h}(t); \mathbf{x}(t))$.

The objective can then be written as

$$\max_{\{\mathbf{h}(t)\}} \int_0^\infty e^{-\rho t}[V(\mathbf{h}(t)) + U(\mathbf{x}(t))]dt \qquad (23)$$

where $\rho \geq 0$ is a discount rate. It should be noted that in principle benefits associated with $V(\mathbf{h}(t))$ can be estimated using market data, while benefits associated with $U(\mathbf{x}(t))$ are hard to estimate because markets for the larger part of the spectrum of ecosystem services are missing. (Valuation of ecosystem services is an open question. For details, see, for example, Bingham et al. 1995.) The social optimum corresponds to the maximization of (23), subject to the constraints imposed by the ecological system. For example, if we use the generalized model of resource competition, the constraints are:

$$\frac{\dot{x}_{ci}}{x_{ci}} = F_{ic}(\mathbf{x}_c, \mathbf{x}_{-c})g_{ic}(\mathbf{R}_c, d_{ic}) - h_{ic}, \forall i, c \qquad (24)$$

$$\dot{R}_{jc} = S_{jc}(\mathbf{R}_c, \mathbf{R}_{-c}) - D_{jc}(\mathbf{x}_c, \mathbf{x}_{-c}, \mathbf{R}_c, \mathbf{R}_{-c}), \forall j, c. \qquad (25)$$

A solution $(\mathbf{h}^*(t), \mathbf{x}^*(t))$ is regarded as the socially optimal solution.

The privately optimal solution is distinguished from the socially optimal by the fact that only harvesting benefits enter the objective function. The assumption is that management is carried out by a 'small' profit-maximizing private agent that ignores the general flows of ecosystem services. In this case, the private agents do not take into account *externalities* associated with their management practices on ecosystem service flow and $U(\mathbf{x}(t)) \equiv 0$. Market externalities associated with the definition of $V(\mathbf{h})$ could relate to imperfections in the markets for the harvested commodities, or to property rights-related externalities, as the well known 'tragedy of the commons' emerging in the harvesting of open access resources.

In general the privately optimal solution $(\mathbf{h}^0(t),\mathbf{x}^0(t))$ will deviate from the socially optimal solution. Another type of externality can be associated with strategic behaviour in resource harvesting if more than one private agent harvests the resource. If $l = 1,\ldots, L$ harvesters are present, then the biomass equation (24) for patch c becomes

$$\frac{\dot{x}_{ci}}{x_{ci}} = F_{ic}(\mathbf{x}_c, \mathbf{x}_{-c})g_{ic}(\mathbf{R}_c, d_{ic}) - \sum_{l=1}^{L} h_{ic}, \forall i, c.$$

In this case the privately optimal solution can be obtained as an *open loop or feedback* Nash equilibrium.

Privately optimal solutions can also be distinguished from the socially optimal by the extent to which the ecological constraints are taken into account. For example, if resource dynamics or trait dynamics are not taken into account in the optimization problem, the management rule will deviate from the social optimum. Furthermore, since *all* the ecological constraints are operating, there will be discrepancies between the perceived evolution of ecosystems under management that ignores certain constraints, and the actual evolution of the ecosystem. Brock and Xepapadeas (2003), show that, by ignoring genetic constraints associated with the development of resistance to genetically modified organisms, the actual system loses any productivity advantage because of resistance development.

These discrepancies might be a cause for *surprises* in ecosystem management. For example, with reference to the co-evolutionary model (18), (19), (20), (21), and (22), profit-maximizing decisions which ignore evolution might steer the system to a certain steady state on a fast time scale, but then the underlying trait dynamics might move the system in slow time to another attractor.

The deviations between the private solution and the social optimum provide a basis for regulation which is similar to the rationale behind the regulation of environmental externalities. Regulation could take the form, in general spatial models of ecosystem management, of species-specific and site-specific taxes on harvesting, or equivalent quota and zoning systems.

Ecological Inference

Gary King, Ori Rosen and Martin Tanner

Abstract

Ecological inference is a general statistical problem where a response variable is not available at the subject level because summary statistics are reported for groups only. It consists of merging information from different databases which are not linked to each other at the record level. We consider an election scenario where in each electoral precinct the fraction of voting-age people who turn out to vote, the fraction of black population and the number of voting-age people are observed. The proportions of blacks and of whites who vote are unobserved because electoral results and census data are not linked.

The Ecological Inference Problem

For expository purposes, we discuss only an important but simple special case of ecological inference, and adopt the running example and notation from King (1997: ch. 2). The basic problem has two observed variables (T_i and X_i) and two unobserved quantities of interest (β_i^b and β_i^w) for each of p observations. Observations represent aggregate units, such as geographic areas, and each individual-level variable within these units is dichotomous.

To be more specific, in Fig. 1 we observe for each electoral precinct $i (i = 1, \ldots, p)$ the fraction of voting age people who turnout to vote (T_i) and who are black (X_i), along with the number of voting age people (N_i). The quantities of interest, which remain unobserved because of the secret ballot, are the proportions of blacks who vote $\left(\beta_i^b\right)$ and whites who vote $\left(\beta_i^w\right)$. The proportions β_i^b and $\left(\beta_i^w\right)$ are not observed because T_i and X_i are from different data sources (electoral results and census data, respectively) and record linkage is impossible (and illegal), and so the cross-tabulation cannot be computed.

Also of interest are the district-wide fractions of blacks and whites who vote, which are respectively

Race of voting age person	Voting decision: Vote	Voting decision: No Vote	
Black	β_i^b	$1 - \beta_i^b$	X_i
White	β_i^w	$1 - \beta_i^w$	$1 - X_i$
	T_i	$1 - T_i$	

Ecological Inference, Fig. 1 Notation for Precinct i. *Note*: The goal is to estimate the quantities of interest, β_i^b (the fraction of blacks who vote) and β_i^b (the fraction of whites who vote), from the aggregate variables X_i (the fraction of voting age people who are black) and T_i (the fraction of people who vote), along with N_i (the known number of voting age people)

$$B^b = \frac{\sum_{i=1}^{p} N_i X_i \beta_i^b}{\sum_{i=1}^{p} N_i X_i}, \text{ and} \tag{1}$$

$$B^w = \frac{\sum_{i=1}^{p} N_i (1 - X_i) \beta_i^w}{\sum_{i=1}^{p} N_i (1 - X_i)}. \tag{2}$$

These are weighted averages of the corresponding precinct-level quantities. Some methods aim to estimate only B^b and B^w without giving estimates of β_i^b and β_i^w for all i.

Deterministic and Statistical Approaches

The ecological inference literature before King (1997) was bifurcated between supporters of the method of bounds, originally proposed by Duncan and Davis (1953), and supporters of statistical approaches, proposed even before Ogburn and Goltra (1919) but first formalized into a coherent statistical model by Goodman (1953, 1959). (For the historians of science among us: although these two monumental articles were written by two colleagues and friends in the same year and in the same department and university – the Department of Sociology at the University of Chicago – the principal did not discuss their work prior to completion. Even by today's standards, nearly a half century after their publication, the articles are models of clarity and creativity.) Although Goodman and Duncan and Davis moved on to other interests following their seminal contributions, most of the ecological inference literature in the five decades since 1953 was an ongoing war between supporters of these two key approaches, and often without the usual academic decorum.

Extracting Deterministic Information: The Method of Bounds

The purpose of the method of bounds and its generalizations is to extract deterministic information, known with certainty, about the quantities of interest.

The intuition behind these quantities is simple. For example, if a precinct contained 150 African-Americans and 87 people in the precinct voted, then how many of the 150 African-American actually cast their ballot? We do not know exactly, but bounds on the answer are easy to obtain: in this case, the answer must lie between 0 and 87. Indeed, conditional only on the data being correct, [0,87] is a 100 per cent confidence interval. Intervals like this are sometimes narrow enough to draw meaningful inferences, and sometimes they are too wide, but the ability to provide (non-trivial) 100 per cent confidence intervals in even some situations is quite rare in any statistical field.

In general, before any data are seen, the unknown parameters β_i^b and β_i^w are each bounded on the unit interval. Once we observe T_i and X_i they are bounded more narrowly, as:

$$\begin{aligned}\beta_i^b &\in \left[\max\left(0, \frac{T_i-(1-X_i)}{X_i}\right), \min\left(\frac{T_i}{X_i}, 1\right)\right] \\ \beta_i^w &\in \left[\max\left(0, \frac{T_i-X_i}{1-X_i}\right), \min\left(\frac{T_i}{1-X_i}, 1\right)\right].\end{aligned} \tag{3}$$

Deterministic bounds on the district-level quantities B^b and B^w are weighted averages of these precinct-level bounds.

The bounds then indicate that the parameters in each case fall within these deterministic bounds with certainty, and in practice they are almost always narrower than [0,1]. Whether they are narrow enough in any one application depends on the nature of the data.

Extracting Statistical Information: Goodman's Regression

Leo Goodman's (1953, 1959) approach is very different from, but just as important as, Duncan and Davis's. He looked at the same data and focused on the statistical information. His approach examines variation in the marginals (X_i and T_i) over the precincts to attempt to reason back to the district-wide fractions of blacks and whites who vote, $B^b$and B^w. The outlines of this approach and the problems with it have been known at least since Ogburn and Goltra (1919). For example, if in precincts with large proportions of black citizens we observe that many people do not vote, then it may seem reasonable to infer that blacks turn out at lower rates than whites. Indeed, it often is reasonable, but not always. The problem is that it could instead be the case that the whites who happen to live in heavily black precincts are the ones who vote less frequently, yielding the opposite ecological inference to the individual-level truth.

What Goodman accomplished was to formalize the logic of the approach in a simple regression model, and to give the conditions under which estimates from such a model are unbiased. To see this, note first that the accounting identity

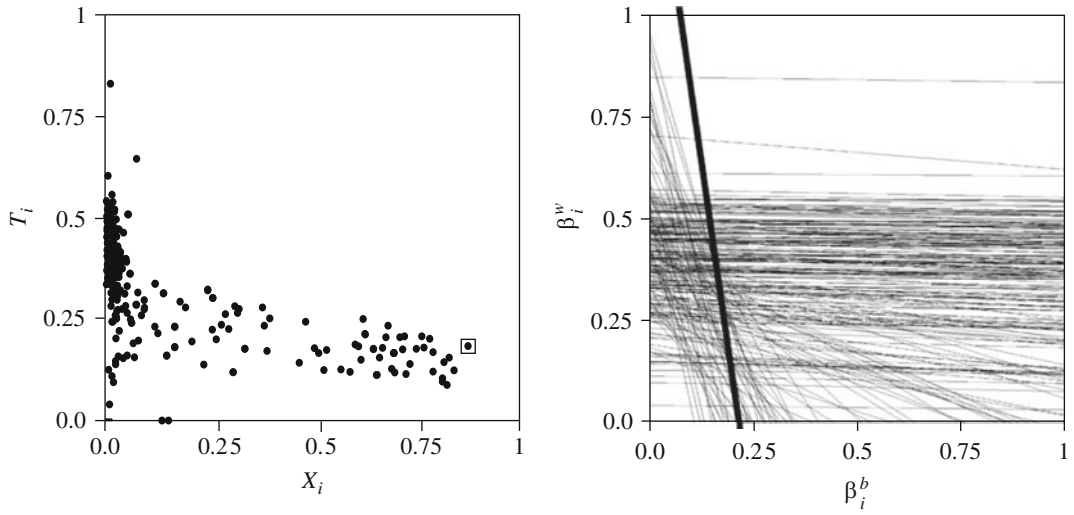
$$T_i = X_i\beta_i^b + (1-X_i)\beta_i^w \tag{4}$$

holds exactly. Then he showed that a regression of T_i on X_i and $(1 - X_i)$ with no constant term could be used to estimate B^b and B^w, respectively. The key assumption necessary for unbiasedness that Goodman identified is that the parameters and X_i be uncorrelated: $\mathrm{Cov}\left(\beta_i^b, X_i\right) = \mathrm{Cov}\left(\beta_i^w, X_i\right) = 0$. In the example, the assumption is that blacks vote in the same proportions in homogeneously black areas as in more integrated areas. Obviously, this is true sometimes and it is false other times. (King 1997: ch. 3, showed that Goodman's assumption was necessary but not sufficient. To have unbiasedness, it must also be true that the parameters and N_i are uncorrelated.)

As Goodman recognized, when this key assumption does not hold, estimates from the model will be biased. Indeed, they can be very biased, outside the deterministic bounds, and even outside the unit interval. This technique has been used extensively since the 1950s, and impossible estimates occur with considerable frequency (some estimates range to a majority of real applications; Achen and Shively 1995).

Extracting Both Deterministic and Statistical Information: King's EI Approach

From 1953 until 1997, the only two approaches used widely in practice were the method of bounds and Goodman's regression. King's



Ecological Inference, Fig. 2 Two views of the same data. *Note*: The left graph is a scatterplot of the observables, X_i by T_i. The right graph displays this same information as a tomography plot of the quantities of interest, β_i^b by β_i^w. Each precinct i that appears as a point in the left graph is a line (rather than a point because of information lost due to aggregation) in the right graph. For example, precinct 52 appears as the dot with a little square around it in the left graph and the dark line in the right graph (*Source*: The data are from King (1997: Figs. 5.1 and 5.5))

(1997) idea was that the insights from these two conflicting literatures in fact do not conflict with each other; the sources of information are largely distinct and can be combined to improve inference overall and synergistically. The idea is to combine the information from the bounds, applied to both quantities of interest for each and every precinct, with a statistical approach for extracting information within the bounds. The amount of information in the bounds depends on the data-set, but for many data-sets it can be considerable. For example, if precincts are spread uniformly over a scatterplot of X_i by T_i, the average bounds on β_i^b and β_i^w are narrowed from [0,1] to less than half of that range – hence eliminating half of the ecological inference problem with certainty. This additional information also helps make the statistical portion of the model far less sensitive to assumptions than previous statistical methods which exclude the information from the bounds.

To illustrate these points, we first present all the information available without making any assumptions, thus extending the bounds approach as far as possible. As a starting point, the left graph in Fig. 2 provides a scatterplot of a sample data set as observed, X_i horizontally by T_i vertically. Each point in this figure corresponds to one precinct, for which we would like to estimate the two unknowns. We display the unknowns in the right graph of the same figure; any point in the right graph portrays values of the two unknowns, β_i^b which is plotted horizontally, and β_i^w which is plotted vertically. Ecological inference involves locating, for each precinct, the one point in this unit square corresponding to the true values of β_i^b and β_i^w, since values outside the square are logically impossible.

To map the knowns onto the unknowns, King begins Goodman's accounting identity from Eq. 4). From this equation, which holds exactly, King solves for one unknown in terms of the other:

$$\beta_i^w = \left(\frac{T_i}{1 - X_i}\right) - \left(\frac{X_i}{1 - X_i}\right)\beta_i^b, \qquad (5)$$

which shows that β_i^w is a *linear* function of β_i^b, where the intercept and slope are known (since they are functions of the data, X_i and T_i).

King then maps the knowns from the left graph onto the right graph by using the linear relationship in Eq. 5). A key point is that each dot on the

left graph can be expressed, without assumptions or loss of information, as what King called a 'tomography' line within the unit square in the right graph. It is precisely the information lost due to aggregation that causes us to have to plot an entire line (on which the true point must fall) rather than the goal of one point for each precinct on the right graph. In fact, the information lost is equivalent to having a graph of the β_i^b by β_i^w points but having the ink smear, making the points into lines and partly but not entirely obscuring the correct positions of the $\left(\beta_i^b, \beta_i^w\right)$ points. (King also showed that the ecological inference problem is mathematically equivalent to the ill-posed 'tomography' problem of many medical imaging procedures, such as CAT and PET scans, where one attempts to reconstruct the inside of an object by passing X-rays through it and gathering information only from the outside. Because the line sketched out by an X-ray is closely analogous to Eq. 5), King labels the latter a *tomography line* and the corresponding graph a *tomography graph*.)

What does a tomography line tell us? Before we know anything, we know that the true $\left(\beta_i^b, \beta_i^w\right)$ point must lie somewhere within the unit square. After X_i and T_i are observed for a precinct, we also know that the true point must fall on a specific line represented by Eq. 5) and appearing in the tomography plot in Fig. 2. In many cases narrowing the region to be searched for the true point from the entire square to the one line in the square can provide a significant amount of information. To see this, consider the point enclosed in a box in the left graph, and the corresponding dark line in the right graph. This precinct, number 52, has observed values of $X_{52} = 0.88$ and $T_{52} = 0.19$. As a result, substituting into Eq. 5) gives $\beta_i^w = 1.58 - 7.33\beta_i^b$, which when plotted appears as the dark line on the right graph. This particular line tells us that, in our search for the true β_{52}^b,β_{52}^w point on the right graph, we can eliminate with certainty all area in the unit square except that on the line, which is clearly an advance over not having the data. Translated into the quantities of interest, this line tells us (by projecting the line downward to the horizontal axis) that, wherever the true point falls on the line, β_{52}^b must fall in the relatively narrow bounds of [0.07,0.21]. Unfortunately, in this case, β_i^w can only be bounded (by projecting to the left) to somewhere within the entire unit interval. More generally, lines that are relatively steep, like this one, tell us a great deal about β_i^b and little about β_i^w. Tomography lines that are relatively flat give narrow bounds on β_{wi} and wide bounds on β_i^b. Lines that cut off the bottom left (or top right) of the figure give narrow bounds on both quantities of interest.

If the only information available to learn about the unknowns in precinct i is X_i and T_i, a tomography line like that in Fig. 2 exhausts all this available information. This line immediately tells us the known bounds on each of the parameters, along with the precise relationship between the two unknowns, but it is not sufficient to narrow in on the right answer any further. Fortunately, additional information exists in the other observations in the same data set (X_j and T_j for all $i \neq j$) which, under the right assumptions, can be used to learn more about β_i^b and β_i^w in our precinct of interest.

In order to borrow statistical strength from all the precincts to learn about β_i^b and β_i^w in precinct i, some assumptions are necessary. The simplest version of King's model (that is, the one most useful for expository purposes) requires three assumptions, each of which can be relaxed in different ways.

First, the set of $\left(\beta_i^b, \beta_i^w\right)$ points must fall in a single cluster within the unit square. The cluster can fall anywhere within the square; it can be widely or narrowly dispersed or highly variable in one unknown and narrow in the other; and the two unknowns can be positively, negatively, or not at all correlated over i. An example that would violate this assumption would be two or more distinct clusters of $\left(\beta_i^b, \beta_i^w\right)$ points, as might result from subsets of observations with fundamentally different data generation processes (such as from markedly different regions). The specific mathematical version of this one-cluster assumption is that β_i^b and β_i^w follow a truncated bivariate normal density

$$\mathrm{TN}\left(\beta_i^b, \beta_i^w \mid \breve{\mathfrak{B}}, \breve{\Sigma}\right) = N\left(\beta_i^b, \beta_i^w \breve{\mathfrak{B}}, \breve{\Sigma}\right) \frac{1\left(\beta_i^b, \beta_i^w\right)}{R\left(\breve{\mathfrak{B}}, \breve{\Sigma}\right)}, \tag{6}$$

where the kernel is the untruncated bivariate normal,

$$\begin{aligned} &\mathrm{N}\left(\beta_i^b, \beta_i^w \breve{\mathfrak{B}}, \breve{\Sigma}\right) \\ &= (2\pi)^{-1} \left|\breve{\Sigma}\right|^{-1/2} \exp\left[-\frac{1}{2}\left(\beta_i - \breve{\mathfrak{B}}\right) \breve{\Sigma}^{-1} \left(\beta_i - \breve{\mathfrak{B}}\right)\right], \end{aligned} \tag{7}$$

and $1\left(\beta_i^b, \beta_i^w\right)$ is an indicator function that equals 1 if $\beta_i^b \in [0,1]$ and $\beta_i^w \in [0,1]$ and zero otherwise. The normalization factor in the denominator, $R\left(\mathfrak{B}^{\cup}, \sum^{\cup}\right)$, is the volume under the untruncated normal distribution above the unit square:

$$R\left(\overset{\cup}{\mathfrak{B}}, \overset{\cup}{\sum}\right) = \int_0^1 \int_0^1 N(\beta^b, \beta^w \mid \overset{\cup}{\mathfrak{B}}, \overset{\cup}{\sum}) d\beta^b d\beta^w \tag{8}$$

When divided into the untruncated normal, this factor keeps the volume under the truncated distribution equal to 1. The parameters of the truncated density, which we summarize as

$$\overset{\cup}{\psi} = \left\{\overset{\cup}{\mathfrak{B}}^b, \overset{\cup}{\mathfrak{B}}^w, \overset{\cup}{\sigma}_b, \overset{\cup}{\sigma}_w, \overset{\cup}{\rho}\right\} = \left\{\overset{\cup}{\mathfrak{B}}, \overset{\cup}{\sum}\right\}, \tag{9}$$

are on the scale of the untruncated normal (and so, for example, $\mathfrak{B}^{b\cup}$ and $\mathfrak{B}^{w\cup}$ need not be constrained to the unit interval even though β_i^b and β_i^w are constrained by this density).

The second assumption, which is necessary to form the likelihood function, is the absence of spatial autocorrelation: conditional on X_i, T_i and T_j are mean independent. Violations of this assumption in empirically reasonable (and even some unreasonable) ways do not seem to induce much if any bias.

The final, and by far the most critical, assumption is that X_i is independent of β_i^b and β_i^w. The three assumptions together produce what has come to be known as King's 'basic' EI model. (The use of EI to name this method comes from the name of his software, available at http://GKing.Harvard.edu) King also generalizes this assumption, in what has come to be known as the 'extended' EI model, by allowing the truncated normal parameters to vary as functions of measured covariates, Z_i^b and Z_i^b, giving:

$$\begin{aligned} \overset{\cup}{\mathfrak{B}} &= \left[\varphi_1 \breve{\sigma}_b^2 + 0.25) + 0.5\right] + \left(Z_i^b - \overline{Z}^b\right) \alpha^b \overset{\cup}{\mathfrak{B}}_i^w \\ &= \left[\varphi_2 \left(\breve{\sigma}_w^2 + 0.25\right) + 0.5\right] + \left(Z_i^w - \overline{Z}^w\right) \alpha^w \end{aligned} \tag{10}$$

where α^b and α^w are parameter vectors to be estimated along with the original model parameters and that have as many elements as Z_i^b and Z_i^w have columns. This relaxes the mean independence assumptions to:

$$\begin{aligned} \mathrm{E}\left(\beta_i^b \mid X_i, Z_i\right) &= \mathrm{E}\left(\beta_i^b \mid Z_i\right) E\left(\beta_i^w \mid X_i, Z_i\right) \\ &= \mathrm{E}\left(\beta_i^w \mid Z_i\right) \end{aligned}$$

Note that this extended model also relaxes the assumptions of truncated bivariate normality, since there is now a separate density being assumed for each observation. Because the bounds, which differ in width and information content for each i, generally provide substantial information, even X_i can be used as a covariate in Z_i. (The recommended default setting in EI includes X_i as a covariate with a prior on its coefficient.) In contrast, under Goodman's regression, which does not include information in the bounds, including X_i leads to an unidentified model (King 1997: sec. 3.2).

These three assumptions – one cluster, no spatial autocorrelation, and mean independence between the regressor and the unknowns conditional on X_i and Z_i – enable one to compute a posterior (or sampling) distribution of the two unknowns in each precinct. A fundamentally important component of EI is that the quantities of interest are not the parameters of the likelihood

but instead come from conditioning on T_i and producing a posterior for β_i^b and β_i^w in each precinct. Failing to condition on T_i and examining the parameters of the truncated bivariate normal only makes sense if the model holds exactly and so is much more model-dependent than King's approach. Since the most important problem in ecological inference modelling is precisely model misspecification, failing to condition on T assumes away the problem without justification. This point is widely regarded as a critical step in applying the EI model (Adolph et al. 2003).

When bounds are narrow, EI model assumptions do not matter much. But, for precincts with wide bounds on a quantity of interest, inferences can become model dependent. This is especially the case with ecological inference problems precisely because of the loss of information due to aggregation. In fact, this loss of information can be expressed by noting that the joint distribution of β_i^b and β_i^w cannot be fully identified from the data without some untestable assumptions. To be precise, distributions with positive mass over *any* curve or combination of curves that connects the bottom left point $\left(\beta_i^b = 0, \beta_i^w = 0\right)$ to the top right point $\left(\beta_i^b = 1, \beta_i^w = 1\right)$ of a tomography plot cannot be rejected by the data (King 1997: 191). Other features of the distribution are estimable. This fundamental indeterminacy is, of course, a problem because it prevents pinning down the quantities of interest with certainty, but it can also be something of an opportunity since different distributional assumptions can lead to the same estimates, especially since only those pieces of the distributions above the tomography lines are used in the final analysis.

Alternative Approaches to Ecological Inference

In the continuing search for more information to bring to bear on ecological inferences, King et al. (1999) extend King's (1997) model another step. They incorporate King's main advance of combining deterministic and statistical information but begin modelling a step earlier at the individuals who make up the counts. They also build a hierarchical Bayesian model, using easily generalizable Markov chain Monte Carlo (MCMC) technology (Tanner 1996).

To define the model formally, let T_i' denote the *number* of voting age people who turn out to vote. At the top level of the hierarchy they assume that T_0' follows a binomial distribution with probability equal to $\theta_i = X_i\beta_i^b + (1 - X_i)\beta_i^w$ and count N_i. Note that at this level it is assumed that the *expectation* of T_i', rather than T_i', is equal to $X_i\beta_i^b + (1 - X_i)\beta_i^w$. In other words, King (1997) models T_i as a continuous proportion, whereas King et al. (1999) recognize the inherently discrete nature of the counts of voters that go into computing this proportion. The two models are connected, of course, since T_i/N_i approaches T_i as N_i gets large.

The connection to King's tomography line can be seen in the contribution of the data from precinct i to the likelihood, which is.

$$\left(X_i\beta_i^b + (1 - X_i\left(\beta_i^w\right)^{T_i'}\right.$$
$$\left.\left(1 - X_i\beta_i^b - (1 - X_i)\beta_i^w\right)^{\left(N_i - T_i'\right)}\right. \tag{11}$$

By taking the logarithm of this contribution to the likelihood and differentiating with respect to $\beta_i^b$and β_i^w , King, Rosen and Tanner show that the maximum of Eq. (11) is not a unique point, but rather a line whose equation is given by the tomography line in Eq. 5). Thus, the log-likelihood for precinct i looks like two playing cards leaning against each other. As long as T_i is fixed and bounded away from 0.5 (and X_i is a fixed known value between 0 and 1), the derivative at this point is seen to increase with N_i, that is, the pitch of the playing cards increases with the sample size. In other words, for large N_i, the log-likelihood for precinct i degenerates from a surface defined over the unit square into a single playing card standing perpendicular to the unit square and oriented along the corresponding tomography line.

At the second level of the hierarchical model, $\beta_i^b$is distributed as a beta density with parameters c_b and d_b and β_i^w follows an independent beta with parameters c_w and d_w. While β_i^b and β_i^w are assumed *a priori* independent, they are *a*

posteriori dependent. At the third and final level of the hierarchical model, the unknown parameters c_b, d_b, c_w and d_w follow an exponential distribution with a large mean.

A key advantage of this model is that it generalizes immediately to arbitrarily large $R \times C$ tables. This approach was pursued by Rosen et al. (2001), who also provided a much faster method of moment-based estimator. For an application, see King et al. (2003).

Wakefield (2004) presents an alternative approach based on the Bayesian paradigm using a Markov chain Monte Carlo inference scheme. King et al. (2004) survey the latest strategies for solving ecological inference problems in various fields, many of which do not fit the textbook case of a 2×2 table with known marginals and unknown cell entries. Staniswalis (2005) proposes a nonparametric model for ecological inference with an application to renal failure data.

Econometric Issues in the Presence of Multiple Equilibria

Francesca Molinari

Abstract

Multiplicity of equilibria implies that the relationship between the outcome variable and the exogenous variables characterising a model is a correspondence rather than a function. This results in an incomplete econometric model. Incompleteness complicates identification and statistical inference on functionals of the probability distribution of the population of interest. This is because it implies that the sampling process and the maintained assumptions may be consistent with a set of values for these functionals, rather than with a single one. As a result, the econometric analysis of models with multiple equilibria needs to either: (1) rely on simplifying assumptions that shift focus to outcome features that are common across equilibria; or (2) augment the model with a "selection mechanism" that chooses the equilibrium played in the regions of multiplicity; or (3) maintain only minimal assumptions that partially identify the functionals of interest. Each of these approaches is reviewed, focusing on static game theoretic models.

The Basic Problem

Finite game theoretic models have been employed to study a wide range of economic decisions, where each agent's utility is allowed to depend on the choice made by each of the other agents. Examples include the analysis of social interaction models (Brock and Durlauf 2001), labour force participation (Bjorn and Vuong 1985), market entry (Bresnahan and Reiss 1988, 1990, 1991; Berry 1992; Bajari et al. 2009; Jia 2008; Ciliberto and Tamer 2009), product differentiation (Mazzeo 2002; Borzekowski and Cohen 2005), advertising (Sweeting 2008), and many others. From the econometric perspective, a finite game is a generalisation of a standard discrete choice model. For example, a bivariate simultaneous response model may give a stochastic representation of equilibria in a two-player, two-action game.

Generically, given a set of payoffs for the agents, finite games may admit multiple equilibria. Multiplicity of equilibria implies that the mapping from the model's exogenous variables to outcomes is a correspondence rather than a function. This violates the classical "principal assumptions" or "coherency conditions" for simultaneous discrete response models discussed extensively in the econometrics literature (e.g. Heckman 1978; Gourieroux et al. 1980; Schmidt 1981; Blundell and Smith 1994; Maddala 1983). Such coherency conditions require the existence of a unique reduced form, mapping the model's exogenous variables and parameters to a unique realisation of the endogenous variable; hence they constrain the model to be recursive or triangular in nature. Tamer (2003), however, clarifies the distinction between a model which is incoherent, so that no reduced form exists, and a model which is incomplete, so that multiple reduced forms may exist. Models with multiple equilibria belong to the latter category. Jovanovic (1989) discusses the observable implications of these models. Berry and Tamer (2007) review and extend a number of results on the identification of entry models extensively used in the empirical literature. The insights in their analysis extend to models where the discrete outcome has larger support.

This article reviews the challenges posed by the presence of multiple equilibria for the econometric analysis of static game theoretic models. These models do not specify how an equilibrium is selected in the regions of the exogenous variables which admit multiple equilibria, and therefore they are "incomplete". Incompleteness complicates identification and statistical inference on functional of the probability distribution of the population of interest, because it implies that the sampling process and the maintained assumptions may be consistent with a set of values for these functionals, rather than with a single one. The literature has provided various approaches to dealing with this basic problem: (1) imposing simplifying assumptions that shift focus to outcome features that are common across equilibria (e.g. Bresnahan and Reiss (1988, 1990, 1991) and Berry (1992), who study entry games where the number, though not the identities, of entrants is uniquely predicted by the model in equilibrium); (2) explicitly modelling a selection mechanism which specifies the equilibrium played in the regions of multiplicity (e.g. Bjorn and Vuong (1985), who choose a constant; and Bajari et al. (2009), who allow for a more flexible, covariate dependent parametrisation); (3) partially identifying and setestimating the parameters, without imposing assumptions on the selection mechanism or on the extent of heterogeneity in payoffs (e.g. Tamer (2003), who also provides large support conditions and exclusion restrictions that guarantee point identification of the payoff parameters, Ciliberto and Tamer (2009), Andrews et al. (2004), Beresteanu et al. (2008)).

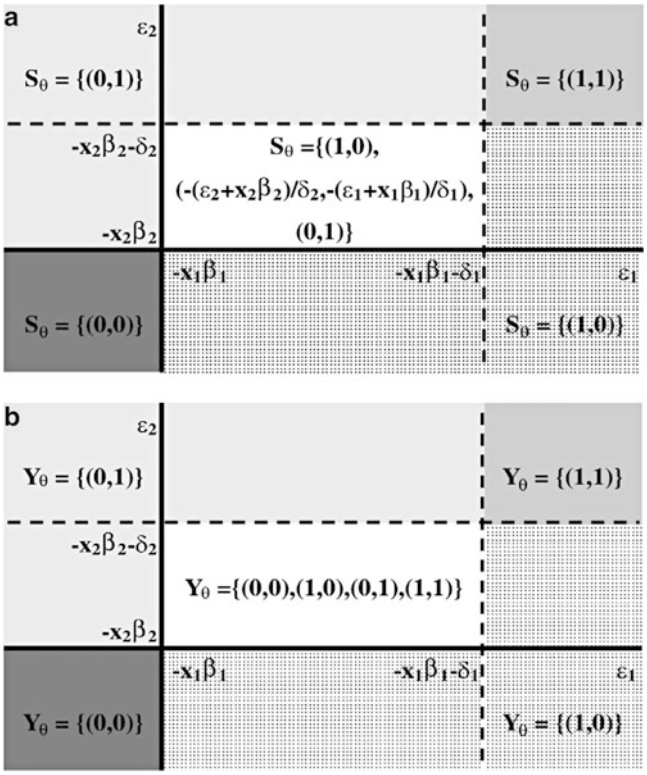
Each of these approaches is reviewed in turn, using the simple example of a complete

information, two-player entry game with multiple mixed strategy Nash equilibria. Similar considerations apply in the econometric analysis of models with more than two players, more than two strategies per player, incomplete information, and/or other solution concepts for the game (e.g. rationalisability, see Aradillas-Lopez and Tamer (2008)). In related models, Brock and Durlauf (2007) and Sweeting (2008) show that the presence of multiple equilibria may actually be beneficial for identification. In this article, however, we do not discuss these cases.

A Simple Example

Consider a static two-player entry game in which players' (stochastic) payoffs are given by $\pi_j = y_j(y_{3-j}\delta_j + x_j\beta_j + \varepsilon_j)$, $j = 1,2$, and mixed strategy Nash equilibrium (MSNE) is the solution concept. Here $y_j \in \{0,1\}$ denotes the action taken by player j, with $y_j = 1$ if player j enters the market and $y_j = 0$ otherwise. Payoff shifters for player j are divided among the ones which are observable both by the players and the econometrician, denoted x_j, and the ones which are observable only by the players, denoted ε_j. For simplicity assume that $(\varepsilon_1,\varepsilon_2)$ is distributed independently of $\underline{x} = (x_1, x_2)$, with a mean-zero normal distribution with covariance matrix Γ. Given the threshold-crossing nature of the model (firms only enter if their profits are positive), let $\gamma_{11} = \gamma_{22} = 1$ and denote the correlation between ε_1 and ε_2 by γ. Let $\sigma_j(\underline{x}, \varepsilon) \in [0, 1]$ denote a mixed strategy for player j, so that she enters the market with probability $\sigma_j(\underline{x}, \varepsilon)$ and stays out of the market with probability $1 - \sigma_j(\underline{x}, \varepsilon)$. The researcher is interested in the parameter vector $\theta = [\delta_1,\delta_2,\beta_1,\beta_2,\gamma] \in \Theta$, with Θ the parameter space. The observable data identify the distribution of equilibrium outcomes and observable payoff shifters, denoted $\mathbf{P}(y, \underline{x})$.

For given $\underline{x}$, Fig. 1a plots the random set of MSNE profiles, denoted $S_\theta(\underline{x}, \varepsilon)$, and Fig. 1b plots the random set of potentially observable MSNE outcomes of the game, denoted $Y_\theta(\underline{x}, \varepsilon)$, as a function of ε_1, ε_2, when $\delta_j < 0$, $j = 1,2$. To



Econometric Issues in the Presence of Multiple Equilibria, Fig. 1 The random set of MSNE profiles S_θ, in panel (**a**), and the random set of potentially observable MSNE outcomes Y_θ, in panel (**b**), in a static, complete information, simultaneous move, two-player entry game with $\delta_j < 0, j = 1, 2$

simplify the notation, in what follows $\mathscr{E}^{t}_{\theta,\underline{x}}$ denotes the region of values for ε where $t \in \{(0,0), (1,0), (0,1), (1,1)\}$ is the unique MSNE of the game; for example, the grey region in Fig. 1a is the region where (0,1) is the unique equilibrium of the game. $\mathscr{E}^{M}_{\theta,\underline{x}}$ denotes the region of values for ε where multiple equilibria occur. In the example, this region is the centre box of Fig. 1a, where (1,0), $\left(\frac{\varepsilon_2+x_2\beta_2}{-\delta_2}, \frac{\varepsilon_1+x_1\beta_1}{-\delta_1}\right)$, (0,1) are the MSNE of the game.

For realisations of $\varepsilon \notin \mathscr{E}^{M}_{\theta,\underline{x}}$, the model admits a unique equilibrium which is in pure strategies, and therefore predicts a unique equilibrium outcome. However, for realisations of $\varepsilon \in \mathscr{E}^{M}_{\theta,\underline{x}}$ the model predicts that any of (0,0), (1,0), (0,1), (1,1) might result as an equilibrium outcome of the game.

One way to reconcile multiplicity of equilibria with the fact that only one equilibrium outcome is realised in each market is to augment the model with an "admissible selection mechanism" $\psi(\cdot; \underline{x}, \varepsilon) : S_\theta(\underline{x}, \varepsilon) \to \Delta^{\kappa-1}$, with $\Delta^{\kappa-1}$ the unit simplex in $\mathscr{R}^{\kappa}$ and κ the cardinality of $S_\theta(\underline{x}, \varepsilon)$. For each $\sigma \in S_\theta(\underline{x}, \varepsilon)$, $\psi(\sigma; \underline{x}, \varepsilon)$ specifies the probability with which that equilibrium is played. (For $\varepsilon \notin \mathscr{E}^{M}_{\theta}$, $S_\theta(\underline{x}, \varepsilon)$ is a singleton and therefore ψ is a scalar identically equal to 1.) For a selection mechanism to be admissible, it is required that $\psi(\sigma; \underline{x}, \varepsilon) \geq 0$ for all $\sigma \in S_\theta(\underline{x}, \varepsilon)$, and $\sum_{\sigma \in S_\theta(\underline{x}, \varepsilon)} \psi(\sigma; \underline{x}, \varepsilon) = 1$. Hence, when no restrictions are placed on it, $\psi(\cdot; \underline{x}, \varepsilon)$ can depend on market unobservables (ε) even after conditioning on market observables ($\underline{x}$). It then follows that given $\underline{x}$, θ, and an admissible ψ, the model predicts that the probability of observing an equilibrium outcome $t \in \{(0,0), (1,0), (0,1), (1,1)\}$ is

$$\mathbf{P}(y = t|\underline{x}; \theta, \psi) = \int \left(\sum_{\sigma \in S_\theta(\underline{x}, \varepsilon)} \psi(\sigma; \underline{x}, \varepsilon) \sigma_1(t_1) \sigma_2(t_2) \right) dF_\theta(\varepsilon).$$

For example, for $t = (0,0)$,

$$\mathbf{P}(y = (0,0)|\underline{x}, \theta, \psi) = \underbrace{\mathbf{P}\left(\varepsilon \in \mathscr{E}^{(0,0)}_{\theta,\underline{x}}\right)}_{\mathbf{P}\left((0,0) \text{ is the unique equilibrium } |\underline{x}\right)} + \underbrace{\int_{\mathscr{E}^{M}_{\theta,\underline{x}}} \left(1 - \frac{\varepsilon_1 + x_1\beta_1}{-\varepsilon_1}\right)\left(1 - \frac{\varepsilon_2 + x_2\beta_2}{-\delta_2}\right)\psi\left(\left(\frac{\varepsilon_2 + x_2\beta_2}{-\delta_2}, \frac{\varepsilon_1 + x_1\beta_1}{-\delta_1}\right), \underline{x}, \varepsilon\right) dF_\theta(\varepsilon)}_{\mathbf{P}\left((0,0) \text{ is observed when multiple equilibria are possible } |\underline{x}\right)}.$$

The identification problem arises because one may find many values for the parameter vector θ which, when coupled with different admissible selection mechanisms ψ, generate the same distribution of outcomes and payoff shifters as the one observed in the data (i.e. $\mathbf{P}(y = t|\underline{x}; \theta, \psi) = \mathbf{P}(y = t|\underline{x})\ \underline{x} - a.s.$).

Point Identification Based on Outcome Features that are Common Across Equilibria

Even in the simple two-player entry game with multiple MSNE described above, multiplicity occurs both in the identity and in the number of players that enter the market in equilibrium. However, if one restricts players to play only pure strategies, and if one assumes $\delta_j < 0$, $j = 1,2$, the model uniquely predicts the equilibrium number of entrants. In other words, there is an outcome feature which is common across equilibria. In this case, under certain restrictions, the "incompleteness" of the model can be circumvented, without the need to introduce a selection mechanism.

Consider first the case that potential entrants are identical in both their observable and unobservable characteristics, so that each firm operating in equilibrium makes the same profit (Bresnahan and Reiss 1991b). With mixed

strategies explicitly ruled out, the equilibrium number of entrants is uniquely predicted by a simple zero profit condition: in equilibrium, no firm will enter if $\delta(1) + x\beta + \varepsilon < 0$, one firm will enter if $\delta(1) + x\beta + \varepsilon \geqslant 0$ and $\delta(2) + x\beta + \varepsilon < 0$, and both firms will enter if $\delta(2) + x\beta + \varepsilon \geqslant 0$. Here $\delta(m)$ denotes the effect on payoffs of m firms entering the market, $m \in \{1,2\}$. Hence point identification of the model's parameters can be achieved, and estimation can be conducted, using familiar techniques for ordered response models. These considerations can be extended to the case where the number of potential entrants is larger, provided that each entrant makes the same profit; see Bresnahan and Reiss (1991b).

Consider now the case that profits differ among firms, as in the example in the previous section (Bresnahan and Reiss 1991a; Berry 1992; Tamer 2003). With heterogeneity in payoffs, but mixed strategies explicitly ruled out, with two players there is still a unique prediction for the number of entrants. Hence the choice probabilities for having an equilibrium with no firms entering the market, and for having an equilibrium with both firms entering the market, are uniquely predicted by the model (this is because (0,0) and (1,1) can only occur as unique equilibrium outcomes of the game), and given by

$$\mathbf{P}(y = (0,0)|\underline{x};\theta) = \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(0,0)}\right),$$
$$\mathbf{P}(y = (1,1)|\underline{x};\theta) = \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(1,1)}\right).$$

In this case, Tamer (2003) shows that under suitable exclusion restrictions and large support conditions on elements of $\underline{x}$, one can use the information in $\mathbf{P}(y = (0, 0)|\underline{x})$ to identify β_1,β_2,γ, and that in $\mathbf{P}(y = (1, 1)|x)$ to identify δ_1, δ_2. A sufficient set of restrictions is as follows. Assume that the matrices x_1 and x_2 have full column rank, and that for either $j = 1$ or $j = 2$, x_j contains an element which is not part of x_{3-j}, has full support, and has a corresponding coefficient in β_j that is nonzero. Then there exist sufficiently large and sufficiently small values of x_j such that player j will always be in or out of the market regardless of what her rival chooses. For these values of x_j, the game simplifies to a single decision problem for player $3 - j$, and one can identify β_{3-j} by using those observations with no entrants and sufficiently small/large values of x_j. One can then learn β_j and γ. Similar reasoning allows one to learn δ_1, δ_2 from $\mathbf{P}(y = (1, 1)|\underline{x})$. Tamer (2003) shows that while using the information contained in the outcomes uniquely predicted by the model suffices for point identification of the parameters of interest, one can obtain efficiency gains by exploiting restrictions on the outcomes of the game resulting from multiple equilibria ((0, 1) and (1, 0)).

Under restrictions on the payoff functions (e.g. homogeneous competition effects) but allowing for a large number of players, Berry (1992) shows that a pure strategy Nash equilibrium for the model exists, and is such that the equilibrium number of entrants is uniquely determined. In this case, inference can be conducted as in nonlinear parametric method of moments problems. Point identification of the model parameters is likely to hold if there is variation in the number of potential entrants across markets; see Berry and Tamer (2007).

Importantly, Tamer (2003) shows that large support and exclusion restrictions can be used to point identify the parameters even when one allows for mixed strategies, and no outcome feature is common across equilibria. Generalisation of this result to games with a larger number of players under related assumptions is discussed in Bajari et al. (2009); see the following section.

Point Identification Based on Specifying a Selection Mechanism

Early on, Bjorn and Vuong (1985) suggested solving the identification problem caused by the presence of multiple equilibria by specifying a selection mechanism that assigns the probability mass of the region of multiplicity among the possible equilibrium outcomes of the game. They considered a two-player, two-action game such as the simple example discussed above, and assumed that players play only pure strategies. (Bjorn and Vuong (1985) were interested in learning the determinants of a husband and wife's

decision to join the labour force. Hence they did not constrain the sign of δ to be known a priori. Here the exposition is simplified by assuming $\delta_j < 0$, $j = 1,2$). For simplicity, they assumed that $\psi((1,0);\underline{x},\varepsilon) = \psi((0,1);\underline{x},\varepsilon) = \frac{1}{2}$ for all $\underline{x}$, ε such that $\varepsilon \in \mathscr{E}^{M}_{\theta,\underline{x}}$. Under this restriction, Bjorn and Vuong (1985) provided a necessary and sufficient condition for the parameters of the model to be point identified, based on the classic criterion of nonsingularity of the information matrix. In their model, estimation can be carried out straightforwardly using maximum likelihood.

Bajari et al. (2009) suggest a more flexible specification of the selection mechanism, while accounting for the possibility that players randomise across their actions. In their model, $\psi(\cdot)$ cannot depend on ($\underline{x}$, ε) directly, but only through players' payoffs. Using this restriction, Bajari et al. (2009) provide a parametrisation of $\psi(\cdot)$ which explicitly accounts for criteria of equilibrium selection often discussed in economic theory. In particular, they assume:

$$\psi(\sigma;\underline{x},\varepsilon) \equiv \psi(\sigma;S_\theta(\underline{x},\varepsilon),\alpha) = \frac{exp(\alpha \cdot z(\sigma,\pi))}{\sum_{\sigma' \in S_\theta(\underline{x},\varepsilon)} exp(\alpha \cdot z(\sigma',\pi))},$$

where z is a vector of covariates including, for example, dummy variables for whether the equilibrium $\sigma \in S_\theta(\underline{x},\varepsilon)$ is in pure strategies, is Pareto dominated, maximises industry profits, and is risk dominant. Bajari et al. (2009) show that under suitable large support conditions on the covariates or with exclusion restrictions, and with scale invariance conditions on $\psi(\cdot)$ (the equilibrium selection probabilities are required to depend only on the relative but not absolute scales of payoffs), both θ and α can be point identified. They then propose a method of simulated moments estimator to estimate these parameters, which embeds a computationally feasible procedure to calculate all the MSNE of the game. Importantly, under the maintained assumptions, this also yields an estimator of the selection mechanism.

Partial Identification of Model Parameters

Given knowledge of $\mathbf{P}(y, \underline{x})$, model parameters can be partially identified even in the absence of assumptions on the nature of competition, heterogeneity of firms, availability of covariates with sufficiently large support and exclusion restrictions, and restrictions on the selection mechanism $\psi(\cdot)$. In particular, the sharp identification region of θ, denoted Θ_I, is given by the set of parameter vectors which are consistent with the sampling process and the maintained modelling assumptions, and therefore may have generated the distribution of observables. Berry and Tamer (2007) provide the following definition of Θ_I in the two-player entry model described in 'A simple example':

$$(0.1) \quad \Theta_I = \left\{ \begin{array}{c} \exists \psi \text{ such that } \forall t \in \{(0,0),(1,0),(0,1),(1,1)\}, \\ \theta \in \Theta : \mathbf{P}(y = t|\underline{x}) = \int \left(\sum_{\sigma \in S_\theta(\underline{x},\varepsilon)} \psi(\sigma;\underline{x},\varepsilon)\sigma_1(t_1)\sigma_2(t_2) \right) dF_\theta(\varepsilon)\underline{x} - a.s. \end{array} \right\}$$

where ψ is an admissible equilibrium selection mechanism as described in 'A simple example'. This formulation is theoretically attractive, but computationally challenging to implement. This is because when no assumptions are placed on it, the selection mechanism ψ may represent an infinite-dimensional nuisance parameter.

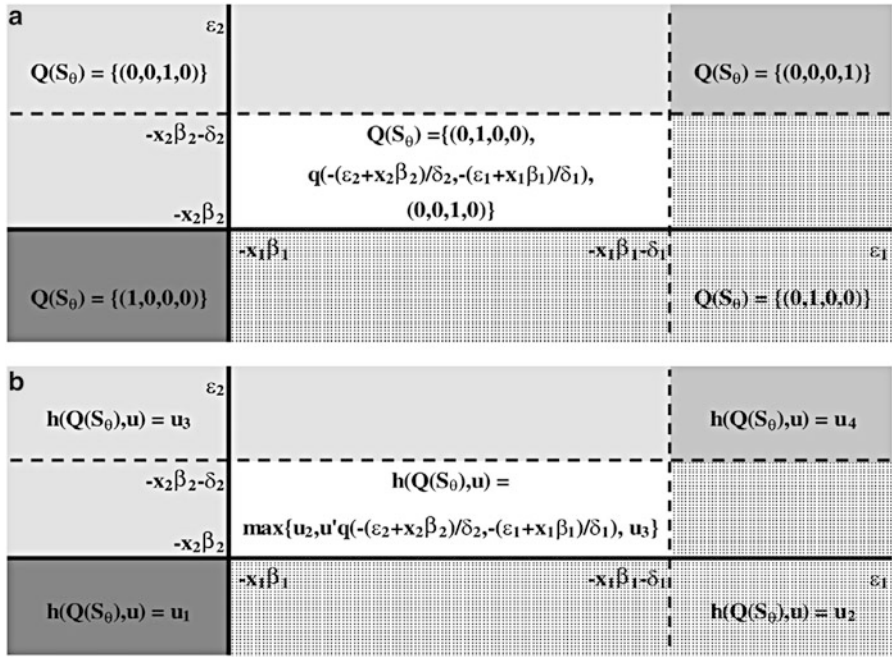
A computationally simple procedure to estimate an outer region for the model parameters is provided by Ciliberto and Tamer (2009). An outer region includes all the parameter values in the parameter space that may have generated the observables, but may include other (infeasible) parameter values as well. They

observe that for a given $t \in \{(0,0), (1,0), (0,1), (1,1)\}$, the model implies that $\mathbf{P}(y = t|\underline{x})$ cannot be larger than the probability that t is *a possible* equilibrium outcome of the game, and cannot be smaller than the probability that t is the *unique* equilibrium outcome of the game. This is because for a given $\theta \in \Theta$ and any realisation of $(\underline{x}, \varepsilon)$ such that t is a possible equilibrium outcome of the game, there can be another outcome $t' \in \{(0,0), (1,0), (0,1), (1,1)\}$ which is also a possible equilibrium outcome of the game, and when both are possible t is selected only part of the time. Similarly, t is certainly realised whenever it is the only possible equilibrium outcome, but it can additionally be realised when it belongs to a set of multiple equilibrium outcomes. In the twoplayer entry game, these considerations yield the following outer region:

$$\Theta_O^{CT} = \left\{ \theta \in \Theta : \begin{array}{c} \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(0,0)}\right) \leq \mathbf{P}(y = (0,0)|\underline{x}) \leq \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(0,0)}\right) \\ + \int_{\mathscr{E}_{\theta,\underline{x}}^{M}} \left(1 - \frac{\varepsilon_1 + x_1\beta_1}{-\delta_1}\right)\left(1 - \frac{\varepsilon_2 + x_2\beta_2}{-\delta_2}\right) dF_\theta(\varepsilon) \\ \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(1,0)}\right) \leq \mathbf{P}(y = (1,0)|\underline{x}) \leq \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(0,0)}\right) \\ + \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{M}\right) \\ \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(0,1)}\right) \leq \mathbf{P}(y = (0,1)|\underline{x}) \leq \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(0,1)}\right) \\ + \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{M}\right) \\ \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(1,1)}\right) \leq \mathbf{P}(y = (1,1)|\underline{x}) \leq \mathbf{P}\left(\varepsilon \in \mathscr{E}_{\theta,\underline{x}}^{(1,1)}\right) \\ + \int_{\mathscr{E}_{\theta,\underline{x}}^{M}} \frac{\varepsilon_1 + x_1\beta_1}{\delta_1} \frac{\varepsilon_2 + x_2\beta_2}{\delta_2} dF_\theta(\varepsilon) \end{array} \right\}$$

Andrews et al. (2004) suggest using only the information provided by the model implication that $\mathbf{P}(y = t|\underline{x})$ cannot be larger than the probability that t is *a possible* equilibrium outcome of the game (hence, using only the upper bounds in the above expression), thereby obtaining an outer region that is simpler to compute than Θ_O^{CT}, but wider.

Exploiting results in Random Set Theory Molchanov (2005), Beresteanu et al. (2008, 2009) propose a formulation of the sharp identification region Θ_I which is computationally tractable. While their formulation is computationally more intensive than Ciliberto and Tamer's, the benefits in terms of identification yielded by their methodology can be substantial; see Beresteanu et al. (2008, 2009) for examples. Their approach can be summarised as follows. Given a $\theta \in \Theta$ and a realisation of $(\underline{x}, \varepsilon)$, one obtains a realisation of the random set of MSNE $S_\theta(\underline{x}, \varepsilon)$; see Fig. 1a. Each of the equilibria in $S_\theta(\underline{x}, \varepsilon)$ determines a probability distribution over the game's outcomes conditional on the realisation of $\underline{x}$ and ε. Denote by $Q(S_\theta(\underline{x}, \varepsilon))$ the random set of such probability distributions; see Fig. 2a. Beresteanu et al. (2008, 2009) establish that the collection of probability distributions over outcomes of the game conditional on $\underline{x}$ which are consistent with the model (i.e. with *all* its implications) is given by the Aumann expectation of $Q(S_\theta(\underline{x}, \varepsilon))$ conditional on $\underline{x}$, denoted $\mathsf{E}(Q(S_\theta(\underline{x}, \varepsilon))|\underline{x})$, which is a closed convex set. (Formally, $\mathsf{E}(Q(S_\theta)|\underline{x}) = \{\mathbf{E}(q|\underline{x}) : q \in Q(S_\theta)$ *a.s.*$\}$, see Molchanov (2005, Definition 2.1.13).) Hence if the model is correctly specified, a candidate value for θ belongs to Θ_I if and only if $\mathbf{P}(y|\underline{x}) \in \mathsf{E}(Q(S_\theta(\underline{x}, \varepsilon))|\underline{x})$, $\underline{x} - a.s.$ In other words, if this condition is satisfied, the candidate θ may have generated the observed conditional distribution $P(y|\underline{x})$. Exploiting the notion of support function of a closed convex set (recall that the support function of a non-empty compact



Econometric Issues in the Presence of Multiple Equilibria, Fig. 2 The random set of probability distributions over outcome profiles implied by MSNE, $Q(S_\theta)$, in panel (**a**), and the support function in direction u of the random set of probability distributions over outcome profiles implied by MSNE, $h(Q(S_\theta),u)$, in panel (**b**), in a static, complete information, simultaneous move, two player entry game with $\delta_j < 0$, $j = 1,2$ and $q(\sigma) = [(1 - \sigma_1)(1 - \sigma_2)\ \sigma_1(1 - \sigma_2)\ (1 - \sigma_1)\sigma_2\ \sigma_1\sigma_2]$

convex set $B \in \mathrm{R}^{ky}$, denoted $h(B,\cdot)$, is given by $h(B, u) = \max_{b \in B} u'b$, $u \in \mathrm{R}^{ky}$), Beresteanu et al. (2008, 2009) show that one can verify this condition by checking if the minimum of a sub-linear (hence convex) function over a convex set is equal to zero. Specifically, they show that

$$\Theta_I = \left\{ \theta \in \Theta : \min_{u:||u||\leq 1.} (\mathbf{E}[h(Q(S_\theta), u)|\underline{x}] - u'\mathbf{P}(y|\underline{x})) = 0 \underline{x} - a.s. \right\},$$

with $h(Q(S_\theta), u)$ the support function of $Q(S_\theta)$ in direction u. This minimisation problem can be solved efficiently using algorithms in convex programming. For certain special cases (e.g., games where players use only pure strategies), Galichon and Henry (2008) provide alternative computational methods based on optimal transportation theory.

Estimation of Θ_I and Θ_O^{CT}, and construction of confidence sets that asymptotically cover these regions with a prespecified probability, can be carried out using the methodology proposed by Chernozhukov et al. (2007).

Econometrics

John Geweke, Joel Horowitz and Hashem Pesaran

Abstract

As a unified discipline, econometrics is still relatively young and has been transforming and expanding very rapidly. Major advances have taken place in the analysis of cross-sectional data by means of semiparametric and nonparametric techniques. Heterogeneity of economic relations across individuals, firms and industries is increasingly acknowledged and attempts have been made to take it into account either by integrating out its effects or by modelling the sources of heterogeneity when suitable panel data exist. The counterfactual considerations that underlie policy analysis and treatment valuation have been given a more satisfactory foundation. New time-series

econometric techniques have been developed and employed extensively in the areas of macroeconometrics and finance. Nonlinear econometric techniques are used increasingly in the analysis of cross-section and time-series observations. Applications of Bayesian techniques to econometric problems have been promoted largely by advances in computer power and computational techniques. The use of Bayesian techniques has in turn provided the investigators with a unifying framework where the tasks of forecasting, decision making, model evaluation and learning can be considered as parts of the same interactive and iterative process, thus providing a basis for 'real time econometrics'.

What Is Econometrics?

Broadly speaking, econometrics aims to give empirical content to economic relations for testing economic theories, forecasting, decision making, and for ex *post* decision/policy evaluation. The term 'econometrics' appears to have been first used by Pawel Ciompa as early as 1910, although it is Ragnar Frisch who takes the credit for coining the term, and for establishing it as a subject in the sense in which it is known today (see Frisch 1936, p. 95; Bjerkholt 1995). By emphasizing the quantitative aspects of economic relationships, econometrics calls for a 'unification' of measurement and theory in economics. Theory without measurement can have only limited relevance for the analysis of actual economic problems; while measurement without theory, being devoid of a framework necessary for the interpretation of the statistical observations, is unlikely to result in a satisfactory explanation of the way economic forces interact with each other. Neither 'theory' nor 'measurement' on its own is sufficient to further our understanding of economic phenomena.

As a unified discipline, econometrics is still relatively young and has been transforming and expanding very rapidly since an earlier version of this article was published in the first edition of *The New Palgrave*: *A Dictionary of Economics* in 1987 (Pesaran 1987a). Major advances have taken place in the analysis of crosssectional data by means of semiparametric and nonparametric techniques. Heterogeneity of economic relations across individuals, firms and industries is increasingly acknowledged, and attempts have been made to take them into account either by integrating out their effects or by modelling the sources of heterogeneity when suitable panel data exists. The counterfactual considerations that underlie policy analysis and treatment evaluation have been given a more satisfactory foundation. New time series econometric techniques have been developed and employed extensively in the areas of macroeconometrics and finance. Nonlinear econometric techniques are used increasingly in the analysis of cross-section and time-series observations. Applications of Bayesian techniques to econometric problems have been given new impetus largely thanks to advances in computer power and computational techniques. The use of Bayesian techniques has in turn provided the investigators with a unifying framework where the tasks of forecasting, decision making, model evaluation and learning can be considered as parts of the same interactive and iterative process; thus paving the way for establishing the foundation of 'real time econometrics'. See Pesaran and Timmermann (2005a).

This article attempts to provide an overview of some of these developments. But to give an idea of the extent to which econometrics has been transformed over the past decades we begin with a brief account of the literature that pre-dates econometrics, and discuss the birth of econometrics and its subsequent developments to the present. Inevitably, our accounts will be brief and non-technical. Readers interested in more details are advised to consultant the specific entries provided in the *New Palgrave* and the excellent general texts by Maddala (2001), Greene (2003), Davidson and MacKinnon (2004), and Wooldridge (2006), as well as texts on specific topics such as Cameron and Trivedi (2005) on microeconometrics, Maddala (1983) on econometric models involving limited-dependent and qualitative variables, Arellano (2003), Baltagi (2005), Hsiao (2003), and Wooldridge (2002) on panel data econometrics, Johansen (1995) on cointegration analysis, Hall (2005) on generalized method of moments, Bauwens et al. (2001), Koop

(2003), Lancaster (2004), and Geweke (2005) on Bayesian econometrics, Bosq (1996), Fan and Gijbels (1996), Horowitz (1998), Härdle (1990), Härdle and Linton (1994), and Pagan and Ullah (1999) on nonparametric and semiparametric econometrics, Campbell et al. (1997) and Gourieroux and Jasiak (2001) on financial econometrics, Granger and Newbold (1986), Lűtkepohl (1991), and Hamilton (1994) on time series analysis.

Quantitative Research in Economics: Historical Backgrounds

Empirical analysis in economics has had a long and fertile history, the origins of which can be traced at least as far back as the work of the 16th-century political arithmeticians such as William Petty, Gregory King and Charles Davenant. The political arithmeticians, led by Sir William Petty, were the first group to make systematic use of facts and figures in their studies. They were primarily interested in the practical issues of their time, ranging from problems of taxation and money to those of international trade and finance. The hallmark of their approach was undoubtedly quantitative, and it was this which distinguished them from their contemporaries. Although the political arithmeticians were primarily and understandably preoccupied with statistical measurement of economic phenomena, the work of Petty, and that of King in particular, represented perhaps the first examples of a unified quantitative–theoretical approach to economics. Indeed Schumpeter in his *History of Economic Analysis* (1954, p. 209) goes as far as to say that the works of the political arithmeticians 'illustrate to perfection, what Econometrics is and what Econometricians are trying to do'.

The first attempt at quantitative economic analysis is attributed to Gregory King, who was the first to fit a linear function of changes in corn prices on deficiencies in the corn harvest, as reported in Charles Davenant (1698). One important consideration in the empirical work of King and others in this early period seems to have been the discovery of 'laws' in economics, very much like those in physics and other natural sciences.

This quest for economic laws was, and to a lesser extent still is, rooted in the desire to give economics the status that Newton had achieved for physics. This was in turn reflected in the conscious adoption of the method of the physical sciences as the dominant mode of empirical enquiry in economics. The Newtonian revolution in physics, and the philosophy of 'physical determinism' that came to be generally accepted in its aftermath, had far-reaching consequences for the method as well as the objectives of research in economics. The uncertain nature of economic relations began to be fully appreciated only with the birth of modern statistics in the late 19th century and as more statistical observations on economic variables started to become available.

The development of statistical theory in the hands of Galton, Edgeworth and Pearson was taken up in economics with speed and diligence. The earliest applications of simple correlation analysis in economics appear to have been carried out by Yule (1895, 1896) on the relationship between pauperism and the method of providing relief, and by Hooker (1901) on the relationship between the marriage rate and the general level of prosperity in the United Kingdom, measured by a variety of economic indicators such as imports, exports, and the movement in corn prices.

Benini (1907), the Italian statistician was the first to make use of the method of multiple regression in economics. But Henry Moore (1914, 1917) was the first to place the statistical estimation of economic relations at the centre of quantitative analysis in economics. Through his relentless efforts, and those of his disciples and followers Paul Douglas, Henry Schultz, Holbrook Working, Fred Waugh and others, Moore in effect laid the foundations of 'statistical economics', the precursor of econometrics. The monumental work of Schultz, *The Theory and the Measurement of Demand* (1938), in the United States and that of Allen and Bowley, *Family Expenditure* (1935), in the United Kingdom, and the pioneering works of Lenoir (1913), Wright (1915, 1928), Working (1927), Tinbergen (1929–1930), and Frisch (1933) on the problem of 'identification'

represented major steps towards this objective. The work of Schultz was exemplary in the way it attempted a unification of theory and measurement in demand analysis; while the work on identification highlighted the importance of 'structural estimation' in econometrics and was a crucial factor in the subsequent developments of econometric methods under the auspices of the Cowles Commission for Research in Economics.

Early empirical research in economics was by no means confined to demand analysis. Louis Bachelier (1900), using time-series data on French equity prices, recognized the random walk character of equity prices, which proved to be the precursor to the vast empirical literature on market efficiency hypothesis that has evolved since the early 1960s. Another important area was research on business cycles, which provided the basis of the later development in time-series analysis and macroeconometric model building and forecasting. Although, through the work of Sir William Petty and other early writers, economists had been aware of the existence of cycles in economic time series, it was not until the early 19th century that the phenomenon of business cycles began to attract the attention that it deserved. Clement Juglar (1819–1905), the French physician turned economist, was the first to make systematic use of time-series data to study business cycles, and is credited with the discovery of an investment cycle of about 7–11 years duration, commonly known as the Juglar cycle. Other economists such as Kitchin, Kuznets and Kondratieff followed Juglar's lead and discovered the inventory cycle (3–5 years duration), the building cycle (15–25 years duration) and the long wave (45–60 years duration), respectively. The emphasis of this early research was on the morphology of cycles and the identification of periodicities. Little attention was paid to the quantification of the relationships that may have underlain the cycles. Indeed, economists working in the National Bureau of Economic Research under the direction of Wesley Mitchell regarded each business cycle as a unique phenomenon and were therefore reluctant to use statistical methods except in a nonparametric manner and for purely descriptive purposes (see, for example, Mitchell 1928; Burns and Mitchell 1947). This view of business cycle research stood in sharp contrast to the econometric approach of Frisch and Tinbergen and culminated in the famous methodological interchange between Tjalling Koopmans and Rutledge Vining about the roles of theory and measurement in applied economics in general and business cycle research in particular. (This interchange appeared in the August 1947 and May 1949 issues of the *Review of Economics and Statistics*.)

The Birth of Econometrics

Although, quantitative economic analysis is a good three centuries old, econometrics as a recognized branch of economics began to emerge only in the 1930s and the 1940s with the foundation of the Econometric Society, the Cowles Commission in the United States, and the Department of Applied Economics (DAE) in Cambridge, England. (An account of the founding of the first two organizations can be found in Christ 1952, 1983, while the history of the DAE is covered in Stone 1978.) This was largely due to the multidisciplinary nature of econometrics, comprising of economic theory, data, econometric methods and computing techniques. Progress in empirical economic analysis often requires synchronous developments in all these four components.

Initially, the emphasis was on the development of econometric methods. The first major debate over econometric method concerned the applicability of the probability calculus and the newly developed sampling theory of R.A. Fisher to the analysis of economic data. Frisch (1934) was highly sceptical of the value of sampling theory and significance tests in econometrics. His objection was not, however, based on the epistemological reasons that lay behind Robbins's and Keynes's criticisms of econometrics. He was more concerned with the problems of multicollinearity and measurement errors which he believed were pervasive in economics; and to deal with the measurement error problem he developed his confluence analysis and the method of 'bunch maps'. Although used by some

econometricians, notably Tinbergen (1939) and Stone (1945), the bunch map analysis did not find much favour with the profession at large. Instead, it was the probabilistic rationalizations of regression analysis, advanced by Koopmans (1937) and Haavelmo (1944), that formed the basis of modern econometrics.

Koopmans did not, however, emphasize the wider issue of the use of stochastic models in econometrics. It was Haavelmo who exploited the idea to the full, and argued for an explicit probability approach to the estimation and testing of economic relations. In his classic paper published as a supplement to *Econometrica* in 1944, Haavelmo defended the probability approach on two grounds. First, he argued that the use of statistical measures such as means, standard errors and correlation coefficients for inferential purposes is justified only if the process generating the data can be cast in terms of a probability model. Second, he argued that the probability approach, far from being limited in its application to economic data, because of its generality is in fact particularly suited for the analysis of 'dependent' and 'nonhomogeneous' observations often encountered in economic research.

The probability model is seen by Haavelmo as a convenient abstraction for the purpose of understanding, or explaining or predicting, events in the real world. But it is not claimed that the model represents reality in all its details. To proceed with quantitative research in any subject, economics included, some degree of formalization is inevitable, and the probability model is one such formalization. The attraction of the probability model as a method of abstraction derives from its generality and flexibility, and the fact that no viable alternative seems to be available. Haavelmo's contribution was also important as it constituted the first systematic defence against Keynes's (1939) influential criticisms of Tinbergen's pioneering research on business cycles and macroeconometric modelling. The objective of Tinbergen's research was twofold: first, to show how a macroeconometric model may be constructed and then used for simulation and policy analysis (Tinbergen 1937); second, 'to submit to statistical test some of the theories which have been put forward regarding the character and causes of cyclical fluctuations in business activity' (Tinbergen 1939, p. 11). Tinbergen assumed a rather limited role for the econometrician in the process of testing economic theories, and argued that it was the responsibility of the 'economist' to specify the theories to be tested. He saw the role of the econometrician as a passive one of estimating the parameters of an economic relation already specified on a priori grounds by an economist. As far as statistical methods were concerned, he employed the regression method and Frisch's method of confluence analysis in a complementary fashion. Although Tinbergen discussed the problems of the determination of time lags, trends, structural stability and the choice of functional forms, he did not propose any systematic methodology for dealing with them. In short, Tinbergen approached the problem of testing theories from a rather weak methodological position. Keynes saw these weaknesses and attacked them with characteristic insight (Keynes 1939). A large part of Keynes's review was in fact concerned with technical difficulties associated with the application of statistical methods to economic data. Apart from the problems of the 'dependent' and 'nonhomogeneous' observations mentioned above, Keynes also emphasized the problems of misspecification, multicollinearity, functional form, dynamic specification, structural stability, and the difficulties associated with the measurement of theoretical variables. By focusing his attack on Tinbergen's attempt at testing economic theories of business cycles, Keynes almost totally ignored the practical significance of Tinbergen's work for econometric model building and policy analysis (for more details, see Pesaran and Smith 1985a).

In his own review of Tinbergen's work, Haavelmo (1943) recognized the main burden of the criticisms of Tinbergen's work by Keynes and others, and argued the need for a general statistical framework to deal with these criticisms. As we have seen, Haavelmo's response, despite the views expressed by Keynes and others, was to rely more, rather than less, on the probability model as the basis of econometric methodology. The technical problems raised by Keynes and

others could now be dealt with in a systematic manner by means of formal probabilistic models. Once the probability model was specified, a solution to the problems of estimation and inference could be obtained by means of either classical or of Bayesian methods. There was little that could now stand in the way of a rapid development of econometric methods.

Early Advances in Econometric Methods

Haavelmo's contribution marked the beginning of a new era in econometrics, and paved the way for the rapid development of econometrics, with the likelihood method gaining importance as a tool for identification, estimation and inference in econometrics.

Identification of Structural Parameters

The first important breakthrough came with a formal solution to the identification problem which had been formulated earlier by Working (1927). By defining the concept of 'structure' in terms of the joint probability distribution of observations, Haavelmo (1944) presented a very general concept of identification and derived the necessary and sufficient conditions for identification of the entire system of equations, including the parameters of the probability distribution of the disturbances. His solution, although general, was rather difficult to apply in practice. Koopmans et al. (1950) used the term 'identification' for the first time in econometrics, and gave the now familiar rank and order conditions for the identification of a single equation in a system of simultaneous *linear* equations. The solution of the identification problem by Koopmans (1949) and Koopmans et al. (1950) was obtained in the case where there are a priori linear restrictions on the structural parameters. They derived rank and order conditions for identifiability of a single equation from a complete system of equations without reference to how the variables of the model are classified as endogenous or exogenous. Other solutions to the identification problem, also allowing for restrictions on the elements of the variance–covariance matrix of the structural disturbances, were later offered by Wegge (1965) and Fisher (1966).

Broadly speaking, a model is said to be identified if all its structural parameters can be obtained from the knowledge of its implied joint probability distribution for the observed variables. In the case of simultaneous equations models prevalent in econometrics, the solution to the identification problem depends on whether there exists a sufficient number of a priori restrictions for the derivation of the structural parameters from the reduced-form parameters. Although the purpose of the model and the focus of the analysis on explaining the variations of some variables in terms of the unexplained variations of other variables is an important consideration, in the final analysis the specification of a minimum number of identifying restrictions was seen by researchers at the Cowles Commission to be the function and the responsibility of 'economic theory'. This attitude was very much reminiscent of the approach adopted earlier by Tinbergen in his business cycle research: the function of economic theory was to provide the specification of the econometric model, and that of econometrics to furnish statistically optimal methods of estimation and inference. More specifically, at the Cowles Commission the primary task of econometrics was seen to be the development of statistically efficient methods for the estimation of structural parameters of an a priori specified system of simultaneous stochastic equations.

More recent developments in identification of structural parameters in context of semiparametric models is discussed below in section "Nonparametric and Semiparametric Estimation". See also Manski (1995).

Estimation and Inference in Simultaneous Equation Models

Initially, under the influence of Haavelmo's contribution, the maximum likelihood (ML) estimation method was emphasized as it yielded consistent estimates. Anderson and Rubin (1949) developed the limited information maximum likelihood (LIML) method, and Koopmans et al. (1950) proposed the full information maximum likelihood (FIML). Both methods are based on the joint probability distribution of the endogenous

variables conditional on the exogenous variables and yield consistent estimates, with the former utilizing all the available a priori restrictions and the latter only those which related to the equation being estimated. Soon, other computationally less demanding estimation methods followed, both for a fully efficient estimation of an entire system of equations and for a consistent estimation of a single equation from a system of equations.

The two-stage least squares (2SLS) procedure was independently proposed by Theil (1954, 1958) and Basmann (1957). At about the same time the instrumental variable (IV) method, which had been developed over a decade earlier by Reiersol (1941, 1945) and Geary (1949) for the estimation of errors-in-variables models, was generalized and applied by Sargan (1958) to the estimation of simultaneous equation models. Sargan's generalized IV estimator (GIVE) provided an asymptotically efficient technique for using surplus instruments in the application of the IV method to econometric problems, and formed the basis of subsequent developments of the generalized method of moments (GMM) estimators introduced subsequently by Hansen (1982). A related class of estimators, known as k-class estimators, was also proposed by Theil (1958). Methods of estimating the entire system of equations which were computationally less demanding than the FIML method were also advanced. These methods also had the advantage that, unlike the FIML, they did not require the full specification of the entire system. These included the three-stage least squares method due to Zellner and Theil (1962), the iterated instrumental variables method based on the work of Lyttkens (1970), Brundy and Jorgenson (1971), and Dhrymes (1971) and the system k-class estimators due to Srivastava (1971) and Savin (1973). Important contributions have also been made in the areas of estimation of simultaneous nonlinear equations (Amemiya 1983), the seemingly unrelated regression equations (SURE) approach proposed by Zellner (1962), and the simultaneous rational expectations models (see section "Model Consistent Expectations" below).

Interest in estimation of simultaneous equation models coincided with the rise of Keynesian economics in early 1960s, and started to wane with the advent of the rational expectations revolution and its emphasis on the GMM estimation of the structural parameters from the Euler equations (first-order optimization conditions). See section "Rational Expectations and the Lucas Critique" below. But, with the rise of the dynamic stochastic general equilibrium models in macroeconometrics, a revival of interest in identification and estimation of nonlinear simultaneous equation models seems quite likely. The recent contribution of Fernandez-Villaverde and Rubio-Ramirez (2005) represents a start in this direction.

Developments in Time Series Econometrics

While the initiative taken at the Cowles Commission led to a rapid expansion of econometric techniques, the application of these techniques to economic problems was rather slow. This was partly due to a lack of adequate computing facilities at the time. A more fundamental reason was the emphasis of the research at the Cowles Commission on the simultaneity problem almost to the exclusion of other econometric problems. Since the early applications of the correlation analysis to economic data by Yule and Hooker, the serial dependence of economic time series and the problem of nonsense or spurious correlation that it could give rise to had been the single most important factor explaining the profession's scepticism concerning the value of regression analysis in economics. A satisfactory solution to the spurious correlation problem was therefore needed before regression analysis of economic time series could be taken seriously. Research on this topic began in the mid-1940s at the Department of Applied Economics (DAE) in Cambridge, England, as a part of a major investigation into the measurement and analysis of consumers' expenditure in the United Kingdom (see Stone et al. 1954). Although the first steps towards the resolution of the spurious correlation problem had been taken by Aitken (1934–1935) and Champernowne (1948), the research in the DAE introduced the problem and its possible solution to the attention of applied economists. Orcutt (1948) studied the autocorrelation pattern of economic time series and showed that most economic time series can be represented

by simple autoregressive processes with similar autoregressive coefficients. Subsequently, Cochrane and Orcutt (1949) made the important point that the major consideration in the analysis of stationary time series was the autocorrelation of the error term in the regression equation and not the autocorrelation of the economic time series themselves. In this way they shifted the focus of attention to the autocorrelation of disturbances as the main source of concern. Although, as it turns out, this is a valid conclusion in the case of regression equations with strictly exogenous regressors, in more realistic set-ups where the regressors are weakly exogenous the serial correlation of the regressors is also likely to be of concern in practice. See, for example, Stambaugh (1999).

Another important and related development was the work of Durbin and Watson (1950, 1951) on the method of testing for residual autocorrelation in the classical regression model. The inferential breakthrough for testing serial correlation in the case of observed time-series data had already been achieved by von Neumann (1941, 1942), and by Hart and von Neumann (1942). The contribution of Durbin and Watson was, however, important from a practical viewpoint as it led to a bounds test for residual autocorrelation which could be applied irrespective of the actual values of the regressors. The independence of the critical bounds of the Durbin–Watson statistic from the matrix of the regressors allowed the application of the statistic as a general diagnostic test, the first of its type in econometrics. The contributions of Cochrane and Orcutt and of Durbin and Watson marked the beginning of a new era in the analysis of economic time-series data and laid down the basis of what is now known as the 'time-series econometrics' approach.

Consolidation and Applications

The work at the Cowles Commission on identification and estimation of the simultaneous equation model and the development of time series techniques paved the way for widespread application of econometric methods to economic and financial problems. This was helped significantly by the rapid expansion of computing facilities, advances in financial and macroeconomic modelling, and the increased availability of economic data-sets, cross section as well as time series.

Macroeconometric Modelling

Inspired by the pioneering work of Tinbergen, Klein (1947, 1950) was the first to construct a macroeconometric model in the tradition of the Cowles Commission. Soon others followed Klein's lead. Over a short space of time macroeconometric models were built for almost every industrialized country, and even for some developing and centrally planned economies. Macroeconometric models became an important tool of ex ante forecasting and economic policy analysis, and started to grow in both size and sophistication. The relatively stable economic environment of the 1950s and 1960s was an important factor in the initial success enjoyed by macroeconometric models. The construction and use of large-scale models presented a number of important computational problems, the solution of which was of fundamental significance, not only for the development of macroeconometric modelling but also for econometric practice in general. In this respect advances in computer technology were clearly instrumental, and without them it is difficult to imagine how the complicated computational problems involved in the estimation and simulation of large-scale models could have been solved. The increasing availability of better and faster computers was also instrumental as far as the types of problems studied and the types of solutions offered in the literature were concerned. For example, recent developments in the area of microeconometrics (see section "Microeconometrics: An Overview" below) could hardly have been possible if it were not for the very important recent advances in computing facilities.

Dynamic Specification

Other areas where econometrics witnessed significant developments included dynamic specification, latent variables, expectations formation, limited dependent variables, discrete choice models, random coefficient models, disequilibrium models, nonlinear estimation, and the

analysis of panel data models. Important advances were also made in the area of Bayesian econometrics, largely thanks to the publication of Zellner's textbook (1971), which built on his earlier work including important papers with George Tiao. The Seminar on Bayesian Inference in Econometrics and Statistics (SBIES) was founded shortly after the publication of the book, and was key in the development and diffusion of Bayesian ideas in econometrics. It was, however, the problem of dynamic specification that initially received the greatest attention. In an important paper, Brown (1952) modelled the hypothesis of habit persistence in consumer behaviour by introducing lagged values of consumption expenditures into an otherwise static Keynesian consumption function. This was a significant step towards the incorporation of dynamics in applied econometric research, and allowed the important distinction to be made between the short-run and the long-run impacts of changes in income on consumption. Soon other researchers followed Brown's lead and employed his autoregressive specification in their empirical work.

The next notable development in the area of dynamic specification was the distributed lag model. Although the idea of distributed lags had been familiar to economists through the pioneering work of Irving Fisher (1930) on the relationship between the nominal interest rate and the expected inflation rate, its application in econometrics was not seriously considered until the mid-1950s. The geometric distributed lag model was used for the first time by Koyck (1954) in a study of investment. Koyck arrived at the geometric distributed lag model via the adaptive expectations hypothesis. This same hypothesis was employed later by Cagan (1956) in a study of demand for money in conditions of hyperinflation, by Friedman (1957) in a study of consumption behaviour and by Nerlove (1958a) in a study of the cobweb phenomenon. The geometric distributed lag model was subsequently generalized by Solow (1960), Jorgenson (1966) and others, and was extensively applied in empirical studies of investment and consumption behaviour. At about the same time Almon (1965) provided a polynomial generalization of I. Fisher's (1937) arithmetic lag distribution which was later extended further by Shiller (1973). Other forms of dynamic specification considered in the literature included the partial adjustment model (Nerlove 1958b; Eisner and Strotz 1963) and the multivariate flexible accelerator model (Treadway 1971) and Sargan's (1964) work on econometric time series analysis which formed the basis of error correction and cointegration analysis that followed next. Following the contributions of Champernowne (1960), Granger and Newbold (1974), and Phillips (1986) the spurious regression problem was better understood, and paved the way for the development of the theory of cointegration. For further details see section "Structural Cointegrating VARs" below.

Techniques for Short-Term Forecasting

Concurrent with the development of dynamic modelling in econometrics there was also a resurgence of interest in time-series methods, used primarily in short-term business forecasting. The dominant work in this field was that of Box and Jenkins (1970), who, building on the pioneering works of Yule (1921, 1926), Slutsky (1927), Wold (1938), Whittle (1963) and others, proposed computationally manageable and asymptotically efficient methods for the estimation and forecasting of univariate autoregressive-moving average (ARMA) processes. Time-series models provided an important and relatively simple benchmark for the evaluation of the forecasting accuracy of econometric models, and further highlighted the significance of dynamic specification in the construction of time-series econometric models. Initially univariate time-series models were viewed as mechanical 'black box' models with little or no basis in economic theory. Their use was seen primarily to be in short-term forecasting. The potential value of modern time-series methods in econometric research was, however, underlined in the work of Cooper (1972) and Nelson (1972) who demonstrated the good forecasting performance of univariate Box–Jenkins models relative to that of large econometric models. These results raised an important question about the adequacy of large econometric models for forecasting as well as for policy analysis. It was argued that a

properly specified structural econometric model should, at least in theory, yield more accurate forecasts than a univariate time-series model. Theoretical justification for this view was provided by Zellner and Palm (1974), followed by Trivedi (1975), Prothero and Wallis (1976), Wallis (1977) and others. These studies showed that Box–Jenkins models could in fact be derived as univariate final form solutions of linear structural econometric models. In theory, the pure time-series model could always be embodied within the structure of an econometric model and in this sense it did not present a 'rival' alternative to econometric modelling. This literature further highlighted the importance of dynamic specification in econometric models and in particular showed that econometric models that are outperformed by simple univariate time-series models most probably suffer from specification errors.

The papers in Elliott et al. (2006) provide excellent reviews of recent developments in economic forecasting techniques.

A New Phase in the Development of Econometrics

With the significant changes taking place in the world economic environment in the 1970s, arising largely from the breakdown of the Bretton Woods system and the quadrupling of oil prices, econometrics entered a new phase of its development. Mainstream macroeconometric models built during the 1950s and 1960s, in an era of relative economic stability with stable energy prices and fixed exchange rates, were no longer capable of adequately capturing the economic realities of the 1970s. As a result, not surprisingly, macroeconometric models and the Keynesian theory that underlay them came under severe attack from theoretical as well as from practical viewpoints. While criticisms of Tinbergen's pioneering attempt at macroeconometric modelling were received with great optimism and led to the development of new and sophisticated estimation techniques and larger and more complicated models, the disenchantment with macroeconometric models in 1970s prompted a much more fundamental reappraisal of quantitative modelling as a tool of forecasting and policy analysis.

At a theoretical level it was argued that econometric relations invariably lack the necessary 'microfoundations', in the sense that they cannot be consistently derived from the optimizing behaviour of economic agents. At a practical level the Cowles Commission approach to the identification and estimation of simultaneous macroeconometric models was questioned by Lucas and Sargent and by Sims, although from different viewpoints (Lucas 1976; Lucas and Sargent 1981; Sims 1980). There was also a move away from macroeconometric models and towards microeconometric research with greater emphasis on matching of econometrics with individual decisions.

It also became increasingly clear that Tinbergen's paradigm where economic relations were taken as given and provided by 'economic theorist' was not adequate. It was rarely the case that economic theory could be relied on for a full specification of the econometric model (Leamer 1978). The emphasis gradually shifted from estimation and inference based on a given tightly parameterized specification to diagnostic testing, specification searches, model uncertainty, model validation, parameter variations, structural breaks, and semiparametric and nonparametric estimation. The choice of approach often governed by the purpose of the investigation, the nature of the economic application, data availability, computing and software technology.

What follows is a brief overview of some of the important developments. Given space limitations there are inevitably significant gaps. These include the important contributions of Granger (1969), Sims (1972), and Engle et al. (1983) on different concepts of 'causality' and 'exogeneity', the literature on disequilibrium models (Quandt 1982; Maddala 1983, 1986), random coefficient models (Swamy 1970; Hsiao and Pesaran 2008, unobserved time series models (Harvey 1989), count regression models (Cameron and Trivedi 1986, 1998), the weak instrument problem (Stock et al. 2002), small sample theory (Phillips 1983; Rothenberg 1984), econometric models of auction pricing (Hendricks and Porter 1988; Laffont et al. 1995).

Rational Expectations and the Lucas Critique

Although the rational expectations hypothesis (REH) was advanced by Muth in 1961, it was not until the early 1970s that it started to have a significant impact on time-series econometrics and on dynamic economic theory in general. What brought the REH into prominence was the work of Lucas (1972, 1973), Sargent (1973), Sargent and Wallace (1975) and others on the new classical explanation of the apparent breakdown of the Phillips curve. The message of the REH for econometrics was clear. By postulating that economic agents form their expectations *endogenously* on the basis of the true model of the economy, and a *correct* understanding of the processes generating exogenous variables of the model, including government policy, the REH raised serious doubts about the invariance of the structural parameters of the mainstream macroeconometric models in the face of changes in government policy. This was highlighted in Lucas's critique of macroeconometric policy evaluation. By means of simple examples Lucas (1976) showed that in models with rational expectations the parameters of the decision rules of economic agents, such as consumption or investment functions, are usually a mixture of the parameters of the agents' objective functions and of the stochastic processes they face as historically given. Therefore, Lucas argued, there is no reason to believe that the 'structure' of the decision rules (or economic relations) would remain invariant under a policy intervention. The implication of the Lucas critique for econometric research was not, however, that policy evaluation could not be done, but rather than the traditional econometric models and methods were not suitable for this purpose. What was required was a separation of the parameters of the policy rule from those of the economic model. Only when these parameters could be identified separately given the knowledge of the joint probability distribution of the variables (both policy and non-policy variables) would it be possible to carry out an econometric analysis of alternative policy options.

There have been a number of reactions to the advent of the rational expectations hypothesis and the Lucas critique that accompanied it.

Model Consistent Expectations

The least controversial reaction has been the adoption of the REH as one of several possible expectations formation hypotheses in an otherwise conventional macroeconometric model containing expectational variables. In this context the REH, by imposing the appropriate cross-equation parametric restrictions, ensures that 'expectations' and 'forecasts' generated by the model are consistent. In this approach the REH is regarded as a convenient and effective method of imposing crossequation parametric restrictions on time series econometric models, and is best viewed as the 'model-consistent' expectations hypothesis. There is now a sizeable literature on solution, identification, and estimation of linear RE models. The canonical form of RE models with forward and backward components is given by

$$\mathbf{y}_t = \mathbf{A}\mathbf{y}_{t-1} + \mathbf{B}E\left(\mathbf{y}_{t+1} \middle| F_t\right) + \mathbf{w}_t,$$

where $\mathbf{y}_t$ is a vector of endogenous variables, $E(.|\ F_t)$ is the expectations operator, F_t the publicly available information at time t, and $\mathbf{w}_t$ is a vector of forcing variables. For example, log-linearized version of dynamic general equilibrium models (to be discussed) can all be written as a special case of this equation with plenty of restrictions on the coefficient matrices A and B. In the typical case where $\mathbf{w}_t$ are serially uncorrelated and the solution of the RE model can be assumed to be unique, the RE solution reduces to the vector autoregression (VAR)

$$\mathbf{y}_t = \Phi\mathbf{y}_{t-1} + \mathbf{G}\mathbf{w}_t$$

where Φ and $\mathbf{G}$ are given in terms of the structural parameters:

$$\mathbf{B}\Phi^2 - \Phi + \mathbf{A} = 0, \quad \text{and}\, \mathrm{G} = (\mathbf{I} - \mathbf{B}\Phi)^{-1}.$$

The solution of the RE model can, therefore, be viewed as a restricted form of VAR popularized in econometrics by Sims (1980) as a response in

macroeconometric modelling to the rational expectations revolution. The nature of restrictions is determined by the particular dependence of A and B on a few 'deep' or structural parameters. For general discussion of solution of RE models see, for example, Broze et al. (1985) and Binder and Pesaran (1995). For studies of identification and estimation of linear RE models see, for example, Hansen and Sargent (1980), Wallis (1980), Wickens (1982), and Pesaran (1981, 1987b). These studies show how the standard econometric methods can in principle be adapted to the econometric analysis of rational expectations models.

Detection and Modelling of Structural Breaks

Another reaction to the Lucas critique has been to treat the problem of 'structural change' emphasized by Lucas as one more potential econometric 'problem'. Clements and Hendry (1998, 1999) provide a taxonomy of factors behind structural breaks and forecast failures. Stock and Watson (1996) provide extensive evidence of structural break in macroeconomic time series. It is argued that structural change can result from many factors and need not be associated solely with intended or expected changes in policy. The econometric lesson has been to pay attention to possible breaks in economic relations. There now exists a large body of work on testing for structural change, detection of breaks (single as well as multiple), and modelling of break processes by means of piece-wise linear or non-linear dynamic models (Chow 1960; Brown et al. 1975; Nyblom 1989; Andrews 1993; Andrews and Ploberger 1994; Bai and Perron 1998; Pesaran and Timmermann 2005b, 2007. See also the surveys by Stock 1994; Clements and Hendry 2006). The implications of breaks for short-term and long-term forecasting have also begun to be addressed (McCulloch and Tsay 1993; Koop and Potter 2004a, b; Pesaran et al. 2006).

VAR Macroeconometrics

Unrestricted VARs

The Lucas critique of mainstream macroeconometric modelling also led some econometricians, notably Sims (1980, 1982), to doubt the validity of the Cowles Commission style of achieving identification in econometric models. Sims focused his critique on macroeconometric models with a vector autoregressive (VAR) specification, which was relatively simple to estimate; and its use soon became prevalent in macroeconometric analysis. The view that economic theory cannot be relied on to yield identification of structural models was not new and had been emphasized in the past, for example, by Liu (1960). Sims took this viewpoint a step further and argued that in presence of rational expectations a priori knowledge of lag lengths is indispensable for identification, even when we have distinct strictly exogenous variables shifting supply and demand schedules (Sims 1980, p. 7). While it is true that the REH complicates the necessary conditions for the identification of structural models, the basic issue in the debate over identification still centres on the validity of the classical dichotomy between exogenous and endogenous variables (Pesaran 1981). In the context of closed-economy macroeconometric models where all variables are treated as endogenous, other forms of identification of the structure will be required. Initially, Sims suggested a recursive identification approach where the matrix of contemporaneous effects was assumed to be lower (upper) triangular and the structural shocks orthogonal. Other non-recursive identification schemes soon followed.

Structural VARs

One prominent example was the identification scheme developed in Blanchard and Quah (1989), who distinguished between permanent and transitory shocks and attempted to identify the structural models through long-run restrictions. For example, Blanchard and Quah argued that the effect of a demand shock on real output should be temporary (that is, it should have a zero long-run impact), while a supply shock should have a permanent effect. This approach is known as 'structural VAR' (SVAR) and has been used extensively in the literature. It continues to assume that structural shocks are orthogonal, but uses a mixture of short-run and long-run

restrictions to identify the structural model. In their work Blanchard and Quah considered a bivariate VAR model in real output and unemployment. They assumed real output to be integrated of order 1, or $I(1)$, and viewed unemployment as an $I(0)$, or a stationary variable. This allowed them to associate the shock to one of the equations as permanent, and the shock to the other equation as transitory. In more general settings, such as the one analysed by Gali (1992) and Wickens and Motto (2001), where there are m endogenous variables and r long-run or cointegrating relations, the SVAR approach provides $m(m-r)$ restrictions which are not sufficient to fully identify the model, unless $m=2$ and $r=1$ which is the simple bivariate model considered by Blanchard and Quah (Pagan and Pesaran 2007). In most applications additional short-term restrictions are required. More recently, attempts have also been made to identify structural shocks by means of qualitative restrictions, such as sign restrictions. Notable examples include Canova and de Nicolo (2002), Uhlig (2005), and Peersman (2005).

The focus of the SVAR literature has been on impulse response analysis and forecast error variance decomposition, with the aim of estimating the time profile of the effects of monetary policy, oil price or technology shocks on output and inflation, and deriving the relative importance of these shocks as possible explanations of forecast error variances at different horizons. Typically such analysis is carried out with respect to a single model specification, and at most only parameter uncertainty is taken into account (Kilian 1998). More recently the problem of model uncertainty and its implications for impulse response analysis and forecasting have been recognized. Bayesian and classical approaches to model and parameter uncertainty have been considered. Initially, Bayesian VAR models were developed for use in forecasting as an effective shrinkage procedure in the case of high-dimensional VAR models (Doan et al. 1984; Litterman 1985). The problem of model uncertainty in cointegrating VARs has been addressed in Garratt et al. (2003b, 2006), and Strachan and van Dijk (2006).

Structural Cointegrating VARs

This approach provides the SVAR with the decomposition of shocks into permanent and transitory and gives economic content to the long-run or cointegrating relations that underlie the transitory components. In the simple example of Blanchard and Quah this task is trivially achieved by assuming real output to be I(1) and the unemployment rate to be an I(0) variable. To have shocks with permanent effects some of the variables in the VAR must be non-stationary. This provides a natural link between the SVAR and the unit root and cointegration literature. Identification of the cointegrating relations can be achieved by recourse to economic theory, solvency or arbitrage conditions (Garratt et al. 2003a). Also there are often long-run overidentifying restrictions that can be tested. Once identified and empirically validated, the long-run relations can be embodied within a VAR structure, and the resultant structural vector error correction model identified using theory-based short-run restrictions. The structural shocks can be decomposed into permanent and temporary components using either the multivariate version of the Beveridge and Nelson (1981) decompositions, or the one more recently proposed by Garratt et al. (2006a).

Two or more variables are said to be cointegrated if they are individually integrated (or have a random walk component), but there exists a linear combination of them which is stationary. The concept of cointegration was first introduced by Granger (1986) and more formally developed in Engle and Granger (1987). Rigorous statistical treatments followed in the papers by Johansen (1988, 1991) and Phillips (1991). Many further developments and extensions have taken place with reviews provided in Johansen (1995), Juselius (2006), and Garratt et al. (2006b). The related unit root literature is reviewed by Stock (1994) and Phillips and Xiao (1998).

Macroeconometric Models with Microeconomic Foundations

For policy analysis macroeconometric models need to be based on decisions by individual

households, firms and governments. This is a daunting undertaking and can be achieved only by gross simplification of the complex economic interconnections that exists across millions of decision-makers worldwide. The dynamic stochastic general equilibrium (DSGE) modelling approach attempts to implement this task by focusing on optimal decisions of a few representative agents operating with rational expectations under complete learning. Initially, DSGE models were small and assumed complete markets with instantaneous price adjustments, and as a result did not fit the macroeconomic time series (Kim and Pagan 1995). More recently, Smets and Wouters (2003) have shown that DSGE models with sticky prices and wages along the lines developed by Christiano et al. (2005) are sufficiently rich to match most of the statistical features of the main macroeconomic time series. Moreover, by applying Bayesian estimation techniques, these authors have shown that even relatively large models can be estimated as a system. Bayesian DSGE models have also shown to perform reasonably well in forecasting as compared with standard and Bayesian vector autoregressions. It is also possible to incorporate long-run cointegrating relations within Bayesian DSGE models. The problems of parameter and model uncertainty can also be readily accommodated using data-coherent DSGE models. Other extensions of the DSGE models to allow for learning, regime switches, time variations in shock variances, asset prices, and multi-country interactions are likely to enhance their policy relevance (Del Negro and Schorfheide 2004; Del Negro et al. 2005; An and Schorfheide 2007; Pesaran and Smith 2006). Further progress will also be welcome in the area of macroeconomic policy analysis under model uncertainty, and robust policymaking (Brock and Durlauf 2006; Hansen and Sargent 2007).

Model and Forecast Evaluation

While in the 1950s and 1960s research in econometrics was primarily concerned with the identification and estimation of econometric models, the dissatisfaction with econometrics during the 1970s caused a shift of focus from problems of estimation to those of model evaluation and testing. This shift has been part of a concerted effort to restore confidence in econometrics, and has received attention from Bayesian as well as classical viewpoints. Both these views reject the 'axiom of correct specification' which lies at the basis of most traditional econometric practices, but they differ markedly as how best to proceed.

It is generally agreed, by Bayesians as well as by non-Bayesians, that model evaluation involves considerations other than the examination of the statistical properties of the models, and personal judgements inevitably enter the evaluation process. Models must meet multiple criteria which are often in conflict. They should be relevant in the sense that they ought to be capable of answering the questions for which they are constructed. They should be consistent with the accounting and/or theoretical structure within which they operate. Finally, they should provide adequate representations of the aspects of reality with which they are concerned. These criteria and their interaction are discussed in Pesaran and Smith (1985b). More detailed breakdowns of the criteria of model evaluation can be found in Hendry and Richard (1982) and McAleer et al. (1985). In econometrics it is, however, the criterion of 'adequacy' which is emphasized, often at the expense of relevance and consistency.

The issue of model adequacy in mainstream econometrics is approached either as a model selection problem or as a problem in statistical inference whereby the hypothesis of interest is tested against general or specific alternatives. The use of absolute criteria such as measures of fit/parsimony or formal Bayesian analysis based on posterior odds are notable examples of model selection procedures, while likelihood ratio, Wald and Lagrange multiplier tests of nested hypotheses and Cox's centred log-likelihood ratio tests of non-nested hypotheses are examples of the latter approach. The distinction between these two general approaches basically stems from the way alternative models are treated. In the case of model selection (or model discrimination) all the models under consideration enjoy the same status

and the investigator is not committed a priori to any one of the alternatives. The aim is to choose the model which is likely to perform best with respect to a particular loss function. By contrast, in the hypothesis-testing framework the null hypothesis (or the maintained model) is treated differently from the remaining hypotheses (or models). One important feature of the model-selection strategy is that its application always leads to one model being chosen in preference to other models. But, in the case of hypothesis testing, rejection of all the models under consideration is not ruled out when the models are non-nested. A more detailed discussion of this point is given in Pesaran and Deaton (1978).

Broadly speaking, classical approaches to the problem of model adequacy can be classified depending on how specific the alternative hypotheses are. These are the *general specification tests, the diagnostic tests,* and the *non-nested tests.* The first of these, pioneered by Durbin (1954) and introduced in econometrics by Ramsey (1969), Wu (1973), Hausman (1978), and subsequently developed further by White (1981, 1982) and Hansen (1982), are designed for circumstances where the nature of the alternative hypothesis is kept (sometimes intentionally) rather vague, the purpose being to test the null against a *broad* class of alternatives. (The pioneering contribution of Durbin 1954, in this area has been documented by Nakamura and Nakamura 1981.) Important examples of general specification tests are Ramsey's regression specification error test (RESET) for omitted variables and/or misspecified functional forms, and the Durbin–Hausman–Wu test of misspecification in the context of measurement error models and/or simultaneous equation models. Such general specification tests are particularly useful in the preliminary stages of the modelling exercise.

In the case of diagnostic tests, the model under consideration (viewed as the null hypothesis) is tested against more specific alternatives by embedding it within a general model. Diagnostic tests can then be constructed using the likelihood ratio, Wald or Lagrange multiplier (LM) principles to test for parametric restrictions imposed on the general model. The application of the LM principle to econometric problems is reviewed in the papers by Breusch and Pagan (1980), Godfrey and Wickens (1982), and Engle (1984). An excellent review is provided in Godfrey (1988). Examples of the restrictions that may be of interest as diagnostic checks of model adequacy include zero restrictions, parameter stability, serial correlation, heteroskedasticity, functional forms, and normality of errors. The distinction made here between diagnostic tests and general specification tests is more apparent than real. In practice some diagnostic tests such as tests for serial correlation can also be viewed as a general test of specification. Nevertheless, the distinction helps to focus attention on the purpose behind the tests and the direction along which high power is sought.

The need for non-nested tests arises when the models under consideration belong to separate parametric families in the sense that no single model can be obtained from the others by means of a suitable limiting process. This situation, which is particularly prevalent in econometric research, may arise when models differ with respect to their theoretical underpinnings and/or their auxiliary assumptions. Unlike the general specification tests and diagnostic tests, the application of non-nested tests is appropriate when specific but rival hypotheses for the explanation of the same economic phenomenon have been advanced. Although non-nested tests can also be used as general specification tests, they are designed primarily to have high power against specific models that are seriously entertained in the literature. Building on the pioneering work of Cox (1961, 1962), a number of such tests for single equation models and systems of simultaneous equations have been proposed (Pesaran and Weeks 2001).

The use of statistical tests in econometrics, however, is not a straightforward matter and in most applications does not admit of a clear-cut interpretation. This is especially so in circumstances where test statistics are used not only for checking the adequacy of a *given* model but also as guides to model construction. Such a process of model construction involves specification searches of the type emphasized by Leamer (1978) and presents insurmountable pre-test

problems which in general tend to produce econometric models whose 'adequacy' is more apparent than real. As a result, in evaluating econometric models less reliance should be placed on those indices of model adequacy that are used as guides to model construction, and more emphasis should be given to the performance of models over other data-sets and against rival models.

A closer link between model evaluation and the underlying decision problem is also needed. Granger and Pesaran (2000a, b) discuss this problem in the context of forecast evaluation. A recent survey of forecast evaluation literature can be found in West (2006). Pesaran and Skouras (2002) provide a review from a decision-theoretic perspective.

The subjective Bayesian approach to the treatment of several models begins by assigning a prior probability to each model, with the prior probabilities summing to 1. Since each model is already endowed with a prior probability distribution for its parameters and for the probability distribution of observable data conditional on its parameters, there is then a complete probability distribution over the space of models, parameters, and observable data. (No particular problems arise from non-nesting of models in this framework.) This probability space can then be augmented with the distribution of an object or vector of objects of interest. For example, in a macroeconomic policy setting the models could include VARs, DSGEs and traditional large-scale macroeconomic models, and the vector of interest might include future output growth, interest rates, inflation and unemployment, whose distribution is implied by each of the models considered. Implicit in this formulation is the conditional distribution of the vector of interest conditional on the observed data. Technically, this requires the integration (or marginalization) of parameters in each model as well as the models themselves. As a practical matter this usually proceeds by first computing the probability of each model conditional on the data, and then using these probabilities as weights in averaging the posterior distribution of the vector of interest in each model. It is not necessary to choose one particular model, and indeed to do so would be suboptimal. The ability to actually carry out this simultaneous consideration of multiple models has been enhanced greatly by recent developments in simulation methods, surveyed in section "Integration and Simulation Methods in Econometrics" below; recent texts by Koop (2003), Lancaster (2004), and Geweke (2005) provide technical details. Geweke and Whiteman (2006) specifically outline these methods in the context of economic forecasting.

E

Microeconometrics: An Overview

Partly as a response to the dissatisfaction with macroeconometric time-series research and partly in view of the increasing availability of micro data and computing facilities, since the mid-1980s significant advances have been made in the analysis of micro data. Important micro data-sets have become available on households and firms especially in the United States in such areas as housing, transportation, labour markets and energy. These data sets include various longitudinal surveys (for example, University of Michigan Panel Study of Income Dynamics, and Ohio State National Longitudinal Study Surveys), cross-sectional surveys of family expenditures, population and labour force surveys. This increasing availability of micro-data, while opening up new possibilities for analysis, has also raised a number of new and interesting econometric issues primarily originating from the nature of the data. The errors of measurement are likely to be important in the case of some micro data-sets. The problem of the heterogeneity of economic agents at the micro level cannot be assumed away as readily as is usually done in the case of macro data by appealing to the idea of a 'representative' firm or a 'representative' household.

The nature of micro data, often being qualitative or limited to a particular range of variations, has also called for new econometric models and techniques. Examples include categorical survey responses ('up', 'same' or 'down'), and censored or truncated observations. The models and issues considered in the microeconometric literature are wide ranging and include fixed and random effect

panel data models (for example, Mundlak 1961, 1978), logit and probit models and their multinominal extensions, discrete choice or quantal response models (Manski and McFadden 1981), continuous time duration models (Heckman and Singer 1984), and microeconometric models of count data (Hausman et al. 1984; Cameron and Trivedi 1986).

The fixed or random effect models provide the basic statistical framework and will be discussed in more detailed below. Discrete choice models are based on an explicit characterization of the choice process and arise when individual decision makers are faced with a finite number of alternatives to choose from. Examples of discrete choice models include transportation mode choice (Domenich and McFadden 1975), labour force participation (Heckman and Willis 1977), occupation choice (Boskin 1974), job or firm location (Duncan 1980), and models with neighbourhood effects (Brock and Durlauf 2002). Limited dependent variables models are commonly encountered in the analysis of survey data and are usually categorized into truncated regression models and censored regression models. If all observations on the dependent as well as on the exogenous variables are lost when the dependent variable falls outside a specified range, the model is called *truncated,* and, if only observations on the dependent variable are lost, it is called *censored.* The literature on censored and truncated regression models is vast and overlaps with developments in other disciplines, particularly in biometrics and engineering. Maddala (1983, ch. 6) provides a survey.

The censored regression model was first introduced into economics by Tobin (1958) in his pioneering study of household expenditure on durable goods, where he explicitly allowed for the fact that the dependent variable, namely, the expenditure on durables, cannot be negative. The model suggested by Tobin and its various generalizations are known in economics as Tobit models and are surveyed in detail by Amemiya (1984), and more recently in Cameron and Trivedi (2005, ch. 14). Continuous time duration models, also known as survival models, have been used in analysis of unemployment duration, the period of time spent between jobs, durability of marriage, and so on. Application of survival models to analyse economic data raises a number of important issues resulting primarily from the non-controlled experimental nature of economic observations, limited sample sizes (that is, time periods), and the heterogeneous nature of the economic environment within which agents operate. These issues are clearly not confined to duration models and are also present in the case of other microeconometric investigations that are based on time series or cross-section or panel data.

Partly in response to the uncertainties inherent in econometric results based on non-experimental data, there has also been a significant move towards social experimentation, and experimental economics in general. A social experiment aims at isolating the effects of a policy change (or a treatment effect) by comparing the consequences of an exogenous variation in the economic environment of a set of experimental subjects known as the 'treatment' group with those of a 'control' group that have not been subject to the change. The basic idea goes back to the early work of R.A. Fisher (1928) on randomized trials, and has been applied extensively in agricultural and biomedical research. The case for social experimentation in economics is discussed in Burtless (1995). Hausman and Wise (1985) and Heckman and Smith (1995) consider a number of actual social experiments carried out in the United States, and discuss their scope and limitations.

Experimental economics tries to avoid some of the limitations of working with observations obtained from natural or social experiments by using data from laboratory experiments to test economic theories by fixing some of the factors and identifying the effects of other factors in a way that allows *ceteris paribus* comparisons. A wide range of topics and issues are covered in this literature, such as individual choice behaviour, bargaining, provision of public goods, theories of learning, auction markets, and behavioural finance. A comprehensive review of major areas of experimental research in economics is provided in Kagel and Roth (1995).

These developments have posed new problems and challenges in the areas of experimental

design, statistical methods and policy analysis. Another important aspect of recent developments in microeconometric literature relates to the use of microanalytic simulation models for policy analysis and evaluation to reform packages in areas such as health care, taxation, social security systems, and transportation networks. Cameron and Trivedi (2005) review the recent developments in methods and application of microeconometrics. Some of these topics will be discussed in more detail below.

Econometrics of Panel Data

Panel data models are used in many areas of econometrics, although initially they were developed primarily for the analysis of micro behaviour, and focused on panels formed from cross-section of N individual households or firms surveyed for T successive time periods. These types of panels are often referred to as 'micropanels'. In social and behavioural sciences they are also known as longitudinal data or panels. The literature on micro-panels typically takes N to be quite large (in hundreds) and T rather small, often less than ten. But more recently, with the increasing availability of financial and macroeconomic data, analyses of panels where both N and T are relatively large have also been considered. Examples of such data-sets include time series of company data from Datastream, country data from International Financial Statistics or the Penn World Table, and county and state data from national statistical offices. There are also pseudo panels of firms and consumers composed of repeated cross sections that cover cross-section units that are not necessarily identical but are observed over relatively long time periods. Since the available cross-section observations do not (necessarily) relate to the same individual unit, some form of grouping of the cross-section units is needed. Once the grouping criteria are set, the estimation can proceed using fixed effects estimation applied to group averages if the number of observations per group is sufficiently large; otherwise possible measurement errors of the group averages also need to be taken into account. Deaton (1985) pioneered the econometric analysis of pseudo panels. Verbeek (2008) provides a recent review.

Use of panels can enhance the power of empirical analysis and allows estimation of parameters that might not have been identified using the time or the cross-section dimensions alone. These benefits come at a cost. In the case of linear panel data models with a short time span the increased power is usually achieved under assumptions of parameter homogeneity and error cross-section independence. Short panels with autocorrelated disturbances also pose a new identification problem, namely, how to distinguished between dynamics and state dependence (Arellano 2003, ch. 5). In panels with fixed effects the homogeneity assumption is relaxed somewhat by allowing the intercepts in the panel regressions to vary freely over the cross-section units, but continues to maintain the error cross-section independence assumption. The random coefficient specification of Swamy (1970) further relaxes the slope homogeneity assumption, and represents an important generalization of the random effects model (Hsiao and Pesaran 2007). In micro-panels where T is small cross-section dependence can be dealt with if it can be attributed to spatial (economic or geographic) effects. Anselin (1988) and Anselin et al. (2007) provide surveys of the literature on spatial econometrics. A number of studies have also used measures such as trade or capital flows to capture economic distance, as in Conley and Topa (2002), Conley and Dupor (2003), and Pesaran et al. (2004).

Allowing for dynamics in panels with fixed effects also presents additional difficulties; for example, the standard within-group estimator will be inconsistent unless $T \to \infty$ (Nickell 1981). In linear dynamic panels the incidental parameter problem (the unobserved heterogeneity) can be resolved by first differencing the model and then estimating the resultant first-differenced specification by instrumental variables or by the method of transformed likelihood (Anderson and Hsiao 1981, 1982; Holtz-Eakin et al. 1988; Arellano and Bond 1991; Hsiao et al. 2002). A similar procedure can also be followed in the case of short T panel VARs (Binder et al. 2005). But other approaches are needed for nonlinear

panel data models. See, for example, Honoré and Kyriazidou (2000) and review of the literature on nonlinear panels in Arellano and Honoré (2001). Relaxing the assumption of slope homogeneity in dynamic panels is also problematic, and neglecting to take account of slope heterogeneity will lead to inconsistent estimators. In the presence of slope heterogeneity Pesaran and Smith (1995) show that the within-group estimator remains inconsistent even if both N and $T \to \infty$. A Bayesian approach to estimation of micro dynamic panels with random slope coefficients is proposed in Hsiao et al. (1999).

To deal with general dynamic specifications, possible slope heterogeneity and error cross-section dependence, large T and N panels are required. In the case of such large panels it is possible to allow for richer dynamics and parameter heterogeneity. Cross-section dependence of errors can also be dealt with using residual common factor structures. These extensions are particularly relevant to the analysis of purchasing power parity hypothesis (O'Connell 1998; Imbs et al. 2005; Pedroni 2001; Smith et al. 2004), output convergence (Durlauf et al. 2005; Pesaran 2007b), the Fisher effect (Westerlund 2005), house price convergence (Holly et al. 2006), regional migration (Fachin 2006), and uncovered interest parity (Moon and Perron 2007). The econometric methods developed for large panels has to take into account the relationship between the increasing number of time periods and cross-section units (Phillips and Moon 1999). The relative expansion rates of N and T could have important consequences for the asymptotic and small sample properties of the panel estimators and tests. This is because fixed T estimation bias tend to magnify with increases in the cross-section dimension, and it is important that any bias in the T dimension is corrected in such a way that its overall impact disappears as both N and $T \to \infty$, jointly.

The first generation panel unit root tests proposed, for example, by Levin et al. (2002) and Im et al. (2003) allowed for parameter heterogeneity but assumed errors were cross-sectionally independent. More recently, panel unit root tests that allow for error cross-section dependence have been proposed by Bai and Ng (2004), Moon and Perron (2004), and Pesaran (2007a). As compared with panel unit root tests, the analysis of cointegration in panels is still at an early stage of its development. So far the focus of the panel cointegration literature has been on residual-based approaches, although there has been a number of attempts at the development of system approaches as well (Pedroni 2004). But once cointegration is established the long-run parameters can be estimated efficiently using techniques similar to the ones proposed in the case of single time-series models. These estimation techniques can also be modified to allow for error cross-section dependence (Pesaran 2007a). Surveys of the panel unit root and cointegration literature are provided by Banerjee (1999), Baltagi and Kao (2000), Choi (2006), and Breitung and Pesaran (2008).

The micro and macro panel literature is vast and growing. For the analysis of many economic problems, further progress is needed in the analysis of nonlinear panels, testing and modelling of error cross-section dependence, dynamics, and neglected heterogeneity. For general reviews of panel data econometrics, see Arellano (2003), Baltagi (2005), Hsiao (2003), and Wooldridge (2002).

Nonparametric and Semiparametric Estimation

Much empirical research is concerned with estimating conditional mean, median, or hazard functions. For example, a wage equation gives the mean, median or, possibly, some other quantile of wages of employed individuals conditional on characteristics such as years of work experience and education. A hedonic price function gives the mean price of a good conditional on its characteristics. The function of interest is rarely known a priori and must be estimated from data on the relevant variables. For example, a wage equation is estimated from data on the wages, experience, education and, possibly, other characteristics of individuals. Economic theory rarely gives useful

guidance on the form (or shape) of a conditional mean, median, or hazard function. Consequently, the form of the function must either be assumed or inferred through the estimation procedure.

The most frequently used estimation methods assume that the function of interest is known up to a set of constant parameters that can be estimated from data. Models in which the only unknown quantities are a finite set of constant parameters are called 'parametric'. A linear model that is estimated by ordinary least squares is a familiar and frequently used example of a parametric model. Indeed, linear models and ordinary least squares have been the workhorses of applied econometrics since its inception. It is not difficult to see why. Linear models and ordinary least squares are easy to work with both analytically and computationally, and the estimation results are easy to interpret. Other examples of widely used parametric models are binary logit and probit models if the dependent variable is binary (for example, an indicator of whether an individual is employed or whether a commuter uses automobile or public transit for a trip to work) and the Weibull hazard model if the dependent variable is a duration (for example, the duration of a spell of employment or unemployment).

Although parametric models are easy to work with, they are rarely justified by theoretical or other a priori considerations and often fit the available data badly. Horowitz (2001), Horowitz and Savin (2001), Horowitz and Lee (2002), and Pagan and Ullah (1999) provide examples. The examples also show that conclusions drawn from a convenient but incorrectly specified model can be very misleading. Of course, applied econometricians are aware of the problem of specification error. Many investigators attempt to deal with it by carrying out a specification search in which several different models are estimated and conclusions are based on the one that appears to fit the data best. Specification searches may be unavoidable in some applications, but they have many undesirable properties. There is no guarantee that a specification search will include the correct model or a good approximation to it. If the search includes the correct model, there is no guarantee that it will be selected by the investigator's model selection criteria. Moreover, the search process invalidates the statistical theory on which inference is based.

Given this situation, it is reasonable to ask whether conditional mean and other functions of interest in applications can be estimated nonparametrically, that is, without making a priori assumptions about their functional forms. The answer is clearly 'yes' in a model whose explanatory variables are all discrete. If the explanatory variables are discrete, then each set of values of these variables defines a data cell. One can estimate the conditional mean of the dependent variable by averaging its values within each cell. Similarly, one can estimate the conditional median cell by cell.

If the explanatory variables are continuous, they cannot be grouped into cells. Nonetheless, it is possible to estimate conditional mean and median functions that satisfy mild smoothness conditions without making a priori assumptions about their shapes. Techniques for doing this have been developed mainly in statistics, beginning with Nadaraya's (1964) and Watson's (1964) nonparametric estimator of a conditional mean function. The Nadaraya–Watson estimator, which is also called a kernel estimator, is a weighted average of the observed values of the dependent variable. More specifically, suppose that the dependent variable is Y, the explanatory variable is X, and the data consist of observations $\{Y_i, X_i : i = 1, \ldots, n\}$. Then the Nadaraya–Watson estimator of the mean of Y at $X = x$ is a weighted average of the Y_i's. Y_i's corresponding to X_i's that are close to x get more weight than do Y_i's corresponding to X_i's that are far from x. The statistical properties of the Nadaraya–Watson estimator have been extensively investigated for both crosssectional and time-series data, and the estimator has been widely used in applications. For example, Blundell et al. (2003) used kernel estimates of Engel curves in an investigation of the consistency of household-level data and revealed preference theory. Hausman and Newey (1995) used kernel estimates of demand functions to estimate the equivalent variation for changes in

gasoline prices and the deadweight losses associated with increases in gasoline taxes. Kernel-based methods have also been developed for estimating conditional quantile and hazard functions.

There are other important nonparametric methods for estimating conditional mean functions. Local linear estimation and series or sieve estimation are especially useful in applications. Local linear estimation consists of estimating the mean of Y at $X = x$ by using a form of weighted least squares to fit a linear model to the data. The weights are such that observations (Y_i, X_i) for which X_i is close to x receive more weight than do observations for which X_i is far from x. In comparison with the Nadaraya–Watson estimator, local linear estimation has important advantages relating to bias and behaviour near the boundaries of the data. These are discussed in the book by Fan and Gijbels (1996), among other places.

A series estimator begins by expressing the true conditional mean (or quantile) function as an infinite series expansion using basis functions such as sines and cosines, orthogonal polynomials, or splines. The coefficients of a truncated version of the series are then estimated by ordinary least squares. The statistical properties of series estimators are described by Newey (1997). Hausman and Newey (1995) give an example of their use in an economic application.

Nonparametric models and estimates essentially eliminate the possibility of misspecification of a conditional mean or quantile function (that is, they consistently estimate the true function), but they have important disadvantages that limit their usefulness in applied econometrics. One important problem is that the precision of a nonparametric estimator decreases rapidly as the dimension of the explanatory variable X increases. This phenomenon is called the 'curse of dimensionality'. It can be understood most easily by considering the case in which the explanatory variables are all discrete. Suppose the data contain 500 observations of Y and X. Suppose, further, that X is a K-component vector and that each component can take five different values. Then the values of X generate 5^k cells. If $K = 4$, which is not unusual in applied econometrics, then there are 625 cells, or more cells than observations. Thus, estimates of the conditional mean function are likely to be very imprecise for most cells because they will contain few observations. Moreover, there will be at least 125 cells that contain no data and, consequently, for which the conditional mean function cannot be estimated at all. It has been proved that the curse of dimensionality is unavoidable in nonparametric estimation. As a result of it, impracticably large samples are usually needed to obtain acceptable estimation precision if X is multidimensional.

Another problem is that nonparametric estimates can be difficult to display, communicate, and interpret when X is multidimensional. Nonparametric estimates do not have simple analytic forms. If X is one-or two-dimensional, then the estimate of the function of interest can be displayed graphically, but only reduced-dimension projections can be displayed when X has three or more components. Many such displays and much skill in interpreting them can be needed to fully convey and comprehend the shape of an estimate.

A further problem with nonparametric estimation is that it does not permit extrapolation. For example, in the case of a conditional mean function it does not provide predictions of the mean of Y at values of x that are outside of the range of the data on X. This is a serious drawback in policy analysis and forecasting, where it is often important to predict what might happen under conditions that do not exist in the available data. Finally, in nonparametric estimation it can be difficult to impose restrictions suggested by economic or other theory. Matzkin (1994) discusses this issue.

The problems of nonparametric estimation have led to the development of so-called semiparametric methods that offer a compromise between parametric and nonparametric estimation. Semiparametric methods make assumptions about functional form that are stronger than those of a nonparametric model but less restrictive than the assumptions of a parametric model, thereby reducing (though not eliminating) the possibility of specification error. Semiparametric methods permit greater estimation precision than do nonparametric methods when X is multidimensional. Semiparametric estimation results are usually

easier to display and interpret than are nonparametric ones, and provide limited capabilities for extrapolation.

In econometrics, semiparametric estimation began with Manski's (1975, 1985) and Cosslett's (1983) work on estimating discrete-choice random-utility models. McFadden had introduced multinomial logit random utility models. These models assume that the random components of the utility function are independently and identically distributed with the Type I extreme value distribution. (The Type I extreme value distribution and density functions are defined, for example, in Eqs. (3.1) and (3.2) Maddala 1983, p. 60.) The resulting choice model is analytically simple but has properties that are undesirable in many applications (for example, the well-known independence-of-irrelevant-alternatives property). Moreover, estimators based on logit models are inconsistent if the distribution of the random components of utility is not Type I extreme value. Manski (1975, 1985) and Cosslett (1983) proposed estimators that do not require a priori knowledge of this distribution. Powell's (1984, 1986) least absolute deviations estimator for censored regression models is another early contribution to econometric research on semiparametric estimation. This estimator was motivated by the observation that estimators of (parametric) Tobit models are inconsistent if the underlying normality assumption is incorrect. Powell's estimator is consistent under very weak distributional assumptions.

Semiparametric estimation has continued to be an active area of econometric research. Semiparametric estimators have been developed for a wide variety of additive, index, partially linear, and hazard models, among others. These estimators all reduce the effective dimension of the estimation problem and overcome the curse of dimensionality by making assumptions that are stronger than those of fully nonparametric estimation but weaker than those of a parametric model. The stronger assumptions also give the models limited extrapolation capabilities. Of course, these benefits come at the price of increased risk of specification error, but the risk is smaller than with simple parametric models. This is because semiparametric models make weaker assumptions than do parametric models, and contain simple parametric models as special cases.

Semiparametric estimation is also an important research field in statistics, and it has led to much interaction between statisticians and econometricians. The early statistics and biostatistics research that is relevant to econometrics was focused on survival (duration) models. Cox's (1972) proportional hazards model and the Buckley and James (1979) estimator for censored regression models are two early examples of this line of research. Somewhat later, Stone (1985) showed that a nonparametric additive model can overcome the curse of dimensionality. Since then, statisticians have contributed actively to research on the same classes of semiparametric models that econometricians have worked on.

Theory-Based Empirical Models

Many econometric models are connected to economic theory only loosely or through essentially arbitrary parametric assumptions about, say, the shapes of utility functions. For example, a logit model of discrete choice assumes that the random components of utility are independently and identically distributed with the Type I extreme value distribution. In addition, it is frequently assumed that the indirect utility function is linear in prices and other characteristics of the alternatives. Because economic theory rarely, if ever, yields a parametric specification of a probability model, it is worth asking whether theory provides useful restrictions on the specification of econometric models, and whether models that are consistent with economic theory can be estimated without making non-theoretical parametric assumptions. The answers to these questions depend on the details of the setting being modelled.

In the case of discrete-choice, random-utility models, the inferential problem is to estimate the distribution of (direct or indirect) utility conditional on observed characteristics of individuals and the alternatives among which they choose. More specifically, in applied research one usually is interested in estimating the systematic

component of utility (that is, the function that gives the mean of utility conditional on the explanatory variables) and the distribution of the random component of utility. Discrete choice is present in a wide range of applications, so it is important to know whether the systematic component of utility and the distribution of the random component can be estimated nonparametrically, thereby avoiding the non-theoretical distributional and functional form assumptions that are required by parametric models. The systematic component and distribution of the random component cannot be estimated unless they are identified. However, economic theory places only weak restrictions on utility functions (for example, shape restrictions such as monotonicity, convexity, and homogeneity), so the classes of conditional mean and utility functions that satisfy the restrictions are large. Indeed, it is not difficult to show that observations of individuals' choices and the values of the explanatory variables, by themselves, do not identify the systematic component of utility and the distribution of the random component without making assumptions that shrink the class of allowed functions.

This issue has been addressed in a series of papers by Matzkin that are summarized in Matzkin (1994). Matzkin gives conditions under which the systematic component of utility and the distribution of the random component are identified without restricting either to a finite-dimensional parametric family. Matzkin also shows how these functions can be estimated consistently when they are identified. Some of the assumptions required for identification may be undesirable in applications. Moreover, Manski (1988) and Horowitz (1998) have given examples in which infinitely many combinations of the systematic component of utility and distribution of the random component are consistent with a binary logit specification of choice probabilities. Thus, discrete-choice, random-utility models can be estimated under assumptions that are considerably weaker than those of, say, logit and probit models, but the systematic component of utility and the distribution of the random component cannot be identified using the restrictions of economic theory alone. It is necessary to make additional assumptions that are not required by economic theory and, because they are required for identification, cannot be tested empirically.

Models of market-entry decisions by oligopolistic firms present identification issues that are closely related to those in discrete-choice, random utility models. Berry and Tamer (2006) explain the identification problems and approaches to resolving them.

The situation is different when the economic setting provides more information about the relation between observables and preferences than is the case in discrete-choice models. This happens in models of certain kinds of auctions, thereby permitting nonparametric estimation of the distribution of values for the auctioned object. An example is a first-price, sealed bid auction within the independent private values paradigm. Here, the problem is to infer the distribution of bidders' values for the auctioned object from observed bids. A game-theory model of bidders' behaviour provides a characterization of the relation between bids and the distribution of private values. Guerre et al. (2000) show that this relation nonparametrically identifies the distribution of values if the analyst observes all bids and certain other mild conditions are satisfied. Guerre et al. (2000) also show how to carry out nonparametric estimation of the value distribution.

Dynamic decision models and equilibrium job-search models are other examples of empirical models that are closely connected to economic theory, though they also rely on non-theoretical parametric assumptions. In a dynamic decision model, an agent makes a certain decision repeatedly over time. For example, an individual may decide each year whether to retire or not. The optimal decision depends on uncertain future events (for example, the state of one's future health) whose probabilities may change over time (for example, the probability of poor health increases as one ages) and depend on the decision. In each period, the decision of an agent who maximizes expected utility is the solution to a stochastic, dynamic programming problem. A large body of research, much of which is reviewed by Rust (1994), shows how to specify and estimate econometric models of the utility

function (or, depending on the application, cost function), probabilities of relevant future events, and the decision process.

An equilibrium search model determines the distributions of job durations and wages endogenously. In such a model, a stochastic process generates wage offers. An unemployed worker accepts an offer if it exceeds his reservation wage. An employed worker accepts an offer if it exceeds his current wage. Employers choose offers to maximize expected profits. Among other things, an equilibrium search model provides an explanation for why seemingly identical workers receive different wages. The theory of equilibrium search models is described in Albrecht and Axell (1984), Mortensen (1990), and Burdett and Mortensen (1998). There is a large body of literature on the estimation of these models. Bowlus et al. (2001) provide a recent example with many references.

The Bootstrap

The exact, finite-sample distributions of econometric estimators and test statistics can rarely be calculated in applications. This is because, except in special cases and under restrictive assumptions (for example, the normal linear model), finite sample distributions depend on the unknown distribution of the population from which the data were sampled. This problem is usually dealt with by making use of large-sample (asymptotic) approximations. A wide variety of econometric estimators and test statistics have distributions that are approximately normal or chi-square when the sample size is large, regardless of the population distribution of the data. The approximation error decreases to zero as the sample size increases. Thus, asymptotic approximations can to be used to obtain confidence intervals for parameters and critical values for tests when the sample size is large.

It has long been known, however, that the asymptotic normal and chi-square approximations can be very inaccurate with the sample sizes encountered in applications. Consequently, there can be large differences between the true and nominal coverage probabilities of confidence intervals and between the true and nominal probabilities with which a test rejects a correct null hypothesis. One approach to dealing with this problem is to use higher-order asymptotic approximations such as Edgeworth or saddlepoint expansions. These received much research attention during 1970s and 1980s, but analytic higher-order expansions are rarely used in applications because of their algebraic complexity.

The bootstrap, which is due to Efron (1979), provides a way to obtain sometimes spectacular improvements in the accuracy of asymptotic approximations while avoiding algebraic complexity. The bootstrap amounts to treating the data as if they were the population. In other words, it creates a pseudo-population whose distribution is the empirical distribution of the data. Under sampling from the pseudo-population, the exact finite sample distribution of any statistic can be estimated with arbitrary accuracy by carrying out a Monte Carlo simulation in which samples are drawn repeatedly from the empirical distribution of the data. That is, the data are repeatedly sampled randomly with replacement. Since the empirical distribution is close to the population distribution when the sample size is large, the bootstrap consistently estimates the asymptotic distribution of a wide range of important statistics. Thus, the bootstrap provides a way to replace analytic calculations with computation. This is useful when the asymptotic distribution is difficult to work with analytically.

More importantly, the bootstrap provides a low-order Edgeworth approximation to the distribution of a wide variety of asymptotically standard normal and chi-square statistics that are used in applied research. Consequently, the bootstrap provides an approximation to the finite-sample distributions of such statistics that is more accurate than the asymptotic normal or chi-square approximation. The theoretical research leading to this conclusion was carried out by statisticians, but the bootstrap's importance has been recognized in econometrics and there is now an important body of econometric research on the topic. In many settings that are important in applications, the bootstrap essentially eliminates errors in the

coverage probabilities of confidence intervals and the rejection probabilities of tests. Thus, the bootstrap is a very important tool for applied econometricians.

There are, however, situations in which the bootstrap does not estimate a statistic's asymptotic distribution consistently. Manski's (1975, 1985) maximum score estimator of the parameters of a binary response model is an example. All known cases of bootstrap inconsistency can be overcome through the use of subsampling methods. In subsampling, the distribution of a statistic is estimated by carrying out a Monte Carlo simulation in which the subsamples of the data are drawn repeatedly. The subsamples are smaller than the original data-set, and they can be drawn randomly with or without replacement. Subsampling provides estimates of asymptotic distributions that are consistent under very weak assumptions, though it is usually less accurate than the bootstrap when the bootstrap is consistent.

Programme Evaluation and Treatment Effects

Programme evaluation is concerned with estimating the causal effect of a treatment or policy intervention on some population. The problem arises in many disciplines, including biomedical research (for example, the effects of a new medical treatment) and economics (for example, the effects of job training or education on earnings). The most obvious way to learn the effects of treatment on a group of individuals by observing each individual's outcome in both the treated and the untreated states. This is not possible in practice, however, because one virtually always observes any given individual in either the treated state or the untreated state but not both. This does not matter if the individuals who receive treatment are identical to those who do not, but that rarely happens. For example, individuals who choose to take a certain drug or whose physicians prescribe it for them may be sicker than individuals who do not receive the drug. Similarly, people who choose to obtain high levels of education may be different from others in ways that affect future earnings.

This problem has been recognized since at least the time of R.A. Fisher. In principle, it can be overcome by assigning individuals randomly to treatment and control groups. One can then estimate the average effect of treatment by the difference between the average outcomes of treated and untreated individuals. This random assignment procedure has become something of a gold standard in the treatment effects literature. Clinical trials use random assignment, and there have been important economic and social experiments based on this procedure. But there are also serious practical problems. First, random assignment may not be possible. For example, one cannot assign high-school students randomly to receive a university education or not. Second, even if random assignment is possible, post-randomization events may disrupt the effects of randomization. For example, individuals may drop out of the experiment or take treatments other than the one to which they are assigned. Both of these things may happen for reasons that are related to the outcome of interest. For example, very ill members of a control group may figure out that they are not receiving treatment and find a way to obtain the drug being tested. In addition, real-world programmes may not operate the way that experimental ones do, so real-world outcomes may not mimic those found in an experiment, even if nothing has disrupted the randomization.

Much research in econometrics, statistics, and biostatistics has been aimed at developing methods for inferring treatment effects when randomization is not possible or is disrupted by post-randomization events. In econometrics, this research dates back at least to Gronau (1974) and Heckman (1974). The fundamental problem is to identify the effects of treatment or, in less formal terms, to separate the effects of treatment from those of other sources of differences between the treated and untreated groups. Manski (1995), among many others, discusses this problem. Large literatures in statistics, biostatistics, and econometrics are concerned with developing

identifying assumptions that are reasonable in applied settings. However, identifying assumptions are not testable empirically and can be controversial. One widely accepted way of dealing with this problem is to conduct a sensitivity analysis in which the sensitivity of the estimated treatment effect to alternative identifying assumptions is assessed. Another possibility is to forgo controversial identifying assumptions and to find the entire set of outcomes that are consistent with the joint distribution of the observed variables. This approach, which has been pioneered by Manski and several co-investigators, is discussed in Manski (1995, 2003), among other places. Hotz et al. (1997) provide an interesting application of bounding methods to measuring the effects of teenage pregnancy on the labour market outcomes of young women.

Integration and Simulation Methods in Econometrics

The integration problem is endemic in economic modelling, arising whenever economic agents do not observe random variables and the behaviour paradigm is the maximization of expected utility. The econometrician inherits this problem in the expression of the corresponding econometric model, even before taking up inference and estimation. The issue is most familiar in dynamic optimization contexts, where it can be addressed by a variety of methods. Taylor and Uhlig (1990) present a comprehensive review of these methods; for later innovations see Keane and Wolpin (1994), Rust (1997), and Santos and Vigo-Aguiar (1998).

The problem is more pervasive in econometrics than in economic modelling, because it arises, in addition, whenever economic agents observe random variables that the econometrician does not. For example, the economic agent may form expectations conditional on an information set not entirely accessible to the econometrician, such as personal characteristics or confidential information. Another example arises in discrete choice settings, where utilities of alternatives are never observed and the prices of alternatives often are not. In these situations the economic model provides a probability distribution of outcomes conditional on three classes of objects: observed variables, available to the econometrician; latent variables, unobserved by the econometrician; and parameters or functions describing the preferences and decision-making environment of the economic agent. The econometrician typically seeks to learn about the parameters or functions given the observed variables.

There are several ways of dealing with this task. Two approaches that are closely related and widely used in the econometrics literature generate integration problems. The first is to maintain a distribution of the latent variables conditional on observed variables, the parameters in the model, and additional parameters required for completing this distribution. (This is the approach taken in maximum likelihood and Bayesian inference.) Combined with the model, this leads to the joint distribution of outcomes and latent variables conditional on observed variables and parameters. Since the marginal distribution of outcomes is the one relevant for the econometrician in this conditional distribution, there is an integration problem for the latent variables. The second approach is weaker: it restricts to zero the values of certain population moments involving the latent and observable variables. (This is the approach taken in generalized method of moments, which can be implemented with both parametric and nonparametric methods.) These moments depend upon the parameters (which is why the method works) and the econometrician must therefore be able to evaluate the moments for any given set of parameter values. This again requires integration over the latent variables.

Ideally, this integral would be evaluated analytically. Often – indeed, typically – this is not possible. The alternative is to use numerical methods. Some of these are deterministic, but the rapid growth in the solution of these problems since (roughly) 1990 has been driven more by simulation methods employing pseudo-random numbers generated by computer hardware and software. This section reviews the most important

these methods and describes their most significant use in non-Bayesian econometrics, namely, simulated method of moments. In Bayesian econometrics the integration problem is inescapable, the structure of the economic model notwithstanding, because parameters are treated explicitly as unobservable random variables. Consequently simulation methods have been central to Bayesian inference in econometrics.

Deterministic Approximation of Integrals

The evaluation of an integral is a problem as old as the calculus itself. In well-catalogued but limited instances analytical solutions are available: Gradshteyn and Ryzhik (1965) is a useful classic reference. For integration in one dimension there are several methods of deterministic approximation, including Newton-Coates (Press et al. 1986, ch. 4; Davis and Rabinowitz 1984, ch. 2), and Gaussian quadrature (Golub and Welsch 1969; Judd 1998, s. 7.2). Gaussian quadrature approximates a smooth function as the product a polynomial of modest order and a smooth basis function, and then uses iterative refinements to compute the approximation. It is incorporated in most mathematical applications software and is used routinely to approximate integrals in one dimension to many significant figures of accuracy.

Integration in several dimensions by means of deterministic approximation is more difficult. Practical generic adaptations of Gaussian quadrature are limited to situations in which the integrand is approximately the product of functions of single variables (Davis and Rabinowitz 1984, pp. 354–9). Even here the logarithm of computation time is approximately linear in the number of variables, a phenomenon sometimes dubbed 'the curse of dimensionality.' Successful extensions of quadrature beyond dimensions of four or five are rare, and these extensions typically require substantial analytical work before they can be applied successfully.

Low discrepancy methods provide an alternative generic approach to deterministic approximation of integrals in higher dimensions. The approximation is the average value of the integrand computed over a well-chosen sequence of points whose configuration amounts to a sophisticated lattice. Different sequences lead to variants on the approach, the best known being the Halton (1960) sequence and the Hammersley (1960) sequence. Niederreiter (1992) reviews these and other variants.

A key property of any method of integral approximation, deterministic or nondeterministic, is that it should provide as a by-product some indicator of the accuracy of the approximation. Deterministic methods typically provide upper bounds on the approximation error, based on worst-case situations. In many situations the actual error is orders of magnitude less than the upper bound, and as a consequence attaining desired error tolerances may appear to be impractical, whereas in fact these tolerances can easily be attained. Geweke (1996, s. 2.3) provides an example.

Simulation Approximation of Integrals

The structure of integration problems encountered in econometrics makes them often more amenable to attack by simulation methods than by nondeterministic methods. Two characteristics are key. First, integrals in many dimensions are required. In some situations the number is proportional to the size of the sample, and, while the structure of the problem may lead to decomposition in terms of many integrals of smaller dimension, the resulting structure and dimension are still unsuitable for deterministic methods. The second characteristic is that the integration problem usually arises as the need to compute the expected value of a function of a random vector with a given probability distribution P:

$$I = \int_S g(\mathbf{x}) p(\mathbf{x}) d\mathbf{x}, \tag{1}$$

where p is the density corresponding to P, g is the function, $\mathbf{x}$ is the random vector, and I is the number to be approximated. The probability distribution P is then the point of departure for the simulation.

For many distributions there are reliable algorithms, implemented in widely available mathematical applications software, for simulation of random vectors x. This yields a sample $\{g(x^{(m)})\}$

($m = 1, \ldots, M$) whose arithmetic mean provides an approximation of I, and for which a central limit theorem provides an assessment of the accuracy of the approximation in the usual way. (This requires the existence of the first two moments of g, which must be shown analytically.) This approach is most useful when p is simple (so that direct simulation of $\mathbf{x}$ is possible) but the structure of g precludes analytical evaluation of I.

This simple approach does not suffice for the integration problem as it typically arises in econometrics. A leading example is the multinomial probit (MNP) model with J discrete choices. For each individual i the utility of the last choice u_{ij} is normalized to be zero, and the utilities of the first $J - 1$ choices are given by the vector

$$\mathbf{u}_i \sim N(\mathbf{X}_i\beta, \Sigma), \tag{2}$$

where $\mathbf{X}$ is a matrix of characteristics of individual i, including the prices and other properties of the choices presented to that individual, and β and $\mathbf{\Sigma}$ are structural parameters of the model. If the j'th element of $\mathbf{u}_i$ is positive and larger than all the other elements of $\mathbf{u}_i$ the individual makes choice j, and if all elements of $\mathbf{u}$ are negative the individual makes choice J. The probability that individual i makes choice j is the integral of the $(n - 1)$-variate normal distribution (1) taken over the subspace $\{\mathbf{u}_i : u_{ik} \leq u_{ij} \; \forall \; k = 1, \ldots, n\}$. This computation is essential in evaluating the likelihood function, and it has no analytical solution. (For discussion and review, see Sandor and Andras 2004.)

Several generic simulation methods have been used for the problem (1) in econometrics. One of the oldest is acceptance sampling, a simple variant of which is described in von Neumann (1951) and Hammersley and Handscomb (1964). Suppose it is possible to draw from the distribution Q with density q, and the ratio $p(\mathbf{x})/q(\mathbf{x})$ is bounded above by the known constant a. If $\mathbf{x}$ is simulated successively from Q but accepted and taken into the sample with probability $p(\mathbf{x})/[aq(\mathbf{x})]$, then the resulting sample is independently distributed with the identical distribution P. Proofs and further discussion are widely available; for example, Press et al. (1992, s. 7.4), Bratley et al. (1987, s. 5.2.5), and Geweke (2005, s. 4.2.1). The unconditional probability of accepting draws from Q is $1/a$. If a is too large the method is impractical, but when acceptance sampling is practical it provides draws directly from P. This is an important component of many of the algorithms underlying the 'black box' generation of random variables in mathematical applications software.

Alternatively, in the same situation all of the draws from Q are retained and taken into a stratified sample in which the weight $w(\mathbf{x}^{(m)}) = p(\mathbf{x}^{(m)})/q(\mathbf{x}^{(m)})$ is associated with the m'th draw. The approximation of I in (1) is then the weighted average of the terms $g(\mathbf{x}^{(m)})$. This approach dates at least to Hammersley and Handscomb (1964, s. 5.4), and was introduced to econometrics by Kloek and van Dijk (1978). The procedure is more general than acceptance sampling in that a known upper bound of w is not required, but if in fact a is large then the weights will display large variation and the approximation will be poor. This is clear in the central limit theorem for the accuracy of approximation provided in Geweke (1989a), which as a practical matter requires that a finite upper bound on w be established analytically. This is a key limitation of acceptance sampling and importance sampling.

Markov chain Monte Carlo (MCMC) methods provide an entirely different approach to the solution of the integration problem (1). These procedures construct a Markov process of the form

$$\mathbf{x}^{(m)} \sim p\left(\mathbf{x}/\mathbf{x}^{(m-1)}\right) \tag{3}$$

in such a way that

$$M^{-1}\sum_{m=1}^{M} g\left(x^{(m)}\right)$$

converges (almost surely) to I. These methods have a history in mathematical physics dating back to the algorithm of Metropolis et al. (1953). Hastings (1970) focused on statistical problems and extended the method to its present form known as the Hastings–Metropolis (HM) algorithm. HM draws a candidate $\mathbf{x}^*$ from a convenient distribution indexed by $\mathbf{x}^{(m-1)}$. It sets

$\mathbf{x}^{(m)} = \mathbf{x}$ with probability $\alpha(\mathbf{x}^{(m-1)}, \mathbf{x}^{(m)})$ and sets $\mathbf{x}^{(m)} = \mathbf{x}^{(m)-1}$ otherwise, the function α being chosen so that the process (3) defined in this way has the desired convergence property. Chib and Greenberg (1995) provide a detailed introduction to HM and its application in econometrics. Tierney (1994) provides a succinct summary of the relevant continuous state space Markov chain theory bearing on the convergence of MCMC.

A version of the HM algorithm particularly suited to image reconstruction and problems in spatial statistics, known as the Gibbs sampling (GS) algorithm, was introduced by Geman and Geman (1984). This was subsequently shown to have great potential for Bayesian computation by Gelfand and Smith (1990). In GS the vector $\mathbf{x}$ is subdivided into component vectors, $\mathbf{x}' = \left(\mathbf{x}_1', \ldots, \mathbf{x}_B'\right)$, in such a way that simulation from the conditional distribution of each $\mathbf{x}_j$ implied by $p(\mathbf{x})$ in (1) is feasible. This method has proven very advantageous in econometrics generally, and it revolutionized Bayesian approaches in particular beginning about 1990.

By the turn of the century HM and GS algorithms were standard tools for likelihood-based econometrics. Their structure and strategic importance for Bayesian econometrics were conveyed in surveys by Geweke (1999) and Chib (2001), as well as in a number of textbooks, including Koop (2003), Lancaster (2004), Geweke (2005), and Rossi et al. (2005). Central limit theorems can be used to assess the quality of approximations as described in Tierney (1994) and Geweke (2005).

Simulation Methods in Non-Bayesian Econometrics

Generalized method of moments estimation has been a staple of non-Bayesian econometrics since its introduction by Hansen (1982). In an econometric model with $k \times 1$ parameter vector $\boldsymbol{\theta}$ economic theory provides the set of sample moment restrictions

$$\mathbf{h}(\boldsymbol{\theta}) = \int_s \mathbf{g}(\mathbf{x}) p(\mathbf{x} | \boldsymbol{\theta}, \mathbf{y}) d\mathbf{x} = 0, \qquad (4)$$

where $\mathbf{g}(\mathbf{x})$ is a $p \times 1$ vector and $\mathbf{y}$ denotes the data including instrumental variables. An example is the MNP model (2). If the observed choices are coded by the variables $d_{ij} = 1$ if individual i makes choice j and $d_{ij} = 0$ otherwise, then the expected value of d_{ij} is the probability that individual i makes choice j, leading to restrictions of the form (4).

The generalized method of moments estimator minimizes the criterion function $\mathbf{h}(\boldsymbol{\theta})'\mathbf{W}\mathbf{h}(\boldsymbol{\theta})$ given a suitably chosen weighting matrix $\mathbf{W}$. If the requisite integrals can be evaluated analytically, $p \geq k$, and other conditions provided in Hansen (1982) are satisfied, then there is a well-developed asymptotic theory of inference for the parameters that by 1990 was a staple of graduate econometrics textbooks. If for one or more elements of $\mathbf{h}$ the integral cannot be evaluated analytically, then for alternative values of it is often possible to approximate the integral appearing in (4) by simulation. This is the situation in the MNP model.

The substitution of a simulation approximation

$$M^{-1} \sum_{m=1}^{M} \mathbf{g}\left(\mathbf{x}^{(m)}\right)$$

for the integral in (4) defines the method of simulated moments (MSM) introduced by McFadden (1989) and Pakes and Pollard (1989), who were concerned with the MNP model (2) in particular and the estimation of discrete response models using cross-section data in general. Later the method was extended to time series models by Lee and Ingram (1991) and Duffie and Singleton (1993). The asymptotic distribution theory established in this literature requires that the number of simulations M increase at least as rapidly as the square of the number of observations. The practical import of this apparently severe requirement is that applied econometric work must establish that changes in M must have little impact on the results; Geweke et al. (1994, 1997) provide examples for MNP. This literature also shows that in general the impact of using direct simulation, as opposed to analytical evaluation of the integral, is to increase the asymptotic variance of the GMM estimator of $\boldsymbol{\theta}$ by the factor M^{-1}, typically trivial in view of the number of simulations required.

Substantial surveys of the details of MSM and leading applications of the method can be found in Gourieroux and Monfort (1993, 1996), Stern (1997), and Liesenfeld and Breitung (1999).

The simulation approximation, unlike the (unavailable) analytical evaluation of the integral in (4), can lead to a criterion function that is discontinuous in $\boldsymbol{\theta}$. This happens in the MNP model using the obvious simulation scheme in which the choice probabilities are replaced by their proportions in the M simulations, as proposed by Lerman and Manski (1981). The asymptotic theory developed by McFadden (1989) and Pakes and Pollard (1989) copes with this possibility, and led McFadden (1989) to used kernel weighting to smooth the probabilities. The most widely used method for smoothing probabilities in the MNP model is the Geweke–Hajivassiliou–Keane (GHK) simulator of Geweke (1989b), Hajivassiliou et al. (1991), and Keane (1990); a full description is provided in Geweke and Keane (2001), and comparisons of alternative methods are given in Hajivassiliou et al. (1996) and Sandor and Andras (2004).

Maximum likelihood estimation of $\boldsymbol{\theta}$ can lead to first-order conditions of the form (4), and thus becomes a special case of MSM. This context highlights some of the complications introduced by simulation. While the simulation approximation of (1) is unbiased, the corresponding expression enters the log likelihood function and its derivatives nonlinearly. Thus for any finite number of simulations M, the evaluation of the first-order conditions is biased in general. Increasing M at a rate faster than the square of the number of observations eliminates the squared bias relative to the variance of the estimator; Lee (1995) provides further details.

Simulation Methods in Bayesian Econometrics

Bayesian econometrics places a common probability distribution on random variables that can be observed (data) and unobservable parameters and latent variables. Inference proceeds using the distribution of these unobservable entities conditional on the data – the posterior distribution. Results are typically expressed in terms of the expectations of parameters or functions of parameters, expectations taken with respect to the posterior distribution. Thus, whereas integration problems are application-specific in non-Bayesian econometrics, they are endemic in Bayesian econometrics.

The development of modern simulation methods had a correspondingly greater impact in Bayesian than in non-Bayesian econometrics. Since 1990 simulation-based Bayesian methods have become practical in the context of most econometric models. The availability of this tool has been influential in the modelling approach taken in addressing applied econometric problems.

The MNP model (2) illustrates the interaction in latent variable models. Given a sample of n individuals, the $(J-1)\times 1$ latent utility vectors $\mathbf{u}_1, \ldots, \mathbf{u}_n$ are regarded explicitly as $n(J-1)$ unknowns to be inferred along with the unknown parameters β and $\boldsymbol{\Sigma}$. Conditional on these parameters and the data, the vectors $\mathbf{u}_1, \ldots, \mathbf{u}_n$ are independently distributed. The distribution of $\mathbf{u}_i$ is (2) truncated to an orthant that depends on the observed choice j: if $j < J$ then $u_{ik} < u_{ij}$ for all $k \neq j$ and $u_{ij} > 0$, whereas for choice J:, $u_{ik} < 0$ for all k. The distribution of each u_{ik}, conditional on all of the other elements of $\mathbf{u}_i$, is truncated univariate normal, and it is relatively straightforward to simulate from this distribution. (Geweke 1991, provides details on sampling from a multivariate normal distribution subject to linear restrictions.) Consequently GS provides a practical algorithm for drawing from the distribution of the latent utility vectors conditional on the parameters.

Conditional on the latent utility vectors – that is, regarding them as observed – the MNP model is a seemingly unrelated regressions model, and the approach taken by Percy (1992) applies. Given conjugate priors the posterior distribution of β, conditional on $\boldsymbol{\Sigma}$ and utilities, is Gaussian, and the conditional distribution of $\boldsymbol{\Sigma}$, conditional on β and utilities, is inverted Wishart. Since GS provides the joint distribution of parameters and latent utilities, the posterior mean of any function of these can be approximated as the sample mean. This approach and the suitability of GS for latent variable models were first recognized by Chib (1992). Similar approaches in other latent variable

models in include McCulloch and Tsay (1994), Chib and Greenberg (1998), McCulloch et al. (2000), and Geweke and Keane (2001).

The Bayesian approach with GS sidesteps the evaluation of the likelihood function and, of any moments in which the approximation is biased given a finite number of simulations, two technical issues that are prominent in MSM. On the other hand, as in all MCMC algorithms, there may be sensitivity to the initial values of parameters and latent variables in the Markov chain, and substantial serial correlation in the chain will reduce the accuracy of the simulation approximation. Geweke (1992, 2005) and Tierney (1994) discuss these issues.

Financial Econometrics

Attempts at testing of the efficient market hypothesis (EMH) provided the impetus for the application of time series econometric methods in finance. The EMH was built on the pioneering work of Bachelier (1900) and evolved in the 1960s from the random walk theory of asset prices advanced by Samuelson (1965). By the early 1970s a consensus had emerged among financial economists suggesting that stock prices could be well approximated by a random walk model and that changes in stock returns were basically unpredictable. Fama (1970) provides an early, definitive statement of this position. He distinguished between different forms of the EMH: the 'weak' form that asserts all price information is fully reflected in asset prices; the 'semi-strong' form that requires asset price changes to fully reflect all publicly available information and not only past prices; and the 'strong' form that postulates that prices fully reflect information even if some investor or group of investors have monopolistic access to some information. Fama regarded the strong form version of the EMH as a benchmark against which the other forms of market efficiencies are to be judged. With respect to the weak form version he concluded that the test results strongly support the hypothesis, and considered the various departures documented as economically unimportant. He reached a similar conclusion with respect to the semi-strong version of the hypothesis. Evidence on the semi-strong form of the EMH was revisited by Fama (1991). By then it was clear that the distinction between the weak and the semi-strong forms of the EMH was redundant. The random walk model could not be maintained either, in view of more recent studies, in particular that of Lo and MacKinlay (1988).

This observation led to a series of empirical studies of stock return predictability over different horizons. It was shown that stock returns can be predicted to some degree by means of interest rates, dividend yields and a variety of macroeconomic variables exhibiting clear business cycle variations. See, for example, Fama and French (1989), Kandel and Stambaugh (1996), and Pesaran and Timmermann (1995) on predictability of equity returns in the United States; and Clare et al. (1994) and Pesaran and Timmermann (2000) on equity return predictability in the UK.

Although it is now generally acknowledged that stock returns could be predictable, there are serious difficulties in interpreting the outcomes of market efficiency tests. Predictability could be due to a number of different factors such as incomplete learning, expectations heterogeneity, time variations in risk premia, transaction costs, or specification searches often carried out in pursuit of predictability. In general, it is not possible to distinguish between the different factors that might lie behind observed predictability of asset returns. As noted by Fama (1991) the test of the EMH involves a joint hypothesis, and can be tested only jointly with an assumed model of market equilibrium. This is not, however, a problem that is unique to financial econometrics; almost all areas of empirical economics are subject to the joint hypotheses problem. The concept of market efficiency is still deemed to be useful as it provides a benchmark and its use in finance has led to significant insights.

Important advances have been made in the development of equilibrium asset pricing models, econometric modelling of asset return volatility (Engle 1982; Bollerslev 1986), analysis of high frequency intraday data, and market microstructures. Some of these developments are reviewed in Campbell et al. (1997), Cochrane (2005),

Shephard (2005), and McAleer and Medeiros (2007). Future advances in financial econometrics are likely to focus on heterogeneity, learning and model uncertainty, real time analysis, and further integration with macroeconometrics. Finance is particularly suited to the application of techniques developed for real time econometrics (Pesaran and Timmermann 2005a).

Appraisals and Future Prospects

Econometrics has come a long way over a relatively short period. Important advances have been made in the compilation of economic data and in the development of concepts, theories and tools for the construction and evaluation of a wide variety of econometric models. Applications of econometric methods can be found in almost every field of economics. Econometric models have been used extensively by government agencies, international organizations and commercial enterprises. Macroeconometric models of differing complexity and size have been constructed for almost every country in the world. In both theory and practice, econometrics has already gone well beyond what its founders envisaged. Time and experience, however, have brought out a number of difficulties that were not apparent at the start.

Econometrics emerged in the 1930s and 1940s in a climate of optimism, in the belief that economic theory could be relied on to identify most, if not all, of the important factors involved in modelling economic reality, and that methods of classical statistical inference could be adapted readily for the purpose of giving empirical content to the received economic theory. This early view of the interaction of theory and measurement in econometrics, however, proved rather illusory. Economic theory is invariably formulated with *ceteris paribus* clauses, and involves unobservable latent variables and general functional forms; it has little to say about adjustment processes, lag lengths and other factors mediating the relationship between the theoretical specification (even if correct) and observables. Even in the choice of variables to be included in econometric relations, the role of economic theory is far more limited than was at first recognized. In a Walrasian general equilibrium model, for example, where everything depends on everything else, there is very little scope for a priori exclusion of variables from equations in an econometric model. There are also institutional features and accounting conventions that have to be allowed for in econometric models but which are either ignored or are only partially dealt with at the theoretical level. All this means that the specification of econometric models inevitably involves important auxiliary assumptions about functional forms, dynamic specifications, latent variables, and so on, with respect to which economic theory is silent or gives only an incomplete guide.

The recognition that economic theory on its own cannot be expected to provide a complete model specification has important consequences for testing and evaluation of economic theories, for forecasting and real time decision making. The incompleteness of economic theories makes the task of testing them a formidable undertaking. In general it will not be possible to say whether the results of the statistical tests have a bearing on the economic theory or the auxiliary assumptions. This ambiguity in testing theories, known as the Duhem–Quine thesis, is not confined to econometrics and arises whenever theories are conjunctions of hypotheses (on this, see for example Cross 1982). The problem is, however, especially serious in econometrics because theory is far less developed in economics than it is in the natural sciences. There are, of course, other difficulties that surround the use of econometric methods for the purpose of testing economic theories. As a rule economic statistics are not the results of designed experiments, but are obtained as by-products of business and government activities often with legal rather than economic considerations in mind. The statistical methods available are generally suitable for large samples while the economic data typically have a rather limited coverage. There are also problems of aggregation over time, commodities and individuals that further complicate the testing of economic theories that are microbased.

Econometric theory and practice seek to provide information required for informed decision-

making in public and private economic policy. This process is limited not only by the adequacy of econometrics but also by the development of economic theory and the adequacy of data and other information. Effective progress, in the future as in the past, will come from simultaneous improvements in econometrics, economic theory and data. Research that specifically addresses the effectiveness of the interface between any two of these three in improving policy – to say nothing of all of them – necessarily transcends traditional sub-disciplinary boundaries within economics. But it is precisely these combinations that hold the greatest promise for the social contribution of academic economics.

Economic Anthropology

Timothy Earle

Abstract

Economic anthropology is an empirical science that describes production, exchange and consumption cross-culturally. All societies have economies, but they are variable. Anthropologists evaluate the operations of individual economies and the applicability of Western theories to these cases. Some economic processes work broadly; for example, strategic decision-making, the law of competitive advantage, and calculations of transaction costs help explain many observed patterns. Human economies, however, are often structured as intertwined sectors with distinctive processes. Differences observed in productivity, specialization, institutional structure and social motivations across history and across modern societies are of theoretical significance when constructing the limits of general theory.

Economic anthropology is an empirical science that seeks to describe how production, exchange and consumption operate outside the West (compare Hunt 1997). The second edition (1952) of Herskovits's (1940) text, titled *Economic Anthropology,* labelled this sub-discipline in anthropology. The broader mission of anthropology has been to make sense of the diversity in the human experience, which became apparent to Europeans during progressive stages of exploration, colonialization and globalization. Underlying anthropological research is the premise that human societies have developed parallel institutions of aesthetics, religion, kinship, politics, and of course economics. All societies have economies, and the economic patterns observed in non-Western economies both comfort and confront theories developed by Western scholars.

Common economic processes, such as rational decision-making, law of competitive advantage, and institutional economics help explain many patterns across human economies based on variable conditions of cost, demand and availability. Additionally, however, human economies appear often to be structured quite differently from Western models, and these differences in institutional structure and motivation are of theoretical significance. From the beginning, economic anthropology has contained, and more or less successfully resolved, a tension between the desire to find cross-culturally general theories and to recognize the uniqueness of each individual case. In economic anthropology this tension has been represented in the formalist–substantivist debate.

Few anthropologists identify themselves primarily as economic anthropologists, but study economic matters as part of a broadly integrative approach to human societies. Founded in 1980, the Society of Economic Anthropology is the primary organization for anthropologists with such interests. Members include ethnographers, applied development anthropologists, archaeologists and ethnohistorians, suggesting that economic studies bridge the diversity of the discipline. The society sponsors annual meetings on themes that range across topics including key institutions of labour, property, markets and consumption, and special topics from the gift to slow foods. *Research Series in Economic Anthropology* and *Society for Economic Anthropology Monographs* offer edited volumes on the sub-discipline.

History of Economic Anthropology

From early in the 20th century, anthropologists have questioned whether theories developed to understand Western market economies apply only to those Western societies for which they were generated. To answer this question, anthropologists have described traditional economies, which survived into the 20th century, which existed in the past, and which have been transformed by engagement with the West. Largely empirical, the work is of substantial theoretical significance for understanding economies cross-culturally. Gudeman (1998) has compiled many of the most highly referenced articles.

Economic anthropology's beginning traces to the landmark ethnography *Argonauts of the Western Pacific,* in which Malinowski (1922) described the circulation of shell valuables among the islands of the Kula Ring. Malinowski used the Trobriand Islanders' obsession with certain shell valuables to challenge simplistic notions of 'economic man', and he argued that a non-Western economy could be fundamentally different from modern market economies in values and socialized exchange relationships. Anthropological studies of traditional economies thrived during the first half of the 20th century. As part of British functionalism, Malinowski and his students developed the approach; in French structuralism, Mauss (1925) focused on the gift as a social phenomenon; and, within American anthropology, Herskovits (1940) defined the sub-field. Much of the work was descriptive, emphasizing how traditional people meet basic needs and how the exchange of primitive valuables fashioned and maintained social relationships.

By mid-century, however, studies of traditional economy were increasingly adopting the terms and concepts of Western economic theory. Both Herskovits (1940) and Firth (1939) revised their original books on traditional economies so as to clarify underlying similarities across world economies. They each took concepts, like scarcity and specialization, and generalized them to show that they apply well to societies in which market penetration is not great. They were making the essential point that traditional economies were not simply driven by the food quest. Although most anthropologists took pains to emphasize the differences between traditional economies and market-integrated systems, some seemed to homogenize the human experience, and a sharp reaction followed.

In the tradition of Max Weber, economic historian Karl Polanyi (1944) wrote his famous treatise *The Great Transformation* to argue that the integrating structure of modern markets, for which prices are set by supply and demand, are a very recent creation of industrialism and capitalism. Theories based on scarcity, rationality,

equilibrating price mechanisms operated, he argued, only in the special case of Western capitalism. Modern market conditions should not be taken as inherent in the human experience, but as a recent social artifact malleable in future societies.

Polanyi's impact on economic anthropology was profound and created the debate between substantivists and formalists that raged in the sub-discipline for a generation. *Trade and Markets in the Early Empires* (Polanyi et al. 1957), the seminal edited book, came out of a discussion group which Polanyi led at Columbia University and which included anthropologists who would be influential in the field. Polanyi's chapter 'The Economy as Instituted Process' characterized the substantivist approach. He defined three forms of distribution found in societies with different structured relationships: reciprocity in egalitarian relationships; redistribution in hierarchical relationships; and market exchange in the anonymous relationships of the market. Because economic relations were so deeply embedded in social structure, variation in social organization was thought to explain the differences in the economies. Substantivists recognized that markets were found widely in traditional economies, but argued that those markets were peripheral to most economic activities, which were deeply embedded in social relationships (Bohannan and Dalton 1962). A compendium collected by Dalton (1967) provided empirical cases that illustrate the embedded nature of traditional economies.

In his critique of those using economic theory in non-Western contexts, Polanyi labelled them as 'formalist', meaning that they focused on 'formal' (mathematical) maximizing models to predict how individuals choose among alternative possibilities to allocate limited time, money and other resources. The substantivists, in contrast, focused on how economies were embedded within cultural institutions to meet the material desires that particular culture might have. The debate raged between the two factions through the 1960s and 1970s. Much of the argument became focused on how extensive markets were in traditional societies. In a classic cross-cultural study, Pryor (1977) showed that markets were very broadly distributed, sometimes moving primitive valuable, tools and food. They certainly did not originate with modern capitalism. In his famously acerbic article, Cook (1969) criticized substantivists for being romantic and naive; after all, even if they had useful points to make, the penetration of market economies, he argued, was so pervasive that formalist theories were *now* effectively universal.

Articles representing the two sides were collected in a reader by LeClair and Schneider (1968) that has been used to teach the debate ever since. Articulating the substantivist position, Sahlins (1972) then argued that many concepts of Western economic theory were inapplicable to traditional economy. He discussed the affluence of hunter-gatherers, underproduction in household economies, and the social determinants of reciprocal exchanges. Schneider (1974) countered with the fully articulated formalist position, summarizing how Western economics can be applied cautiously to a wide range of non-Western transactions and decisions, including marriage payments, primitive money, the prestige economy and household production. The debate came to focus on definitions of rationality, scarcity and institutional constraints, but those reading the papers increasingly saw that the participants were talking past each other.

The formalist and substantivist factions represented the inherent tension within anthropology: on the one hand, to seek cross-cultural regularities that reflect shared social process; on the other, to recognize the cultural relativity and uniqueness of each culture. The two sides of the debate fought to exhaustion, as both presented compelling approaches that could be seen as more complementary than alternative. In 1980, Schneider helped organize the Society for Economic Anthropology in order to resolve the debate by bringing the full spectrum of economic anthropologists together. The first meeting, published as *Economic Anthropology*: *Topics and Theories* (Ortiz 1983) gathered an eclectic group of scholars to bridge the theoretical divides within the sub-discipline, with broad interests in marketing, institutions, Marxism, ecology, and economic

development. An edited text, *Economic Anthropology* (Plattner 1989), provided a new generation of students with the breadth of economies and economic conditions that anthropologists were trying to make sense of.

Important to the new harmony has been respect for the different objectives of economic anthropologists, including ethnographic work on traditional economies, applied work on developing economies, and archaeological and historical studies of economies. The field has recognized diversity in both the theoretical and historical nature of human economies. To maintain a proper balance between substantivists and formalists (relativists and universalists) in economic anthropology, the role of archaeological and historical studies has been especially important. As ethnographers increasingly study variants of a single modern system, historical and archaeological studies continue to study the true variation in how human economies are organized and operate. Earle (2002), for example, looks at the alternative means by which political economies have emerged to finance the evolution of chiefdoms and states, showing that the development of market systems is quite rare and specific in that process. Although no careful comparative study exists, the extent of exchange in prehistory appears to have been highly variable.

During the 1980s and 1990s, as economic anthropology matured as a sub-discipline, it became marginalized within anthropology. As in many of the social sciences and humanities, postmodernism became popular, and its anti-materialist, anti-scientific critiques were antithetical to much of what the sub-discipline advocated. As the excesses of postmodernism have receded, however, economic anthropology has regained some of its former popularity, and its potential significance for anthropology and economics seems promising. Perhaps the greatest challenge now is that economics and economic anthropology have remained far apart because of the strongly formal (theoretical) basis of the former and empirical basis of the later. The two approaches would, however, seem complementary.

Economic Anthropology and Its Perspective on World Economies

Economists should consider the empirical value of economic anthropology, and a good place to begin is the compendium *Theory in Economic Anthropology* (Ensminger 2002a). Economic anthropologists are committed to models of reality. The empirical observations and theoretical inferences of anthropology should help recognize the specific frames of applicability for grand theories. In essence, anthropology makes clear that all things are never equal. In this section, I summarize a few conclusions derived from economic anthropology that make a difference to studies of economies. These involve human rationality, consumer behaviour, commodity chains, and the multi-sectored quality of human economies. This list is not meant to be exhaustive, but only to illustrate the importance of cross-cultural evaluations for the models that economists develop. As economics begins to look at such concepts as behavioural economics and personalized networks, the relevance of anthropology's research on these topics becomes particularly significant.

Human decision-making is to a degree rational, and empirical anthropological work significantly improves an understanding of decision-making processes from a cross-cultural and evolutionary perspective. Although rationality underpins much economic theorizing, human cognitive abilities and goals have been under theorized. Recent trends to rectify this within behavioural economics emphasize that individuals do not always act rationally with primary economic objectives and it would appear that economic anthropology could provide valuable cross-cultural validation of these new ideas. Humans prove to be fairly poor decision makers; they appear rather to use simplified proximate measures to estimate such considerations as value and cost (Henrich 2002). Anthropologists have experimented with various economic games given under controlled conditions in non-Western societies, and their results are often counter-intuitive (Ensminger 2002b). In

a sample of societies representing different levels of economic development, for example, as market integration increases cooperation can be shown in such game-playing experiments to become more highly prized.

To understand the evolutionary roots of human rationality, anthropological research has looked at decision-making in small-scale hunting and gathering societies (see for example, Cashdan 1989). As seen by the rapid expansion in brain size deep in history, humans must have been under strong selective pressure for expanded cognitive abilities, and this selective pressure took place when humans were low-density hunter-gatherers. Such hunter-gatherers make daily a wide range of decisions about what foods to eat, where to camp, what groups to join, and the like, and the relative scarcity and abundance of food and their different nutritional qualities appear to be considered. Human cognitive skill determines the ability of hunter-gatherers to adjust rapidly to changing conditions of food availability, to occupy diverse habitats from the Arctic to the tropical forests, and to intensify food procurement as required by population growth. In short, cognitive abilities in the food quest, in movement through the landscape, and in deciding which groups to join must have provided a strong selective advantage that resulted in the moulding of human rationality.

As illustrated by economic anthropology, human decisions often have little direct relationship to economic factors of cost and financial gain. Although of more interest recently to economists, with the notable exception of Thorstein Veblen, economic theory has not attempted systematically to explain how potential consumer outcomes are ranked. Rather, within the West, consumer behaviour has been studied with a rather eclectic and under-theorized set of assumptions. Anthropologists, however, have tried to understand consumption cross-culturally as a social process involving issues of identity and association (Rutz and Orlove 1989). From the anthropological literature, we know how valued objects signify social relationships. The giving and receiving of gifts impart form and meaning to social relationships, and materialize the social distance between actors (Sahlins 1972).

Economic anthropologists frequently study the movements of objects around the globe. These commodity chains describe how goods are produced, distributed and transformed as they move through a sequence of markets (Hansen 2002; Obukhova and Guyer 2002). Commodity chains illustrate how goods, like used clothing, are transformed in value, form and meaning as they pass through a sequence of social worlds and economic sectors. Social considerations of prestige and personal worth are always of great concern in this highly creative process of economic decision-making.

Economic anthropologists have emphasized that economies are multilayered and that the specific character of an economy has historical routes. Although economists often refer to 'dual economy', implying a vestigial survival of traditional practices, they have been reluctant to accept that economies are always multilayered mosaics with spheres of exchange that only partially articulate the different sectors. Economic theory thus radically simplifies reality by focusing on decision-making and outcomes under market conditions, and this simplification makes very different economies appear superficial similar. In the emergence and development of capitalism, since wealth was made in the markets, the primary concern of economists became directed there. As anthropologists seek to understand the different motives and dynamics of economies as articulated in specific social contexts, they have, however, realized that human economies are highly variable, combining subsistence, social, political, and market sectors, each with distinct logics and historical traditions.

The subsistence sector is family-based and involves the daily struggles to meet basic needs. It is universal and represents the economic world of survival in which humans evolved as a species. The primary motivation of humans has probably always been the satisfaction of a family's basic needs. The construction of a general theory of human economies should thus start with how households and communities make a living. Until recently, household requirements were handled largely by family production. Although markets have a long history in human societies, they

were typically quite marginal to subsistence needs. Theorized as the domestic mode of production (DMP; Sahlins 1972), households were oriented to meeting their subsistence needs, and distribution involved sharing between family members with different tasks appropriate to an elementary division of labour by age and gender. In the model, the household is economically self-sufficient, and the economy is not inherently growth-oriented. The amazing conclusion of considerable anthropological research is that the DMP is often at least the model of what the economy should be, and the amounts of goods consumed by households that are produced outside the family have often been but a fraction of the households' overall consumption budget. Prior to the development of full-scale markets, households probably produced 75 per cent or more of everything that they consumed.

The social sector is community-based and involves the lifetime strategies of individuals to define identity and relationships within a broader social group. The social sector is probably universal, finding its roots among early hunter-gatherers and their need to form networks of support, cooperation and exclusion. In cross-cultural perspective, much of the social sector involves reciprocal exchanges within highly social worlds that can be manipulated to emphasize personal prestige. In traditional societies, such competitive exchanges commonly produce social ranking in what has been called a 'prestige economy'. The social sector was elaborated following the Neolithic revolution, as the creation of local corporate groups must have placed a premium on group identity and status. With deep and enduring roots in human history, the social sector would seem to provide a cross-cultural understanding of consumer behaviour as part of processes much broader than capitalism.

Economics now questions assumptions about anonymous markets organized independently of other social institutions. Goods and services are seen as flowing through personalized networks that create the institutions for expanding economic transactions. Greif (2006), for example, argues that the social networks of medieval Europe provided the frameworks for an emergent modern economy. Almost self-evident to anthropologists, such conclusions suggest how economic theory can gain from insights from comparative empirical studies of non-industrial political forms.

Political sectors mobilize and allocate goods to finance regional and interregional institutions of domination and stratification (Earle 2002). Importantly, political economies are not universal. From the fourth millennium bc, the political sector of the economy developed along with chiefdoms and then states. Goods became mobilized as a tax or tribute and then 'redistributed' by dominant political organizations as means to finance their activities. Recent archaeology has studied how political sectors were developed and functioned. An inherent contrast is between staple finance and wealth finance. In staple finance, food goods are mobilized and stored centrally as a means to support craftsmen, warriors and labourers working for the state. Many of these systems, especially in chiefdoms but also some states, functioned with few or no markets. Subsistence and social sectors continued largely unchanged, but new patterns of land ownership and domination required the production of a surplus for ruling institutions. Wealth finance worked similarly, but the local surplus was used to support the production of wealth for tribute payments.

And what about the market sector, so fundamental to most economic theorizing? Archaeological evidence documents that exchange and markets were not universal. From case to case, the amount and types of goods exchanged varied greatly according to specific conditions of availability and production costs and to specific objects of value. Based on ethnographic analogies, until quite recently most of the goods traded were probably handled by down-the-line exchanges between social partners. Goods moving any distance were primarily primitive valuables, items of display and tribute. The extent of exchange in Neolithic and later Bronze Age communities, for example, has been discussed for Europe, where the comparative advantage of one region over another would have been based on the availability of special materials (Sherratt 1997). Subsistence and technological items were rarely exchanged over long distances until the end of the medieval

age. Earlier, some market exchange certainly existed, but their extent and elaboration were apparently quite small.

This empirical record from economic anthropology contests economic theories based on asserted long-term trends in the emergence of marketing. A common assumption among economists from Adam Smith onwards has been that the creation of wealth is an outcome of the development of efficiencies associated with specialization and trade. For example, in his analysis of institutional economics, North (1990) argues that states developed to lower transaction costs between locally specialized but political independent regions. To simplify the logic, technological development and specialization should have created increasing productive economies that, with the emergence of integrating political systems to guarantee the peace of the market, would generate the surplus used to support the growth of civilizations.

The development of markets, however, was quite late and episodic. Following North, economics might suggest that such failure of markets to develop was an outcome of high transaction costs that made exchange unprofitable. Empirically such a conclusion, however, can be shown to be wrong. As political superstructures were developed and imposed broad regional peace that would have radically lowered transactions costs, markets surprisingly did not emerge. The reason appears to be linked to the nature of finance. When finance was based on staples, markets were only rudimentary and peripheral. The complex Hawaiian chiefdoms, for example, conquered and integrated several islands with local specialties in food, stone and other materials, but trade remained very small-scale and local despite the regional peace. Archaeology has documented only minor trade in basaltic adzes and obsidian in Hawaiian prehistory, and these exchanges did not increase with the formation of the large-scale chiefdoms. As a dramatic example, the Inka empire conquered a massive territory that extended 3000 km up the spine of the Andes, imposed an effective regional peace across that territory, and constructed nearly 30,000 km of roads to integrate it. Although these actions would certainly have lowered transaction costs, the regional and distant movements of goods, like metal, ceramics, and foods, remained very limited and completely unchanged from the pre-imperial period (Earle 2002).

Both markets and currencies seem to have expanded in other circumstances where they were linked with wealth finance of states. In the Aztec empire, tribute to the state was in wealth objects like textiles that could be easily transported long distances, centrally stored, and then used as payment to those working for the state. But the use of wealth objects in payment required that the objects be convertible into the staple goods and other consumables desired by state personnel. The Aztec market system provided the mechanism for conversion and was apparently developed by the state (Brumfiel 1980). Afterwards, markets appear to have escaped from state sponsorship and control to take on many of the characterizations commonly associated with market systems.

What are the possibilities for a grand theory of economies? The relatively low status of historical and comparative studies within economics is not promising, but economics would do well to test theories claimed for generally applicability by looking closely at the anthropological literature. To the degree that economic models are used to design economic development in non-Western societies, the general relevance of the economic models must demonstrated. Using a uniform method of analysis, the economist Pryor (2005) has compared industrial economies and traditional (hunter-gatherer and agricultural) economies. His primary conclusions are startling, suggesting the advantages of such comparative analyses. All economies appear to consist of a small number of component parts, probably reflecting the processes and constraints involved in the production and movement of material goods. Economies are thus comparable. Furthermore, the factors that affect such variables as gross productivity or volume of exchange appear not to be determined by social structure but by the particular internal characteristics of the economy. Thus, Polanyi would appear to be wrong; economies are rather independent engines of essential processes. As recent work in economics has relaxed simplifying

assumptions about information, frictionless trade, and anonymity of markets, the potential links between economics and economic anthropology take on reciprocal value.

Economic Calculation in Socialist Countries

Michael Ellman

Abstract

In the 1930s, when the classical socialist system emerged, economic decisions were based not on detailed and precise economic methods of calculation but on rough and ready political methods. An important method of economic calculation – particularly in the post-Stalin period – was that of incrementalism. Input norms were a very important method of both inter-industry and consumption planning.

Material balances, and later input–output, were also widely used. Project evaluation, linear programming, comparisons with the West, and economic intuition were other methods used. The influence of methods of economic calculation on economic outcomes should not be exaggerated.

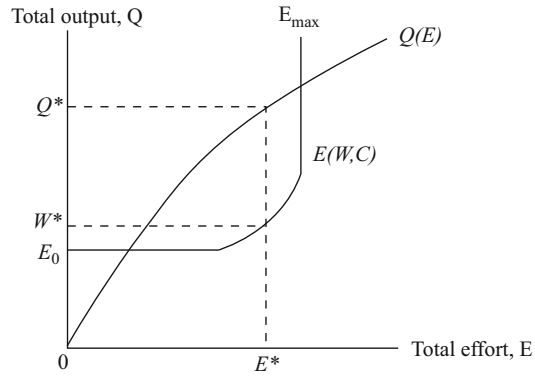
Economic Calculation and Political Decisions

An important result of the archival revolution of the 1990s (that is, the access to former Soviet archives made possible by the collapse of the USSR) was the additional knowledge it provided about economic decision-making in the USSR in the Stalin period. This made it clear that in the 1930s, when the socialist economic system emerged, economic decisions were based not on detailed and precise economic methods of calculation but on rough and ready political methods. Interesting light has been thrown on the significance of this for macroeconomic, mesoeconomic and microeconomic decision making.



Economic Calculation in Socialist Countries, Fig. 1 Maximizing the investible surplus (*Source*: Adapted from Gregory and Harrison 2005, p. 732)

Macroeconomic policy in the Stalin era aimed to maximize investment subject to the need to provide sufficient consumer goods (mainly food) to maintain labour productivity. The consumer goods were obtained from agriculture by force and allocated by the state in a way which it was hoped would enable investment to be maximized. A schematic representation of short-term macroeconomic calculation under these circumstances is set out in Fig. 1.

Figure 1 shows an output curve OQ which depends on the effort the workers provide, and an effort curve E_oE_{max} which depends on the real wage and the level of coercion. If the state chooses too low a level of wages, output will decline and the intended investment level will be impossible to meet. If wages are set at the fair wage level, output will be maximized but investment less than desired. At the wage level W^*, investment will be maximized. Hence, macroeconomic calculation involved gathering information about worker attitudes (via the state security organizations), allocating the available food to crucial groups of workers, and using coercive or ideological methods to reduce the food–output ratio.

Mesopolicy aimed at developing heavy industry and the defence sector. An important result was what has been termed the 'structural militarization' of the Soviet economy. This resulted from the Soviet view of international relations, the stress on mobilization planning, the lessons

of 1941, and the use by the general staff of absurdly inflated estimates of the mobilization capacity of the USA and other countries. An example is the USSR's capacity at the end of the 1980s to produce about four million tons of aluminium annually. This was greatly in excess of the peacetime economy's need for aluminium. However, in the event of mobilization it would have enabled the country to produce huge numbers of military airplanes. This situation arose as a result of using as a method of economic calculation the attainment of Western levels and of these levels in the military sphere being systematically exaggerated.

On the microeconomic level, Lazarev and Gregory (2003) have studied the allocation of motor vehicles (cars/autos and lorries/trucks) from the central reserve fund in 1932 and 1933. This showed that an economic planning model was unable to explain their allocation (in the regressions the economic variables were insignificant and frequently had the wrong signs). But a political model, in which their allocation was explained as part of a gift-exchange process, explained the data quite well.

Incrementalism

A basic method of economic calculation used in the state socialist countries – particularly in the post-Stalin period – was that of incrementalism, or, as it was known in the USSR, 'planning from the achieved level'. The starting point of all economic plans was the actual or expected outcome of the previous period. The planners adjusted this by reference to anticipated growth rates, current economic policy, shortages and technical progress. For nearly all products, the planned output for next year was the anticipated output for this year plus a few per cent added on. The advantages of incrementalism as a method of economic calculation were its simplicity, realism and compatibility with the functioning of a hierarchical bureaucracy. Its disadvantages were that it provided no method for making technically efficient or consistent decisions, nor did it ensure that the population derived maximum satisfaction from the resources available.

Planning and Counter-Planning

A widely used method of economic calculation was that of planning and counter-planning. If the plan were simply handed down to the enterprises from above, in accordance with the planners' view of national economic requirements but in ignorance of the real possibilities of each enterprise, then it would be unfeasible (if it was too high) or wasteful (if it was too low) or both at the same time (that is, unfeasible for some products and wasteful for others). Conversely, if plans were simply drawn up by each enterprise, they might have failed to use resources in accordance with national economic requirements. The process of planning and counter-planning involved a mutual submission and discussion of planning suggestions, designed to lead to the adoption of a plan which was feasible for the enterprise and ensured that the resources of each enterprise were used in accordance with national requirements.

Unfortunately, the bureaucratic complexity of this procedure militated against both efficiency and consistency.

Input Norms

The main method of economic calculation used to ensure efficiency was that of input norms. An input norm is simply a number assumed to describe an efficient process of transformation of inputs into outputs. For example, suppose that the norm for the utilization of coal in the production of one ton of steel is x tons. Then the efficient production of z tons of steel is assumed to require zx tons of coal.

The method of norms was widely used in Soviet planning, and considerable effort was devoted to updating them. Very detailed norm fixing took place for expenditures of fuel and energy. Much attention was devoted to the development of norms for the expenditure of metal,

cement, and timber in construction. All this work was directed by the department of norms and normatives of Gosplan (the State Planning Commission). Responsibility for elaborating and improving the norms lay with Gosplan's Scientific Research Institute of Planning and Norms.

Nevertheless, the method of norms was incapable of ensuring efficiency. The norms used in planning calculations were simply averages of input requirements, weighted somewhat in favour of efficient producers. Actual technologies showed a wide dispersion in input–output relations. Furthermore, given norms took no account of the possibilities of substitution of inputs for one another in the production process, non-constant returns to scale, and the results of technical progress. Thus in general, the method of norms did not make it possible to calculate efficient input requirements, and plans calculated in this way were always inefficient.

The method of norms was used not only in inter-industry planning but also in consumption planning. In calculating the volume of particular consumer goods and services required, the planners used two main methods. One was forecasts of consumer behaviour, based on extrapolation, expenditure patterns of higher-income groups, income and price elasticities of demand, and consumer behaviour in the more advanced countries. The other method was that of consumption norms. The former method attempted to foresee consumer demand, the latter to shape it.

An example of the method of norms, and its policy implications, is set out in Table 1.

Table 1 makes clear the logic of the Soviet policy in the Brezhnev era (1964–82) of expanding the livestock sector, and also importing fodder and livestock products. Since the consumption of livestock products was below the norm level, the government sought to make possible an increase in their consumption.

The method of consumption norms was an alternative to the price mechanism for the determination of output. It has also been used, however, in Western countries. It is used there in those cases where distribution on the basis of purchasing power has been replaced by distribution on the basis of need. Examples include the provision of housing, hospitals, schools and parks. Calculations of the desirable number of rooms, hospital beds and school places per person are a familiar tool of planning in welfare states.

Economic Calculation in Socialist Countries, Table 1 The soviet diet

	Norm (kgs/head/year)	Per capita consumption in 1976 as % of norm
Bread and bread products	120	128
Potatoes	97	123
Vegetables and melons	37	59
Vegetable oil and margarine	7	85
Meat and meat products	82	68
Fish and fish products	18	101
Milk and milk products	434	78
Eggs	17	72

Sources: Weitzman (1974), Agababyan and Yakovleva (1979, p. 142)

There are two main problems with the norm method of consumption planning. The first is that of substitution between products. Although consumers may well have a medically necessary need for x grams of protein per day, they can obtain these proteins from a wide variety of foods. Second, consumers may choose to spend their money 'irrationally', for example, to buy spirits instead of children's shoes.

Material Balances

A material balance is a balance sheet for a particular commodity showing, on the one hand, the economy's resources and potential output, and, on the other, the economy's need for a particular product. Material (and labour) balances were the main methods used in calculating production and distribution plans for goods, supply plans and labour plans. Soviet planners took great pride in the balance method and considered it one of the greatest achievements of planning theory and practice. Material balances were drawn up for different periods (for example, for annual or five

year periods), by different organizations (for example, Gosplan, Gossnab – the body responsible for allocating supplies of inputs – and the ministries) and at different levels (for example, national and republican). The material balances were also drawn up with different degrees of aggregation. Highly aggregated balances were drawn up for the Five Year Plans, and highly disaggregated balances by the chief administrations of Gossnab for annual supply planning. The aim of the material balance method was to ensure the consistency of the plans.

Normally, at the start of the planning work, the anticipated availability of a commodity was not sufficient to meet anticipated requirements. To balance the two, the planners sought possibilities of economizing on scarce products and substituting for scarce materials; they investigated the possibilities of increasing production or importing raw materials or equipment, or in the last resort they determined the priority needs to be fulfilled by the scarce commodity. Even with great efforts, achieving a balance was difficult. The complexity of an economy in which a great variety of goods are produced by different processes, all of which are subject to continuous technological change, was often too great for anything more than a balance that balanced only on paper. Hence it was normal, during the 'planned' period, for the plan to be altered, often repeatedly, as imbalances came to light. Particularly important problems with the use of material balances were the highly aggregated nature of the balances and their interrelated nature.

Input–Output

A wide variety of input–output tables were regularly constructed in socialist countries. *Ex post* national tables in value terms, planning national tables in value and physical terms, regional tables, and capital stock matrices were widely constructed and used. An interesting and important use concerned variant calculations of the structure of production in medium-term planning.

Because an input–output table can be represented by a simple mathematical model, and because of the assumption of constant coefficients, an input–output table can be utilized for variant calculations.

$$X = (I - A)^{-1} Y$$

On the assumption that A is given, X can be calculated for varying values of Y. Variant calculations of the structure of production were not undertaken with material balances because of their great labour intensity. Variant calculations played a useful role in medium-term planning because they enabled the planners to experiment with a wide range of possibilities. The first major use of variant calculations of the structure of production in Soviet national economic planning was in connection with the 1966–70 Five Year Plan. Gosplan's economic research institute analysed the results of various possible shares of investment in the national income for 1966–70. It became clear that stepping up the share of investment in the national income would increase the rate of growth of the national income, but that this would have very little effect on the rate of growth of consumption (because almost all of the increased output would be producer goods). The results of the calculations are set out in Tables 2 and 3.

Economic Calculation in Socialist Countries, Table 2 Output of steel on various assumptions

	Variants				
	I	II	III	IV	V
Production of steel in 1970 (millions of tonnes)	109	115	121	128	136

Economic Calculation in Socialist Countries, Table 3 Average annual growth rates of selected industries, 1966–1970 (%)

	Variants				
	I	II	III	IV	V
Engineering and metal working	7.1	8.2	9.3	10.4	11.4
Light industry	6.3	6.6	6.8	7.0	7.2
Food industry	7.1	7.3	7.4	7.5	7.6

Source: Ellman (1973, p. 71)

The five variants are for the share of investment in the national income, I being the lowest and V the highest. A sharp increase in the share of investment in the national income in the Five Year Plan 1966–70 would have led to a sharp fall in the share of consumption in the national income, and only a small increase in the rate of growth of consumption (within a Five Year Plan period). What is very sensitive to the share of investment in the national income is the output of the producer goods industries, as Tables 2 and 3 show.

These results are along the lines of what one would expect on the basis of Fel'dman's model, but the input–output technique improves on Fel'dman's model since it enables the effect of different strategies to be seen at the industry level rather than merely in terms of macroeconomic aggregates.

Another example of the use of input–output for economic calculations concerns the statistical data about the relations between industries contained in the national *ex post* tables in value terms. In his controversial 1968 book *Mezhotraslevye svyazi sel'skogo khozyaistva*, M. Lemeshev, then deputy head of the sector for forecasting the development of agriculture of the USSR Gosplan's Economic Research Institute, used the Soviet input–output table for 1959 as the basis for a powerful plea for more industrial inputs to be made available to agriculture.

He began by observing that from the 1959 input–output table it was clear that of the current material inputs into agriculture in that year only 23.4 per cent came from industry, while 54.7 per cent came from agriculture itself (feed, seed and so on). He argued that this was most unsatisfactory. In the section on the relationship between agriculture and engineering Lemeshev argued that the supply to agriculture of agricultural machinery was inadequate, in the section on the relationship between agriculture and the chemical industry he argued that the supply of fertilizers was inadequate, and in the section on agriculture and electricity he argued that the supply of electricity to the villages for both productive and unproductive needs was inadequate. In addition, in the section on the relationship between agriculture and the processing industry he argued that the latter was not helping agriculture as it should do; for example, it was sometimes impossible to accept vegetables (although the consumption of these in the towns was below the norms) because of inadequate processing and distribution facilities. Furthermore, he argued that the supply of concentrated feed was inadequate and the processing of milk wasteful. In view of the inadequate development of the food processing industry, he argued for the development of processing enterprises by the farms themselves.

The chapter on the productive relations between agriculture and the building industry was an extensive critique of the practice of productive, and of housing and communal, building in the villages. Lemeshev argued that the state should take on responsibility for building on the collective farms. The chapter on the relationship between agriculture and transport was critical of the shortage of river freight boats. The chapter on investment argued that investment in agriculture was inadequate, and that in the period 1959–65 there was an unwarranted increase in the proportion of investment in the collective farms which they had to finance themselves. He also argued that a greater proportion of agricultural investment should be financed by bank loans, and that as a criterion of investment efficiency the recoupment period was satisfactory. The concluding chapter was concerned with improving the productive relations between agriculture and the rest of the economy. The author argued for improving central planning by the use of input–output, for replacing procurement plans by free contracts between farms and the procurement organs (if a shortage of a particular product threatened then its price could be raised), and for the elimination of the supply system (that is, the rationing of producer goods) which hindered farms from receiving the goods they wanted and sometimes supplied them with goods that they did not want. Lemeshev also argued for higher pay in agriculture and for the reorganization of the labour process within state and collective farms on the basis of small groups which were paid by results.

This book was a good example of the use of input–output to provide statistical data which could be used, alongside other information, to

provide a description of important economic relations and to support a case for important institutional and policy changes.

Project Evaluation

In the USSR of the 1930s, it was officially considered that there was no problem of project evaluation to which economists could contribute. The sectoral allocation of investment was a matter for the central political leadership to decide. It was they who decided in which sectors and at which locations production should be expanded. These decisions were based on the experience of the more advanced countries, the traditions of the Russian state (for example, stress on railway building) and of the Bolshevik movement (for example, stress on electrification and on the metal-using industries) and on the needs of defence. As far as decisions within sectors were concerned, here the main idea was to fulfil the plan by using the world's most advanced technology.

The practical study of methods for choosing between variants within sectors was begun by engineers in the electricity and railway industries. The problem analysed was that of comparing the cost of alternative ways of meeting particular plan targets. A classic example of the type of problem considered was the choice between producing electricity by a hydro station and by a thermal station.

During Stalin's lifetime, the elaboration by orthodox economists and the adoption by the planners of economic criteria for project evaluation were impossible because they were outside Stalin's conception of the proper role of economists (apologetics). When economists did make a contribution in this area, as was done by Novozhilov, it was ignored. After Stalin's death, however, it became possible for Soviet economists to contribute to the elaboration of methods of economic calculation for use in the decision-making process. An early and important example was in the field of project evaluation. An official method for project evaluation was adopted in 1960, and revised versions in 1964, 1966, 1969 and 1981. In a very abbreviated and summary form, the 1981 version was as follows.

In evaluating investment projects, a wide variety of factors have to be taken into account, for example, the effect of the investment on labour productivity, capital productivity, consumption of current material inputs (such as metals and fuel), costs of production, environmental effects, technical progress, the location of economic activity and so on. Two indices which give useful synthetic information about economic efficiency (but are not necessarily decisive in choosing between investment projects) are the coefficient of absolute economic effectiveness and the coefficient of relative economic effectiveness.

At the national level, the coefficient of absolute effectiveness is defined as the incremental output–capital ratio.

$$E_p = \frac{\Delta Y}{I}$$

where E_p is the coefficient of absolute effectiveness for a particular project, ΔY is the increase in national income generated by the project, and I is the investment cost. The value of E_p calculated in this way for a particular investment has to be compared with E_a, the normative coefficient of absolute effectiveness, which is fixed for each Five Year Plan and varies between sectors. In the 11th Five Year Plan (1981–85) it was 0.16 in industry, 0.07 in agriculture, 0.05 in transport and communications, 0.22 in construction and 0.25 in trade.

$$\text{If } E_p > E_a$$

then the project is considered efficient.

For calculating the criterion of absolute effectiveness at the level of individual industries, net output is used in the numerator instead of national income. At the level of individual enterprises and associations, in particular when a firm's own money or bank loans are the source of finance, profit is used instead of national income.

The coefficient of relative effectiveness is used in the comparison of alternative ways of producing particular products. In the two products case

$$E = \frac{C_1 - C_2}{K_2 - K_1}$$

where E is the coefficient of relative effectiveness, C_i is the current cost of the ith variant, and K_i is the capital cost of the ith variant.

If E > En, where En is the officially established normative coefficient of relative economic efficiency, then the more capital intensive variant is economically justified. In the 11th Five Year Plan, En was in general 0.12, but exceptions were officially permitted in the range 0.08/0.10–0.20/0.25.

In the more than two variants case, they should be compared according to the formula

$$C_i + E_n K_i \rightarrow \text{minimum}$$

that is, choose that variant which minimizes the sum of current and capital costs.

At one time a rationalist misinterpretation of socialist planning was widespread. According to this view, a planned economy was one in which rational decisions were made after a dispassionate analysis by omniscient and all-powerful planners of all the alternative possibilities. In such a system, the adoption of rational criteria for project evaluation would have been of enormous importance. Socialist planning, however, was just one part of the social relations between individuals and groups in the course of which decisions were taken, all of which were imperfect and many of which produced results quite at variance with the intentions of the top economic and political leadership.

A good example of the factors actually influencing investment decisions under state socialism was the commencement of the construction of the Baoshan steel plant near Shanghai. The site was apparently chosen because of the political influence of a high-ranking Shanghai party official. The location decision ignored the fact that, because of the swampy nature of the site, necessitating large expenditures on the foundations, this was in fact the most expensive of the sites considered. Very expensive, dogged with cost overruns, involving major pollution problems, the whole project was kept alive for some time by a powerful steel lobby. In due course, as a result of a national policy reversal in Beijing, the second phase was deferred and those involved publicly criticized. To judge from its initial costs of production, it produced gold rather than steel.

In general, the choice of projects owed more to inter-organization bargaining in an environment characterized by investment hunger than it did to the detached choice of a cost-minimizing variant. The development of new and better criteria for project evaluation turned out to be no guarantee that project evaluation would improve since the criteria were often not in fact used to evaluate projects. Their main function was to provide an acceptable common language in which various bureaucratic agencies conducted their struggles. Agencies adopted projects on normal bureaucratic grounds and then tried to get them adopted by higher agencies, or defended them against attack, by presenting efficiency calculations using the official methodology but relying on carefully selected data.

Linear Programming and Extensions

Linear programming was discovered by the Soviet mathematician Kantorovich in the late 1930s. Its relevance for Soviet planning was widely discussed in the USSR in the 1960s and extensive efforts were made actually to use it in Soviet planning in the 1970s. Three examples of its use follow.

Production Scheduling in the Steel Industry

Linear programming was discovered by Kantorovich in the course of solving the problem, presented to him by the Laboratory of the all-Union Plywood Trust, of allocating productive tasks between machines in such a way as to maximize output given the assortment plan. From a mathematical point of view, the problem of optimal production scheduling for tube mills and rolling mills in the steel industry, which was tackled by Kantorovich in the 1960s, is very similar to the Plywood Trust problem, the difference being its huge dimensions.

The problem arose in the following way. As part of the planning of supply, Soyuzglavmetal (the department of Gossnab concerned with the metal industries), after the quotas had been specified, had to work out production schedules and attachment plans in such a way that all the orders were satisfied and none of the producers received an impossible plan. In the 1960s an extensive research programme was initiated by the department of mathematical economics (which was headed by Academician Kantorovich) of the Institute of Mathematics of the Siberian branch of the Academy of Sciences, to apply optimizing methods to this problem. The chief difficulties were the huge dimensions of the problem and the lack of the necessary data. About 1,000,000 orders, involving 60,000 users, more than 500 producers and tens of thousands of products, were issued each year for rolled metal. Formulated as a linear programming problem it had more than a million unknowns and 30,000 constraints. Collecting the necessary data took about six years. Optimal production scheduling was first applied to the tube mills producing tubes for gas pipelines (these were a scarce commodity in the USSR). In 1970 this made possible an output of tubes 108,000 tons greater than it would otherwise have been, and a substantial reduction in transport costs was also achieved.

The introduction of optimal production scheduling into the work of Soyuzglavmetal was only part of the work initiated in the late 1960s on creating a management information and control system in the steel industry. This was intended to be an integrated computer system which would embrace the determination of requirements, production scheduling, stock control, the distribution of output and accounting. Such systems were widely introduced in Western steel firms in the late 1960s. Work on the introduction of management information and control systems in the Soviet economy was widespread in the 1970s, but by the 1980s there was widespread scepticism in the USSR about their usefulness. This largely resulted from the failure to fulfil the earlier exaggerated hopes about the returns to be obtained from their introduction in the economy.

Industry Investment Plans

In the state socialist countries investment plans were worked out for the country as a whole, and also for industries, ministries, departments, associations, enterprises, republics, economic regions and cities. An important level of investment planning was the industry. Industry investment planning is concerned with such problems as the choice of products, of plants to be expanded, location of new plants, technology to be used, and sources of raw materials.

The main method used in the 1970s and 1980s in the Council for Mutual Economic Assistance (CMEA, known in the West as Comecon) countries for processing the data relating to possible investment plans into actual investment plans was mathematical programming. After extensive experience in this field, in 1977 a Standard Methodology for doing such calculations was adopted by the Presidium of the USSR Academy of Sciences.

The Soviet Standard Methodology presented models for three standard problems. They were: a static multi-product production problem with discrete variables, a multi-product dynamic production problem with discrete variables, and a multi-product static problem of the production-transport type with discrete variables.

The former can be set out as follows:

Let i = 1, ... , n be the finished goods or resources, j = 1,... , m be the production units, r = 1, . . . , Rj be the production technique in a unit, a_{ij}^r be the output of good I = 1 , . . . , n′ or input of resource i = n′ + 1 , . . . , n, using technique r of production in unit j; C_j^r are the costs of production using technique r in unit j; D_i is the given level of output of good i, $I = 1 , . . . , n'$; Pi is the total use of resource i, $i = n' + 1 , . . . , n$ allocated to the industry; Z_j^r is the unknown intensity of use of technique r at unit j.

The problem is to find values of the variables Z_j^r that minimize the objective function

$$\sum_{j=1}^{m} \sum_{j=1}^{R_j} C_j^r Z_j^r \qquad (1)$$

that is, minimize costs of production subject to

$$\sum_{j=1}^{m} \sum_{r=1}^{R_j} a_{ij}^r Z_j^r \geq D_i, \quad i = 1, ..., n' \qquad (2)$$

that is, each output must be produced in at least the required quantities

$$\sum_{j=1}^{m} \sum_{r=1}^{R_j} a_{ij}^r Z_j^r \leq p_i, \quad i = n' + 1, ..., n \qquad (3)$$

that is, the total use of resources cannot exceed the level allocated to the branch

$$\sum_{r=1}^{R_j} Z_j^r \leq 1, j = 1, ..., m \qquad (4)$$

$$Z_j^r = 0 \text{ or } 1, j = 1, ..., m, r = 1, ..., R_j \qquad (5)$$

that is, either a single technique of production for unit j is included in the plan or unit j is not included in the plan.

In order to illustrate the method, an example will be given which is taken from the Hungarian experience of the 1950s in working out an investment plan for the cotton weaving industry for the 1961–65 Five Year Plan. The method of working out the plan can be presented schematically by looking at the decision problems, the constraints, the objective function and the results.

The decision problems to be resolved were:

(a) How should the output of fabrics be increased, by modernizing the existing weaving mills or by building new ones?
(b) For part of the existing machinery, there were three possibilities. It could be operated in its existing form, modernized by way of alterations or supplementary investments, or else scrapped. Which should be chosen?
(c) For the other part of the existing machinery, it could be either retained or scrapped. What should be done?
(d) If new machines are purchased, a choice has to be made between many types. Which types should be chosen, and how many of a particular type should be purchased?

The constraints consisted of the output plan for cloth, the investment fund, the hard currency quota, the building quota and the material balances for various kinds of yarn. The objective function was to meet the given plan at minimum cost.

The results provided answers to all the decision problems. An important feature of the results was the conclusion that it was cheaper to increase production by modernizing and expanding existing mills than by building new ones.

It would clearly be unsatisfactory to optimize the investment plan of each industry taken in isolation. If the calculations show that it is possible to reduce the inputs into a particular industry below those originally envisaged, then it is desirable to reduce planned outputs in other industries, or increase the planned output of the industry in question, or adopt some combination of these strategies. Accordingly, the experiments in working out optimal industry investment plans, begun in Hungary in the 1950s, led to the construction of multi-level plans linking the optimal plans of the separate industries to each other and to the macroeconomic plan variables. Multilevel planning of this type was first developed in Hungary, but subsequently spread to the other CMEA countries. Extensive work on the multi-level optimization of investment planning was undertaken in the USSR in connection with the 1976–90 long-term plan. (The 1976–90 plan, like all previous Soviet attempts to compile a long-term plan, was soon overtaken by events. The plan itself seems never to have been finished and was replaced by ten-year guidelines for 1981–90.)

The Determination of Costs in the Resource Sector

In view of the wide dispersion of production costs in the resource sector, the use of average costs (and of prices based on average costs) in allocation decisions is likely to lead to serious waste. An important outcome of the work of Kantorovich and his school for practical policy was (after a

long lag) official acceptance of this proposition and of linear programming as a way of calculating the relevant marginal costs. For example, in 1979 in the USSR the State Committee for Science and Technology and the State Committee for Prices jointly approved an official method for the economic evaluation of raw material deposits. This was a prescribed method for the economic evaluation of exploration and development of raw material deposits. What was new in principle about this document was that it permitted the output derived from the deposits to be evaluated either in actual (or forecast) wholesale prices or in marginal costs. For the fuel-energy sector, a lot of work was done to calculate actual (and forecast) marginal costs for each fuel at different locations throughout the country and for different periods. These figures were regularly calculated on optimizing models (they were the dual variables to the output maximizing primal) and were widely used in planning practice for many years.

Comparison with the West

An important method of economic calculation in socialist countries was comparison with the West. If a particular product or method of production had already been introduced (or phased out) in the West, this was generally considered a good argument to introduce it (or phase it out) in the socialist countries, subject to national priorities and economic feasibility. Obtaining advanced technology from abroad (by purchase, Lend-Lease, reparations, espionage, direct investment) was an integral part of socialist planning, the importance of the different elements varying over time. Comparisons with the West were particularly important in an economic system which lagged behind the leading countries, lacked institutions which automatically introduced innovations into production (that is, profit-seeking business firms), and found it difficult (because of the ignorance of the planners, stable cost-plus prices and the self-interest of rival bureaucratic agencies) to notice, appraise realistically when noticed, and adopt, innovations.

Economic Calculation and Economic Results

It is important not to exaggerate the influence of methods of economic calculation on the performance of an economy. The performance of an economy is largely determined by external factors (such as the world market), economic policy (for example, the decision to import foreign capital or to declare a moratorium), economic institutions (like collective farms) and the behaviour of the actors within the system (for example, underestimation of investment costs by initiators of investment projects). It is entirely possible for an improvement in the methods of economic calculation to coincide with a worsening of economic performance (as happened in the USSR in the Brezhnev period). Realization of these facts led in the 1970s to a shift from the traditional normative approach (which concentrates on the methods of economic calculation and which regards their improvement as the main key to improved economic performance and the main role of the economist) in the study of planned economies, to the systems and behavioural approaches.

Economic Calculation and Economic Intuition

In view of bounded rationality, and the huge volume, and distorted nature, of the information available to the central leadership, really existing decision-making relied heavily on rules of thumb and the 'feel' for reality of the top decision-makers (sometimes known as 'planning by feel'). This could quickly lead to an equilibrium, but an inefficient one.

Economic Consequences of Weather, The

Jordan Rappaport

Abstract

Households in the United States and a number of other wealthy nations have been migrating to places with nice weather. This likely reflects an increase in the relative valuation of the weather's direct contribution to household utility. Several different amenity explanations are discussed that can account for the increased valuation and ongoing move.

Introduction

> A cloudy day or a little sunshine have as great an influence on many constitutions as the most recent blessings or misfortunes.
> Joseph Addison (1672–1719), English essayist, poet and politician

> Don't knock the weather. If it didn't change once in a while, nine out of ten people couldn't start a conversation.
> Kin Hubbard (1868–1930) American cartoonist, humorist and journalist

It is hard to find a research subject more important than the weather. From ice ages to epic floods to endless droughts to malarial heat to the present warming of the earth, human welfare has always depended closely on it. Less awe-inspiring but also important is that weather is a direct source of significant consumption. Nice weather underpins the enjoyment of most outdoor activities from picnics to sports games to beach days, to an infinite set of other possibilities. The discussion that follows will focus primarily on this latter, consumption dimension of weather. While such a focus may seem shallow in the face of the significant challenges weather poses to humanity, those challenges do not negate the fact that normal weather variations – the sorts that have been experienced year after year by current and recent generations – continue to be a large source of consumption benefits.

The discussion below will argue that rising incomes in the United States and other developed nations have increased households' willingness to pay to live in a place with nice weather. As a result there has been a shift in population towards such places. Before we consider this consumption dimension of weather, however, a brief discussion of the weather's day-to-day contribution to production is warranted.

Weather as a Production Amenity

Agriculture is the industry that most obviously depends on weather as a productive input. This dependence is multidimensional in the sense that temperature, humidity, cloud cover and rainfall – each over the entire growing season – all matter. A large enough deviation by just one of these can be sufficient to seriously impair yields. To be sure, advancing agricultural science has allowed crops to thrive in a wider range of weather conditions. But even loosened, the constraints imposed by weather remain significant.

Of course, different agricultural goods thrive in different weather. But abstracting from heterogeneity, it is easy to see that farmland in places with weather most conducive to growing will be valued especially highly. Farmers, assumed to be mobile across locations, will bid up the price of productive farmland until the weather's expected contribution to profits becomes fully capitalized into land values. The higher productivity of farms in ideal-weather locations simultaneously makes it possible to pay workers there relatively high wages while still attaining the profits that could be made elsewhere. Note that the farm workers in such high productivity locations are not necessarily any better off than mobile farm workers elsewhere. General equilibrium considerations imply that their higher wages will be offset by higher prices for non-traded goods such as housing.

As with agriculture, the weather serves as a productive input into numerous industrial processes. Gunpowder, macaroni, tobacco, gum and chocolate are among the many products whose production requires constant, low humidity. Inside weather conditions are thus an extremely important productive input. Of course, in present-day developed countries, inside and outside weather are typically disconnected. But prior to air conditioning and central heating, inside weather depended closely on outside weather. Thus Oi (1997) argues that the spread of workplace air conditioning underpinned the rise of manufacturing in the south of the United States.

Nice weather also turns out to be empirically correlated with very-short-term stock market returns (Saunders 1993; Hirshleifer and Shumway 2003). Specifically, daily measures of sunshine in cities that host major stock exchanges are positively correlated with daily returns on those exchanges. In this case, weather's contribution is potentially productive only for day traders with very low transaction costs. The hypothesized mechanism is that nice weather uplifts traders' mood and optimism. Such a mechanism has much more the flavour of a consumption amenity than a productive one.

Weather as a Consumption Amenity

Just as weather's contribution to production puts upward pressure on the price of land and of

housing, so too does its direct contribution to household utility. But as a consumption amenity, weather puts downward pressure on wages rather than upward pressure.

The expected correlations from weather's role as a production amenity and as a consumption amenity derive from the compensating differential framework (Rosen 1979; Roback 1982). An economy is assumed to be made up of a number of geographically distinct labour markets where households live and work and firms produce. The labour market locations may differ from one another with respect to numerous exogenous production and consumption amenities such as proximity to navigable water, access to natural resources, low risk of natural disasters, and – in a multidimensional sense – the weather. Production and consumption amenities may also be endogenous, for instance if increasing returns to scale lower input costs or expand the variety of consumer goods. The assumed high mobility of firms implies that they must be at least as profitable in their present location as they would be anywhere else. The assumed high mobility of households implies that they must derive at least as much utility in their present location as they would anywhere else.

The key to the compensating differential framework is that prices – in particular for land, labour and housing services – adjust to equate profits and utility across the numerous locations. In locations with high production amenities, firms are willing to pay higher prices for inputs, including for labour. These higher input prices are required to lower what would otherwise be higher profits than could be achieved from locating elsewhere. Similarly, in locations with high consumption amenities, households are willing to accept lower wages and pay a higher price for housing services. Such households thus trade off lower tangible consumption of market goods for higher intangible consumption of amenities.

The empirical implementation of this model typically focuses exclusively on households and consumption amenities rather than firms and production amenities. The reason is the difficulty of observing the full range of firm input prices. Notable exceptions include Gabriel and Rosenthal (2004) and Chen and Rosenthal (2008), which treat housing service prices as a proxy for non-labour input prices.

For households, the most common empirical methodology is to separately regress micro data of household income and a proxy for housing service price on respective vectors of attributes meant to control for differences in human capital and differences in the quantity and quality of housing services. The residuals from these regressions can then be regressed on location-specific attributes, including weather. Summing the extra annual housing service cost implied by a coefficient on a locational attribute in the housing regression with the lost income implied by the coefficient on the same locational attribute in the income regression gives the marginal consumption that a household forgoes to obtain a small increase in that local attribute.

Estimated compensating differentials for weather attributes from implementing this methodology tend to be extremely large. For example, the valuation per representative household for one extra sunny day over the course of a year is somewhere from US$21 (at 2005 prices) to $36. The midpoint of this estimated range implies an aggregate valuation of $57 million per year for a metropolitan area with a population of 2 million. Over 30 years using a three per cent discount rate, the implied net present value is $560 million. Whether households really require such a huge transfer to accept just a single extra cloudy day per year seems questionable. Other estimated weather valuations include one less rainy day over the course of a year, $36 per household; one less inch of precipitation, $-63 to $37 per household; and one inch less snow per year, $33 per household (Blomquist et al. 1988; Gyourko and Tracy 1991; Stover and Leven 1992).

Heterogeneity of household preferences suggests that these estimates may understate the consumption benefits from weather. With heterogeneity, it is no longer necessary that all households be indifferent about where to live. The distribution of wages and house prices across locations that clears the labour, traded goods, and housing markets will be driven in large part by 'marginal' households, who tend to value

consumption amenities by less than average. 'Inframarginal' households, in contrast, tend to value at least some consumption amenities highly. In order to live in a location where such amenities are abundant, inframarginal households are willing to accept a lower wage and pay a higher housing-service price than is actually required. Hence they enjoy a surplus that is missed by the compensating valuations above.

An even bigger empirical challenge to valuing weather and other consumption amenities is the difficulty of controlling for individual-specific and house-specific characteristics. A low wage may represent compensation for amenities, but it also may represent low human capital. A high expenditure on housing may compensate for high amenities, but it also may reflect a high quality and quantity of housing services being purchased. The characteristics typically used as controls when estimating the wage compensation include age, experience, education, sex, industry and occupation. For estimating the house price compensation, typical controls include rooms, bedrooms, units in structure, and appliances. These sets of attributes miss substantial sources of individual and housing-unit variation. Probably most important for present purposes is the difficulty of distinguishing between high amenities and low human capital. The sorting of human capital across metro areas suggests that unobserved human capital characteristics may be correlated with the weather. The consequences of not sufficiently controlling for individual and housing service characteristics are evident in quality-of-life rankings of metro areas based on compensating differentials, which tend to contrast sharply with subjective rankings (Rappaport 2008).

A complementary 'quantity' approach to the compensating differential literature's 'price' approach explicitly models population, capital inputs, land and housing supply. As is intuitive, high levels of consumption amenities attract households to a location, resulting in higher population and population density. (Henceforth, I shall make no distinction between the level of population and its density.) The higher population in turn supports the higher housing prices and lower wages of the compensating equilibrium (Haurin 1980; Rappaport 2008).

The seemingly obvious empirical implication of the quantity approach is to regress a cross-section of local population on exogenous local attributes such as the weather to infer whether such attributes are an amenity (with respect to either production or consumption). However, the extremely high persistence of local population implies that the correlation of population with an attribute might reflect an amenity contribution in the distant past that no longer exists. Instead, a crosssection of population growth rates can be regressed on the exogenous attributes. The resulting coefficients can be interpreted as reflecting the accumulation of past changes of the attributes' amenity contributions (Mueser and Graves 1995; Rappaport 2007). In other words, a positive partial correlation between population growth and a particular attribute suggests that the attribute's amenity contribution increased – becoming either more positive or less negative – in the intermediate past. The high persistence of population growth in the United States suggests that the 'intermediate past' probably reaches back at least several decades (Greenwood et al. 1991; Rappaport 2004; Glaeser and Gyourko 2005).

Empirically implementing the quantity approach establishes that population growth in the United States has been highly correlated with nice weather. Growth has been fastest where winters and summers are mild and the number of rainy days is moderate. The quantitatively strongest relationship, robust to numerous controls, is a positive quadratic correlation of growth with winter temperature. For the period 1970 to 2000, increasing January temperature from one standard deviation below its sample mean to one standard deviation above its sample mean (from 29 °F to 54 °F) is associated with faster growth of 1.3 per cent per year for US counties (Rappaport 2007). Miami's temperature in January implies expected annual growth that is 3.4 per cent faster than that of US counties with mean January temperature. For comparison, the mean population growth rate of counties over this period was 0.9 per cent per year.

Population growth is negatively correlated with summer temperature and humidity (controlling for winter temperature, and robust to the inclusion of numerous other attributes). An increase in July heat index from one standard deviation below its sample mean to one standard deviation above its sample mean (from 87 °F to 109 °F) is associated with slower growth of 0.5 per cent per year. An increase in relative humidity from one standard deviation below its sample mean to one standard deviation above its sample mean (from 56 per cent to 75 per cent) is associated with slower growth of 0.9 per cent per year. Miami's temperature and humidity in July imply expected annual growth that is 0.7 per cent slower that that of counties with mean heat and humidity.

Finally, population growth is characterized by a negative quadratic partial relationship with the number of rainy days. Increasing the number of rainy days by one standard deviation (25 days) above the mean (94 days) leaves expected population growth essentially unchanged. But increasing rainy days by a second and then a third standard deviation slows growth by 0.3 percentage points and then an additional 0.6 percentage points. For Seattle, with an average of 182 rainy days per year, annual expected population growth is 1.3 percentage points lower than that of a location with mean annual precipitation.

The weather accounts for a very large share of the variation in local population growth rates. The four weather variables just discussed, entered linearly and quadratically, along with annual precipitation entered similarly, can account for 27 percent of the variation in US county population growth from 1970 to 2000. This is only slightly less than is accounted for by dummies for each US state. For metro areas, winter weather alone accounts for 44 percent of the variation in growth from 1950 to 2000.

Results similar to those above hold for a number of nations, for a number of geographies within them, and for a variety of time periods. Similar partial correlations of growth with weather characterize US metro area growth from 1950 to 1980 (Mueser and Graves 1995). In Europe, nice weather has been a major driver of population flows from 1980 to 2000 within countries although not across them (Cheshire and Magrini 2006). And net migration among Japanese prefectures from 1955 to 1990 was negatively correlated with a measure of extreme temperature (Barro and Sala-i-Martin 1995).

The partial correlations strongly suggest that the amenity value of nice weather increased beginning at some point in the intermediate past, via either consumption or production. If the former, such places became inherently more desirable as the marginal utility from nice weather rose relative to the marginal utility of private consumption. If the latter, nice-weather places became more desirable because firms there could pay relatively higher wages.

The quantity framework allows for numerous explanations, many complementary, of the empirical migration to nice weather places. The common element of these explanations is that they posit a change in the valuation of some aspect of weather's amenity contribution, or else a change in the valuation of an amenity correlated with weather. One such explanation is that the approximate sixfold rise in per capita income over the course of the 20th century lowered the marginal utility from the consumption of private goods and services and so increased the quantity of these that households were willing to forgo in order to live in a place with nice weather. Consistent with this consumption amenity explanation, Costa and Kahn (2003), using the compensating differential framework, estimate that a representative household's valuation of enjoying the weather of San Francisco rather than that of Chicago increased more than fivefold between 1970 and 1990.

This rising income explanation for the move to nice weather might intuitively, but incorrectly, be understood to depend on weather's being a luxury good. In fact, it depends only on there being sufficient complementarity between weather and private consumption in the household utility function. Even with a homothetic utility function over private consumption and weather, an increase in income requires a sufficient increase in the valuation of nice weather to dissuade people from moving. More specifically, if the elasticity of substitution between private consumption and weather is exactly 1 (Cobb Douglas), wages and

house service prices can adjust to maintain a spatial equilibrium without any population movement (Rappaport 2009). Essentially a rise in the compensating price of nice weather can exactly cancel an income-driven increase in demand for nice weather. But if instead the elasticity of substitution between weather and private consumption is less than 1, the incomedriven increase in demand is stronger and the larger required offsetting price increase can be supported only if more people move to nice-weather places, thereby driving up housing prices and driving down wages to their general equilibrium values. Conversely, an elasticity of substitution less than 1 will cause the increase in demand for nice weather from increasing incomes to be somewhat weaker. In this case, the required increase in the compensating price is too low to be sustained without some movement away from places with nice weather. Intuitively, a broad, tfp-based increase in wages across all locations can increase the utility cost from not being where wage rates are highest.

A first alternative amenity explanation, based on production, is that the shift to nice weather reflected the movement out of the agriculture and manufacturing sectors. As the share of the labour force employed in agriculture fell from 36 per cent in 1900 to 12 per cent in 1970 to 2 per cent in 2000, the productive amenity contribution of weather to the marginal product of labour averaged over all workers probably decreased greatly. Hence the valuation of weather attributes directly increasing utility *relative* to the valuation of weather attributes conducive to growing would have increased. More recently, as the manufacturing share of employment fell from 25 per cent in 1970 to 14 per cent in 2000, the opportunity cost of moving within the United States from places with perceived less nice weather has probably fallen. On reason is the concentration of heavy manufacturing in the US Midwest, in part due to the proximity of raw materials and notwithstanding winters that are colder and summers that are hotter than many US households desire.

While the declines of agriculture and manufacturing surely contributed to the move to nice weather, they are unlikely to be the main cause. The partial correlation of population growth with nice weather is mostly unaffected by the inclusion of extensive controls for agriculture and other industrial structure. Moreover, the largest part of the move out of agriculture was over by 1970, which is the start date for the growth correlations reported above. Conversely, the move to nice weather began in the 1920s, when manufacturing employment was still growing vigorously.

A second alternative amenity story, based on consumption, is that the move to nice weather reflected the increased mobility and prosperity of the elderly. Rather than the population as a whole, it was primarily the elderly who increased their valuation of nice weather as it became part of their locational choice set. The increase in choice set followed from numerous trends, including the passage of Social Security (pensions for the elderly), increased longevity, and falling transportation and communications costs. Certainly, some warm-weather states such as Florida and Arizona have attracted a disproportionate number of elderly residents from elsewhere. But the strength of the correlation of growth with nice weather is nearly the same for working-age individuals as it is for seniors. Moreover, the move to nice weather began long before the large increases in senior longevity and prosperity.

A third, related, amenity explanation is that for a broad swathe of the US population, mobility costs fell over the course of the 20th century. High moving costs allow for the possibility of rents for those residing in nice-weather places, with the negative compensating differential settling lower (in absolute value) than it would be with free mobility. To the extent that mobility increased – for example, due to falling transportation and communication costs – nice-weather places would have grown disproportionately fast until they reached their free-mobility equilibrium. While this explanation has intuitive appeal, the extent to which mobility increased is unclear. The state-to-state gross migration rate was approximately flat from 1947 to 1975, then fell slightly through 2000.

A fourth alternative consumption amenity explanation for the move to nice weather is that

it was caused by air conditioning. Air conditioning ameliorated the disamenity of hot and humid summer weather, which in turn is correlated with warm winter weather. Hence households no longer needed to be compensated as much to live in hot and humid places, which in turn should have caused a shift in population towards such places. Doubtless there is some truth to this hypothesis, as many of the US metropolitan areas that grew most rapidly from 1950 to 2000 have summer weather that would seem insufferable without air conditioning (for example, the daily high heat index in July for Austin, Texas averages 118 °F). However, the move to nice weather began decades before the widespread diffusion of air conditioning. Moreover, the negative partial correlation of population growth with summer heat and summer humidity is exactly the opposite of what air conditioning is expected to cause. Also tempering the air conditioning explanation is the extremely rapid growth of coastal southern California, where summer weather is relatively mild.

An alternative, nonamenity explanation argues that the correlation of population growth with nice weather is largely a coincidence. Glaeser and Tobio (2008) conclude that the post-war movement to places with nice weather arose from faster productivity growth in nice-weather places accompanied by a high elasticity of housing supply there. The latter was due to some combination of plentiful land and minimal government restrictions on building. The conclusion that weather was not an important driver of the population move to nice weather follows primarily from wage and house price compensating-differential regressions using data from the 1950 through 2000 decennial censuses. These regressions suggest that wages rose quicker but house prices rose slower in places with nice weather than elsewhere. Both of these comparative growth rates suggest that households' relative valuation of nice weather was decreasing over this period.

Certainly, the convergence of productivity in the US South to the national level was an important aspect of the rapid growth of many nice-weather places (Barro and Sala-i-Martin 1991, 1992; Caselli and Coleman 2001). But in the absence of any increase in amenity valuation, the relatively high density and congestion that have come to characterize many nice-weather cities would require productivity there to surpass its level elsewhere, not just converge to it.

Similarly, a relatively elastic housing supply is certainly a necessary condition for the rapid growth that was sustained over 50 years by a number of nice-weather metro areas. In the quantity model described above, the house supply elasticity governs the magnitude of the growth response to a change in amenities. But the impetus for the growth is solely the amenity change. Elastic housing supply, on its own, is not sufficient. Many sparsely populated and declining metro areas throughout the US Midwest and deep South also have plentiful land, light regulation, and in many cases an excess supply of existing buildings.

An additional consideration is the generic unreliability of the compensating differential methodology. The estimated rising wages by Glaeser and Tobio (2008) in nice-weather places may partly reflect an upgrading of unobserved human capital. The increase in the average skills of workers in such metro areas may have been faster than elsewhere. For example, workers who moved to nice-weather places may have had higher skills on average than the skills of workers who already lived there. And slower-than-expected house price growth might reflect that the (negative) compensation for nice weather is being paid, in part, by longer commutes, increased traffic, and other sorts of metro area congestion.

Conclusions

The conclusion that households are shifting towards places with nice weather, at least for the United States, is not very surprising. Indeed, the US business magazine *Forbes* parodied some of the research on the population shift to nice weather with the headline, 'Duh!' (Kellner 2004). Much more important is why households are doing so. The explanations above together suggest that rising incomes caused individuals to

sufficiently increase their valuation of weather as a consumption amenity so as to require a shift in population towards nice weather places. For the increase in valuation to be sufficiently large, weather must have been a complement to private consumption rather than a substitute. The shift towards nice weather was likely reinforced by the change in industrial composition away from agriculture and manufacturing, the increase in productivity throughout the southern United States, the spread of air conditioning, and the increasing mobility and financial security of seniors. Lastly, a high elasticity of housing supply in many nice-weather places implied that the population influxes required to support the increased valuation were quite large.

An important implication of the income result is that valuations of other local consumption amenities are likely to have increased as well. While local governments may be unable to affect their local weather, they may want to consider increasing the supply of other consumption amenities in its place.

A last question is whether the increasing valuation of nice weather and the shift in population towards it are likely to continue. Unambiguously, a continuing increase in income will cause a continuing increase in the valuation of nice weather. For the actual *movement* to nice weather to continue, the increase in valuation must be sufficiently large that it cannot be supported by the existing distribution of population across locations. With sufficient complementarity between weather and private consumption, theory suggests that the move can continue forever, though at a diminishing pace (Rappaport 2009). The increasingly swollen populations of many nice-weather places put downward pressure on their abilities to elastically supply housing and address other sorts of congestion. As housing supply becomes less elastic and other sources of congestion rise, a smaller increase in population can support a given required increase in compensation for local amenities. Consistent with a diminishing shift, decade-by-decade regressions indeed show that the move towards nice weather peaked in the 1970s, and then slowed in each of the 1980s and 1990s.

Economic Demography

Allen C. Kelley and Robert M. Schmidt

Abstract

Economic demography is an area of study that examines the determinants and consequences of demographic change, including fertility, mortality, marriage, divorce, location (urbanisation, migration, density), age, gender, ethnicity, population size and population growth. This article reviews and critically evaluates important macroeconomic dimensions of the 'population debates' between the 'optimists' and the 'pessimists' since 1950. It concludes with an examination of demography in the popular 'convergence' growth models of the 1990s.

Economic demography is an area of study that examines the determinants and consequences of demographic change, including fertility, mortality, marriage, divorce, location (urbanisation, migration, density), age, gender, ethnicity, population size, and population growth. An applied area of research, economic demography draws upon the theoretical and applied fields of economics. For example, the determinants of fertility or migration primarily draw upon microeconomic theory and labour economics, while the consequences of population growth or ageing primarily draw upon macroeconomic theory and development economics.

The field has had a long tradition of controversy, beginning with the publication in 1798 of *An Essay on the Principle of Population* by the Reverend Thomas Malthus. The basic Malthusian model is founded on two propositions: (*a*) population, *when unchecked*, increases at a geometric rate (for example, 1, 2, 4, 8…) and (*b*) food, in contrast, expands at an arithmetic rate (for example, 1, 2, 3, 4…). The result is a population trapped at a meagre standard of living. Short of 'preventive checks' (birth control), population is constrained to live at subsistence by 'positive

checks' (deaths, war, famines and pestilence). In later writings Malthus admitted the possibility of 'moral restraint' that could deter births, primarily through the postponement of marriage. However, he held little hope for a notable attenuation of the 'natural passions' of the working class.

While much of the controversy relating to Malthusianism has focused on the determinants of population growth, a second premise of his model relates to its economic underpinnings: the determinants of agricultural growth. Here Malthus appealed to the historical law of diminishing returns in agriculture. While this proposition engendered relatively little dispute at the time, history has since documented widespread and sometimes notable improvements in agricultural technology. Indeed, food production has represented an engine of growth in many of the areas that Malthus investigated. In some areas today, governments worry about 'excess' food production that depresses prices and farmers' living standards. Unfortunately, the pessimistic food-production predictions, when confronted by rapid population growth, caused economics to be dubbed the 'dismal science'.

The enormous popularity of the Malthusian ideas was the result of several factors: the model's simplicity and its explanation of poverty (the poor failed to exercise moral restraint, ending up with large families); the appeal of the message that subsidising the poor is of questionable efficacy; and the plausibility of the Malthusian argument given the unexpected 'population explosion' revealed by the 1801 census. These and other elements of the 'Malthusian debate' provide a useful taxonomy for organising the present article.

Specifically, we highlight the macroeconomic dimensions of the economic consequences of population growth since 1950. As with the early Malthusian debates, an assessment of the macroeconomic impacts of demographic change on economic production has resulted in an outpouring of research, which has spawned further debate. There are periods when vigorous Malthusian-like alarmism has carried the day; there are periods of counter-challenges; and, since the mid-1980s, there has been a productive 'revisionist' movement. In short, the simplistic Malthusian notion of diminishing returns in production has given way to more informed modelling of economic–demographic interactions. An assessment of the historical evolution of this literature will constitute the bulk of this review and appropriately delimits the scope of our essay since a wide range of important microeconomic themes are taken up in other articles in this dictionary (see ▶ "Fertility in Developing Countries," ▶ "Family Decision Making," ▶ "Marriage and Divorce," and ▶ "Retirement," and multiple articles dealing with the topics of gender, ageing and mortality).

We begin by examining population impacts in one-sector growth models. This leads nicely into a more detailed assessment of factor accumulation, and in particular, the impacts of demography on saving, investment and technological change. This is in turn followed by an analytical description of the evolution of economic–demographic thinking since 1950. Such a perspective exposes many of the key analytical and empirical linkages of interest. The article concludes with an examination of 'convergence modelling', a useful paradigm that exposes the roles of changing demographic structures that take place over the demographic transition.

Theory: Modelling Economic–Demographic Change

One-Sector Growth Models

The aggregate production function constitutes the primary organising device for delineating the impacts of demographic change on economic growth. Within this model, labour productivity depends on the availability of complementary factors of production (land, natural resources, human and physical capital) and technology. If we assume, for convenience, that labour is a constant fraction of population, then population size directly affects aggregate output.

In a production function with constant returns to scale, an increase in population growth will lower the average availability of other factors of production – a 'resource-shallowing' effect, and, through diminishing returns, reduce the growth of worker productivity. Such an adverse

demographic impact can be magnified (or attenuated) if population growth diminishes (raises) the growth rate of complementary factors.

In a standard growth model with factor inputs of labour and capital, and a saving rate and pace of technological change that are exogenous with respect to population growth, demography affects the long-run *level* but not the long-run *growth rate* of output per capita. This is because the capital-shallowing effect of increased population will eventually reduce the capital per worker ratio to a level sufficient to be maintained by a fixed rate of saving. In this case, long-run growth is determined by the pace of technological change. The determinants of the 'fixed' saving rate and pace of technology growth, both considered in more detail below, are central to the analysis.

If one relaxes some of the assumptions of this model, the impact of population growth on per capita output growth can be ambiguous. Negative impacts can arise through diminishing returns, diseconomies of scale, and perhaps savings, while positive impacts can arise through induced technological change, economies of scale, and possibly savings. Most economists believe that adverse capital-shallowing impacts will dominate positive feedback effects, although the magnitude of the demographic impacts may not be all that large.

Saving

Possibly the most investigated linkage of population growth to economic growth has been the impact of demographic change on saving. Two perspectives dominate.

Adult equivalency. Rapid (slow) rates of population growth result in a disproportionate number of children (elderly adults) who consume, but contribute relatively little to, household income. In recognising that these 'dependents' consume less than a working-age adult, the notion of an 'adult equivalent' consumer was born. The financing of an additional child's 'adult-equivalent' consumption has been hypothesised to be out of saving. Such a view, however, has been challenged by consideration of several offsetting alternatives. Specifically, children may (*a*) substitute for other forms of consumption, (*b*) contribute directly to household market and non-market income, (*c*) encourage parents to work more (or less), (*d*) stimulate the amassing (or reduction) of estates, and (*e*) encourage (or discourage) the accumulation of certain types of assets (for example, education or farm implements). The net impact of changing dependency rates on saving is therefore theoretically ambiguous. This is particularly the case if one views human capital as an investment financed in part by households and governments. At any rate, empirical evidence showing negative impacts of youth dependency on saving are found in several studies.

The life-cycle. A second population-saving linkage is based on a life-cycle formulation incorporated into a lifetime household utility function. Specifically, households attempt to even out their lifetime consumption by setting aside earnings during working years to finance consumption by their children as well as for their own retirement. This formulation can yield positive or negative impacts on aggregate saving depending on the relative sizes of the dissaving youth and elderly cohorts. While empirical evidence from life-cycle modelling is mixed, those studies do tend to show linkages between age structure and saving. However, the direction and magnitude of that impact depends upon time and place. (See, for example, Mason 1987; Higgins 1998; and Lee et al. 2001.)

Population-Sensitive Government Spending

Government spending on population-sensitive activities such as schooling (youth) and health (elderly) has been alleged both to reduce saving and to crowd out spending on relatively growth-oriented investments. These two hypotheses constitute the core of Ansley J. Coale and Edgar M. Hoover's (1958) path-breaking study of India. While these premises are appealing, they require qualification. Governments have many options to accommodate population pressures. Indeed, limited empirical evidence (for example, Schultz 1987) has shown that education financing can be met all or in part by (*a*) trade-offs within the public sector, (*b*) reductions in per pupil expenditures, and (*c*) efficiency gains. While the second approach can be expected to reduce the quality of

education (and therefore future productivity), the importance of population pressures on government spending or educational quality is uncertain.

Technological Change: Density, Size and Endogenous Growth

While development economists have for decades harkened the pace of technological change as a (the?) major source of economic growth, most standard growth theory models take the rate of technological change as exogenous. With technological change independent of demographic change, population growth per se will have no impact on the pace of economic growth in long-run equilibrium. By contrast, if technological change is all or in part *embodied* in new investment, then a vintage specification is appropriate whereby new capital is relatively more productive than old. In this set-up, population growth can be economic-growth enhancing by expanding the rate at which technology is incorporated into production. In yet another specification, population growth can directly affect the rate of technological change and/or its form (factor bias). Kenneth J. Arrow (1962) has hypothesised that learning by doing is quickened in an environment of rapid employment growth.

A fourth linkage between technology and demography is found in 'endogenous growth' models that relate the pace of technology directly to population *size.* In particular, the benefits of R&D are assumed to be available to all firms without cost; that is, an R&D industry generates a non-rival stock of knowledge. As a result, if we hold constant the share of resources used for research, an increase in population size advances technological change without limit. This somewhat controversial prediction has been qualified by models that incorporate various firm- or industry-specific constraints on R&D production. Such models typically reduce, but do not eliminate, the positive impacts of population size which, as in the embodiment models above, are manifested largely during the 'transition' to long-run equilibrium.

Evidence on the roles of demographic-technology linkages and growth has been fragmentary and sparse. A pioneering study by Hollis Chenery and Moises Syrquin (1975) draws upon the experience of 101 countries across the income spectrum over the period 1950–70. They find that the structure of development reveals strong and pervasive scale effects (measured by population size) that vary by stage of development. Basically, small countries develop a modern productive industrial structure more slowly and later, while large countries have higher levels of accumulation and (presumably) higher rates of technological change. Although these roles for demography may have been important historically, the impacts plausibly have waned somewhat: (*a*) economies in infrastructure are judged to be substantially exhausted in cities of moderate size; (*b*) specialisation through international trade provides a means of garnering some or many of the benefits of size; and (*c*) scale effects are most prevalent in industries with relatively high capital–labour ratios and such industries are inappropriate to the factor proportions of developing countries.

It is in agriculture where the positive benefits of population size have been most discussed. Higher population densities can lower per unit costs and increase the efficiency of transport, irrigation, extension services, markets and communications (Glover and Simon 1975). Possibly the most cited work is that by Ester Boserup (1965, 1981), who observes that increasingly productive agricultural technologies are made economically attractive in response to higher land densities. While this is probably true, the issue becomes one of identifying the quantitative magnitude of such effects over varying population sizes and in differing institutional settings. One must be cautious in attributing causation. For example, while high population densities may have accounted for a portion of expanded agricultural output in recent decades, in several important Asian countries these densities were sufficiently high decades ago to justify the investments associated with the new technologies. Boserup in more recent writing has been less sanguine about the benefits of population size because densities appropriate to modern technologies in Asia are three to four times the average for Africa and Latin America.

In short, a wide-ranging review of the literature does not provide a strong consensus on the

quantitative linkages between the size and growth of population, on the one hand, and the pace of technological change and economic growth, on the other hand.

The Bottom Line

An evaluation of population growth on economic growth through the filter of formal economic-growth modelling yields limited results: population growth affects the level but not the growth of per capita income in long-run equilibrium. Moreover, the key determinants of long-run growth are saving and technology. Only if these factors depend on demographic change does population matter. This somewhat constraining limitation of growth theory has caused researchers to branch out and explore a host of economic–demographic interactions using less formal paradigms. This blossoming literature has been extensive, lively and sometimes contentious.

Evolution of Population-Impacts Thinking: 1950–90

Four major studies, two by the United Nations (1953, 1973) and two by the National Academy of Sciences (1971, 1986), reveal well the evolution of thinking on population matters over the period 1950–90. Three individual scholars, Coale and Hoover and Simon, also played prominent and important roles. (This section draws on Kelley 2001.)

United Nations, 1953

The 1953 United Nations report, *Determinants and Consequences of Population Trends*, easily represents the most important contribution to population thinking since the writings of Malthus. Unlike Malthus, however, the UN study was balanced and exhaustive both in detail and in coverage. Some 21 linkages between population and the economy were taken up. For example, the impacts of population on the economy can be: (*a*) positive due to economies of scale and organisation; (*b*) negative due to diminishing returns; or (*c*) neutral due to technology and social progress. An evaluation of these and other linkages led to a mildly negative overall assessment that was both cautious and qualified.

The most notable feature of this report was its methodology. More than any major study on population to that time, the UN Report embraced a methodology that would ultimately represent elements of modern-day 'revisionism'. Specifically, the report (*a*) downgraded the importance of population growth's impact on economic growth by placing it on a par with several other determinants of equal or greater impact; (*b*) assessed the consequences of population over a long period of time; and (*c*) emphasised the importance of feedbacks within and between the economic and political systems.

Coale and Hoover, 1958

The next major contribution to the population-impacts literature was provided by Ansley J. Coale and Edgar M. Hoover in their 1958 book *Population Growth and Economic Development in Low-Income Countries*. Based on simulations of a mathematical model calibrated with Indian data, they concluded that India's development would be enhanced by lower population growth. This was due to the hypothesised adverse impacts of population on household saving. It was also proffered that 'unproductive' investments in human capital (such as health and education) would partially displace investments in 'relatively productive' forms (such as machines and factories). Economic growth would diminish in response.

Empirically, the above hypotheses have not been convincingly established. While several studies have exposed negative dependency-rate impacts on saving, there are others that show little or no impact. Overall, the findings are mixed, with a tilt toward supporting the Coale and Hoover formulation. (See section "Saving" above for a discussion of the trade-offs that households can make to maintain saving in response to expanding family size.)

Similarly, there are alternative ways for governments to organise and finance schooling in response to population pressures. Unfortunately, studies of this are limited, although one by T. Paul Schultz (1987) finds no support for the Coale and Hoover (1958) formulation.

National Academy of Sciences, 1971

Arguably the most pessimistic assessment of the consequences of population growth was a study compiled by the National Academy of Sciences (NAS). The panel's final submission, *Rapid Population Growth: Consequences and Policy Implications*, issued in 1971, appeared in two volumes: volume 1, *Summary and Recommendations*, and volume 2, *Research Papers*. Unfortunately, the *Summary* volume appeared to be more political than academic in goal and orientation, and was not faithful to many of the underlying research reports assembled by the panel. Indeed, the *Summary* volume highlighted some 25 alleged negative consequences of population growth, whereas it downplayed or eliminated impacts that could be considered as 'neutral' or 'favourable'. As a result, the *Summary* represents an upper bound on the negative consequences of population growth. (A detailed documentation exposing the somewhat controversial way in which the *Summary* was compiled is provided by Kelley 2001.)

What can be learned from the NAS study? First, given its apparent bias and the lack of a systematic vetting of volume 1 by members of the panel, it is difficult to use that volume, either in full or in part. However, the individual papers are available and they, in total, offer a more balanced treatment. Second, by its own acknowledgment, the study focused on the short run when negative impacts of population change are most likely to prevail. ('We have limited ourselves to relatively short term issues'; 1971, p. vi.) By contrast, 'direct' (short-run) impacts of demographic change are almost always attenuated (and sometimes offset) by 'indirect feedbacks' that occur over longer periods of time. Thus the decision by the NAS panel to focus only on the short-run direct impacts resulted in an overly negative assessment of the consequences of population growth.

Third, economists were underrepresented on both the panel and in providing background reports. This is relevant since economists have substantial faith in the capacity of markets, individuals and institutions to adjust in the face of population pressures. Such adjustments, of course, take time and they are not without cost. Finally, this NAS Report provides a striking example of the difficulty of maintaining objectivity when social science research enters the public policy domain.

United Nations, 1973

In 1973 the United Nations weighed in with an update of its previous seminal work (United Nations 1953). In contrast to the broadly eclectic stance in the earlier report, the new one ended with a mild to moderate negative overall assessment of rapid population growth. The authors were concerned with the ability of agriculture to feed expanding populations (à la Malthus) and the difficulty of offsetting capital shallowing (à la Coale and Hoover). Still, the 1973 Report, whose conclusions are highly qualified, is not alarmist, nor is it all that pessimistic. The reason for this moderate stance was the exceptionally influential empirical finding of Simon Kuznets (1960, pp. 19–20, 63) that notable negative correlations between population growth and per capita output growth were largely absent in the data. Given the strong priors of some contributors to the UN study, a failure to find a negative association in the aggregate data by a scholar with impeccable credentials had a profound impact. Indeed, this singular finding arguably kept the population debate alive for yet another round of assessments in the 1980s.

Revisionism, 1980s and Beyond

The 1980s represented a decade when many of the underlying assumptions and conclusions of earlier studies of population–development interactions were subjected to critical scrutiny. The result was a revisionist rendering that was both surprising and controversial. Specifically, the revisionists downgraded the prominence of population growth as either a major source of, or a constraint on, economic prosperity in the Third World. The basis of this somewhat startling conclusion was the revisionists' methodology that (*a*) assessed the consequences of demographic change over longer periods of time and (*b*) expanded the analysis to take into account *indirect feedbacks* within economic and political systems. In general, empirical assessments of population growth will be smaller

(less negative or less positive) when using the revisionist's methodology than when focusing on the short run and ignoring feedbacks. On net, most revisionists conclude that many, if not most, Third World countries would benefit from slower population growth.

Julian L. Simon, 1981

No one was more important in stimulating the new round of debates in the 1980s than Julian L. Simon, author of *The Ultimate Resource* (1981). This book attracted enormous attention, substantially because of two factors. First, it concluded that population growth would likely provide a *positive* impact on economic development of many developed, and some less developed, countries. Second, the book was accessible, well written, and organised in a 'debating', confrontational style. This included goading and prodding, the setting up and knocking down of straw men, and an examination of albeit popular, but somewhat extreme, anti-natalist positions. Simon's powerful book helped spawn a group of survey articles in the 1980s.

What accounts for Simon's positive assessments? Simon was an early advocate of evaluating the full effects of population over the intermediate to long run. He argued that the negative 'direct' impacts in the short run will probably be moderated, or sometimes overturned, when households, businesses, and/or governments react to changing prices which signal problems of resource scarcity. Two important examples of responses to population pressures can be cited: those relating to technological change and those relating to natural resource scarcity, both highlighted by Simon.

Technological change. Simon hypothesised and attempted to document that the pace of technological change, and its bias, can be stimulated by population pressures. Technological change, in turn, plays a central role in economic growth theory and has been shown in sources-of-growth studies to be a (the?) key to economic growth. Additionally, with respect to population size impacts in general, Simon observes that major social overhead projects (for example, roads, communications and irrigation) have benefited from expanded populations and scale. (For more detail, see section "Technological Change: Density, Size and Endogenous Growth" above.)

Resource depletion. Consider next the impacts of population growth on natural resource depletion. Theoretically an exhaustion of non-renewable resources (for example, coal and minerals) would appear to be inevitable in the long run. However, such a period may be in the indeterminably distant future. By contrast, Simon argued that the most relevant measure of resource scarcity is its price. He prepared many graphs of US non-renewable resource prices (deflated by price indexes in order to focus on 'real' resource trends).

Surprisingly, virtually every resource has experienced a *declining* real price over lengthy periods of time. This means, à la Simon, that resources are becoming *more* abundant over time. It seems that the more resources are used, the more abundant they become! How can this happen? Simple. A rising resource price, due in part to population pressures, triggers several reactions that reduce or even eliminate the apparent resource scarcity. Specifically, in the short run, rising prices encourage an economising of the resource at every level of production and consumption. In the longer run, rising prices stimulate exploration, new methods of extraction and process, and the search for substitutes.

Nevertheless, Simon recognised that market failures, institutional failures, and political factors can all result in less-than-complete adjustments when population and economic development press against resource availabilities. This is particularly the case with renewable resources (such as rain forests, fisheries, the environment, and so forth) where market or institutional failures are pervasive. Without mechanisms to assign and maintain property rights, internalise externalities, and address free rider problems of public and quasi-public goods, government regulation may be required to safeguard renewable resources over time.

National Academy of Sciences, 1986

Some 15 years after the 1971 National Academy Report that highlighted 25 negative consequences of population growth, a new National Academy

Report was released. In contrast to the previous study, the new report was balanced, eclectic and non-alarmist. A careful examination of its bottom line is instructive.

> *On balance*, we reach the *qualitative* conclusion that *slower* population growth would be beneficial to economic development of *most* developing countries. (1986, p. 90; emphasis added)

This qualified assessment reveals key features found in most population assessments in the 1980s. Specifically: (*a*) there are both positive and negative impacts of demographic change (thus 'on balance'); (*b*) the magnitude of the net impacts cannot be determined given current evidence (thus 'qualitative'); (*c*) only the direction of the impact from high to low growth rates can be ascertained (thus 'slower' rather than 'slow'); and (*d*) the net impact varies from country to country. In most cases it will be negative; in some positive; and in others of little impact (thus, 'most developing countries').

What accounts for the dramatic turnaround in the two National Academy assessments? Several factors can be advanced. First, the 1986 report extends the short-run time horizon of the 1971 report to examine individual and institutional responses to the initial impacts of population change: conservation in response to scarcity, substitution of abundant for scarce factors of production, innovation and adoption of technologies to exploit profitable opportunities, and the like. These responses are considered to be pervasive and they are judged to be important. According to the report writers: 'the key [is the] mediating role that human behaviour and human institutions play in the relation between population growth and economic processes' (1986, p. 4).

Second, the 1986 study was assembled almost entirely by economists whose understanding of and faith in markets to induce responses that modify initial direct impacts of population change is far greater than that of other social and biological scientists.

Third, research accumulating over the 15 years between the two reports revealed a need to downgrade: (1) the concern about non-renewable resource exhaustion; (2) the adverse impact of children on the capacity to save, and in turn to undertake productive investments; and (3) the inability to invest in schooling and health facilities.

Finally, the 1986 Report upgrades the concern about population impacts on *renewable* natural resources (such as fishing areas and rain forests) where property rights are difficult to assign and maintain. Overuse can result. It is recognised that the problems of overuse are not solely due to population growth per se, but rather institutional failure. Cutting population growth by one half, or even to zero, would not solve the problem. Rather it would slow the process and postpone the date of resource exhaustion. Government policies are needed to account for negative externalities and market failure. Slowing population growth provides time for institutional response.

New Paradigms for Modelling Demography's Role in Economic Growth: 1990 and Beyond

As noted previously, Kuznets's empirical finding of an absence of notable negative correlations between population growth and per capita output growth influenced the population debate throughout the 1970s and 1980s. Simple correlations stimulated research during the 1990s as well. This time, however, statistically significant negative correlations during the 1980s drove the discussion. Interestingly, economic–demographic modelling continued in the 'revisionist' vein, incorporating positive and negative as well as short- and long-run influences into an economic growth model. The modelling challenge remains one of accommodating correlations that can be negative, positive or insignificant depending upon time and place.

Convergence Growth Models: A Framework for Assessing Demography's Impact

Renewed interest in modelling the impacts of demographic change on economic growth coincided with the emergence in the economic growth literature of the 'technology gap' or 'convergence' model. This model, formulated initially

by Barro and Sala-i-Martin (1991), has been used widely to explore many hypothesised influences on economic growth, including openness to trade, form of government, and the rule of law. Since this type of modelling highlights the dynamics of the adjustment process, it is particularly relevant to examining the impacts of major shifts in the population's age distribution associated with birth and death rates that change systematically over the demographic transition. As a result, economic demographers have employed convergence paradigms to explore demographic–economic interactions.

Briefly stated, convergence models focus on the pace at which countries move from their current level of labour productivity to their long-run or steady-state level of labour productivity. The model assumes that all countries converge at the same rate from their current to their long-run levels (which can vary across countries and over time). The greater the productivity gap, the greater are the gaps of physical capital, human capital and technical efficiency from their long-run levels. Large gaps allow for 'catching up' through (physical and human) capital accumulation, and technology creation and diffusion across countries and over time. Indeed, many empirical studies indicate that growth rates do slow down as a country approaches its long-run productivity level, especially those studies that provide for country- and period-specific conditions that influence the long-run level of labour productivity.

Since long-run labour productivity is unobservable, empirical implementations of the model substitute a vector of 'conditioning' variables thought to influence long-run labour productivity. The actual specification of these conditioning variables varies notably. Consider two of their many representations. The first, by Barro (1997), highlights inflation, government consumption ratios, the rule of law, the form of the political system, terms of trade, human capital, the total fertility rate, and life expectancy at birth (a proxy for health). The second formulation, by Bloom and Williamson (1998), highlights two categories of growth-rate determinants: economic structure variables (natural resources, schooling, access to ports, location in the tropics, whether landlocked, and extent of coastline); and economic and political policies (openness to trade, quality of institutions, and government savings share of GDP). Clearly there are many defensible perspectives on variable choice, and much is yet to be learned about the appropriate configuration of conditioning variables that influence long-run productivity levels.

Alternative Demographic Renderings Within a Convergence Framework

The 1990s witnessed attempts by various researchers to model demography in a manner that accommodates both the insignificant correlations of the 1960s and 1970s as well as the significant negative correlations of the 1980s and 1990s. Three different approaches are described here. All three employ a convergence-type growth model and all employ a broad set of countries spanning the income spectrum.

Modelling through aggregate measures of fertility and mortality. Barro (1997) includes two demographic aggregate measures among his list of conditioning variables, the total fertility rate (TFR) and life expectancy. Barro's formulation thus has demography impacting the long-run equilibrium level of per capita income. The TFR captures, for example, the adverse capital-shallowing impact of more rapid population growth as well as the resource opportunity costs of bringing up children. Furthermore, while Barro treats life expectancy as a human capital proxy for health, demographers consider it to be a demographic variable. Both are statistically significant, with a higher TFR inhibiting, and longer life expectancy enhancing economic growth.

Modelling through population growth components. Kelley and Schmidt (1995) decompose population growth by examining two components (births and deaths) and by modelling their contemporaneous and lagged impacts. This approach allows for disparate impacts of fertility and mortality as well as negative short-run effects (costs of high birth and death rates) and positive long-run effects (favourable impacts of past births on current labour force growth and declining mortality). Consistent with Kuznets's earlier work, they

found an absence of a net demographic impact on economic growth in the 1960s and 1970 – the separate impacts of births and deaths are notable but offsetting. Consistent with empirical work of the early 1990s, they found negative impacts throughout the 1980s. These negative correlations were in part the result of (*a*) rising short-run costs of high birth rates, (*b*) declining benefits of mortality reduction, and (*c*) insufficient labour force entry from past births to offset these increased costs.

Modelling through differential age-structure growth. In a series of papers beginning in the late 1990s, several Harvard economists argued for a demographic rendering that incorporates not only population growth but also labour growth (see, for example, Bloom and Williamson 1998; and Bloom et al. 2000). They note that, while theorists conceptualise the economic growth process in labour productivity terms, empirical growth models are generally specified in per capita terms. This makes no difference when population and labour grow at the same rate, but does when they grow at different rates.

The authors argue that the post-war period was exactly such a time since during that period demographic transitions took place in different countries at different times and at different paces. At various stages of the demographic transition, the population and working ages (used within this framework as a proxy for labour) can grow at very different rates. In a predictable pattern, the population initially grows faster, then slower, and then faster than the working-aged population during the transition from a high-fertility, high-mortality to a low-fertility, low-mortality demographic steady-state equilibrium. (For an historical evolution of economic, sociological, and biological factors during the demographic transition, see R.A. Easterlin 1978.)

Without allowing for differential growth rates of the population and working ages, demographic coefficient estimates (mainly population growth) will be biased. In that case the population–growth coefficient captures net demographic impacts that can be positive, negative, or neutral, depending upon time and place. Bloom and Williamson (1998) demonstrate this point for a broad cross-section of countries over the period 1965–90 in a convergence model that also includes life expectancy as a human capital variable. Consistent with some studies, their simple demographic rendering results in a positive but insignificant coefficient for the population growth rate. When supplemented by the working-age growth rate, however, that coefficient turns negative and the coefficient for the working-age growth rate is positive, both statistically significant.

Effectively, the Harvard economists append an accounting structure to translate labour productivity impacts into per capita terms. The resulting demographic specification is elegant in its simplicity, incorporating only two demographic variables that have unambiguous predicted coefficient values of – 1 (for population rate of growth, Ngr) and +1 (for working-age population rate of growth, WAgr) when used to expose demography's impact on income growth per capita relative to income growth per working-age population. In that context, demography exerts its primary impact on the pace at which the long-run equilibrium is reached (Bloom and Williamson 1998, p. 419) rather than on the long-run equilibrium level of productivity.

This is an intriguing specification. The interpretation is clear: if labour force growth exceeds population growth, then the rate of per capita income growth is boosted by demography. The Harvard economists label this phenomenon the 'demographic gift' that may be reaped for several decades after the onset of fertility decline as new labour force entrants from earlier large birth cohorts outpace fertility. The 'gift' was large throughout the 1965–90 period for Japan and other Asian Tigers because of the early and rapid pace of their demographic transition. Of course, the converse of the 'gift' began to be felt in the 1990s as new labour force entry from smaller birth cohorts was outpaced by labour force exit of the ageing population. The model predicts productivity outpacing per capita income growth over several decades into the future in these Asian (and other) countries.

Note that the qualitative predictions are based on theoretically determined coefficients on WAgr and Ngr of +1 and −1, respectively. To the extent

that estimated coefficients deviate from +1 and −1, WAgr and Ngr play an additional role in the determination of the long-run productivity level. The Harvard studies provide some guidance in this area. In their earlier study, Bloom and Williamson (1998) estimate coefficients that differ significantly from +1 and −1. However, in a later study that further elucidates the accounting, Bloom et al. (2000) find no significant difference from those values. If that is the case, then the model at once makes an important contribution and is somewhat narrower than many in the literature which admit both short-run and long-run impacts of demographic change as a part of the theoretical structure. Yet modelling demography in growth equations tends to be both imprecise and ad hoc. In contrast, the Bloom and Williamson model is relatively clear in interpretation, and it targets the shorter-run impacts that are of primary interest to policymakers.

The Bottom Line

Bloom and Williamson (1998) estimated that as much as one-third of the average per capita income growth rate in East Asian countries over the period 1965–90 is explained by population dynamics. Kelley and Schmidt (2001) evaluated eight distinct demographic renderings within a convergence model using a consistent set of conditioning variables – those described above for Barro's variant. Among others, these renderings included Barro's TFR; a 'naive' variant predating the 1990s work that simply includes Ngr; a 'components' model (contemporaneous and lagged birth rates and the death rate: Kelley and Schmidt 2001); two variants of the Harvard transitions framework; and demographic extensions to several variants.

Kelley and Schmidt (2001) find that on average, across all eight demographic formulations and over their full 86-country sample (covering the full income spectrum), approximately 21 per cent of the combined impacts on change in the per capita income growth rate is accounted for by changes in the demographic variables in the various models. What is striking about this result is that the 21 per cent is fairly stable across all eight demographic renderings, from one that is quite simplistic (Ngr only) to those that incorporate short-, intermediate- and long-term population effects. On the one hand, this should not be terribly surprising because of the interconnectedness of all of the demographic measures. On the other hand, while population matters, it is still important to determine why.

Although there is an emerging consensus that the magnitude of the impacts of population growth have been sizeable (for example, 21 per cent globally and as much as 33 per cent in East Asia), the reasons why this is the case are still both contestable and not well understood. Are the demographic determinants primarily longer-run impacts, or are they mainly shorter-run transitional dynamics that are diminishing? Will the so-called 'demographic gift' of these dynamics in the past reveal themselves as a 'demographic drag' in the future, deriving from reduced fertility, slow population growth and ageing? Or will a new mechanism reveal itself? For example, (*a*) will future modelling better expose the components of labour force change (for example, utilisation rates, age- and/or gender-specific participation rates); and (*b*) will fertility and mortality be endogenously specified to better reveal the dynamics of the demographic transition about which the field of economic demography has much to say? Whatever the outcome, the stage is set for another round of research, pinning down the results of the past with the goal of understanding the future.

Economic Development and the Environment

Ian Coxhead

Abstract

Economic development in low-income economies is initially highly resource-intensive. Resource depletion and pollution damage is often estimated to reduce 'real' GDP growth by between one and two per cent per year. Growth and structural change alter the environment–development nexus in nonlinear fashion. Policy reforms, global market integration, and institutional development all alter the propensity for growth to generate environmental damage. The emergence of new trade patterns among developing countries has created

new challenges in the measurement and analysis of development–environment interactions. Larger developing economies are now emerging as major sources of emissions that contribute to global climate change.

Economic development depends on sustained per capita income growth and entails dramatic changes in production structure. In low-income economies, growth typically stimulates markets and promotes the evolution of institutions that constrain behaviour according to social norms. The expansion of trade in relation to GDP is another common accompaniment to growth. Each of these has effects on 'the environment', which in a developing-country setting refers not only to phenomena such as water and air quality but also, importantly, to natural resource stocks such as forests, fisheries and soils.

Conversely, changes in environmental quality, including resource stock drawdowns, may affect economic development in a dynamic interaction. This feedback is hard to quantify; however, the World Bank's *World Development Indicators* series now includes 'adjusted' national accounts data reporting GDP and savings net of the implied value of resource depletion and environmental damage (Bolt et al. 2002). These indicate that environmental damage can reduce GDP growth by as much as one to two per cent per year. On a broader scale, growth of large low-income economies like China and India is beginning to have ramifications not only for their own environmental conditions, but also for the global environment through transboundary pollution spillovers and greenhouse gas (GHG) emissions.

The welfare of the poor in low-income countries is intimately linked to their access to environmental assets, and especially to the natural resource base. Despite this, the central concerns of environmental and resource economics – the economic costs of pollution and natural resource depletion – have only recently begun to be linked to models of economic development. Publication of the so-called Brundtland Report (WCED 1987) was a watershed event; since then, 'no account of economic development would be regarded as adequate if the environmental-resource base were absent from it' (Dasgupta and Mäler 1995, p. 2734).

Growth in low-income economies is inevitably associated with higher resource demands and increased pollution intensity per unit of income generated. Other things equal, more economic activity generates more environmental damage monotonically through a scale effect. The relationship may be nonlinear, however. As income grows, environmental damage per unit of additional income may initially rise, then decline. This conjecture, known as the environmental Kuznets curve (EKC), posits that scale effects dominate all other influences on the growth–environment relationship at low income levels, but that, as incomes rise, changes in the composition of production, technological improvements, and income-elastic preferences for conservation and a cleaner environment become more influential (Grossman and Krueger 1993). Institutional and legal constraints on pollution and resource depletion, initially so weak as to create a form of open access for polluters and resource depleters, may also evolve or be applied with greater vigour as incomes increase, whether due to income effects or to increased recognition of limits to growth imposed by pollution and resource scarcity (Stokey 1998). Despite the heuristic value of EKC, however, empirical tests in low-income economies are plagued by data and measurement

problems. Most notably, there is no robust evidence of an EKC for resource-depleting activities such as deforestation.

Changes in production structure and factor demands are also inherent to development. The most prominent manifestation of structural change in low-income countries is the relative decline of agricultural and resource sectors as contributors to GDP and employment. This has clear environmental implications when the majority of the population is initially dependent on the natural resource base. In capital-scarce economies, forest and land conversion for agriculture and the exploitation of fisheries and other resource stocks are standard strategies for increasing labour productivity and generating surpluses. Accordingly, early stages of development are characterized by rapid resource depletion – most visibly in the form of tropical deforestation. Such processes are abetted by conditions of open access (Barbier 2005).

Whether the depletion rate eventually slows – a prerequisite for sustainable development – depends largely on the extent to which surpluses are used to build capacity in secondary and tertiary industries making more intensive use of reproducible resources such as labour, technology and human capital. In this way, the central story of structural change in low-income economies is intimately linked to the evolution of demands on the environmental and natural resource base. Sustained growth leads to a relative reduction in dependence on natural resources, and thus makes it easier for society to agree to promote conservation, biodiversity retention and non-use amenities. Conversely, macroeconomic failures, often in combination with rapid population growth, high transactions costs and market failures, can lead low-income economies into unsustainable cycles of poverty, resource over-exploitation, and institutional failure.

Trade is another influential source of structural change. Early development policies stressing import substitution and de-emphasizing trade have, in most countries, been supplanted by greater outward orientation. Trade-to-GDP ratios have risen and domestic prices have tended to converge on world market prices, thus altering domestic production and investment incentives. With the exception of resource-poor East Asian countries like Korea and Taiwan, the pursuit of comparative advantage in low-income countries initially means expanded exports of tropical agriculture, forestry and fisheries and of resource-based semi-manufactures such as sawnwood. Both the growth of global demand and the pro-trade effects of policy reforms encourage accelerated resource drawdowns; unless property rights and externalities are adequately dealt with, these are likely to occur at socially excessive rates (Coxhead and Jayasuriya 2003). A related idea known as the pollution haven hypothesis posits that weak environmental laws and unresolved externalities may lead developing countries to specialize in pollution-intensive industrial activities (Copeland and Taylor 1994).

Whereas early policy advice to developing countries typically stressed the desirability of exploiting resource wealth to create jobs and earn foreign exchange, contemporary concerns about exhaustibility and the integrity of ecological systems have led to more cautious counsel and an emphasis on sustainable development. Such advice, however, is often difficult to implement as policy in the face of pressures to promote growth and alleviate poverty in the current generation.

New issues in the development–environment relationship continue to emerge as economies grow and become more globalized. Traditionally, trade-environment analyses used Ricardian or Heckscher–Ohlin models of North–South interactions in which welfare growth in resource-abundant South is contingent on trade with industrialized North and on domestic externalities or market failures (for example, Chichilnisky 1994). However, South–South trade – or, in the case of China's emergence as a major market for resource exports from Asia, Africa, and Latin America, 'East–South' trade – is now growing much faster than trade of the North–South type. South–South trade is a form of internationally fragmented production in which primary products or semi-manufactures are exported from one low-income country to another to be used in production of final goods. The latter low-income economy thus moves to 'clean' growth based on labour-intensive

manufactures, while growth in the former becomes more resource-intensive. Countries in the South may have comparative advantage in either clean or dirty goods – or both. Conventional models and measures for evaluating environmental costs of growth must be adapted to such new modalities.

Other new trends reflect the growing global influence of large developing economies. In poor countries, about 50 per cent of carbon dioxide emissions (the primary sources of GHGs) comes from land conversion. But total emissions increase rapidly with energy demands driven by growth, urbanization and industrialization. According to the International Energy Agency, China accounted for 13 per cent of global energy-related CO_2 emissions in 2006, and is expected to overtake the USA as the largest CO_2 source by 2009; India is now following a similar path (IEA 2006). Under the 1997 Kyoto Protocol, these economies are not required to limit GHG emissions. But, even if they do take major steps to limit pollution intensity, scale effects of their growth will ensure that global pollution externalities will continue to expand for the foreseeable future. In turn, concerns over the global environmental consequences of growth in low-income countries will find increasingly forceful expression in international negotiations not only on the environment but also on trade and other forms of international integration.

Economic Epidemiology

Tomas J. Philipson

Abstract

The economic analysis of epidemiological issues has different implications for disease and its optimal control from those of traditional analysis of such issues. It views undesirable disease occurrence as the result of self-interested behaviour in the presence of constraints. Unlike with methods used in public health, the effects and desirability of disease-reducing public interventions are then evaluated in terms of how they improve the private behaviour essential to controlling disease. Economic epidemiology has been applied to a wide range of topics, including infectious diseases such as AIDS, and also to non-infectious behaviour such as smoking, obesity, and crime.

The fast-growing literature on the economic analysis of epidemiological issues (see Philipson 2000, for a review) delivers very different implications about disease occurrence and its optimal control from those of traditional analysis of the same issues in the field of public health. At the risk of vastly oversimplifying the positive component of the public health approach, the traditional analysis comprises empirical methods and analysis aimed at identifying and quantifying the effects of 'risk factors' on health outcomes. These factors are typically defined as covariates that negatively affect the measured health outcomes – for example, the effects of smoking on lung cancer or the effects of obesity on heart disease. Thereafter, the normative component of the public health approach is concerned with attempts to reduce the measured risk factors, whether through private or public intervention, and to thereby improve health outcomes.

This approach drastically differs from that of economic epidemiology, which attempts to explain undesirable disease occurrence as the result of self-interested behaviour in the presence of constraints. The effects and desirability of disease- reducing public interventions are then evaluated in terms of how they improve the private behaviour essential to controlling disease in the first place. In some sense, the public health approach aims to improve health, whereas the economic approach aims to improve economic efficiency, even if that does not necessarily improve health. Just as closing highways would improve health but impair economic efficiency, the two approaches often clash in desired interventions. The public health approach, therefore, more often favours public intervention, and sometimes simply assumes that the existence of a health problem is sufficient cause for intervention, potentially because it lacks a theory about how private incentives affect the observed level of disease across time and populations.

Economic Epidemiology and Infectious Disease

Infectious diseases cause roughly one-third of all deaths worldwide and represent the primary cause of mortality in the world. Historically, the share of worldwide mortality due to infectious diseases has been even greater, although data tend to be less reliable for earlier periods. Morbidity and mortality from infectious diseases such as tuberculosis, malaria and acute respiratory infection have always been at the forefront of public policy in developing countries, where infectious diseases accounted for nearly one-half of mortality in the 1990s.

Worldwide concern about infectious disease has received renewed interest in public policy discussions given the disastrous impacts of HIV/AIDS and the potential threat of bird flu. Like most communicable diseases, especially those that are potentially fatal, HIV has incited an extensive governmental response, consisting of regulatory measures, subsidies for research, education, treatment, testing and counselling. Here we review the main contributions of economic epidemiology in predicting both the short- and the long-run behaviour of infectious disease, as well as the effects and desirability of public health interventions that attempt to reduce such disease.

Philipson and Posner (1993) provide the first systematic analysis of rational infectious disease epidemics in the context of AIDS. Kremer (1996) analyses the effects of a reduction in the number of one's sexual partners on the growth of disease. The predictions of such models rely crucially on the prevalence elasticity of private demand for prevention against disease, that is, the degree to which prevention increases in response to disease occurrence. Prevalence-elastic behaviour has different implications for the susceptibility to infection than standard epidemiological models of disease occurrence as discussed in Philipson (1995). Evidence of the degree of prevalence-elastic demand is discussed in Ahituv et al. (1996) and Auld (2003, 2006). Oster (2006) attempts to explain the lack of

prevalence-elastic demand in Africa by the competing risks that lower the demand for prevention in that part of the world. Lakdawalla et al. (2006) provide evidence that demand is sensitive to overall risk, both in terms of prevalence and the cost of infection as when reduced by new medical technologies.

This type of prevalence-elastic behaviour has two major implications. First, growth of infectious disease is self-limiting because it induces preventive behaviour. Second, since the decline of a disease discourages prevention, initially successful public health efforts actually make it progressively harder to eradicate infectious diseases. Geoffard and Philipson (1996) discuss a very general result concerning the inability of private markets to eradicate disease when demand is prevalence-elastic because a disappearing disease implies less prevention. Barrett (2003) and Barrett and Hoel (2004) also analyses the implications of economic efficiency for optimal eradication. See also Gersovitz and Hammer (2003, 2004, 2005).

Regarding the value of public health interventions, Mechoulan (2004) analyses the prevalence and efficiency implications of HIV testing. Geoffard and Philipson (1996) argue that eradication is never Pareto optimal when only the current generation is considered. However, the missing market is dynamic: future generations cannot pay vaccine producers for the benefit they derive from the producers' product. Brito et al. (1991) analyse the nonstandard efficiency implications of mandatory vaccinations.

Moreover, the prevalence elasticity of demand lowers the price elasticity of demand, which implies that Pigouvian-style subsidies to stimulate prevention may have only limited success. This occurs because demand rises among those who are subsidized and falls among those who are not – in the extreme case, total demand is inelastic to subsidies. In addition, prevalence competes with public interventions in inducing protective activity, which makes the timing of the public intervention a crucial factor in determining its economic efficiency. If the subsidy is not prompt enough, the growth in prevalence will have already induced protection.

A growing literature examines the optimal control of infectious diseases in the presence of antibiotic resistance (see, for example, Laxminarayan and Brown 2001; Laxminarayan and Weitzman 2002; Laxminarayan 2002; and Horowitz and Moehring 2004). The standard, positive external effect of treating more individuals with an infectious disease is partly or fully offset by the negative external effect induced by increased antibiotic resistance. The R&D problem induced by external consumption effects such as antibiotic resistance is discussed in Philipson et al. (2006).

Economic epidemiology has also considered the welfare losses induced by disease, the welfare effects of R&D in developing new methods of prevention and treatment (Philipson 1995), and how these contrast with cost-of-illness studies of disease burden.

Spread of Economic Epidemiology to Other Fields

Several other topics have grown out of this more systematic analysis of infectious disease by economists. One strand is the analysis of public health-related issues such as obesity (Philipson and Posner 2003; Lakdawalla et al. 2005). The addictive aspect of obesity is analysed by Cawley (1999). Empirical studies explaining the observed growth in obesity, whether it includes a rise in caloric intake or fall in caloric expenditure, include Cutler et al. (2003). Chou et al. (2004) and Rashad and Grossman (2004) analyse the co-variation between the growth of obesity and smoking and fast-food establishments in the United States. The important and rich set of issues raised by growth in obesity promises a useful role for economic analysis.

Another area in which economic analysis of epidemiological issues has emerged is the economic analysis of clinical trials (see, for example, Philipson and DeSimone 1997; Philipson and Hedges 1998; Malani 2006). This literature deals with the non- traditional aspects of programme evaluation that are unique to clinical trials – for example, the blinding of subjects. Economic

analysis of clinical trials differs from bio-statistical analysis in that subjects are assumed to act in their best interest rather than be passively observed.

The stark difference between economic explanations of disease occurrence on the one hand and the evaluation of public interventions aimed at limiting disease on the other implies that economics may have a very useful role to play in understanding these issues.

Economic Freedom

Alan Peacock

Economic freedom describes a particular condition in which the individual finds himself as a result of certain characteristics in his economic environment. Taking a simple formulation of decision-making in which it is assumed that the individual maximizes his satisfaction both as a consumer of private and government goods and services and as a supplier of factor services, his position may be depicted as follows:

$$\text{Max } U^i = U^i\left(x^i, q_k, a^i\right) \tag{1}$$

Subject to

$$p_k^c \cdot x^i + T_k^i = Y^i = \varphi\left(a^i\right) = p_k^a \cdot a^i \tag{2}$$

where x_i is a vector of 'private goods', q_k is a vector of goods supplied by government, a^i is a vector of factor inputs, p_k^c is a vector of product prices for private goods, p_k^a is a vector of factor prices, T_k^i is net tax liability of individual ^{i} (tax obligation *less* transfers), Y^i is personal income before tax of individual ^{i} and subscript k denotes an exogenously determined variable.

Assuming the budget constraint (2) is exactly satisfied, the individual maximizes his satisfaction solving for the vector of private-goods consumption in terms of their prices, disposable income and predetermined levels of public goods available for consumption, where goods prices and factor prices, quantities of factor inputs and tax liabilities are either known or predicted by the individual.

Economic freedom requires that the various terms in the budget constraint reflect the absence of 'preference or restraint' (Adam Smith) on the individual. Therefore p_k^c is a vector of product prices which result from the operation of competitive market forces with the individual being free to choose between alternatives. Similarly, p_k^a must be characterized by competition in the factor market with the individual being 'free to bring both his industry and capital into competition with those of any other man or order or men' (Adam Smith). There is less certainty concerning the constraints placed on T_k and q_k. Some writers would argue that economic freedom requires a pre-established limit on the values of T_k and q_k either expressed or implied in a country's constitution (Nozick's 'minimal state'; see Nozick 1974). Others would argue that within a system of democratic government it should be possible to devise voting systems through which individuals express their preferences for values of T_k and q_k which simulate if they do not replicate the competitive market in the private sector (see Buchanan 1975). All agree, however, that economic freedom is not compatible with large values of T and q in relation to values of x^i, mainly because a large public sector increases the monopoly power of public servants both as suppliers of public goods and factor services to produce them and encourages the growth of private monopolies as a defence against public monopsony buying.

Economic Freedom and Libertarian Philosophy

There are features of this attempt at a 'technical' definition which may be called in question and which must be considered later, but it will be recognizable to those economists who have elevated economic freedom to an important goal in its own right and have claimed that it is the most important means for ensuring that the economy develops at the right 'tempo'. Discussion of the usefulness of the concept of economic freedom, therefore, centres in these two libertarian propositions.

The first proposition is contained in a striking passage in Book III of his *Essay on Liberty*: J.S. Mill wrote:

> He who lets the world, or his own portion of it, choose his plan of life for him, has no need of any other faculty than the ape-like one of imitation. He who chooses to plan for himself, employs all his faculties. He must use observation to see, reasoning

> and judgment to foresee, activity to gain materials for decision, discrimination to decide and, when he has decided, firmness and self-control to hold to his deliberate decision. . . It is possible that he might be guided on some good path, and kept out of harm's way, without any of these things. But what will be his comparative worth as a human being? It really is of importance, not only what men do, but also what manner of men they are that do it. (Mill 1859)

The passage captures the essence of the libertarian view of the good society, clearly implying that it requires that individuals should accept the necessity for choosing and for recognizing their responsibility for making choices. It must simultaneously require that, to develop the capacity for choosing, individuals must have the widest possible freedom of choice in the acquisition and disposal of resources. Two further conclusions follow.

The only restriction on economic freedom experienced by the individual should be when such freedom harms others.

The individual is not accountable to society for his actions and this, together with the different and changing preferences of individuals, makes libertarians distance themselves from attempts to establish a 'social welfare function' (cf. Rowley and Peacock 1975).

The second proposition maintains that economic freedom brings the added bonus of promoting the economic welfare of both the individual and of society. Economic freedom encourages the individual to 'better his condition' (Smith 1776) by exploiting opportunities for specialization and gains from trade which will be fully realized through the spontaneous emergence of markets. Not only is economic freedom regarded as the only material condition compatible with human dignity but it is also a necessary condition for the economic growth of the economy and for its adjustment to the changing preference structures of its members in response to market forces. The market is a 'discovery process' (Hayek 1979) in which participants adjust to change giving rise to the notion of the 'invisible hand' which coordinates human economic actions automatically without recourse to government intervention. *Pace* Hahn (1982) and others, libertarians do not attach importance to a general equilibrium solution, attained by the operation of competitive market forces (cf. Barry 1985). Indeed, though some exceptions will be noted below, it is claimed by supporters of the doctrine of economic freedom that disturbance of the natural process of exchange by government intervention assumes knowledge of the intricacies of the economy which is vouchsafed to no one, but there is no guarantee that officials, who maximize their private interests like everyone else, would be willing to maximize some social optimum even if they knew how to do so.

It was clearly recognized, by Hume and Smith for example, that for markets to work efficiently there must be a well-defined system of property rights and that costs of contracting between individuals in order to benefit from gains-from-trade would need to be minimized. The promotion of market efficiency was therefore bound to require some government intervention. No specialization or gains-from-trade would take place in a society in which there was no machinery for settling disputes and for preserving law and order. Acceptance of coercive intervention, however, requires that the 'rule of law' prevails. The law must be prospective and never retrospective in its operation, the law must be known and, as far as possible, certain, and the law must apply with equal force to all individuals without exception or discrimination. The state could also have a role in reducing the costs of contracting both by the removal of barriers to trade and to factor mobility and by the positive encouragement to the reduction in the costs of transport. In this latter respect Adam Smith supported reduction in the 'expense of carriage' by state financing of road building and supervision of financial methods to promote road maintenance and improvement.

At no stage therefore in the development of the doctrine of economic freedom, as understood by economists, was it regarded as synonymous with 'laissez-faire'. At the same time, the role of the state in respect of the promotion of economic freedom was and has remained strictly limited in libertarian thinking. Indeed, some modern libertarians devote much discussion to the possibilities of 'privatizing' even such traditional functions of the state as the maintenance of law and order.

Some Problems Raised by the Concept of Economic Freedom

The most obvious question posed to libertarians by those who are sceptical of their position is that the system of economic freedom is silent on the question of the distribution of property rights. In terms of our simple model, what principle should determine the values of $Y^1, \ldots, Y^i, \ldots, Y^n$ which, when aggregated, would describe some initial distribution of income as measured, say, by the shape of the Lorenz Curve? What reason have we for supposing that the 'optimal' distribution of income would emerge from the process of economic exchange between individuals?

The answer to this question does not find libertarians speaking with one voice. The problem is not one of principle, for the ultimate test to them is how far any government intervention represents a restriction of freedom. The problem is one of interpretation. It would be difficult today to find libertarians who would object to government intervention designed to assure protection to those who are severely deprived. Thus Hayek has argued that so long as 'a uniform minimum income is provided outside the market to all those who, for any reason, are unable to earn in the market an adequate maintenance, this need not lead to a restriction of freedom, or conflict with the Rule of Law'. This still leaves room for much disagreement among libertarians as to the precise level of the minimum and how to decide on who is entitled to receive it. Some supporters of the libertarian position, including the present author, would go much further and argue, along with J.S. Mill, that concentrations of wealth sustained over lengthy time periods can endanger economic freedom, not to speak of political freedom, by the association of such concentrations with the concentration of power of wealthy individuals over the less fortunate.

If the concept of economic freedom cannot embrace some precise guidance about the extent to which economic exchanges should be interfered with, it certainly places limits on the form of that interference. Thus libertarians, to the extent that they accept the need for a state-guaranteed minimum standard of living, prefer the use of money transfers to individuals rather than the provision of social services below or at zero cost, that is to say the economic condition of individuals in receipt of state support should be reflected in reduction in T_k^i (whose value may have to be negative) rather than an increase in q_k. Thus it is argued that individuals then retain responsibility for the purchase of goods and services designed to promote their own welfare and that the power of the state over the individual by bureaucratic dictatorship of preferences and by the lack of incentives in the public sector to economize in resource use is circumscribed.

A more severe test for the practicality of libertarian measures, designed to permit some redistribution without increasing the power of the state, arises in the case of any attack on the concentration of wealth. Clearly, a system of inheritance taxation which results in the transfer of capital from the private to the public sector would not conform to libertarian thinking, not only because this would discourage private saving but also because it would build up the power of the state. A system of taxation would have to be devised which not only did not discourage accumulation of private capital but also simultaneously encouraged legators to disseminate capital in favour of those with little capital. It is a long time since libertarians have plucked up the courage to try to develop such a system, given that eminent public finance specialists have failed in their attempts to fulfil these requirements.

The second major question arises from the persistent objection of Marxists and other Socialist writers that the system of economic freedom, as depicted by the libertarians, fails to solve the problem of 'worker alienation'. It may be that the system of economic freedom can allow employees alone or in combination with others to influence the price of factor inputs (p_k^a) and the work/leisure combination (a^i), variables which play a crucial part in individual welfare. The fact remains that the system of property rights, which libertarians support, includes the individual ownership of capital and the use of capitalistic methods of production which imply an authority relationship between employer and worker. The hierarchical order at the place of work

seems at complete variance with the independence of economic action attributed to the individual by the supporters of economic freedom.

Reactions to this argument by libertarians are sometimes reminiscent of the Scots preacher who, on recognizing a theological difficulty in his sermon, recommended his congregation to look the difficulty squarely in the face and pass it by. However, even Socialist writers, notably the prominent Marxist Ota Sik (1974), have recognized that the alternative to market capitalism – collectivist production – does not solve the problem for it is not synonymous with democratization at the shop-floor level. In other words, the basis of alienation is technological and not institutional. Some libertarians, notably Mill, have made common cause with Socialists by arguing that alienation must not be taken to be an inevitable consequence of productive activity. Mill sought one solution in the encouragement of firms owned and managed by the labour force, but still subject to competition. Utopian Socialists have claimed that the only solution is to reject altogether the technology which imposes hierarchical relations in the first place. Both 'solutions' are still the subject of living debate in both the professional and political arena.

Economic Governance

Avinash K. Dixit

Abstract

Economic governance consists of the processes that support economic activity and economic transactions by protecting property rights, enforcing contracts, and taking collective action to provide appropriate physical and organizational infrastructure. These processes are carried out within institutions, formal and informal. The field of economic governance studies and compares the performance of different institutions under different conditions, the evolution of these institutions, and the transitions from one set of institutions to another.

Formal and informal institutions arise and evolve to underpin economic activity and exchange by protecting property rights, enforcing contracts, and collectively providing physical and organizational infrastructure. The field of economic governance studies and compares these institutions: state politico-legal institutions, private ordering within the law (credible contracting, arbitration), for-profit governance (credit-rating agencies, organized crime), and social networks and norms. Private institutions can outperform the state's legal system in obtaining and interpreting relevant information, and imposing social sanctions on the violators of norms. But private institutions are often limited in size; as economic activity expands, a transition towards more formal institutions is usually observed.

Concepts and Taxonomies

The term 'governance' has exploded from obscurity to ubiquity in economics since the 1970s. A search of the EconLit database shows clear evidence of this explosion. In the relevant categories (title, keywords and abstracts), there are just five occurrences of the word from 1970 to 1979. The number jumps to 112 for the 1980s and 3,825 for the 1990s. Since 2000 to the time of this writing (December 2005), there are already 7,948.

The Oxford English Dictionary gives several definitions of the word 'governance': (*a*) the action or manner of governing; controlling, directing, or regulating influence; control, sway, mastery; the state of being governed; good order; (*b*) the office, function, or power of governing; authority or permission to govern; that which governs; (*c*) the manner in which something is governed or regulated; method of management, system of regulations; a rule of practice, a discipline; and (*d*) the conduct of life or business; mode of living; behaviour, demeanour; discreet or virtuous behaviour; wise self-command. These diverse meanings allow the word to be used (and sometimes misused) for almost any context of economic decision-making or policy.

Two areas of application merit special mention. One is *corporate governance*. This analyses the internal management of a corporation – organizational structure and the design of incentives for managers and workers – and the rules and procedures by which the corporation deals with its shareholders and other stakeholders.

The second is *economic governance*; Williamson (2005) expresses its theme as the 'study of good order and workable arrangements'. This includes the institutions and organizations that underpin economic transactions by protecting property rights, enforcing contracts, and organizing collective action to provide the infrastructure of rules, regulations, and information that are needed to lend feasibility or workability to the interactions among different economic actors, individual and corporate. Different economies at different times have used different institutions to perform these functions, with different degrees of success. The field of economic governance studies and compares these different institutions. It includes theoretical models and empirical and case studies of the performance of different institutions under different circumstances, of how they relate to each other, of how they evolve over time, and of whether and how transitions from one to another occur as the nature and scope of economic activity and its institutional requirements change.

Corporate governance and economic governance are connected because the boundary of a corporation is itself endogenous, determined by the same considerations of information and commitment costs that raise problems of internal organization as well as those of property and contract (Coase 1937). Specifically, the nature of transaction costs may make it more efficient to handle some problems of governance by merging the two parties, for example by vertical integration (Williamson 1975, 1995). But it is analytically convenient to separate the two. This article concerns economic governance. To avoid constant repetition, I will simply call it 'governance' here unless some explicit reference to corporate governance is relevant.

Governance was neglected by economists for a long time, perhaps because they expected the government to provide it efficiently. However, experience with less developed and reforming economies, and observations from economic history, have led economists to study non-governmental institutions of governance.

Governance is not a field per se; it is an organizing or encompassing concept that bears on issues in many fields, including institutions and organizational behaviour, economic development and growth, industrial organization, law and economics, political economy, comparative economic systems, and various subfields of these.

We can organize the subject by classifying institutions along different dimensions. As is usual with such taxonomies, these are conceptual categories to help organize our thinking and analysis. In reality, there are significant differences within each category and overlaps across categories.

The first dimension concerns the purpose of the institution. The categories are: (*a*) protection of property rights against theft by other individuals and usurpation by the state itself or its agents, (*b*) enforcement of voluntary contracts among individuals, and (*c*) provision of the physical and regulatory infrastructure to facilitate economic activity and the functioning of the first two categories of institutions. We might also consider a fourth category, namely, the deep institutions that are essential to avoid serious cleavages or alienation that threaten the cohesion of the society itself. But this has not been studied in this context so far.

The second dimension concerns the nature of the institution. The categories are: (*a*) the formal state institutions that enact and enforce the laws, including the legislature, police, judiciary and regulatory, agencies, (*b*) institutions of private ordering that function under the umbrella of state law, for example various forums for arbitration, (*c*) private for-profit institutions that provide information and enforcement, and (*d*) self-enforcement within social or ethnic groups and network. My discussion is organized in sections along this dimension.

A third dimension distinguishes institutions that arise and evolve organically from those that are designed purposively; self-enforcing groups are often organic while the first three categories in the second dimension usually require some measure of design. This matters for the evolution of institutions of governance (see Greif 2006, especially ch. 6; Williamson 2005 p. 1).

Formal Institutions of the State

There is broad agreement that the quality of institutions of governance significantly affects economic outcomes. The importance of protecting property rights, both from other individuals and from predation by the state itself, is generally recognized and documented (for example, De Soto 2000). But serious disputes about the precise measures of quality of institutions, and about many details of the causal mechanisms by which they affect economic outcomes, remain.

At the broadest level, the distinction is between democracy and authoritarianism, each of which comes in many different varieties. Democracy has many normative virtues, but its worth in governance is less clear. Barro (1999, p. 61) finds an inverse U-shaped relationship between economic growth and a continuous measure of democracy – 'more democracy raises growth when political freedoms are weak, but depresses growth when a moderate amount of freedom is already established' – but the fit is relatively poor. Persson (2005), using cross-sectional as well as

panel data, finds that the crude distinction between democratic and non-democratic forms of government is not enough. The precise form of democracy matters for policy design and economic outcomes: 'parliamentary, proportional, and permanent democracies seem to foster the adoption of more growth-promoting structural policies, whereas ... presidential, majoritarian, and temporary democracy do not' (Persson 2005, p. 22). However, Keefer (2004, p. 10), after surveying a wide-ranging literature on electoral rules and legislative organizations, concludes that they affect policies but are not a crucial determinant of success: 'electoral rules ... almost surely do not explain why some countries grow and others do not', and 'the mere fact that developing countries are more likely to have presidential forms of government is unlikely to be a key factor to explain slow development.'

Democracy can be important for governance because its reliance on rules and procedures provides citizens with protection against predation by the state or its agents. Indeed, the elite, which might otherwise prefer to rule unconstrained, may find it in its own interest to make a credible commitment not to steal from the population by creating and fostering democracy (Acemoglu 2003; Acemoglu and Robinson 2005). Greif et al. (1994) discuss how groups of traders (guilds) in late medieval Europe took collective action to counter rulers' incentives to violate their members' property rights.

Even in a democracy, agents of the state may pursue their private interests using corruption, complex regulations to extract rent, and favouritism. In fact, an emerging literature argues that economic growth, at least in its early stages, is better promoted under suitably authoritarian regimes. Glaeser et al. (2004) argue that less developed countries that achieve economic success do so by pursuing good policies, often under dictatorships, and only then do they democratize. While these conclusions are controversial, these authors' criticisms of the measures of institutions used in the research that argues for the primacy of institutions in general, and of democracy in particular, are telling. Giavazzi and Tabellini (2005) find a positive feedback between economic and political reform, but they also find that the sequence of reforms matters, and countries that implement economic liberalization first and then democratize do much better in most dimensions than those that follow the opposite route. In practice, of course, it is difficult to ensure *ex ante* that an authoritarian ruler will implement good governance.

Many different measures of institutional quality exist. World Bank researchers Kaufman et al. (2005, which contains citations to their earlier work) have constructed six: (*a*) Voice and Accountability – measuring political, civil and human rights; (*b*) Political Instability and Violence – measuring the likelihood of violent threats to, or changes in, government, including terrorism; (*c*) Government Effectiveness – measuring the competence of the bureaucracy and the quality of public service delivery; (*d*) Regulatory Burden – measuring the incidence of market-unfriendly policies; (*e*) Rule of Law – measuring the quality of contract enforcement, the police, and the courts, as well as the likelihood of crime and violence; and (*f*) Control of Corruption – measuring the exercise of public power for private gain, including both petty and grand corruption and state capture. Of these, (*e*), (*f*) and also (*b*) concern the most basic institutions for protection of property rights and enforcement of contracts, (*a*) relates to governance because voice and accountability can reduce the severity of the agency problem between the citizens and the agencies of the state, and (*c*) and (*d*) pertain to what I called provision of the infrastructure of governance. Conceptually they are a mixed bag; the quality of some of them can itself depend on the quality of other more basic ones, and some are closer to being measures of effects than of causes. Their method of construction relies on subjective perceptions, and is subject to error. But when used with caution, they have proved significant as explanatory variables in empirical studies of economic growth, and for observing changes in governance quality over time in specific countries. Corruption and regulatory burdens are major themes of the World Bank's research on governance in many countries (see World Bank Institute, website).

Empirical estimations of the level or growth of GDP on various measures of institutional quality confront many conceptual and econometric problems. Researchers have tackled the issue of reverse causation by using various instruments, such as the nationality of colonizers (Hall and Jones 1999), mortality among colonizers (Acemoglu et al. 2001), and whether a colony had rich mineral resources or climatic and soil conditions conducive to plantation agriculture and a large or dense native population, or was sparsely populated and poor in the 1500 s (Engerman and Sokoloff 2002; Acemoglu et al. 2002). The general idea is that in the former circumstances the European colonizers established institutions of slavery and inequality to facilitate the exploitation of labour on a large scale, whereas in the latter conditions, where the colonizers had to exert their own effort, their institutions provided the correct incentives and became conducive to longer-term economic success. The debate on the factual and econometric validity and the economic interpretation of these findings is fierce and continuing; Hoff (2003) surveys and discusses this literature in detail.

La Porta et al. (1998, 1999) contrast different legal traditions for protecting the rights of small shareholders. If such protection is poor, that will inhibit the flows of capital to its most efficient uses. They find that systems based on common law are better in this regard than those based on civil law. But Rajan and Zingales (2003) and Lamoreaux and Rosenthal (2005) argue that in practice there was little difference between the systems during critical periods of industrialization.

These debates are sure to continue, and this section will get out of date very quickly.

At the international level, formal governance works through bodies like the World Trade Organization. Their members are sovereign countries; therefore their procedures must be subject to self-enforcement in repeated interactions, whether through bilateral or multilateral sanctions. These institutions are therefore basically similar to the social networks discussed below. See Maggi (1999) and Bagwell and Staiger (2003) for detailed analyses.

Private Institutions

The policing functions for property right protection supplied by the state are often supplemented by private security systems that serve specific clients and purposes – firms employ or hire security personnel, gated communities and neighbourhoods have private (hired or volunteer) patrols. These generally merely supplement the functions of the police for their specific context and work cooperatively with the police, but the two may clash if the private security system goes beyond its permissible functions.

Private institutions of contract enforcement similarly coexist with formal law, and become essential when the latter is weak or nonexistent. Explicit or implicit private contractual arrangements are also important for assignment of property rights as a part of Coasean contracting for efficient outcomes. Therefore, analyses of private institutions often focus on the governance of contracts.

The basic problem of contract enforcement is control of opportunism. If one or both parties have to make transaction-specific investments, the other can attempt to secure a greater part of the benefit by reneging or demanding renegotiation. The prospect of this can jeopardize the potentially mutually beneficial deal in the first place. Williamson (1975, 1995) pioneered the analysis of this issue under the title of transaction cost economics.

Information constitutes a major source of advantage for private ordering over formal law. Enforcement of a contract in a court requires offering proof of misconduct by the other party in the dispute; the relevant information must be verifiable to outsiders. Therefore, formal contracts can stipulate actions by the parties conditional only on verifiable information. Other or more detailed information may be observable to the parties themselves, or can be inferred by specialist insiders to the industry, but cannot be verified to non-specialist judges or juries of the state's legal system, or can be verified only at excessive cost.

The informational advantage of private ordering may be offset by a disadvantage in enforcement. Informal arrangements must be made to

overcome each participant's temptation to behave opportunistically at the others' expense. Different methods of this kind underlie the various institutions of informal governance, and achieve different degrees of success. Some are able to exert coercion for immediate punishment of misbehaviour. Others create long-run costs, typically in the form of exclusion from future participation or worse future opportunities, to offset the short-run advantages of opportunism. This is the standard theory of self-enforcing cooperation in repeated Prisoner's Dilemmas. The following sections discuss some of these alternatives.

Private Ordering with Formal Law in the Background

Perhaps the most remarkable thing about formal legal institutions and mechanisms for the enforcement of commercial contracts is how rarely they are actually used. Business transactions often do have underlying formal contracts, but when disputes arise recourse to the law is often the last resort. Other private alternatives are tried first; these include bilateral negotiation, arbitration by industry experts, and so on. Filing a suit in a formal court of law often signals the end of a business relationship. Most actual practice in business contracting is therefore better characterized as 'private ordering under the shadow of the law' (Macaulay 1963; Williamson 1995, pp. 95–100, 121–2).

If one of the parties to an ongoing informal relationship behaves opportunistically, the most common alternative is to fall back on a formal contract based on verifiable contingencies alone. Suppose an outcome based on a tacit understanding of what each party should do in any one exchange (including good-faith negotiation to adapt to changing circumstances) yields both of them higher payoffs than does a formal contract. Consider the implicit arrangement where, if one party deviates from the agreed course of action to its own advantage and to the detriment of the other, their future exchanges will be governed by the formal contract. This yields a subgame-perfect (credible) equilibrium of the repeated game if each party's one-time gain from opportunism does not exceed the capitalized value of the future difference of payoffs between the tacit and the formal contracts. Williamson (2005, p. 2) expresses this well: 'continuity can be put in jeopardy by defecting from the spirit of cooperation and reverting to the letter.'

When such relationship-based implicit contracting prevails, partial improvement in the formal system can worsen the outcome, due to a problem of the second-best. The partial improvement raises the payoffs the two parties could get from the fallback formal contract. This in turn reduces the future cost of a current deviation from the implicit contract or spirit of cooperation. It tightens the incentive-compatibility constraints, and therefore worsens what can be achieved by relational contracting (Baker et al. 1994; Dixit 2004, ch. 2).

Arbitration comes in two prominent forms. One is industry-specific, based on expert knowledge of insiders. More information is verifiable in such settings; therefore richer contracts specifying actions for more detailed contingencies become feasible. In many industries there is a large common-knowledge basis of custom and practice, which may even make it unnecessary to write down a contingent contract in great detail. Arbitration can also provide an opportunity for the parties to communicate and renegotiate adaptations to new circumstances. Formal legal systems often recognize these advantages of expert arbitration, and courts stand ready to enforce the decisions of arbitrators if the losing party tries to evade the sanctions. However, industry arbitrators often have severe sanctions at their own disposal; they can essentially drive the miscreant out of business, and even ostracize him or her from the social group of that business community. Examples of arbitration institutions include Bernstein's (1992) classic study of the diamond industry. For further discussion and modelling, see Dixit (2004, ch. 2) and Williamson (2005, p. 14).

The other prominent forums of arbitration deal with international contracts (Dezalay and Garth 1996; Mattli 2001). There are several of these, specializing in different legal traditions. They lack direct power to enforce their decisions, but

are backed by treaties that ensure enforcement by national courts. These forums do not have industry-specific knowledge, their processes can be slow and costly, and their decisions can be somewhat arbitrary. But parties in transnational transactions may prefer them to either country's courts, suspecting that these will be biased in favour of their own nationals.

For-Profit Private Institutions

If the state is unwilling to protect certain kinds of property or enforce certain kinds of contracts (for example in illegal activities), or is unable to do so (for example in weak and failing states), or is itself predatory, then private institutions can emerge to perform these functions for a profit. Organized crime often fills the niches uncovered by the state. Gambetta (1993), Bandiera (2003) and others argue that the Mafia emerged in just such a situation to fill the vacuum of protection in late 19th-century Sicily. Landowners began to hire guards of former feudal lords, and even the toughest among bandits, to protect their property. Gambetta describes how the Mafia's role expanded to providing contract enforcement in illegal or grey markets. Similarly, the Japanese Yakuza was instrumental in organizing markets at the end of the Second World War in August and September 1945 when the Japanese state had collapsed (Dower 1999, pp. 140–8), and mafias grew in Russia after the collapse of the Soviet regime (Varese 2001).

Gambetta (1993, p. 19) argues that this 'business of protection' is the core business of the Mafia. It may engage in other activities using in-house protection, but that is just downstream vertical integration – the opposite of upstream integration where an ordinary business firm has its in-house security department. A transaction-cost analysis of the internal organization of mafias, and of their vertical integration decisions, may provide an interesting link between economic governance and corporate governance. Another dimension in which the protection business can expand is extortion; although private protectors may be welcome when state protection has collapsed, 'protectors, once enlisted, invariably overstay their welcome' (Gambetta 1993, p. 198).

The Mafia can provide contract enforcement because, even though two traders may not have sufficiently frequent dealings with each other to achieve good outcomes in an ongoing bilateral relationship, each trader can be a regular customer of the enforcer. This converts multiple one-shot Prisoner's Dilemma games among the whole group of traders into several bilateral repeated games of each trader with the enforcer. The intermediary can provide information (keeping track of previous contract violations and informing a customer of the history of a potential trading partner) and/or actual punishment if a customer's trading partner violates their contract. The information role of the Mafioso is similar to that of credit rating agencies and Better Business Bureaus in the United States. Dixit (2004, ch. 4) constructs a model of such for-profit governance, and establishes the conditions for an equilibrium with for-profit private enforcement. These are lower bounds on the shares of the surplus that the customer and the Mafioso must have, so as to overcome the trader's temptation to cheat and the Mafioso' temptation to double-cross the customer. Milgrom et al. (1990) have a related and complementary model of private judges at medieval European trade fairs. They specify the game of each trade, and investigation in the event of cheating, in greater detail, but do not examine the issue of the judges' honesty.

Group Enforcement Through Social Networks and Norms

Any institution of contract enforcement must solve three key problems: (*a*) detection of opportunistic deviations from the contractually stipulated behaviour, (*b*) preservation and dissemination of information about the histories of the participants' behaviour, and (*c*) inflicting appropriate punishments to reduce future payoffs of any deviators. The first is often constrained by the available technology of monitoring, although institutions and regulations such as reporting

requirements and auditing can improve the technology. The second and third problems are best resolved in bilateral ongoing relationships: each party has a natural incentive to detect and remember the other's cheating, and can punish the other by breaking off the relationship. However, governance is often needed in groups each of whose members interacts frequently with someone else in the group, but not necessarily bilaterally with the same person every time. Now remembering and transmitting information about your current partner's behaviour to others, and refusing a potentially beneficial deal because the counterparty has cheated someone else in the past, are privately costly activities and therefore require their own governance mechanisms.

Formal state institutions of governance can solve these problems by fiat; the legal system compels the whole group of traders to commit to good behaviour by subjecting themselves to detection and punishment if they cheat. A third-party supplier of information or enforcement serves similar functions. In the case of a Mafia enforcer, anyone who trades with a customer of the Mafioso subjects himself to the grim punishment if he cheats. In the case of a Better Business Bureau, a firm that joins the organization thereby gives hostage to its own good behaviour: if it misbehaves it will get a poor rating or blacklisting. Transactions vary in their characteristics; therefore we should expect the effectiveness of such reputation mechanisms to vary also, and should not expect universal success from any one.

An institution of social networks and norms can solve the problems of information and punishment in a decentralized manner. Each participant can transmit information about his or her current trading partner's behaviour to others in the group to whom he or she is linked. And each can play his or her assigned part in punishment, typically by refusing to trade, if he or she gets matched with a potential partner who is known to have misbehaved in past dealings with others in the group. Incentives to transmit information or refuse potentially good trades can be established by a norm that regards refusal to do so as itself a punishable offence, as in Abreu's (1986) penal codes for repeated games; see Calvert (1995a, b). Extrinsic incentives may even be unnecessary if people have sufficiently strong natural instincts to punish social cheaters, as found by Fehr and Gächter (2000).

Numerous empirical and case studies of governance based on social relations have been conducted; space constraints allow mention of only a few. Greif's (1993) historical analysis of Maghribi traders' system of communication and collective punishment is well known. So is Ostrom's (1990) synthesis of the evidence on common-pool resource management; she emphasizes the importance of local knowledge and communication, of appropriately designed (generally graduated) punishments, and of incentives for individuals to perform their assigned roles and actions in the system. Fafchamps (2004) studies and compares many different market institutions in Africa; his work highlights the importance of designing systems appropriate to the conditions of each country or group. Ensminger (1992) describes a similarly rich complex of arrangements for trade and employment relationships among the Orma tribe of Kenya, and examines how formal institutions of property right enforcement including title registration can interact dysfunctionally with traditional arrangements based on family and tribal connections. Johnson et al. (2002) present and analyse findings from survey research in former socialist economies. Of particular interest are the links between evolving formal and informal governance. Even without a backup of courts, trust in bilateral relationships can build quickly in response to good experiences. New or transient customers are more likely to be offered credit if courts work better, but the effectiveness of courts becomes largely irrelevant for the functioning of established relationships. Casella and Rauch (2002) study the role of ethnic networks in international trade.

Li (2003) points out a key difference between the costs of operating such a system and those of formal governance. A relation-based system of networks and norms has low fixed costs, but high and rising marginal costs. Trading on a small scale naturally starts among the most closely connected people who have sufficiently good

communication and common understanding to sustain honesty. No fixed costs need be incurred to establish any formal rules or mechanisms of enforcement. But as trade expands, potential partners added at the margin are almost by definition less well-connected, making it harder to communicate information with them and to ensure their participation in any punishments. By contrast, formal or rule-based governance has high fixed costs of setting up the legal system and the information mechanism, but once these are incurred, marginal costs of dealing with strangers are low. Therefore, relation-based governance is better for small groups and rule-based governance better for large groups. Greif's (1994) comparison between the relation-based system of Maghribi traders and the formal institutions of Genoese traders supports this theory. Dixit (2004, ch. 3) constructs a formal model that compares relation-based and rule-based systems. This characterizes the maximum size of a self-enforcing group, and finds that, when the group exceeds this critical size, the maximum scope of sustainable honesty shrinks absolutely. The intuition is as follows. At the critical size, each trader is indifferent between honesty and cheating when dealing with the most distant person. When more traders are added, this weakens the communication between the previously marginal person and other almost equally distant ones, tipping the balance toward cheating.

Kranton (1996) models individuals who can either choose bilateral long-lived self-enforcing trading relationships or search for one-time trading partners in an anonymous market with external enforcement. The market thus provides the outside opportunity in the repeated game of bilateral trade. If more people trade in the anonymous market, it becomes thicker and offers better prospects for successful search. Then parties in bilateral relationships have better outside opportunities, which makes it harder to sustain tacit cooperation there, further increasing the relative attraction of the market. Therefore the system can have multiple equilibria – no one uses the market because no one else uses it, or everyone uses the market because everyone else does – and can get locked into a Pareto-inferior equilibrium.

Evolution and Transformation of Governance Institutions

A persistent theme in this survey has been that different governance institutions are optimal for different societies, for different kinds of economic activity, and at different times. Changes in underlying technologies of production, exchange and communication change the relative merits of different methods of governance. As the volume and scope of trade expand, formal institutions generally become superior to informal ones, but informal ones serve useful roles under the shadow of formal ones even in the most advanced economies and sectors. All this raises the question of whether we should expect institutions to adapt and evolve optimally.

Williamson's famous 'discriminating alignment hypothesis' says that transactions, with their different attributes, align with institutions, with their different costs and competencies; see his recent exposition (2005, p. 6). This gives ground for optimism for synergistic evolution of the need for governance and the institutions that supply it. Others are less sanguine. North (1990) and others argue that institutional change is subject to long delays due to resistance by organized interests favouring the status quo, problems of coordinating collective action to bring about a discrete change in equilibrium, and so on. Dixit (2004, pp. 79–85) discusses some of these problems for transition from relation-based to rule-based contract enforcement. Eggertson (2005) gives a dramatic example of how institutions restricting fishing and requiring costly mutual insurance persisted in Iceland for centuries after they had become obstacles to good economic performance.

I believe that a balanced approach is needed, recognizing the tendency towards synergistic alignment but also the obstacles to its realization. The net outcome will depend on many specifics of each context. Understanding and predicting the process requires a combination of approaches: case-based and analytical, inductive and deductive. Greif (2006) discusses, develops and applies such methodologies using historical studies of trade in medieval Europe.

Economic Growth

Peter Howitt and David N. Weil

Abstract

Economic growth is the increase in a country's standard of living over time. Growth economists study how living standards differ across countries as well as across time. This article discusses some of the broad facts of economic growth and some of the main approaches to its study.

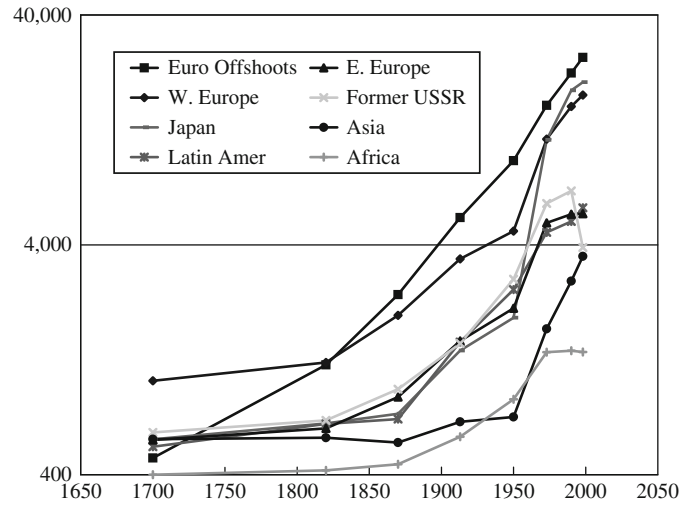
Economic growth is typically measured as the change in per capita gross domestic product (GDP). Sustained long-term economic growth at a positive rate is a fairly recent phenomenon in human history, most of it having occurred in the last 200 years. According to Maddison's (2001) estimates, per capita GDP in the world economy was no higher in the year 1000 than in the year 1, and only 53 per cent higher in 1820 than in 1000, implying an average annual growth rate of only one- nineteenth of one per cent over the latter 820-year period. Some time around 1820, the world growth rate started to rise, averaging just over one-half of one per cent per year from 1820 to 1870, and peaking during what Maddison calls the 'golden age', the period from 1950 to 1973, when it averaged 2.93 per cent per year. By 2000, world per capita GDP had risen to more than 8.5 times its 1820 value.

Growth has been uneven not only across time but also across countries. Since 1820, living standards in Western Europe and its offshoots in North America and the Antipodes have raced ahead of the rest of the world, with the exception of Japan, in what is often referred to as the 'Great Divergence'. As shown in Fig. 1 below, the proportional gap in per capita GDP between the richest group of countries and the poorest group (as classified by Maddison) grew from three in 1820 to 19 in 1998. Pritchett (1997) tells a similar story, estimating that the proportional gap between the richest and poorest countries grew more than fivefold from 1870 to 1990.

This widening of the cross-country income distribution seems to have slowed during the second half of the 20th century, at least among a large group of nations. Indeed, Fig. 1, which is drawn on a proportional scale, shows that with the acceleration of growth in Asia there has been a narrowing of the spread between the richest and the second poorest group since 1950. Evans (1996) shows a narrowing of the top end of the distribution (that is, among Organisation for Economic Cooperation and Development, OECD, countries) over the period. However, not all countries have taken part in this convergence process, as the gap between the leading countries as a whole and the very poorest countries has continued to widen. In Fig. 1 the gap between the Western Offshoots and Africa grew by a factor of 1.75 between 1950 and 1998. Likewise, the proportional income gap between Mayer-Foulkes's (2002) richest and poorest convergence groups grew by a factor of 2.6 between 1960 and 1995.



Economic Growth, Fig. 1 Per capita GDP, 1650–2000, 1990 international dollars (*Source:* Maddison (2001))

Jones (1997) argues that continuing divergence of the poorest countries from the rest of the world does not imply rising income inequality among the world's population, mainly because China and India, which contain about 40 per cent of that population, are rising rapidly from near the bottom of the distribution. Indeed, Sala-i- Martin (2006) shows, using data on within-country income distributions, that the cross-individual distribution of world income narrowed considerably between 1970 and 2000, even as the cross-country distribution continued to widen somewhat. But between-country inequality is still extremely important; in 1992 it explained 60 per cent of overall world inequality (Bourguignon and Morrison 2002). Another reason that growth economists are typically more concerned with the cross-country than the cross-individual distribution is that many of the determinants of economic growth vary across countries but not across individuals within countries.

The Production Function Approach

The main task of growth theory is to explain this variation of living standards across time and countries. One way to organize one's thinking about the sources of growth is in terms of an aggregate production function, which indicates how a country's output per worker y depends on the (per worker) stocks of physical, human, and natural capital, represented by the vector k, according to

$$y = f(k, A), \tag{1}$$

where A is a productivity parameter. Economic growth, as measured by the growth rate of y, depends therefore on the rate of capital accumulation and the rate of productivity growth. Similarly, countries can differ in their levels of GDP per capita either because of differences in capital or because of differences in productivity. Much recent work on the economics of growth has focused on trying to identify the relative contributions of these two fundamental factors to differences in growth rates or income levels among countries.

Modern growth theory started with the neoclassical model of Solow (1956) and Swan (1956), who showed that in the long run growth cannot be sustained by capital accumulation alone. In their formulation, the diminishing marginal product of capital (augmented by an Inada condition that makes the marginal product asymptote to zero as capital grows) will always terminate any temporary burst of growth in excess of the growth rate of labour-augmenting productivity. But this perspective has been challenged by more recent endogenous growth theory. In the *AK* theory of Frankel (1962) and Romer (1986), growth in productivity is functionally dependent on growth in capital, through learning by doing and technology spillovers, so that an increase in investment rates in physical capital can also sustain a permanent increase in productivity growth and hence in the rate of economic growth. In the innovation- based theory that followed *AK* theory, the Solow model has been combined with a Schumpeterian theory of productivity growth, in which capital accumulation is one of the factors that can lead to a permanently higher rate of productivity growth (Howitt and Aghion 1998).

Capital

Having introduced the production function in a general sense, we now examine the accumulation of different types of capital in more detail, and then turn to an assessment of the relative importance of factor accumulation and productivity in explaining income differences among countries and growth over time.

Physical Capital

Physical capital is made up of tools, machines, buildings, and infrastructure such as roads and ports. Its key characteristics are, first, that it is produced (via investment), and second that it is in turn used in producing output. Physical capital differs importantly from technology (which, as is discussed below, is also both produced and productive) in that physical capital is rival in its use: only a limited number of workers can use a single piece of physical capital at a time.

Differences in physical capital between rich are poor countries are very large. In the year 2000, for example, physical capital per worker was 148,091 dollars in the United States, 42,991 dollars in Mexico, and 6270 dollars in India. These large differences in physical capital are clearly contributors to income differences among countries in a proximate sense. That is, if the United States had India's level of capital it would be a poorer country. The magnitude of this proximate effect can be calculated by using the production function. For example, using a value for capital's share of national income of 1/3 (which is consistent with the findings of Gollin (2002) for a cross-section of countries), the ratio of capital per worker in the United States to that in India would by itself explain a ratio of income per capita in the two countries of 7.9 ($= (148{,}091/6270)^{1/3}$).

Differences in physical capital among countries can result from several factors. First, countries may differ in their levels of investment in physical capital relative to output. In an economy closed to external capital flows, the investment rate will equal the national saving rate. Saving rates can differ among countries because of differences in the security of property rights, due to the availability of a financial system to bring together savers and investors, because of government policies like budget deficits or pay-as-you-go old age pensions, differences in cultural attitudes towards present versus future consumption, or simply because deferring consumption to the future is a luxury that very poor people cannot afford.

A second factor that drives differences in investment rates among countries is the relative price of capital. The price of investment goods in relation to consumption goods is two to three times as high in poor countries as in rich countries. If one measures both output and investment at international prices, investment as a fraction of GDP is strongly correlated with GDP per capita (correlation of 0.50), and poor countries have on average between one half and one quarter of the investment rate of rich countries. When investment rates are expressed in domestic prices, the correlation between investment rates and GDP per capita falls to 0.05 (Hsieh and Klenow 2007).

But levels of capital can also differ among countries for reasons that have nothing to do with the rate of accumulation. Differences in productivity (the A term in Eq. 1) will produce different levels of capital even in countries with the same rates of physical capital investment. Similarly, differences in the accumulation of other factors of production will produce differences in the level of physical capital per worker.

Human Capital

Human capital refers to qualities such as education and health that allow a worker to produce more output and which themselves are the result of past investment. Like physical capital, human capital can earn an economic return for its owner. However, the two types of capital differ in several important respects. Most significantly, human capital is 'installed' in a person. This makes it very difficult for one person to own human capital that is used by someone else. Human capital investment is a significant expense. In the United States in the year 2000, spending by governments and families on education amounted to 6.2 per cent of GDP; forgone wages by students were of a similar magnitude.

Information on the productivity of human capital can be derived from comparing wages of workers with different levels of education. So called 'Mincer regressions' of log wage on years of education, controlling by various means for bias due to the endogeneity of schooling, yield estimated returns to schooling of about ten per cent per year. In the year 2000, the average schooling of workers in advanced countries was 9.8 years and among workers in developing countries 5.1 years. Applying a rate of return of ten per cent implies that the average worker in the advanced countries supplied 56 per cent more labour input because of this education difference. If labour's share in a Cobb–Douglas production function is two-thirds, this would imply that education differences would explain a factor of 1.35 difference in income between the advanced and developing countries, which is very small relative to the observed gap in income. Allowing for differences in school quality increases somewhat the income differences explained by human capital in the form of schooling.

A second form of human capital is health. The importance of health as an input into production can be estimated by looking at microeconomic data on how health affects individual wages. Health differences between rich and poor countries are large, and in wealthy countries worker health has improved significantly over the last 200 years (Fogel 1997). Weil (2007), using the adult survival rate as a proxy for worker health, estimates that eliminating gaps in worker health among countries would reduce the log variance of GDP per worker by 9.9 per cent.

Natural Capital

Natural capital is the value of a country's agricultural and pasture lands, forests and subsoil resources. Like physical and human capital, natural capital is an input into production of goods and services. Unlike other forms of capital, however, it is not itself produced.

Natural capital per worker and GDP per worker are positively correlated, but the link is much weaker than for the other measures of capital discussed above. The poor performance of many resource-rich countries has led many observers to identify a 'resource curse' by which the availability of natural capital undermines other forms of capital accumulation or reduces productivity. Among the suggested channels by which this happens are that resource booms lead countries to raise consumption to unsustainable levels, thus depressing saving and investment (Rodriguez and Sachs 1999); that exploitation of natural resources suppresses the development of a local manufacturing sector, which holds back growth because manufacturing is inherently more technologically dynamic than other parts of the economy (this is the so called Dutch disease); and that economic inefficiencies are associated with political competition or even civil war to appropriate the rents generated by natural resources.

Population and Economic Growth

Population affects the accumulation of all three forms of capital discussed above, and through them the level of output per worker. Rapid population growth dilutes the quantities of physical and human capital per worker, raising the rates of investment and school expenditure required to maintain output per worker. The interaction of natural capital with population growth is at the centre of the model of Malthus (1798). For a fixed stock of natural capital, higher population lowers output per capita. Combined with a positive feedback from the level of income to population growth, this resource constraint produces a stable steady state level of output per capita and, with technology fixed, a stable level of population as well. This Malthusian feedback is the explanation for the long period of nearly constant living standards that preceded the Industrial Revolution (Galor and Weil 2000). Because of resource-saving technological progress, as well as expansion of international trade, which allows countries to evade resource constraints, the interaction of population and natural capital is much less important today than in the past, with the exception of very poor countries that are reliant on subsistence agriculture.

In addition to its effect on the level of factors of production per worker, population also matters for economic growth because demographic change produces important changes in the age structure of the population. A reduction in fertility, for example, will produce a long period of reduced dependency, in which the ratio of children and the elderly, on the one hand, to working age adults, on the other, is temporarily below its sustainable steady state level. This is the so-called 'demographic dividend' (see population ageing).

In addition to these effects of population on the level of income per capital, there is also causality that runs from the economic to the demographic. Over the course of economic development, countries generally move through a demographic transition in which mortality rates fall first, followed by fertility rates. While the decline in mortality is easily explained as a consequence of higher income and technological progress, the decline in fertility is not fully understood. Among the factors thought to contribute to the decline in fertility are falling mortality, a shift along a quality–quantity trade-off due to rising returns to human capital, the rise of women's relative wages, the reduced importance

of children as a means of old age support, and improvements in the availability of contraception.

Growth Accounting and Development Accounting

The discussion above makes clear that stocks of different forms of capital are positively correlated with GDP per capita. Similarly, as countries grow, levels of capital per worker grow as well. It is natural to ask whether these variations in capital are sufficiently large to explain the matching variations in growth. The techniques of growth accounting (Solow 1957) and development accounting (Klenow and Rodriguez-Clare 1997; Hall and Jones 1999) attempt to give quantitative answers to this question. Using a parameterized production function and measures of the quantities of human and physical capital, one can back out relative levels of productivity among countries and rates of productivity growth within a country.

Caselli (2005) presents a review of development accounting along with his own thorough estimates. His finding is that if human and physical capital per worker were equalized across countries, the variance of log GDP per worker would fall by only 39 per cent. In other words, the majority of variation in income is due to differences in productivity, not factor accumulation. Differences in productivity growth, rather than differences in the growth of physical and human capital, are also the dominant determinants of differences in income growth rates among countries (Weil 2005, ch. 7; Klenow and Rodriguez-Clare 1997); differences in productivity levels among countries are striking. For example, comparing the countries at the 90th and 10th percentiles of the income distribution (which differ in income by a factor of 21), the former would produce seven times as much output as the latter with equal quantities of human and physical capital.

Productivity, Technology and Efficiency

Development accounting shows that productivity differences among countries are the dominant explanation for income differences. Similarly, differences in productivity growth are the most important explanation for differences in income growth rates among countries. And as a theoretical matter, the Solow model shows that as long as there are decreasing returns to capital per worker, productivity growth can be the only source of long-term growth. The question is: what explains these changes over time and differences in the level of productivity? Over the long term it is natural to associate productivity growth with technological change. However, especially as an explanation for differences in productivity at a given point in time, a second possibility is that productivity differences reflect differences not in technology, in the sense of inventions, blueprints, and so on, but rather differences in how economies are organized and use available technology and inputs. We label this second contributor to productivity as 'efficiency'.

Technology

Technology consists of the knowledge of how to transform basic inputs into final utility. This knowledge can be thought of as another form of capital, an intangible intellectual capital. What distinguishes technology from human or physical capital is its non-rival character. For example, the knowledge that a particular kind of corn will be immune to caterpillars, or the knowledge of how to produce a 3 GHz CPU for a portable computer, can be used any number of times by any number of people without diminishing anyone's ability to use it again. By contrast, if you drive a lorry for an hour, or if you employ the skills of a doctor for an hour, then that lorry or those skills are not available to anyone else during that hour.

Different growth theories have different approaches to modelling the accumulation of technology – that is, technical progress. According to neoclassical theory, for example, the relationship between technology and the economy is a one-way street, with all of the causation running from technology to the economy. It portrays technical progress as emanating from a scientific progress that operates outside the realm of economics, and thus takes the rate of technical progress as being given exogenously.

This neoclassical view has never been accepted universally. Specialists in economic history and the economics of technology have generally believed that technical progress comes in the form of new products, new techniques and new markets, which do not spring directly from the scientific laboratory; instead they come from discoveries made by private business enterprises, operating in competitive markets, and motivated by the search for profits. For example, the transistor, which underlies so much recent technological progress, was discovered by scientists working for the AT&T telephone company on the practical problem of how to improve the performance of switch boxes that were using vacuum tubes. Rosenberg (1981) describes many other examples of scientific and technological breakthroughs that originated in profit-oriented economic activity.

What kept this view of endogenous technology from entering the mainstream of economics until recently was the difficulty of incorporating increasing returns to scale into dynamic general equilibrium theory. Increasing returns arise once one considers technology as a kind of capital that can be accumulated, because of its non-rival nature; that is, the cost of developing a technology for producing a particular product is a fixed set-up cost, which does not have to be repeated when more of the product is produced. Once the technology has been developed then there should be at least constant returns to scale in the factors that use that technology, on the grounds that if you can do something once then you can do it twice. But this means that there are increasing returns in the broad set of factors that includes the technology itself. Increasing returns creates a problem because it generally implies that a competitive equilibrium will not exist, at least not without externalities.

These technical difficulties were overcome by the new 'endogenous growth theory' introduced by Romer (1986) and Lucas (1988), which incorporated techniques that had been developed for dealing with increasing returns in the theories of industrial organization and international trade. The first generation of endogenous growth theory to enter the mainstream was the 'AAK theory', according to which technological progress takes place as a result of externalities in learning to produce capital goods more efficiently. The second generation was the innovation-based theory of Romer (1990) and Aghion and Howitt (1992), which emphasizes the distinction between technological knowledge and other forms of capital, and analyses technological innovation as a separate activity from saving and schooling.

Historically, technical progress has engendered much social conflict, because it involves what Schumpeter (1942) called 'creative destruction'; that is, new technologies render old technologies obsolete. As a result, technical progress is a game with losers as well as winners. From the handloom weavers of early 19th century Britain to the former giants of mainframe computing in the late 20th century, many people's skills, capital equipment and technological knowledge have been devalued and their livelihoods imperilled by the same innovations that have created fortunes for others.

The destructive side of technical progress shows up most clearly during periods when a new 'general purpose technology' (GPT) is being introduced. A GPT is a basic enabling technology that is used in many sectors of the economy, such as the steam engine, the electric dynamo, the laser or the computer. As Lipsey et al. (2005) have emphasized, a GPT typically arrives only partially formed, creates technological complementarities and opens a window on new technological possibilities. Thus it is typically associated with a wave of new innovations. Moreover, the period in which the new GPT is diffusing through the economy is typically a period of rapid obsolescence, costly learning and wrenching adjustment. Greenwood and Yorukoglu (1997) argue that the productivity slowdown of the 1970s is attributable to the arrival of the computer, and Howitt (1998) argues that the rapid obsolescence generated by a new GPT can cause per capita income to fall for many years before eventually paying off in a much higher standard of living.

New technologies are often opposed by those who would lose from their introduction. Some of this opposition takes place within the economic sphere, where workers threaten action against

firms that adopt labour-saving technologies and firms try to pre-empt innovations by rivals. But much of it also takes place within the political sphere, where governments protect favoured firms from more technically advanced foreign competitors, and where people sometimes vote for politicians promising to preserve traditional ways of life by blocking the adoption of new technologies.

The leading industrial nations of the world spend large amounts on R&D for generating innovations. In the United States, for example, R&D expenditures constituted between 2.2 and 2.9 per cent of GDP every year from 1957 to 2004. But not much cutting-edge R&D takes place outside a small group of countries. In 1996, for example, 73 per cent of the world's R&D expenditure, as measured by UNESCO, was accounted for by just five countries (in decreasing order of R&D expenditure they are the United States, Japan, Germany, France and United Kingdom). In the majority of countries that undertake very little measured R&D, technology advances not so much by making frontier innovations as by implementing technologies that have already been developed elsewhere. But the process of implementation is not costless, because technologies tend to be context- dependent and technological knowledge tends to be tacit. So implementation requires an up-front investment to adapt the technology to a new environment (see, for example, Evenson and Westphal 1995). This investment plays the same role analytically in the implementing country as R&D does in the original innovating country.

Implementation is important in accounting for the patterns of cross-country convergence and divergence noted above. This is because a country in which firms are induced to spend on implementation have what Gerschenkron (1952) called an 'advantage of backwardness'. That is, the further they fall behind the world's technology frontier the faster they will grow with any given level of implementation expenditures, because the bigger is the improvement in productivity when they implement any given foreign technology. In the long run, as Howitt (2000) has shown, this force can cause all countries that engage in R&D or implementation to grow at the same rate, while countries in which firms are not induced to make such investments will stagnate. But technology transfer through implementation expenditures is no guarantee of convergence, because the technologies that are being developed in the rich R&D-performing countries are not necessarily appropriate for conditions in poor implementing countries (Basu and Weil 1998; Acemoglu and Zilibotti 2001) and because financial constraints may prevent poor countries from spending at a level needed to keep pace with the frontier (Aghion et al. 2005).

Efficiency

The efficiency with which a technology is used is not likely to play a major role in accounting for long-run growth rates, because there is a finite limit to how high you can raise living standards simply by using the same technologies more efficiently. But there is good reason to believe that differences in efficiency account for much of the cross-country variation in the level of productivity.

Inefficiencies take several different forms. Economic resources are sometimes allocated to unproductive uses, or even unused, as when union featherbedding agreements kick in. Resources can be misallocated as the result of taxes, subsidies and imperfect competition, all of which create discrepancies between marginal rates of substitution. Technologies can be blocked by those who would lose from their implementation and have more market power or political influence than those who would win.

The distinction between differences in technology and differences in efficiency is often unclear. Suppose firms in country A are using the same machinery and the same number of workers per machine as in country B, but output per worker is higher in A than B. This may appear to be an obvious case of inefficiency, since the technology embodied in the machines used by workers in the two countries is the same. But maybe it is just that people in country B lack the knowledge of how best to use the machines, in which case it may actually be a case of differences in technology. As an example, General Motors has had little success in their attempts to emulate the manufacturing

methods that Toyota has deployed successfully for many years even in their US operations.

Moreover, identical technologies will have different effects in different countries, because of differences in language, raw materials, consumer preferences, workers expectations and the like. Euro Disney, for example, was plagued initially with labour disputes when it first opened its park in the outskirts of Paris in 1987. It took the American managers several years to realize that the problem was not recalcitrant workers but rather that French workers consider it an intolerable indignity to be forced to wear items such as mouse ears when serving the public. A minor adjustment in amusement park technology was needed to make it as productive in France as it had been in the United States.

Deeper Determinants of Growth

Even if we knew how much of the cross-country variation in growth rates or income levels to attribute to different kinds of capital or to technology or efficiency, we would still be faced with the deeper question of why these differences in capital and productivity arise. A large number of candidate explanations have been offered in the literature. These candidates can be classified into four broad categories: geography, institutions, policy and culture.

Geographical differences are perhaps the most obvious. As Sachs (2003) has emphasized, countries that are landlocked, that suffer from a hazardous disease environment and that have difficult obstacles in the way of internal transport, will almost certainly produce at a lower level than countries without these problems, even if they use the same technology and the same array of capital. In addition, the lower productivity of these countries will serve to reduce the rate of return to accumulating capital and to generating new technologies.

Institutions matter because of the way they affect private contracts and also because of the way they affect the extent to which the returns to different kinds of investments can be appropriated by the government. The origin of a country's legal system has been shown by La Porta et al. (1998) to have an important effect on private contracts. In particular, these authors show that countries with British legal origins tend of offer greater protection of investor and creditor rights, which in turn is likely to affect both capital accumulation and investment in technology by making outside finance more easily available.

Because long-term productivity growth requires technical progress, it depends on political, institutional and regulatory factors that affect the way the conflict between the winners and losers of technical progress will be resolved, and hence affect the incentives to create and adopt new technologies. For example, the way intellectual property is protected will affect the incentive to innovate, because on the one hand no one will want to spend resources creating new technologies that his or her rivals can easily copy, while on the other hand a firm that is protected from competition by patent laws that make it difficult for rivals to innovate in the same product lines will be under less pressure to innovate. Likewise, a populist political regime may erect barriers to labour-saving innovation, resulting in slower technical progress.

Economic policies matter not only because of the way they affect the return to investing in capital and technology but also because of the inefficiencies that can be created by taxes and subsidies. But how these policies affect economic growth can vary from one country to another. In particular, Aghion and Howitt (2006) have argued that growth-promoting policies in technologically advanced countries are not necessarily growth-promoting in poorer countries, because innovation and implementation are affected differently by the same variables. For example, tighter competition policy in a relatively backward country might retard technology development by local firms that will be discouraged by the threat of foreign entry, whereas in more advanced countries firms will be spurred on to make even greater R&D investments when threatened by competition.

As this example suggests, international trade is one of the policy domains most likely to matter for growth and income differences, because of the

huge productivity advantage that is squandered by policies that run counter to comparative advantage, because protected firms tend to become technologically backward firms, and because for many countries international trade is the only way for firms to gain a market large enough to cover the expense of developing leading-edge technologies. So it is probably no accident that export promotion has been a prominent feature of all the East Asian countries that began escaping from the lower end of the world income distribution towards the end of the 20th century, whereas import substitution was a prominent feature of several Latin American countries that fell from the upper end of the distribution early in the 20th century.

Culture is a difficult factor to measure. In principle, however, it is capable of explaining a great deal of cross-country variation in growth, because a society in which people are socialized to trust each other, to work hard, to value technical expertise and to respect law and order is certainly going to be thriftier and more productive than a society in which these traits do not apply. Recent work has begun to quantify the role of culture using measures of social capital, social capability, ethnolinguistic fractionalization, religious belief, the spread of Anglo-Saxon culture and many other variables.

Economic Growth in the Very Long Run

Oded Galor

E

Abstract

The evolution of economies during the major portion of human history was marked by Malthusian stagnation. The transition from an epoch of stagnation to a state of sustained economic growth has shaped the contemporary world economy and has led to the great divergence in income per capita across the globe in the past two centuries. This article examines the process of development over the course of human history in light of recent advances in unified growth theory.

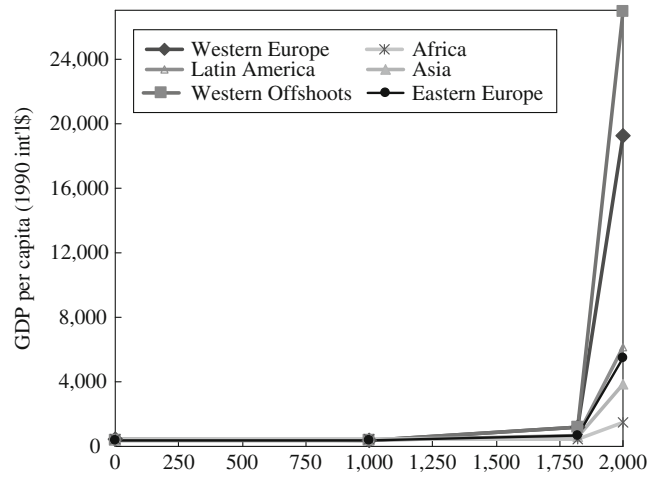
The evolution of economies during the major portion of human history was marked by Malthusian stagnation. Technological progress and population growth were minuscule by modern standards, and

the average growth rates of income per capita in various regions of the world were even slower due to the offsetting effect of population growth on the expansion of resources per capita.

In the past two centuries the pace of technological progress increased significantly in association with the process of industrialization. Various regions of the world departed from the Malthusian trap and experienced a considerable rise in the growth rates of income per capita and population. Unlike episodes of technological progress in the pre-Industrial Revolution era that failed to generate sustained economic growth, the increasing role of human capital in the production process in the second phase of industrialization ultimately prompted a demographic transition, liberating the gains in productivity from the counterbalancing effects of population growth. The decline in the growth rate of population and the enhancement of human capital formation and technological progress paved the way for the emergence of the modern state of sustained economic growth. Variations in the timing of the transitions from a Malthusian epoch to a state of sustained economic growth across countries lead to a considerable rise in the ratio of GDP per capita between the richest and the poorest regions of the world from 3:1 in 1820 to 18:1 in 2000 (see Fig. 1).

The transition from stagnation to growth and the associated phenomenon of the great divergence have been the subject of intensive research in the growth literature in recent years (Galor and Weil 1999, 2000; Galor and Moav 2002; Lucas 2002; Hansen and Prescott 2002; Jones 2001; Hazan and Berdugo 2002; Doepke 2004; Lagerlof 2003, 2006; Galor and Mountford 2003, 2006). The inconsistency of exogenous and endogenous growth models with some of the most fundamental features of the process of development has led to a search for a unified theory that would unveil the underlying microfoundations of the growth process in its entirety, and would capture in a single framework the epoch of Malthusian stagnation that characterized most of human history, the contemporary era of modern economic growth, and the driving forces that triggered the recent transition between these regimes.

The advance of unified growth theory was fuelled by the conviction that the understanding of the contemporary growth process would be fragile and incomplete unless growth theory were based on proper microfoundations that reflect the various qualitative aspects of the growth process and their central driving forces. Moreover, it has become apparent that a comprehensive understanding of the hurdles faced by less developed economies in reaching a state of sustained economic growth would remain obscure unless the factors that prompted the transition of the currently developed economies into a state of sustained economic growth could be identified and modified to account for the differences in the growth structure of less developed economies in an interdependent world.



Economic Growth in the Very Long Run, Fig. 1 The evolution of regional income per capita, 1–2000 (Source: Maddison (2001))

Unified growth theory explores the fundamental factors that generated the remarkable escape from the Malthusian epoch and their significance in understanding the contemporary growth process of developed and less developed economies. Moreover, it sheds light on the perplexing phenomenon of the great divergence in income per capita across regions of the world in the past two centuries. It suggests that the transition from stagnation to growth is an inevitable outcome of the process of development. The inherent Malthusian interaction between the level of technology and the size and the composition of the population accelerated the pace of technological progress and ultimately raised the importance of human capital in the production process. The rise in the demand for human capital in the second phase of industrialization and its impact on the formation of human capital as well as on the onset of the demographic transition brought about significant technological advances along with a reduction in fertility rates and population growth, enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of income per capita, and paving the way for the emergence of sustained economic growth.

Differences in the timing of the take-off from stagnation to growth across countries (for example, England's earlier industrialization in comparison with China) contributed significantly to the great divergence and to the emergence of convergence clubs. These variations reflect initial differences in geographical factors and historical accidents and their manifestation in diversity in institutional, demographic, and cultural factors, trade patterns, colonial status, and public policy. In particular, once a technologically driven demand for human capital emerged in the second phase of industrialization, the prevalence of human capital-promoting institutions determined the extensiveness of human capital formation, the timing of the demographic transition, and the pace of the transition from stagnation to growth. Thus, unified growth theory provides the natural framework of analysis in which variations in the economic performance across countries and regions could be examined based on the effect of variations in educational, institutional, geographical, and cultural factors on the pace of the transition from stagnation to growth.

The Process of Development

The process of economic development has been characterized by of three fundamental regimes: the Malthusian epoch, the post-Malthusian regime, and the sustained growth regime.

The Malthusian Epoch

During the Malthusian epoch that characterized most of human history, humans were subjected to a persistent struggle for existence. Resources generated by technological progress and land expansion were channeled primarily towards an increase in the size of the population, with a minor long-run effect on income per capita. Improvements in the technological environment or in the availability of land generated temporary gains in income per capita, leading eventually to a larger but not richer population. Technologically superior countries ultimately had denser populations but their standard of living did not reflect the degree of their technological advancement.

During the Malthusian epoch the average growth rate of output per capita was negligible and the standard of living did not differ greatly across countries. The average level of income per capita in the world during the first millennium fluctuated around $450 per year (in 1990 international dollars) and the average growth rate of output per capita was nearly zero (Maddison 2001). This state of Malthusian stagnation persisted until the end of the 18th century. In the years 1000–1820, the average level of income per capita in the world economy was below $670 per year, and the average growth rate of the world income per capita was minuscule, creeping at a rate of about 0.05 per cent per year. Nevertheless, income per capita fluctuated significantly within regions, deviating from their sluggish long-run trend over decades and sometimes centuries.

Population growth over this era followed the Malthusian pattern as well. The gradual increase in income per capita during the Malthusian epoch was

associated with a monotonic increase in the average rate of growth of world population. The slow pace of resource expansion in the first millennium was reflected in a modest increase in the population of the world from 231 million people in 1 CE to 268 million in 1000 CE: a minuscule average growth rate of 0.02 per cent per year. The more rapid (but still very slow) expansion of resources in the period 1000–1500 permitted the world population to increase by 63 per cent, from 268 million in 1000 to 438 million in 1500; a slow 0.1 per cent average growth rate per year. Resource expansion over the period 1500–1820 had a more significant impact on the world population, which grew 138 per cent from 438 million in 1500 to 1041 million in 1820: an average pace of 0.27 per cent per year.

Variations in population density across countries during the Malthusian epoch reflected primarily cross-country differences in technology and land productivity. Due to the positive adjustment of the population to an increase in income per capita, differences in technology or in land productivity across countries resulted in variations in population density rather than in the standard of living. For instance, China's technological advancement in the period 1500–1820 permitted its share of world population to increase from 23.5 per cent to 36.6 per cent, while its income per capita in the beginning and the end of this time interval remained approximately $600 per year.

The Post-Malthusian Regime

During the post-Malthusian regime, the pace of technological progress markedly increased in association with the process of industrialization, triggering a take-off from the Malthusian trap. The growth rate of income per capita increased significantly but the positive Malthusian effect of income per capita on population growth was still maintained, generating a sizeable increase in population growth that offset some of the potential gains in income per capita.

The take-off of developed regions from the Malthusian regime occurred at the beginning of the 19th century and was associated with the Industrial Revolution, whereas the take-off of less developed regions occurred towards the beginning of the 20th century and was delayed in some countries well into the 20th century. During the post-Malthusian regime the average growth rate of output per capita increased significantly and the standard of living began to differ considerably across countries. The average growth rate of output per capita in the world soared from 0.05 per cent per year during the period 1500–1820 to 0.53 per cent per year in the years 1820–70, and 1.3 per cent per year during the period 1870–1913. The timing of the take-off and its magnitude differed across regions. The take-off from the Malthusian epoch and the transition to the post-Malthusian regime occurred in western Europe, the Western offshoots (that is, the United States, Canada, Australia and New Zealand), and eastern Europe at the beginning of the 19th century, whereas in Latin America, Asia and Africa it occurred towards the beginning of the 20th century.

The rapid increase in income per capita in the post-Malthusian regime was channeled partly towards an increase in the size of the population. During this period, the Malthusian mechanism linking higher income to higher population growth continued to function. However, the effect of higher population on the dilution of resources per capita was counteracted by accelerated technological progress and capital accumulation, allowing income per capita to rise despite the offsetting effects of population growth.

The western European take-off along with that of the Western offshoots brought about a sharp increase in population growth in these regions and consequently a modest rise in population growth in the world as a whole. The subsequent take-off of less developed regions, and the associated increase in their rates of population growth, brought about a significant rise in population growth in the world. The rate of population growth in the world increased from an average rate of 0.27 per cent per year in the period 1500–1820 to 0.4 per cent per year in the years 1820–70, and to 0.8 per cent per year in the time interval 1870–1913. Despite the decline in population growth in western Europe and the Western offshoots towards the end of the 19th century and the beginning of the 20th century, the delayed take-off of less developed regions, and the

significant increase in their income per capita prior to their demographic transitions, generated a further increase in the rate of population growth in the world to 0.93 per cent per year in the period 1913–50, and 1.92 per cent per year in the period 1950–73. Ultimately, the onset of the demographic transition in less developed economies during the second half of the 20th century reduced population growth rates to 1.66 per cent per year in the 1973–98 period (Maddison 2001).

It appears that the significant rise in income per capita in the post-Malthusian regime increased the desired number of surviving offspring and thus, despite the decline in mortality rates, fertility increased significantly so as to enable households to reach this higher desired level of surviving offspring. Fertility was controlled during this period, despite the absence of modern contraceptive methods, partly via adjustment in marriage rates. Increased fertility was achieved by earlier female age of marriage, and a decline in fertility by a delay in the marriage age.

The take-off in the developed regions was accompanied by a rapid process of industrialization. Per-capita level of industrialization increased significantly in the United Kingdom, rising 50 per cent over the 1750–1800 period, quadrupling in the years 1800–60, and nearly doubling in the time period 1860–1913. Similarly, per capita level of industrialization accelerated in the United States, doubling in the 1750–1800 as well as 1800–60 periods, and increasing sixfold in the years 1860–1913. A similar pattern was experienced in Germany, France, Sweden, Switzerland, Belgium and Canada. The take-off of less developed economies in the 20th century was associated with increased industrialization as well. However, during the 19th century these economies experienced a decline in per capita industrialization, reflecting the adverse effect of the sizeable increase in population on the level of industrial production per capita as well as the forces of globalization and colonialism, which induced less developed economies to specialize in the production of raw materials (Galor and Mountford 2003, 2006).

The acceleration in technological progress during the post-Malthusian regime and the associated increase in income per capita stimulated the accumulation of human capital in the form of literacy rates, schooling, and health. The increase in the investment in human capital was induced by the rise in income per capita, as well as by qualitative changes in the economic environment that increased the demand for human capital and induced households to invest in the education of their offspring.

In the first phase of the Industrial Revolution, human capital had a limited role in the production process. Education was motivated by a variety of reasons, such as religion, enlightenment, social control, moral conformity, socio-political stability, social and national cohesion, and military efficiency. The extensiveness of public education was therefore not necessarily correlated with industrial development, and it differed across countries due to political, cultural, social, historical and institutional factors. In the second phase of the Industrial Revolution, however, the demand for education increased, reflecting the increasing skill requirements in the process of industrialization. The economic interests of capitalists were a significant driving force behind the implementation of educational reforms (Galor and Moav 2006). The process of industrialization has been characterized by a gradual increase in the relative importance of human capital in less developed economies as well and educational attainment increased significantly across all less developed regions in the post-Malthusian regime.

The Sustained Growth Regime

The acceleration in the rate of technological progress in the second phase of industrialization, and its interaction with human capital formation, triggered a demographic transition, paving the way to a transition to an era of sustained economic growth. In the post demographic-transition period, the rise in aggregate income due to technological progress and factors accumulation was no longer counterbalanced by population growth, permitting sustained growth in income per capita in regions that experienced sustained technological progress and accumulation of physical and human capital.

The transition of the developed regions of western Europe and the Western offshoots to the state of sustained economic growth occurred

towards the end of the 19th century, and their income per capita in the 20th century has advanced at a stable rate of about two per cent per year. The transition of some less developed countries in Asia and Latin America occurred towards the end of the 20th century. Africa, in contrast, is still struggling to make this transition.

The transition to a state of sustained economic growth was characterized by a gradual increase in the importance of the accumulation of human capital relative to physical capital as well as with a sharp decline in fertility rates. In the first phase of the Industrial Revolution (1760–1830), capital accumulation as a fraction of GDP significantly increased whereas literacy rates remained largely unchanged. Skills and literacy requirements were minimal, the state devoted virtually no resources to raise the level of literacy of the masses, and workers developed skills primarily through on-the-job training (Green 1990; Mokyr 1993). Consequently, literacy rates did not increase during the period 1750–1830 (Sanderson 1995).

In the second phase of the Industrial Revolution, however, the pace of capital accumulation subsided, skills became necessary for production and the education of the labour force markedly increased. The investment ratio in the UK, which increased from six per cent in 1760 to 11.7 per cent in 1831, remained at around 11 per cent on average in the years 1856–1913 (Crafts 1985). In contrast, the average years of schooling of males in the labour force that did not change significantly until the 1830s tripled by the beginning of the 20th century. The drastic rise in the level of income per capita in England as of 1865 was associated with an increase in school enrolment of ten-year-old children from 40 per cent in 1870 to 100 per cent in 1900. Moreover, total fertility rate in England sharply declined over this period from about five in 1875, to nearly two in 1925.

The demographic transition swept the world in the course of the 20th century. The unprecedented increase in population growth during the post-Malthusian regime was reversed and the demographic transition brought about a significant reduction in fertility rates and population growth in various regions of the world, enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of income per capita. The demographic transition enhanced the growth process via three channels: (*a*) reductions in the dilution of the stocks of capital and natural resources, (*b*) enhancements in human capital formation, and (*c*) changes in the age distribution of the population, temporarily increasing the size of the labour force relative to the population as a whole.

The timing of the demographic transition differed significantly across regions. The reduction in population growth occurred in Western Europe, the Western offshoots, and eastern Europe towards the end of the 19th century and in the beginning of the 20th century, whereas Latin America and Asia experienced a decline in the rate of population growth only in the last decades of the 20th century. Africa's population growth, in contrast, has been rising steadily.

The process of industrialization was characterized by a gradual increase in the relative importance of human capital in the production process. The acceleration in the rate of technological progress gradually increased the demand for human capital, inducing individuals to invest in education, and stimulating further technological advancement. Moreover, in developed as well as less developed regions, the onset of the process of human capital accumulation preceded the onset of the demographic transition, suggesting that the rise in the demand for human capital in the process of industrialization and the subsequent accumulation of human capital played a significant role in the demographic transition and the shift to a state of sustained economic growth.

Notably, the reversal of the Malthusian relation between income and population growth during the demographic transition corresponded to an increase in the level of resources invested in each child. For example, literacy rate among men in England was stable at around 65 per cent in the first phase of the Industrial Revolution and increased significantly during the second phase, reaching nearly 100 per cent at the end of the 19th century. In addition, the proportion of children aged 5 to 14 in primary schools increased from 11 per cent in 1855 to 74 per cent in 1900.

A similar pattern is observed in other European societies (Flora, Kraus and Pfenning 1983).

The process of industrialization was characterized by a gradual increase in the relative importance of human capital in less developed economies as well. Educational attainment increased significantly across all less developed regions. Moreover, in line with the pattern that emerged among developed economies in the 19th century, the increase in educational attainment preceded or occurred simultaneously with the decline in total fertility rates.

The Great Divergence

The differential timing of the take-off from stagnation to growth across countries and the corresponding variations in the timing of the demographic transition led to a great divergence in income per capita as well as population growth. Inequality in the world economy was negligible till the 19th century. The ratio of GDP per capita between the richest region and the poorest region in the world was only 1.1:1 in 1000, 2:1 in 1500 and 3:1 in 1820. In the past two centuries, however, the ratio of GDP per capita between the richest group (Western offshoots) and the poorest region (Africa) has widened considerably from a modest 3:1 ratio in 1820, to 5:1 ratio in 1870, 9:1 ratio in 1913, 15:1 ratio in 1950, and 18:1 ratio in 2001.

An equally momentous transformation occurred in the distribution of world population across regions. The earlier take-off of western European countries increased the amount of resources that could be devoted for the increase in family size, permitting a 16 per cent increase in the share of their population in the world from 12.8 per cent in 1820 to 14.8 per cent in 1870. However, the early onset in the western European demographic transition and the long delay in the demographic transition of less developed regions, well into the second half of the 20th century, led to a decline in the share of western European population in the world, from 14.8 per cent in 1870 to 6.6 per cent in 1998. In contrast, the prolongation of the post-Malthusian period among less developed regions, in association with the delay in their demographic transition well into the second half of 20th century, channelled their increased resources towards a significant increase in their population. Africa's share of world population increased from seven per cent in 1913 to 12.9 per cent in 1998, Asia's share of world population increased from 51.7 per cent in 1913 to 57.4 per cent in 1998, and Latin American countries increased their share in world population from two per cent in 1820 to 8.6 per cent in 1998.

E

Unified Growth Theory

Galor and Weil (2000) advanced a unified growth theory that captures the three regimes that have characterized the process of development as well as the fundamental driving forces that generated the transition from an epoch of Malthusian stagnation to a state of sustained economic growth. The theory replicates the observed time paths of population, income per capita, and human capital, generating: (*a*) the Malthusian oscillations in population and output per capita during the Malthusian epoch, (*b*) an endogenous take-off from Malthusian stagnation that is associated with an acceleration in technological progress and is accompanied initially by a rapid increase in population growth, and (*c*) a rise in the demand for human capital, followed by a demographic transition and sustained economic growth. These qualitative patterns are confirmed in the calibration of the theory by Lagerlof (2006).

The theory proposes that in early stages of development economies were in the proximity of a stable Malthusian equilibrium. Technology advanced rather slowly, and generated proportional increases in output and population. The inherent positive interaction between population and technology in this epoch, however, gradually increased the pace of technological progress, and due to the delayed adjustment of population, output per capita advanced at a minuscule rate. The slow pace of technological progress in the Malthusian epoch provided a limited scope for human capital in the production process and parents, therefore, had no incentive to reallocate resources towards human capital formation of their offspring.

The Malthusian interaction between technology and population accelerated the pace of technological progress and permitted a take-off to the post-Malthusian regime. The expansion of resources was partially counterbalanced by the enlargement of population, and the economy was characterized by rapid growth rates of income per capita and population. The acceleration in technological progress eventually increased the demand for human capital, generating two opposing effects on population growth. On the one hand, it eased households' budget constraints, allowing the allocation of more resources for raising children. On the other hand, it induced a reallocation of resources towards child quality. In the post-Malthusian regime, due to the modest demand for human capital, the first effect dominated, and the rise in real income permitted households to increase the number as well the quality of their children.

As investment in human capital took place, the Malthusian steady-state equilibrium vanished and the economy started to be attracted by the gravitational forces of the modern growth regime. The interaction between investment in human capital and technological progress generated a virtuous circle: human capital generated faster technological progress, which in turn further raised the demand for human capital, inducing further investment in child quality, and eventually triggering the onset of the demographic transition and the emergence of a state of sustained economic growth.

The theory suggests that the transition from stagnation to growth is an inevitable outcome of the process of development. The inherent Malthusian interaction between the level of technology and the size of the population accelerated the pace of technological progress, and ultimately raised the importance of human capital in the production process. The rise in the demand for human capital in the second phase of the Industrial Revolution and its impact on the formation of human capital as well as on the onset of the demographic transition brought about significant technological advancements along with a reduction in fertility rates and population growth, enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of income per capita, and paving the way for the emergence of sustained economic growth. Quantitative analysis of unified growth theories (Doepke 2004); Lagerlof 2006) indeed suggest that the rise in the demand for human capital was a significant force behind the demographic transition and the emergence of a state of sustained economic growth.

Variations in the timing of the transition from stagnation to growth and thus in economic performance across countries reflect initial differences in geographical factors and historical accidents and their manifestation in diversity in institutional, demographic, and cultural factors, trade patterns, colonial status, and public policy. In particular, once a technologically driven demand for human capital emerged in the second phase of industrialization, the prevalence of human capital-promoting institutions determined the extensiveness of human capital formation, the timing of the demographic transition, and the pace of the transition from stagnation to growth.

The theory proposes that the growth process is characterized by stages of development and it evolves nonlinearly. Technological leaders experienced a monotonic increase in the growth rates of their income per capita. Their growth was rather slow in early stages of development, increased rapidly during the take-off from the Malthusian epoch, and continued to rise, often stabilizing at higher levels. In contrast, technological followers that made the transition to sustained economic growth experienced a non-monotonic increase in the growth rates of their income per capita. Their growth rate was rather slow in early stages of development, but increased rapidly in the early stages of the take-off from the Malthusian epoch, boosted by the adoption of technologies from the existing technological frontier. However, once these economies reached the technological frontier, their growth rates dropped to the level of the technological leaders. Hence, consistently with contemporary evidence about the existence of multiple growth regimes (Durlauf and Quah 1999), the differential timing of the take-off from stagnation to growth across economies generated convergence clubs characterized

by a group of poor countries in the vicinity of the Malthusian equilibrium, a group of rich countries in the vicinity of the sustained growth equilibrium, and a third group in the transition from one club to another.

Economic Growth Non-linearities

Chih Ming Tan

Abstract

Nonlinearities in growth have important implications for cross-country income inequality. In particular, they imply that countries may spend long periods of time in a low-growth poverty trap. However, finding evidence of such nonlinearities in the data and accounting for their emergence pose unique challenges to researchers.

Nonlinear Growth Models

Nonlinear growth models are characterized by a country's subsequent performance being critically dependent upon its initial conditions. In particular, these models tend to imply that countries which have unfavourable initial conditions may either experience substantial periods of time in low-growth/low-income poverty traps or be altogether caught in one. In some cases, it has been explicitly suggested that active (exogenous) policy interventions may be necessary in order to kick-start a country into a more favourable equilibrium. Nonlinear growth models can be broadly classified into two classes: structural change (or 'stages of development') models, and models that emphasize endogenous technological development and cross-country interactions in terms of technological diffusion.

Structural change models focus on the (internal) transformations of an economy as it transits through critical phases or 'stages' (see Lewis 1956; Rostow 1960) leading to industrialization. The aim of this work is to clarify the conditions for such transitions to occur. Early work in the economic development literature (see Rosenstein-Rodan 1943; Nurkse 1953; Scitovsky 1954; Fleming 1955; formalized by Murphy et al. 1989) emphasized the importance of increasing returns and the size of the market in industrialization. The key idea behind this view is that countries could be locked in a no-industrialization trap because of the small size of the market for each sector of the economy. No single sector can achieve growth on its own. However, the growth of one sector results in the enlargement of markets for other sectors. The enlargement of markets then encourages investment and growth in the corresponding sectors. These spillover effects and strategic complementarities imply that a 'big push' – that is, coordinated investments (or 'balanced growth') across sectors – may be sufficient to push the economy out of the trap and into a 'take-off' towards industrialization. Other models are explicitly informed by the analysis of historical data (see Maddison 2004), and emphasize the importance of explaining simultaneously both historical patterns of other state variables associated with growth and growth itself. An important recent work that models the demographic transition in growth take-offs is Galor and Weil (2000). Because these models require that certain conditions be met before countries are able to achieve take-off, those who do not meet these requirements could find themselves trapped in a phase of economic stagnation for extended periods of time.

The second class of models focuses on the role of technological progress in growth. In particular, the emphasis of these models is on the diffusion of technology from countries which are technological leaders to less developed countries. Lucas (2000) is a seminal work in this area (see also Basu and Weil 1998; Parente and Prescott 1994; Howitt and Mayer-Foulkes 2005). Particular attention has been paid to exploring the channels through which less advanced countries imitate or adopt technologies in leader countries. If there are no barriers to technological diffusion across countries, then these models typically predict that rich and poor countries would gradually converge in per capita income. However, if such barriers exist, then countries may differ in their ability to adopt technologies leading to the creation of 'clusters' of countries defined by a set of common barriers to technological adoption. Countries within each of these clusters or 'convergence clubs' converge to common levels of mean per capita income. Nevertheless, the per capita incomes across convergence clubs need never converge and the polarization of per capita incomes across countries may be permanent.

Growth Empirics

In both classes of models, therefore, the primary concern is that countries may become separated – perhaps permanently – into multiple growth regimes corresponding to different levels of long-run per capita income. The fact that nonlinear growth models imply that global inequality may be persistent has sparked major advances in the area of cross-country growth empirics. Driven by such concerns, the central preoccupation of growth empirics has been to evaluate the

conditions under which poor countries catch up with rich ones or fail to do so. Initial work along these lines focused on the concept of 'conditional convergence'. Conditional convergence is said to occur if permanent per capita income differences between countries can be accounted for solely by structural differences (and not initial conditions). Researchers initially argued that because conditional convergence was predicted by the canonical neoclassical growth model (see Ramsey 1928; Solow 1956; Swan 1956; Cass 1965; Koopmans 1965) whereas nonlinear growth models potentially predict dependence on initial conditions, tests for conditional convergence could be used to discriminate between these classes of theories.

Following Mankiw et al. (1992) and Barro and Sala-i-Martin (1992), the canonical way such tests were conducted was to first construct a linearized version of the neoclassical growth model about the (unique) steady state with average growth rates across a time period as the dependent variable, and measures of physical and human capital, population growth rates, and initial per capita income as covariates. Researchers then applied the linearized neoclassical model to cross-country data with the aim of testing to see whether the data supported a negative coefficient on initial per capita income. A finding of a negative coefficient on initial per capita income was taken to imply that, conditional on countries having similar structural characteristics (as defined by the set of covariates), poorer countries would close the income gap with the rich – that is, conditional convergence.

An important outcome of the, oftentimes heated (see Sala-i-Martin 1996), convergence debates of the 1990s was precisely to weaken the idea that such tests of convergence could be interpreted as model selection tests. In a highly influential work, Bernard and Durlauf (1996) strongly disputed the interpretation of such 'conditional convergence' tests by pointing out that these tests were not able to discriminate against a class of nonlinear growth theories that have dramatically different ergodic implications from the neoclassical model. The class of models they were referring to was developed by Azariadis and Drazen (1990). Azariadis and Drazen extended the spillover models of Lucas (1988) and Romer (1986) and showed that, if (local) nonconvexities in the production function were sufficiently strong, then countries that are similar in all aspects except for initial conditions may nevertheless be organized into multiple growth regimes, each of which corresponds to a different steady state for long-run per capita income.

Bernard and Durlauf showed that the multiple-regimes Azariadis–Drazen model was theoretically consistent with a finding of conditional convergence in the data. Therefore, even in the narrowly restricted sense of countries being structurally similar, the finding of a negative coefficient to initial income in the data was no guarantee that countries would converge to a common steady state. Galor (1997) lent further support to the relevance of the Azariadis–Drazen model by arguing that standard ways of augmenting the traditional Solow model increased the likelihood that the true data-generating process followed a multiple-regimes rather than a single steady-state model. Clearly, evidence of multiple regimes and nonlinearities in growth raises questions about misspecification in empirical studies that assume that all countries follow the same growth process, and casts doubt on inferences and policy recommendations that are drawn from these studies.

The work by Bernard and Durlauf has spurred a large quantity of research searching for the existence of multiple-growth regimes. One direction of this new research has been to argue that the finding of parameter heterogeneity in the neoclassical model may be suggestive of the existence of multiple growth regimes. In a seminal work, Durlauf and Johnson (1995), employing a classification and regression tree methodology, implemented a version of Azariadis and Drazen's model and showed that there was evidence in the data to suggest that countries grouped according to initial per capita income and literacy rates correspond to four different growth regimes. Their work has inspired a long list of confirmatory works using a wide variety of econometric approaches (for example, Bloom et al. 2003; Canova 2004; Durlauf et al. 2001; Kourtellos 2005; Liu and Stengos 1999; and Tan 2005).

While there now is a strong consensus in the literature that there exists substantial heterogeneity

across countries, it should be emphasized that this finding is only suggestive of multiple-growth regimes and is not conclusive evidence of it. These heterogeneities could arise because of small deviations in the specification of the production function (see Masanjala and Papageorgiou 2004) which need not correspond to multiple-growth regimes. Further, even within the context of Azariadis–Drazen model, if non-convexities in the production function are not strong enough, the finding of parameter heterogeneity would not imply the existence of multiple regimes (see Durlauf and Johnson 1995, Figure 2).

An alternative approach to investigating the existence of multiple regimes or convergence clubs has focused on the evolution of the world distribution of per capita income. The aim of this research has been to look for evidence of emerging multimodality (typically, bimodality) in the world income distribution. A secondary aim has been to evaluate the degree of churning within the multimodal distribution. If the world income distribution is characterized by emerging multimodality with little evidence of countries moving freely within the distribution (that is, churning), then this finding would suggest, in a manner analogous with the finding of multiple-growth regimes, that global income inequality is real, intensifying and persistent in nature. In fact, these are the precise findings by Quah (1993). By estimating transition probabilities for the cross-country per capita income distribution, Quah finds emerging 'twin peaks' in the world income distribution as well as substantial persistence within the distribution. Quah's seminal work has been confirmed by subsequent work (for example, Bianchi 1997; Fiaschi and Lavezzi 2003; and Paap and van Dijk 1998) even though there had been questions about the robustness of his initial methodology (see Kremer et al. 2001).

While the findings of the 'twin peaks' literature have been suggestive of growth nonlinearities and multiple equilibria, it is not definitive. It is quite possible, for instance, that the aggregate production functions across countries actually exhibit decreasing marginal productivity of capital, so that there is only one steady state. However, other growth factors are sufficiently strong to overcome the convergence effect of diminishing marginal returns to produce divergence and bimodality in cross-country incomes nevertheless. Without an explicit theory to explain the observed income divergence, there is also the question of whether the bimodality in the cross-country income distribution is a transitional or permanent feature of growth (see Galor 1997; Lucas 2000).

Conclusion

Nonlinearities in growth have been highly influential in shaping the thinking of both growth theorists and empiricists in recent years. The work on multiple-growth regimes and the world income distribution suggests that there may exist growth factors strong enough to overcome the decreasing marginal productivity of the neoclassical production function, thereby producing increasing inequality across countries. Nevertheless, while an increasingly large body of work finds evidence that is suggestive of growth nonlinearities, many questions remain open and are the subject of current research. What are the factors that are responsible for generating multiple growth regimes or convergence clubs? Are the effects of these factors transient or permanent? If the former, what are the applicable timescales? This area of research continues to be promising and fruitful.

Economic Growth, Empirical Regularities in

Steven N. Durlauf and Paul A. Johnson

Abstract

The evolution of economic growth theory throughout the post-war period has been deeply influenced by the effort to explain

broad patterns in cross-country behaviour. We discuss some of the salient empirical regularities associated with neoclassical and new growth economics and consider the shift in focus that has occurred. We first describe the stylized facts of Kaldor that played an important role in the assessment of neoclassical growth models. Next, we consider how a switch in focus to a different class of regularities is associated with the new growth economics that began in the 1980s and dominates contemporary research.

The evolution of economic growth theory throughout the post-war period has been deeply influenced by the effort to explain broad patterns in cross-country behaviour. In this entry, we discuss some of the salient empirical regularities associated with neoclassical and new growth economics and consider the shift in focus that has occurred. We first describe the role of empirical regularities in neoclassical growth theory as it emerged in the 1950s. Next, we consider how a switch in focus to a different class of regularities is associated with the new growth economics that developed in the 1980s and continues to dominate contemporary research. Finally, we assess this shift. Durlauf et al. (2005) contains details of the data and methods used to substantiate the claims made here.

Empirical Regularities and Neoclassical Growth

Neoclassical growth theory is commonly associated with Kaldor's (1961) well-known 'stylized facts' of long-run economic behaviour, which primarily focused on the invariance of long run behaviour for advanced economies. Four of his six facts – (1) the constancy of the growth rate of output per worker over long time horizons, (2) the constancy of the growth rate of capital which is lower than the growth rate of the labour supply, (3) the absence of any systematic trends in the capital–output ratio and (4) the constancy of the rate of profit (and, by implication with the other facts, factor shares in national income) – emphasize common behaviour across countries. Only the fifth and sixth facts – the presence of substantial differences in output per worker across countries, and the positive relationship between the rate of profit and the investment – output ratio – focus on heterogeneity. Kaldor (1957) cites the prediction of constant factor shares as an important test of alternative growth models. An important empirical study at the time was Klein and Kosobud (1961) who investigated constancy by testing for a trend in labour's share, finding none using US data from 1900 to 1953.

While these facts are generally cited as a motivation of neoclassical growth models, their actual relationship to the theory is in fact more complicated. In Solow (1956), for example, the objective is the explanation of long-run economic growth and the constancy of factor shares is only mentioned in passing as an implication of the Cobb–Douglas technology. Indeed Solow (1958) criticizes the literature studying the constancy of factor shares for lacking a precise notion of constancy given that exact constancy cannot reasonably be expected. Bronfenbrenner (1960) argues that, for a wide range of values of the elasticity of substitution between capital and labour, and for reasonable variation in the capital–labour ratio, the theoretical variation in factor shares is consistent with that observed. He concludes that the constancy or otherwise of factor shares is not useful in the assessment of (distribution) theories. Put differently, the first three of Kaldor's stylized facts seem most important to understanding the motivation of the neoclassical program; Solow (2000, p. 4) (in a discussion originally published in 1970) remarks that growth theory is largely

> devoted to analyzing the properties of steady states and to finding out whether an economy not initially in a steady state will evolve into one . . .

How do Kaldor's stylized facts appear from the vantage point of modern empirical growth research? Barro and Sala-i-Martin (2004, pp. 12–16) assess the concordance of Kaldor's stylized facts with the data and conclude that, with the exception of the constant rate of profit, each of the first five holds 'reasonably well' for developed economies. They cite evidence suggesting some tendency for the real rate of return to decline in some economies. The evidence they present, and that which we discuss below, shows that, at least as far as it concerns the rate of growth of labour productivity, the sixth of Kaldor's facts also fits well with the data.

Kaldor's stylized facts are therefore of contemporary use in understanding long- run output behaviour. That said, the facts are no longer central to the research efforts in growth economics as other regularities (or the lack thereof) have become the primary focus of research. We therefore turn to those regularities that have become the focus of contemporary work.

Empirical Regularities and the New Growth Economics

The renaissance in growth theory associated with the rise of endogenous growth models was influenced by interest in the determinants of heterogeneity in growth experiences. While not usually called stylized facts, there is a set of general propositions about heterogeneity that have been very important in influencing research. The most prominent global features evident in the data are the divergence in living standards over the past three centuries and the large disparities in living standards at the end of the twentieth century. By modern standards, all countries were poor in 1700 but since then sustained growth, first in the United Kingdom and parts of Western Europe, and more recently in the United States and parts of the Asia–Pacific region, has resulted in large cross-country differences in living standards. In 2000 average GDP per worker in some countries was about one-fiftieth that in the United States while more than 40% of the world's population lived in countries with average levels of GDP per worker of no more than ten per cent of that in the United States.

Divergence in living standards over the 1960–2000 period is also evident in the large group of countries covered by the Penn World Tables (PWT) (Heston et al. 2002). While a substantial group of countries has exhibited prolonged growth over this period, there remains a large mass of countries at the bottom of the distribution. One result was a hollowing out of the middle of the distribution – a phenomenon labelled 'twin peaks' by Quah (1996; 1997). Moreover, there is strong persistence within the cross-country income distribution with a Spearman rank correlation of 0.84 between GDP per worker in 1960 and that in 2000. This degree of correlation is not peculiar to the PWT data. Easterly et al. (1993) report a rank correlation of 0.82 between GDP per capita in 1988 and that in 1870 for the 28 countries in Maddison (1989). This sense of a lack of mobility is reinforced by Bianchi (1997), who found that very few of the possible crossings from one end of the distribution to the other actually occurred between 1970 and 1989.

The persistence in levels of GDP per worker contrasts sharply with the wide cross-country variation in the growth rates of GDP per worker especially for those countries with relatively low levels of GDP per worker in 1960. The data show scant support for the proposition that the countries of the world are converging to a common level of income per person or for the belief that poor countries have always grown slowly. Both growth 'miracles' – countries exhibited consistently strong growth over the 1960–2000 period – and growth 'disasters' – countries that did poorly, often having negative average growth rates – are present in the data. East and South East Asian countries are well represented among the former group while the later is dominated by countries in sub-Saharan Africa. Taiwan, for example, grew at an average annual rate of over six per cent during this 40-year period and increased GDP per worker by a factor of 11 in the process. Hong Kong,

Korea and Singapore were not far behind in either respect. By contrast, Mauritania, Senegal, Chad, Mozambique, Madagascar, Zambia, Mali, Niger, Nigeria, the Central African Republic, Angola and the Democratic Republic of the Congo all had negative average growth over this period.

For most countries, the average growth rate from 1980 to 2000 was lower than that from 1960 to 1980. The notable exceptions to this observation are China and India. Moreover, past growth does not seem to be a good predictor of future growth as, for example, the correlation between growth in 1960–1980 and that in 1980–2000 is just 0.40. Easterly et al. (1993) suggest that the lack of persistence in growth rates indicates the importance of good luck in economic development. Nevertheless, the cross-decade correlations in growth rates have tended to increase during the 1960–1980 period, indicating a sorting of countries into distinct groups of winners and losers.

There seems to be little relationship between the 1960 level of GDP per worker and subsequent average growth rates. The cross-country dispersion of growth rates tends to fall as initial income rises largely due to the rarity of poor performance among the countries with relatively high levels of GDP per worker in 1960. There is, however, a close relationship between geographical group membership and economic growth between 1960 and 2000. As alluded to above, the countries of sub-Saharan Africa performed poorly over this period, with three-quarters of them growing at an average annual rate of less than just 1.3%. The countries in South and Central America did somewhat better with three-quarters of them having grown at an average of less than 1.5%. Among the East and South East Asian countries, three-quarters grew at an average rate of over 3.8%, and a similar fraction of the South Asian countries grew at over 1.9%.

Many of the poor countries of the world were unable to break out of stagnation between 1960 and 2000. A country growing at two per cent per year for 40 years would enjoy a 120% increase in income per person over that period. Yet, between 1960 and 2000, about a quarter of countries never exceeded their 1960 income level by more than 60%, and about ten per cent of countries never exceeded their 1960 level by more than 30%. One reason for this stagnation is the disposition of some economies to large, abrupt output collapses. About half of countries experienced a 3-year output collapse of 15% or more between 1960 and 2000. Over the same period, the largest 3-year output collapse in the United States was 5.4%, and in the United Kingdom 3.6%, both in 1979–1982.

In sum, there are large cross-countries disparities in GDP per worker and hence in living standards. These disparities have grown wider since 1960 and the middle of cross-country income distribution has thinned since 1960. There is substantial immobility in a country's position in the distribution. Growth rates are much less persistent and have tended to fall since 1980. In general, the countries of sub- Saharan Africa performed poorly over the 1960–2000 period. The countries in South and Central America did somewhat better while the South Asian countries did better still. The East and South East Asian countries did best of all.

The Changing Empirical Focus of Growth Economics

The two sets of empirical regularities we have described, while appearing to differ greatly in terms of their implications for understanding the determinants of the growth process, may in fact be reconciled. A key difference between neoclassical and modern growth economics is its domain of explanation: whereas neoclassical theory attempted to understand the long-run behaviour of advanced industrialized economies, the new growth economics attempts to understand worldwide growth patterns. As a result, the differences between the advanced industrialized economies and the rest of the world take on primary importance. Lucas (2002, pp. 2–3) describes his motivation as

> to see whether modern growth theory could also be adapted for use as a theory of economic development. Adaptation of some kind was evidently necessary: The balanced path of growth theory, with

> constant income growth, and the assumed absence of population pressures, obviously did not fit all of economic history or even all the behavior that can be seen in today's world. The theory is, and was designed to be, a model of the recent past of a subset of countries.

Thus, as the domain of inquiry in growth economics has evolved, the stylized facts of interest have shifted to identifying features of international divergence rather than international convergence.

Further, the effort to identify patterns that characterize the differences in crosscountry growth experiences has led to empirical research that focuses on the identification of particular factors in generating the divergence. Theoretical work in growth economics moved away from the traditional emphasis on factor accumulation and towards the analysis of a wide range of social, historical, geographic, and political factors as sources of cross-country heterogeneity. For example, a major strand of contemporary research focuses on the ways that institutional quality affects growth and development; see Acemoglu et al. (2005) for a detailed survey. The richness of the modern growth literature has led to the widespread use of regression methods to allow for the simultaneous consideration of multiple growth determinants, with a focus on identifying which determinants in fact matter.

The move towards regression methods as the basis for empirical growth research has altered the nature of the sorts of regularities that link data and theory. It is still the case that theoretical analyses are often motivated by the identification of a bivariate relationship between some factor of interest and growth rates. However, relationships of this type do not represent basic growth regularities in the way that Kaldor's stylized facts did. The reason for this transition is that the different growth factors that have expanded the domain of growth economics are typically mutually consistent (Brock and Durlauf 2001) and so the empirical significance of one factor can only be assessed when others are considered as well. Put differently, the finding of a bivariate relationship, or lack thereof, can always be rationalized as reflecting a failure to control for other factors.

As a result, the empirical regularities that matter for contemporary research, such as the coefficient relating a measure of institutional quality to growth, are derivative from statistical analyses of the entire growth process. But statistical models of growth are subject to many forms of model uncertainty, ranging from uncertainty about the appropriate theories to employ to uncertainty about the empirical measurement of the qualitative factors identified by a theory to uncertainty about the details of the statistical specification of a model; see Durlauf and Quah (1999) and Durlauf et al. (2005) for a delineation of these issues. Model uncertainty has meant that there is relatively little consensus on the empirically salient determinants of growth and so little consensus on which regularities should be of primary interest. Thus current growth economics has been handicapped as different papers identify different salient empirical regularities, with inadequate attention to the robustness of such claims. The development of sturdy inferences about the growth process thus represents a very active area of current work.

Economic Harmony

Israel M. Kirzner

This term has been introduced frequently into economic discussion, and especially into discussions concerning the history of economic thought. Yet there seems to be a good deal of ambiguity as to what it is to mean. Moreover, there has developed considerable disagreement concerning the centrality of the 'harmony' idea to the development of economic thought, and similar disagreement concerning the extent to which the classical economists, in particular, are to be seen as harmony-theorists. We will return a little later to distinguish various different senses that have been attached to the term 'harmony' in economics. For each of these different senses, however, acceptance of the harmony thesis has been held to imply a favourable stance towards a policy of laissez-faire. It is thus not surprising that 18th-century precursors of the notion of harmony have been discovered in Cantillon and in Quesnay (Schumpeter 1954, p. 234). And we are not surprised to find some writers emphasizing the harmony ideas they see in the classical economists, especially in Adam Smith (Halévy 1901–4, p. 89; Heimann 1945, p. 65), while others vehemently question the unqualified identification of these writers with harmony theories (Robbins 1952, pp. 22–9; Samuels 1966, pp. 6–8; Sowell 1974, pp. 16f). It was in the middle of the 19th century that the best–known writings appeared concerning economic harmony. The term appeared in the title of two books by the American economist Henry C. Carey (Carey 1836, 1852). These works were followed by a general treatise stressing the same theme (Carey 1858–60). The term also appeared in the title of a book by the French economic writer Frédéric Bastiat (1850). For a (muted) defence of Bastiat against widespread 19th-century charges that his work in this respect was a crude plagiarism of Carey, see Teilhac (1936, pp. 100–113), who points to the inspiration that both Carey and Bastiat received from J.B. Say. Subsequent references to harmony theories in economics generally tended to be critical, as economists began to argue (from the latter decades of the 19th century into the 20th century) for greater state intervention in market economies on perceived grounds of economic efficiency or economic justice. During most of the 20th century economists, even when they have defended the efficiency and justice of markets, have generally not couched their arguments explicitly in terms of harmony theory. Even Ludwig von Mises who, as we shall see, was an important exception to this last generalization, relegated the notion of

harmony to a distinctly subsidiary role in his system. Recent re-awakened attention to 18th-century theories of spontaneous order, especially as rediscovered and expanded in the work of Hayek, has not had the effect of reintroducing the term 'economic harmony' to current usage. We turn now to take notice of the several different (although certainly interrelated) senses in which this term has been used during the history of economics.

Harmony as Flowing from Divine Providence

A harmony 'theory' is not, in this sense, one that flows out of economic science; rather it represents an attitude of (usually religious) optimism and faith, which itself suggests and guides the course of scientific investigation.

Just as Kepler was inspired by the doctrine of harmony in the spheres to discover the laws which govern the orbits of the planets, so the early economists were inspired by the doctrine that there is a harmony of interests in a society to formulate economic laws (Streeten 1954, p. 208).

It was from this sense of the term that Lord Robbins vigorously dissociated the classical school. It was this optimistic doctrine that came to be referred to contemptuously by the German term 'Harmonielehre'. Archbishop Whately, who in 1832 set up a chair of political economy at Trinity College, Dublin, was an influential harmony theorist in this sense. He saw the purpose of the chair as that of combatting the irreligious implications, as he saw them, of Ricardian economics. The early Dublin professors 'were under pressure to present an optimistic or harmonious picture of how the market economy operates' and the resulting critical attitude towards Ricardian theory reflected 'these extrascientific concerns' (Moss 1976, p. 153). A variant of this approach to the harmony doctrine was the Enlightenment view, in which Deistic philosophy perceived a natural order as responsible for 'predetermined harmony' (Mises 1949, p. 239; Heimann 1945, p. 49).

Harmony Theory as the Doctrine of Maximum Satisfaction

When major neoclassical economists such as Marshall (1920, p. 470) and Wicksell (1901, p. 73) referred to harmony theorists, they evidently had in mind those who believed that economic theory demonstrates that free competitive markets generate maximum total satisfaction for society as a whole. 'Harmony theory' thus referred to a very specific conclusion of economic science, a conclusion central to welfare economics, but a conclusion whose validity both Marshall and Wicksell were concerned to refute. Of special concern, in this context, was the issue of whether the new marginal utility doctrines had been successfully deployed by Jevons, or by Walras, to arrive at 'harmony' conclusions similar to those that had been reached, on other grounds, by Bastiat.

Parallel to this sense of harmony was that which attributed *ethical* virtues to the distributive results of competitive markets. Thus J.B. Clark's demonstration of the justice of marginal-productivity incomes is seen as 'harmony doctrine' (Myrdal 1932, p. 148).

Harmony Doctrine as the Denial of Class Conflict

One sense in which harmony doctrines have been understood throughout the history of economics is that in which it is sought to demonstrate the mutual compatibility of the interests of the various individuals and groups in society. In particular, such doctrines tend to dismiss the notion of inherent class conflict under capitalism. A 20th-century economist who has himself emphasized this idea of harmony of interests in the market society, put the genesis of this idea as follows:

When the classical economists [asserted 'the theorem of the harmony of the rightly understood interests of all members of the market society' they were stressing] two points: First, that everybody is interested in the preservation of the social division of labour, the system that multiplies the productivity of human efforts. Second, that in the

market society consumers' demand ultimately directs all production activities (Mises 1949, p. 674).

Mises, indeed, saw these ideas as important results of economic science, having wide application. 'There is no conflict between the interests of the buyers and those of the sellers, between the interest of the producers and those of the consumers' (Mises 1949, p. 357). Only in the special case of resource monopoly ownership may it happen that the 'emergence of monopoly prices... creates a discrepancy between the interests of the monopolist and those of the consumers' (Mises 1949, p. 680).

Harmony and the Spontaneous Order Tradition

Since the early 1940s F.A. Hayek has succeeded in drawing the attention of economists and others to a line of social analysis since the 18th century, an approach often termed the 'spontaneous order tradition'. The emphasis, in this tradition, is on the evolution of institutions and social outcomes 'which are indeed the results of human action, but not the execution of any human design' (Ferguson 1767, p. 187, cited in Hayek 1967, p. 96). There is no doubt that the term 'economic harmony' has often been applied as an expression of belief in the *possibility and social benignity of undesigned social outcomes*. To some extent, of course, this sense of the term overlaps those listed above, but the emphasis here is not in the denial of conflict, not on any particular welfare theorem, certainly not on any religiously based optimism, but on the counter-intuitive possibility of orderly results emerging without deliberate design from the spontaneous interplay of independently acting individuals. 'Order' in this context has come to mean 'mutually reinforcing expectations'. The following reference to this notion of harmony expresses this usage of the term:

The great general rule governing human action at the beginning, namely that it must conform to fair expectations, is still the scientific rule. All the forms of conduct complying with this rule are consistent with each other and become the recognized customs. The body of custom therefore tends to become a harmonious system (Carter 1907, p. 331, cited in Hayek 1973, p. 169).

The above survey has been confined to notions of economic harmony believed to be achieved spontaneously, 'naturally', without design. For the sake of completeness it should perhaps be noted that the term 'harmony' has occasionally been used to describe the objective of *deliberate* social policy. Thus a well-known debate was initiated by E. Halévy in his claim that Bentham and the philosophical Radicals subscribed to two partly contradictory principles: the 'economic' principle of 'natural identity' (i.e. harmony) of interests, and the 'juristic' principle of the 'artificial identification of interests' (Halévy 1901–4, pp. 15, 17, 489). Lord Robbins, in disputing Halévy concerning any contradiction in the Benthamite position, refers to the juristic principle as contending it to be 'the function of the legislator to bring about an artificial harmonization of interest' (Robbins 1952, pp. 190f). While occasional references may be found to harmony sought to be artificially accomplished, the term has, in general, been associated almost invariably with harmony achieved undeliberately in a decentralized system.

Economic History

Alexander J. Field

Abstract

Economic history focuses on the historical study of growth and development. Originating in the German historical school and studies of the Industrial Revolution in England, it became professionally differentiated from economics proper with the establishment of associations in Britain (1926) and the United States (1941). As economics continued on its increasingly mathematical and ahistorical path in the 1960s, the 'new economic history' advocated applying theory to history. But its emphasis on data analysis retained a bridge to older traditions. As economists have rediscovered an interest in long-term economic growth, often applying traditional institutional approaches, there is continuing evidence of rapprochement.

Economic history is a sub-discipline within economics and, to a lesser degree, within history, whose main focus is the study of economic growth and development over time. It is to be distinguished from the history of economic thought, a branch of intellectual history.

Studies in economic growth, whether historical or contemporary, develop and analyse quantitative measures of increases in output and output per capita, emphasizing in particular changes in saving rates and rates of technological innovation and their consequences. Economic development is a larger and more encompassing rubric, also including consideration of the role of cultural changes and changes in formal institutions.

Economic history has its origins in two main traditions. The first is the German historical school, a group of scholars in the 19th and early 20th centuries, including Gustav Schmoller and Max Weber, who ranged widely over human history with special emphasis on the consequences of institutional variation for economic as well as political performance. The second tradition stems from the efforts of a group of writers who

viewed the complex of innovations in steam power, iron manufacture, and textiles in late 18th-century Britain as an epochal event – an industrial revolution – equivalent in its significance for human welfare to the Neolithic revolution which gave birth to agriculture around ten millennia earlier. The study of the causes, dimensions and consequences of the emergence of sustained increases in per capita incomes – what Simon Kuznets (1966) called modern economic growth – along with a focus on the consequences of institutional variation, continues to define much of what economic historians do.

Although historians have practised their craft at least since the time of Herodotus (the fifth century BC), economics emerged as a separate social science with the work of Adam Smith or, perhaps, as some have argued, that of the Mercantilists and the Physiocrats. Classical economists, with the notable exception of Ricardo, were almost all also historical economists. The reader of Smith, Mill, Marx, or even Marshall ploughs through thick volumes in which propositions in economic theory are embedded in often lengthy descriptions of historical events or the course of economic history. Throughout most of the 19th century, the divide between economists and economic historians was weak.

With the professionalization of economics that picked up speed in the 20th century (the American Economics Association was founded in 1885; the Royal Economic Society in 1890), economic history began to emerge as a distinct and to some degree separate sub-discipline. The Economic History Society was founded in Britain in 1926; the Economic History Association in the United States in 1941. The trend towards a separate identity accelerated in the third quarter of the 20th century, with the increasing emphasis within economics on formal mathematical modelling and the weakening within the general profession of ties to historical traditions. In the economic history societies, in contrast, those trained as historians as well as economists remained active; in Britain, distinctiveness was accentuated by the establishment of separate university departments of economic history.

As the intellectual paths taken by economics and economic history seemed increasingly to diverge, a countervailing intellectual movement known variously as 'cliometrics' or the 'new economic history' emerged. Its pioneers knew their history, but emphasized by argument and example that, if economic history was to remain influential within economics, it had to make more use of formal models as well as place increased emphasis on quantitative (rather than just qualitative) data and more advanced statistical techniques (econometrics) to analyse them.

The use of mathematical models was anathema within historical traditions, but by the 1960s widely accepted in economics. Thus, the new economic history represented something of a gauntlet thrown down to those trained in history or allied with its traditions. The push for quantitative data analysis, in contrast, was more cross-cutting in the challenges it implied. Many traditional economic historians had in fact examined such data, although the statistical techniques they used were often quite rudimentary. Within some economic circles, on the other hand, an emphasis on data was becoming suspect. Here, some scholars were comfortable with the evolution of economic theory as a branch of applied mathematics, constrained and judged by the rules of logic and consistency, but governed in its realism, if at all, by intuition rather than systematic empirical inquiry.

The effort to force formal theory upon traditional economic history often lacked acknowledgement that the relation between economic history and formal theory might usefully be a two-way street. The emphasis on data analysis, in contrast, offered a bridge between economics and economic history. It helped reaffirm within economics the importance of empirical inquiry, and encouraged those historically trained to become more sophisticated in their statistical analyses.

Nevertheless, the stress on quantitative data could not help but draw attention away from economic history's traditional concern with legal and institutional variation, where the source documents were almost uniformly qualitative. How would this theme, one of the defining features of

economic history since its inception, survive the new economic history? The initial 'solution' was to try to make institutions endogenous. Blending a mix of influences from technologically deterministic Marxism to the emerging law and economics and public choice literatures, a number of scholars suggested that institutions could be understood as epiphenomenal: reflective of more fundamental givens. The high point of such efforts was probably the short book by North and Thomas (1973).

These efforts, however, gradually disintegrated under the force of the ad hoc twists required to make the framework consistent with known historical evidence (Field 1981), and even proponents such as North eventually backed away from this agenda. Formal rules often vary where technologies and endowments are similar, and are often similar when more fundamental givens differ, and such variation has consequences for economic performance. Had the endogenization initiative been successful, it would have eliminated from economic history one of the most important perspectives it offers to general economics.

The old economic historians had taken it as obvious that, at critical historical junctures, changes in formal institutions such as laws or constitutions had powerful influences on the course of a country or region's economic development, and that these changes were not always predictable *ex ante.* The breakdown of the former Soviet Empire, and the opportunities afforded to Western scholars actually to influence the design of formal institutions, gave a powerful impetus to returning to thinking about such designs as consequential, and increasingly this perspective came to be reflected in research by scholars who did not necessarily think of themselves as economic historians.

If the main subject of economic history continues to be the history of economic growth and development, the influence of variations in formal and informal institutions in both the private and public arenas will remain an important theme. These institutions and a broader economic culture help structure the environment in which individuals pursue their interests. But the success of an economy in raising output and output per person also depends on available technologies, on the size, composition, and characteristics of the labour force, on natural resources, and on the accumulation of physical capital. The study of the evolution of these inputs suggests some of the other themes around which economic historians organize their work. In particular, there is a rich tradition, particularly in the United States, examining issues in and applying methods from modern labour economics within an historical context.

The basic agenda of economic history has not changed since the first edition of *The New Palgrave.* Interest in the causes and dimensions of the Industrial Revolution, for example, remains strong, particularly in Britain. But the field has evolved in new directions, with several discernable trends. First, scholars have concerned themselves with a broadening range of topics under the umbrella of growth and development. In the 1960s and 1970s, especially in the United States, railroads and slavery dominated much of the discussion. In recent decades, it is not possible to point to one or two issues around which research and discussion has coalesced to the same degree. Instead, there have been a number of new initiatives; one example would be the growing exploitation of anthropometric data to make inferences about variation in standards of living.

Associated with this has been a broadening of the scope of the discipline, both in terms of the countries in which economic history research is conducted and in the geographical range of topics, which extends, somewhat more so than in earlier decades, beyond Western Europe and North America to Asia, Latin America, Australia, and Africa. One illustration of this has been a range of cross-national studies, exploring such issues as economic convergence.

A third trend has been a growing willingness to think of the 20th century as an historical epoch in its own right. When the new economic history began, the Second World War had barely ended and the Great Depression was recent history. The main focus of research was the 18th and 19th centuries. Treating the 20th century as an historical period promises to reduce the gap between economics and economic history. The Great

Depression, of course, continues to attract attention, but interest in the 20th century is beginning to expand beyond this. The data and events of recent decades can now more easily be seen in an historical context. The result can be a smoother continuum between topics understood as economic history and the analysis of contemporary data.

Placing more recent developments within a longer-run perspective has already begun to pay important dividends. Many trends that economists and economic historians expected at mid-century would characterize the 20th century as a whole moderated, became erratic, or in some cases reversed themselves in the last quarter of the century (Field 2001). In 1950, for example, it looked as if the United States (and other countries) would continue to experience decreases in wealth and income inequality, robust and perhaps rising shares of union membership in the labour force, a growing role for government, and a continuing high contribution of total factor productivity (TFP) growth to growth in output per hour. In fact, inequality has generally increased, union membership has fallen, and TFP growth basically disappeared in much of the developed world between 1973 and the 1990s. The size and role of government, which many predicted would continue to expand, has in fact displayed a more complex dynamic.

A fourth and related trend has been a reinvigoration within mainstream economics of interest in what has always been a primary subject of economic history: economic growth. Much of economic theory in the 1950s and 1960s modelled production and allocation within a static economy. The revived interest in the study of growth, combined with the growing willingness of economists to adopt traditional institutional approaches, reflects the persisting influence of the original concerns and approaches of economic history within the larger profession.

Whatever the labels people apply to themselves and others, if we want better understanding of the processes of growth and development, we will continue to need scholars familiar with how to work with data and interpret the influences on economic outcomes of institutional, political, and cultural variation. Doctoral training with a specialization in economic history is well suited to imparting such knowledge and the skills for acquiring it, capabilities that will remain essential in developing improved theory and policy in the area.

Economic Impact of the Olympic Games

Andrew Zimbalist

Abstract

The Olympic Games are among the largest and most visible sporting events in the world. Every two years, the world's best athletes

from some 200 countries come together to compete in lavish new venues in front of thousands of spectators. Hundreds of millions of sports fans worldwide watch the Games on television. Although Pierre de Coubertin, who founded the modern Olympics in the late 19th century, may have had altruistic, idealistic notions of pure amateur competition, unsullied by financial motivations, the Olympic Games have become a big business. The participants are effectively professional athletes; the organizers are highly compensated, professional bureaucrats; hosting the Games involves huge construction and renovation projects that take nearly a decade to complete, and these expenditures are usually justified by claims of extraordinary economic benefits that will accrue to the host city or region as a direct result of hosting the Games. This article examines the financing of the Olympic Games, explores how the awarding of the Games has become a high-stakes contest, and analyzes the costs of running the Games and their economic impact on the host city and nation.

Financing the Olympics

The modern Olympic Games began in 1896, but it was not until 1976 that a watershed event shook up the financing model for the Games and set the Olympics on its current economic course. In that year the city of Montreal hosted the Summer Games, which were originally predicted to cost $124 million. In fact, Montreal incurred a debt of $2.8 billion (approximately $10 billion in 2010 dollars) that was only finally paid off in 2005 (Burton 2003). Annual debt service created a large budgetary hole for the city for three decades.

By the end of the Montreal Games, the 1980 Olympics had already been set for Moscow, but no city wanted to bid for the right to host the 1984 Games. After some scrambling, Los Angeles agreed to host the Games, but only on the condition that it took on no financial obligation. With no alternative, the International Olympic Committee (IOC) accepted this condition and Los Angeles was awarded the 1984 Summer Games on 1 July 1978.

That year also marked the first significant relaxation of Olympic amateur rules under then IOC president Lord Killanin. Rule 26 of the Olympic Charter was modified so that athletes were allowed openly to earn money from endorsements, if the money went to their national sports federation or their country's National Olympic Committee (NOC). The receiving organization was then permitted to pay the athlete's expenses, including 'pocket money'. 'Broken-time' payments for time away from the athlete's regular job were also authorized if the athlete had a regular job. But the rule continued to declare that professional athletes were ineligible.

During the 1980–2001 reign of IOC President Juan Antonio Samaranch complete professionalization and commercialization of the Olympics were realized. In 1982, the amateur rules were revised to permit payments into a trust fund that provided expenses during the athlete's active career – and substantial sums thereafter. Eventually, decisions about accepting professionals were left to the International Federation (IF) of each sport. The new professional era was heralded during the 1992 Games in Barcelona, when the USA sent its 'Dream Team' of National Basketball Association (NBA) stars which went on to win the gold medal. Nominally, for the 2004 Games in Athens, boxing was the only sport that did not accept professionals, but even this distinction is dubious, because the National Olympic Committees (NOCs) of many countries gave their boxing medalists cash prizes.

These changes also led to increased commercialization and increased TV and sponsorship money, which in turn led to corruption and

scandal within the IOC. Before 1980, the 112 IOC representatives had to pay their own way to cities bidding for the Games. Within a year they were receiving first-class tickets and all expenses, as well as lavish entertainment. Outrageous tales of the excesses enjoyed by IOC representatives abounded.

Revelations of bribery and corruption around the Salt Lake City bid for the 2002 Games plunged the IOC into scandal: six members were expelled, four resigned and 10 were warned. Since then, the IOC has reformed itself by reducing the number of voters and by officially declaring an outright ban on gifts.

Meanwhile, the modest financial success of the 1984 Games in Los Angeles led to a new era of international competition among cities to host the Games. The relative success of Los Angeles, however, was *sui generis*. Los Angeles had very little construction expense and the chair of the Los Angeles Organizing Committee for the Olympic Games (LAOCOG), Peter Ueberroth, was able to raise substantial sums by selling sponsorships to corporations. LAOCOG generated a modest surplus (just over $300 million) and reset the Olympic financial model for less public and more private financing.

Nonetheless, other host cities have found it impossible to procure the same proportion of private support and have relied upon large public expenditures. Several billion dollars of public monies were committed in Seoul (1988), Barcelona (1992), Nagano (1998), Sydney (2000), Athens (2004) and Beijing (2008). In some cases, the local OCOG ran a modest surplus (20% of any surplus must be shared with the IOC; Preuss 2003, p. 194), but the local government laid out billions of dollars to help finance the activities of the OCOG. In the case of Athens, for instance, the public investment exceeded $10 billion – some of this public investment resulted in improved, more modern infrastructure for the city, but some of it resulted in white elephants. Many facilities built especially for the Games go unused or underutilized after the period of Olympic competition itself, while requiring tens of millions of dollars annually to maintain and occupying increasingly scarce real estate. Public investment for the 2008 Beijing Olympics exceeded $40 billion.

Salt Lake City Olympiad chief and former governor of Massachusetts Mitt Romney questioned whether US cities should enter bids to host the Olympic Games, stating that they were increasingly driven by 'giganticism' with the addition of new sports and more frills.

Present Day Financial Arrangements

The IOC presents the financing of the Olympic Games in terms of the related organizations: the local organizing committee (OCOG), the NOC, the IFs, and itself. The OCOG budget is not the same as the budgetary impact on the local city that hosts the games. The local city and its regional and national government may provide billions of dollars of subsidies to the OCOG, and the OCOG may report a surplus. This surplus has little meaning regarding the budgetary impact on public bodies from hosting the Games.

For instance, for the recent Games hosted in the USA, the federal government provided $1.3 billion in Salt Lake City in 2002; $609 million in Atlanta in 1996; and $75 million in Los Angeles in 1984 (all reckoned in 1999 prices) (Ungar 2000, p. 5). For the 2010 Winter Games in Vancouver, in addition to the provincial government of British Columbia and the federal government of Canada each budgeting $9.1 million to help finance the bidding process, the provincial government was scheduled to put up $1.25 billion to finance the Games (and provide a guarantee to cover cost overruns) and the federal government was budgeted to contribute another $330 million. The city of Vancouver was budgeted to contribute $170.3 million (http://www.mapleleafweb.com/, accessed 22 August 2007). Not surprisingly, financing did not work out as planned, in part due to the worldwide recession of 2008–09. In fact, the IOC provided a $423 million subsidy to the Vancouver Organizing Committee (VANOC) and 'sources said that the IOC agreed to the first-of-its-kind bailout because without it, spending for the games would have come to a screeching halt and major cutbacks would have been

necessary' (*Sports Business Daily* 2009a). VANOC also received an $87 million public bail-out loan (*Sports Business Journal* 2009a) and Standard & Poor's lowered the city of Vancouver's credit rating due to Olympic financing shortfalls, raising the city's borrowing costs (*Sports Business Daily* 2009b). The *New York Times* reported that: 'The immediate legacy for this city of 580,000 is a nearly $1 billion debt from bailing out the Olympic Village development. Beyond that, people in Vancouver and British Columbia have already seen cuts in services like education, health care and arts financing from their provincial government, which stuck with many other Olympics-related costs' (Austen 2010).

Moreover, it is common practice for the OCOG budget to consist entirely (or almost entirely) of operating, as opposed to capital, expenditures (Preuss 2003, p. 195). Nonetheless, to the extent that the OCOG receives funding from the IOC or from private sources, the lower will be the financing burden that falls on the local, state and national government that hosts the Games. What follows, then, is a discussion of how the IOC distributes the revenue that is collected from the staging of each Olympic Games.

Table 1 presents the total revenue that accrues to the IOC or any of its constituent organizations during each quadrennial Olympic cycle, consisting of one Winter and one Summer Games. It shows a healthy revenue growth in each of the major categories, with television revenues the largest single source of revenue by a factor of 3. The TOP marketing program consists of 11 companies that hold exclusive category sponsorships as the official Olympic company.

TOP (The Olympic Partner) Programme revenues go 50% to the local OCOGs, 40% to the NOCs and 10% to the IOC (International Olympic Committee 2007). Broadcast revenue goes 49% to the host OCOG and 51% to the IOC, which in turn distributes the lion's share of this revenue to the NOCs and IFs. Prior to 2004, the host OCOGs received 60% of broadcast revenue. Beginning in 2012, it has been determined that OCOGs will receive a fixed amount, rather than a fixed percentage, as broadcast revenues continue to rise (Preuss 2003, p. 100). Overall, the IOC has retained 8% of Olympic revenue; the remaining 92% has been shared by the OCOGs, NOCs and IFs.

Table 2 depicts the astronomical growth in television broadcasting revenue for the Summer and Winter Games since 1960. Not surprisingly, the largest share of broadcast revenue comes from the USA. For instance, for the 2004 Athens Games, the IOC contract with NBC yielded $793.5 million, or 53.1% of the total. Following the US rights fee were Europe ($394 million), Japan ($155 million), Australia ($50.5 million), Canada ($37 million) and South Korea ($15.5 million). All told, there were 80 rights holders televising the Athens Games to 220 countries and 2 billion potential viewers worldwide. Ten thousand media personnel were on hand to cover the Games (International Olympic Committee 2007, pp. 51–54).

The US share of total media rights has trended downward over time, from 83.4% during 1986–89, to 60% during 2001–04, to 52.6% during 2009–12 (*Sports Business Journal* 2009b). Because of the high US share, the US Olympic Committee (USOC) has received a

disproportionate share of the total collected fees. Out of 205 NOCs in 2009, USOC received 12.75% of all media rights fees from the Olympics. (This share had been 10% until 1996, when it was raised.) In 2009, after sharp disagreement, a negotiation between USOC and the IOC led to a new agreement that in 2020 the USOC share would be lowered again. The new level, however, was not agreed upon.

OCOGs do not cover all their expenses from the above sources. For instance, the Nagano OCOG in 1998 had revenues of $990 million, of which approximately $435 million came from the IOC. Similarly, the Salt Lake OCOG had revenues of $1.348 billion, of which approximately $570 million came from the IOC (International Olympic Committee 2007, pp. 82–83; from the Salt Lake Games revenues, the IOC also provided $305 million to the NOCs.).

Economic Results

Economic theory would suggest that any expected local economic benefit would be bid away as cities compete with each other to host the Games. More precisely, with perfect information the city with the highest expected gain could win the Games by bidding $1 more than the expected gain to the second highest city. Such an outcome could yield a small benefit to the winning city, but this would require perfect information and an open market bidding process. In fact, the bidding process is not done in dollar amounts, but comes rather in the form of providing facilities and guaranteeing financing and security. In the post-9/11 world, security costs are far from trivial. Total security costs in Athens in 2004 came to $1.4 billion, with 40,000 security people; Beijing in 2008 was projected to have over 80,000 security personnel working the Games.

It is also widely acknowledged that the bidding process is laden with political considerations. Moreover, the bidding cities are more likely to be motivated by gains to particular private interests within the city (developers, construction companies, hotels, investment bankers, architects, real estate companies, etc.) than by a clear sense that the city as a whole will benefit economically.

In contrast, the IOC views its principal role as promoting sport, not economic development. It requires buildings and infrastructure to be financed with non-Olympic money (Preuss 2003, p. 195).

Accordingly, even though a local OCOG may break even or have a small surplus, the greatest likelihood is that the city itself (and state and national governments) experiences a fiscal deficit

from the Games (of course, not all OCOGs manage to break even: the Albertville OCOG lost $57 million: Burton 2003, p. 3). On the one hand, the only tax revenue that would accrue to host governmental bodies would be from incremental sales and income resulting from hosting the Olympic Games. (Other taxes, such as real estate taxes, might come into play depending on the local tax system and whether or not the Games affected real estate values, positively or negatively. See, for instance, Ahlfeldt and Maennig (2009), which finds a positive impact of sports facilities on real estate values within two miles of a new facility.) The evidence on this score is not encouraging. On the other hand, hosting governmental bodies, together with any private support, must pay for facility construction, upgrade and infrastructural improvements necessitated by the Games. It must also pay for the opening and award ceremonies, transportation of the athletes to the various venues, entertainment, a telecommunications/broadcasting centre, and security, among other things. Naturally, to the extent that some of this public spending is on productive infrastructure, these fiscal deficits may prove to be beneficial in the long term to the economy.

The initial publicized budgets of the OCOGs invariably understate both the ultimate cost to the OCOG and, to a much greater degree, the total cost of staging the Games. The former escalates for several reasons:

1. Construction costs inflate significantly as land values increase with growing scarcity during the roughly ten-year cycle of Olympic host planning, bidding, selection and preparation.
2. It is usually in the interest of the bidding team to under-represent the true costs, as they seek public endorsement.
3. As the would-be host city enters into competition with other bidders, there is a natural tendency to match their competitors' proposals and to embellish their original plans.

The total cost escalates because it includes infrastructure and facility costs, whereas the publicized OCOG budget includes only operating costs. The infrastructure and facility costs usually form the largest component of total expenses, and often do so by a substantial margin.

Thus Athens initially projected that its Games would cost $1.6 billion, but they ended up costing closer to $16 billion (including facility and infrastructure costs). Beijing's projected budget was $1.6 billion, but ended up in total costing over $40 billion (inclusive of facility and infrastructure costs). The 2014 Winter Games in Sochi, Russia, were initially budgeted at around $12 billion; the projected price tag in late 2009 reached $33 billion. Of this, $23 billion would come from public sources (*Sports Business Daily* 2009c).

London expected its 2012 Games to cost under $4 billion, but they are now projected to cost over $19 billion (Carlin 2007; Simon 2006; *Sports Business Daily* 2008a). As expenses have escalated for London, some of the projects have been scaled back, such as the abandonment of the planned roof over the Olympic Stadium. The stadium was originally projected to cost $406 million and will end up costing over $850 million. Further, its construction will be financed by taxpayers and the government has been unsuccessful in its effort to find a soccer or a rugby team to be the facility's anchor tenant after the 2012 Games. This will saddle the British taxpayers with the extra burden of millions of dollars annually to keep the facility operating. It is little wonder that the London Olympics Minister Tessa Jowell stated: 'Had we known what we know now, would we have bid for the Olympics? Almost certainly not'. (*Sports Business Daily* (2008b), citing a story in *Daily Telegraph* (2008). The Olympic Village was to be privately financed, but the plan fell through and will instead cost the taxpayers nearly $1 billion. The government hopes that the apartments will be sold after the Games and the financing will be recouped.)

In a world where total revenue from the Games is in the neighborhood of $4–$5 billion for the Summer Olympics and roughly half that for the Winter Games, costs above these levels mean that someone has to pay. (To be sure, the Winter Games involve fewer participants, fewer venues and less construction; hence the cost of these Games is lower than for the summer Games.) While private companies often contribute a share

of the capital costs (beyond the purchase of sponsorships), host governmental bodies usually pick up a substantial part of the tab. Moreover, as we have seen, not all the money generated at the Games stays in the host city to pay for the Games; rather, close to half the money goes to support the activities of the IFs, the NOCs and the IOC itself.

Thus, while the Sydney OCOG in 2000 reported that it broke even, the Australian state auditor estimated that the Games' true long-term cost was $2.2 billion. In part, this was because it is now costing $30 million a year to operate the 90,000-seat Olympic Stadium. The story was little different for the 2004 Games in Athens, where maintenance costs on the Olympics facilities in 2005 will reportedly come in around $124 million and there appears to be little to no local interest being expressed in the two Olympic soccer stadiums. According to one report, 21 of the 22 stadiums built for the 2004 Summer Games in Athens were unoccupied in 2010.

Similarly, the 1992 Olympics in Barcelona generated a reported surplus of $3 million for the local organizing committee, but it created a debt of $4 billion for the central Spanish government and of $2.1 billion for the city and provincial governments. (The total reported cost of the Barcelona Games was $9.3 billion, of which private sources covered $3.2 billion and public sources covered $6.1 billion (Burton 2003, p. 39). For a related account of large public expenditures on infrastructure for the Salt Lake City Olympics, see Bartlett and Steele (2001), who reported that the US government spent $1.5 billion of taxpayers' money on the purchase of land, road construction, sewers, parking lots, housing, buses, fencing, a light rail system, airport improvements, and security equipment, *inter alia*. Some have argued that a part of these expenditures would have occurred even if Salt Lake City had not hosted the Olympics.) The Nagano Organizing Committee (Winter Games 1998) showed a $28 million surplus, but the various units of Japanese government were left with an $11 billion debt (Burton and O'Reilly 2009).

For all of the foregoing reasons, if there is to be an economic benefit from hosting the Olympic Games, it is unlikely in the extreme to come in the form of improving the budgets of local governments. This raises the question of whether there are broader, longer-term or less tangible economic gains that accrue from hosting the Olympic Games.

How Do the Olympic Games Affect the Economy?

In general, sporting events produce two types of economic benefit: direct and indirect. Direct economic benefits include net spending by tourists who travel from out of town to attend the event; spending on capital and infrastructure construction related to the event; long-run benefits – for example lower transportation costs attributable to an improved road or rail network – generated by this infrastructure; and the effect of hosting a sporting event on local security markets, primarily stock markets. Indirect benefits include possible advertising effects that make the host city or country more visible as a potential tourist destination or business location in the future and increases in civic pride, local sense of community, and the perceived stature of the host city or country relative to other cities or countries.

Among the direct economic benefits generated by the Olympic Games, tourist spending is probably the most prominent. From Table 3, an average of 5.1 million tickets were sold for the past six Summer Olympic Games, including almost six million tickets to the 1984 Games in Los Angeles. The Winter Games are considerably smaller, averaging 1.3 million tickets over the past five Winter Olympics. Even though most spectators buy tickets to multiple events, so that selling five million tickets does not mean that there are five million spectators, and many of the tickets are sold to local residents, especially for the Summer Games, which typically take place in large metropolitan areas, a sporting event of this size and scope has the potential to attract a significant number of visitors from outside the host city. Also, since the Games are often spread over more than two weeks, these visitors may spend a significant amount of time in the host area,

Economic Impact of the Olympic Games, Table 3 Ticket revenues (current $)

Games	Tickets sold (millions)	% capacity	Revenue to OCOG ($million)
1984 Los Angeles	5.7	83	156
1988 Calgary	1.6	78	32
1988 Seoul	3.3	75	36
1992 Albertville	0.9	75	32
1992 Barcelona	3.0	80	79
1994 Lillehammer	1.2	87	26
1996 Atlanta	8.3	82	425
1998 Nagano	1.3	89	74
2000 Sydney	6.7	88	551
2002 Salt Lake	1.5	95	183
2004 Athens	3.8	72	228
2008 Beijing	6.5	96	185

generating substantial spending in the lodging, and food and beverage sectors.

The Olympic Games require large spending on constructing and updating venues. In addition to venue construction, hosting the Olympic Games often requires expansive infrastructure to move the participants, officials, and fans to and from the venues. Host cities and regions have also spent considerable sums on roads and airport construction, as well as on the renovation and construction of public transportation systems (Essex and Chalkley 2004). In less developed cities, the building of a modern telecommunications capacity also represents a substantial investment.

After the construction period, Olympics-generated infrastructure can provide the host metropolitan area or region with a continuing stream of economic benefits in the form of reduced production costs and prices charged by local businesses (Rephann and Isserman 1994). The indirect economic benefits generated by the Olympic Games are potentially more important than the direct benefits, and also more difficult to quantify. One possible indirect benefit is the advertising effect of the Olympic Games. Many Olympic host metropolitan areas and regions view the Olympics as a way to raise their profile on the world stage. If hosting the Olympic Games leads tourists who would not have otherwise considered this to be a destination to visit the host city or region, then this advertising effect can generate economic benefits over a long period of time.

The Evidence on Economic Impact

The evidence on the economic impact of the Olympic Games falls into four categories: (1) retrospective evidence based on econometric analysis; (2) case studies of individual Olympic Games; (3) evidence derived from computable general equilibrium (CGE) models; and (4) 'multiplier-based' estimates of future economic impact. Note the important temporal element associated with each of these types of evidence. The 'multiplier-based' estimates are prospective; these studies are basically forecasts of economic benefits that will take place at some time in the future. Because this type of evidence is a forecast, it should be judged by the same criteria as any other economic forecast. The other three types of evidence are retrospective. They are based on an examination of what actually happened in the past when a metropolitan area or region hosted the Olympic Games. This fundamental difference between 'multiplier-based' estimates and other types of evidence is critically important for understanding the differences in estimates of the economic impact of the Olympic Games.

Econometric-based evidence on the economic impact of sporting events uses historic data on the performance of the local economy before, during and after the event takes place. This approach uses statistical methods to determine how much of the past local economic activity could be attributed to the sporting event, and

how much would have taken place without the sporting event occurring.

Case studies of the economic impact use a similar approach to the econometric method. This approach examines past indicators of economic activity, but does not use sophisticated regression techniques. Case studies often examine a broader set of economic indicators than econometric studies, and use unconditional statistical tests like tests of differences in means, cross-tabs, or chi square tests of statistical independence.

CGE models are complex representations of the entire economy, including sectors that are not related to sporting events. These models explicitly account for the interconnected nature of the economy. Because the Olympic Games are large-scale events, involving significant numbers of participants, officials, staff and spectators, the effects of the Games may spread beyond the immediate area and affect a number of distinct sectors of the economy in different ways. CGE models can account for complex economic effects, such as the effect of the additional borrowing needed to finance venue and infrastructure construction on the availability (or price) of funds to finance other construction projects in the economy. CGE models can also explicitly account for long-run economic effects.

The basic idea behind multipliers is straightforward, and emerges from input–output models of the economy. When a consumer purchases a $1 pack of gum at a local store, the economic effects of that transaction extend well beyond the consumer handing a dollar to the cashier, who places that dollar in the till. Some of that $1 in spending finds its way into the pocket of the cashier, in the form of wages; some finds its way into the pocket of the store owner; some into the pocket of the driver who delivered the gum; and so on. If the clerk, store owner and delivery person live in the local community, then this money is further distributed in the local economy as these individuals pay rent, buy groceries, and so on. A multiplier is an analytical device used to estimate the broad economic impact of each dollar spent in the local economy in terms of the total amount of additional revenues earned by firms, the total amount of personal income, and the number of jobs generated in the local economy.

Estimating the economic impact of a sporting event using the multiplier approach is relatively simple in theory. First, estimate the number of people who attend the sporting event; second, estimate the amount of spending by these attendees; third, apply a multiplier to this spending to estimate the broad, overall impact of this spending on the economy. However, on closer examination, this process requires a significant amount of discretionary input on the part of the researcher, and coming up with accurate estimates of several of these components is not a straightforward process.

The Problem with Multipliers

Multiplier-based estimates of the economic impact potentially have several problems; See, for one, the discussion in Crompton (1995). First, multiplier-based estimates stem from the estimate of the number of attendees. New economic impact can only be generated by the spending of spectators, participants and officials from outside the host area. Estimating the total number of attendees is much easier than estimating the number of attendees from outside the host area. From Table 3, 8.3 million tickets were sold to events at the 1996 Atlanta Summer Olympic Games. Some of these tickets were clearly sold to residents of Atlanta. But how many of these 8.3 million tickets were purchased by Atlantans?

Further complicating the process are ‘time switchers’ and ‘casuals’. “Time switchers” are attendees who would have visited the host area at some other time, for some other reason, but instead choose to visit the host area during the sporting event. ‘Casuals’ are attendees who visit the host area at the same time as the sporting event for some other reason and decide to attend the event out of convenience. The spending by both types of attendees needs to be removed from the economic impact estimate, as it cannot be directly attributable to the sporting event. Failure to remove this spending leads to overestimates of the economic impact generated by the event.

Second, multiplier-based economic impact estimates fail to account for crowding out. In many cases, the host area for the Olympic Games is a tourist destination in its own right; tourists would visit this area even if the Olympic Games were held elsewhere; London, for example, is a major tourist destination. Crowding out takes place when outside visitors attending the Olympic Games buy hotel rooms, meals and other travel-related goods and services that would have been purchased by other visitors absent the Olympic Games. Crowding out implies that each dollar of new economic impact estimated by multiplier-based methods needs to be offset by some corresponding lost economic impact that was crowded out, or else the net economic impact will be overstated.

It is extremely difficult to determine how much crowding out actually takes place when an area hosts the Olympic Games. However, one study found that gate arrivals at the Atlanta airport during the 1996 Summer Games were identical to gate arrivals in the same months in 1995 and 1997, implying that quite a few tourists to Atlanta were crowded out by the 1996 Games (Porter 1999). In late 2004, Athens tourism officials were estimating about a 10% drop in summer tourism in 2004 due to the Olympics. The Utah Skier Survey found that nearly 50% of non-residents would stay away from Utah in 2002 due to the expectation of more crowds and higher prices. The Beijing Tourism Bureau projected that the number of visitors to the city in August 2008 during the Games would not be greater than in August 2007. An additional problem for Beijing was that in order to abate the city's intense pollution during the summer months, the government ordered many of the city's factories closed leading up to and during the Games, and it imposed severely restrictive driving regulations.

Third, multiplier-based estimates overlook the displacement phenomenon. Some local residents may choose to leave town to avoid the congestion during the Games. The displaced people spend money outside the local area that they would have spent locally absent the Games. For instance, a survey in Barcelona indicated that fully one-sixth of the city's residents planned to travel outside the city during the 1996 Olympics.

Fourth, multiplier-based estimates depend critically on the selection of the multiplier. Economic theory does not provide exact guidance on the size of the multiplier to use in any particular application. The size of the multiplier used is at the discretion of the analyst. This creates an incentive for researchers to systematically choose large multipliers in order to generate large estimates of the economic impact of sporting events.

Despite all these problems, the majority of published estimates of the economic impact of the Olympic Games come from multiplier-based estimates. Multiplier-based estimates are widely used because, relative to the other approaches discussed above, this approach requires little data, little technical expertise, and very little in the way of computing power. Multiplier-based estimates are relatively cheap to produce and easy to manipulate.

Considering the size and prominence of the event, relatively little objective evidence on the economic impact of the Olympic Games exists. Much of the existing evidence has been developed by the host cities or regions, which have a vested interest in justifying the large expenditures on the games that were documented above. These 'promotional' studies, which have produced widely disparate estimated impacts of between $40 million and $16 billion for different Olympic Games between 1984 and 2006, suffer from the flaws discussed, and should be viewed sceptically. For a more detailed discussion of these studies, see Humphreys and Zimbalist (2008).

Estimates of the economic impact of the Olympic Games derived from academic research published in peer-reviewed journals tend to be more reliable. Only a few such studies, however, exist (Hotchkiss et al. 2003; Jasman and Maennig 2008; Feddersen and Maennig 2008; Lybbert and Hilmany 2000; Teigland 1999; Ritchie and Smith 1991).

The results of these studies present a consistent picture of the economic impact of hosting the Olympic Games on regions. Some jobs will be created as a result of hosting the Games. However, there appears to be no detectable effect on income,

suggesting that existing workers do not benefit from the Games. Moreover, the overall economic impact of hosting the Games depends on the overall labour market response to the new jobs created by the Games. When taking into account the overall labour market situation, the net impact of the Games on a region may not be positive. The negative impact on regional income found by the study that examined four North American regions is consistent with a negative overall labour market response to hosting the Games. Furthermore, the long-run impacts on tourism in the host region may be overstated, based on evidence from Lillehammer. Clearly, the weak results from academic research on the economic impact of hosting the Olympic Games call into question the reported economic impact from the promotional studies.

Some economists also have looked beyond income and employment measures for evidence that hosting the Olympic Games has an economic impact on the host economy. One area examined is stock markets (Berman et al. 2000; Veraros et al. 2004). The relationship between hosting the Olympic Games and stock markets is straightforward. To the extent that hosting the Olympic Games generates any benefits, including tangible economic benefits associated with increased tourism, or intangible benefits like national pride, sporting benefits, increased visibility etc., stock markets should be efficient mechanisms for valuing these benefits far into the future and discounting them back to the present. Positive benefits, if present, may be capitalized into stock prices at the time that the Games are awarded.

Research on the effect of hosting the Olympic Games on stock markets exploits the nature of the process through which the Games are awarded. Until the announcement of the winning city is made, there is considerable uncertainty about who will be awarded the games, and the contest is winner-take-all. The announcement about the winner of the Games takes place at a specific time (seven years prior to the Games) and represents a natural experiment in stock prices.

The existing evidence is mixed. The announcement that Sydney would host the 2000 Summer Olympic Games produced modest increases in stock returns in a limited number of industries: building materials, developers and contracts, and engineering. The announcement that Athens would host the 2004 Summer Olympic Games produced a short-term, significant increase in overall stock returns on the Athens Stock Exchange, but had no impact on the Milan Stock Exchange. Milan was one of the cities in the running for the 2004 Summer Games. Stock returns in construction related industries on the Athens Stock Exchange increased more than other sectors following the announcement, suggesting that much of the economic benefit accrues to this sector.

This evidence is limited to only two Olympic Games, and the increases in stock returns reported in the studies are modest, short-term, and primarily limited to the construction industry and related sectors of the economy. The empirical model used to analyze stock returns on the Athens Stock Exchange explains only 6% of the observed variation in returns. Overall, the evidence from this literature suggests that stock markets do not forecast large positive economic impacts flowing from the Olympic Games. While the idea that hosting the Olympic Games affects stock returns may appear important to the general public, a careful reading of this literature reveals that the underlying effects are small, transitory and limited to a few sectors of the economy. This evidence does not support net economic impact to the host city or region on the order of those publicized in promotional reports. Further, to the extent that hosting the Games may produce substantial fiscal deficits and growing public debt, the long-term effect on securities markets may well be negative.

Can the Olympic Games Be an Economic Success?

This review reveals relatively little evidence that hosting the Games produces significant economic benefits for the host city or region. If the economic gains are modest, or perhaps non-existent, what can host cities and regions do to maximize the potential gains from hosting the Olympic Games? A careful examination of past experiences suggests two important avenues for leveraging the

Olympic Games: host cities or regions need to make careful land use decisions and exploit the post-Olympic Games use of new and renovated facilities and infrastructure.

Land is an increasingly scarce resource both in the large urban areas that typically host the Summer Games and in the mountainous areas that host the Winter Games. Hosting the Olympic Games requires a significant amount of land for facilities, the Olympic Village, housing for the media and staff, accommodations for spectators, and parking. Unsuccessful Games leave behind legacies of seldom or never used structures taking up valuable land.

Successful Games, like the 1984 Los Angeles Summer Games, utilize existing facilities as much as possible, consuming as little scarce urban land as possible. The stadium used for the opening and closing ceremonies in the 1996 Atlanta Games was reconfigured to a baseball stadium immediately following the conclusion of the Games. The bullet train built for the Nagano Games greatly reduced the travel time between that city and Tokyo.

Tying up scarce land for seldom-used Olympic venues in both urban areas and alpine recreation areas cannot be an optimal use of this valuable resource. Olympic planners need to design facilities that will be useful for a long time after the Games are over, and are constructively integrated into the host city or region.

Clearly, the impact of the Olympic Games will vary according to the differing levels of development in the host city and country. Properly planned, hosting the Games can catalyze the construction of a modern transportation, communications and sport infrastructure. Such a potential benefit is bound to be greater for less developed areas. But even in such areas, hosting the Games will require a significant outlay of public funds to finance the infrastructural improvements. These improvements can also be made without hosting the Games. Thus it is relevant to ask whether the planning for the Olympics produces an optimal use of scarce public monies. It is also relevant to consider that in many circumstances the public policy process is so gridlocked that needed infrastructural investments may be delayed for years, if not decades, without the Olympic catalyst and that the Games do provide at least some capital to facilitate the completion of desirable projects.

Conversely, in more developed regions, where land is even more scarce during the initial bid planning (and destined to become scarcer still over the ten-year period of Olympic planning, bidding, selection and preparation) and labour and resource markets are tight, hosting the Games can occasion a gross misuse of land as well as provoke wage and resource price pressure leading to higher inflation.

Finally, it is important to recognize that hosting the Olympic Games may generate significant non-pecuniary benefits to the host city or region. The residents of the host city or region are likely to derive significant pride and sense of community from hosting the Games. Their homes are the focus of the world's attention for a brief but intense period. The planning and work required to host the Games takes considerable time and effort, and much of the hard work is done by volunteers. Pulling off such a huge endeavour is a source of considerable local and national pride. These factors are both important and valuable, even though researchers find it difficult to place a dollar value on them.

Some recent research has attempted to quantify the value of the non-pecuniary benefits generated by the Olympic Games (Atkinson et al. 2008). Economists have used the Contingent Valuation Method (CVM) to place a dollar value on such diverse intangible benefits as cleaning up oil spills in pristine wilderness areas and preserving green space in urban areas. The basic approach in CVM is to elicit people's willingness to pay for some intangible through hypothetical questions involving referendum voting or changes in taxes. A recent estimate of the total willingness to pay for the intangible benefits generated in the United Kingdom from hosting the 2012 Summer Games was in excess of d2 billion.

In the end, the economic and non-economic value to hosting the Olympic Games is a complex matter, likely to vary from one situation to another. Simple conclusions are impossible to draw. Prospective hosts of future Games would do well to steer clear of the inevitable Olympic

hype and to take a long, hard and sober look at the long-run development goals of their region.

Economic Integration

Bela Balassa

In everyday parlance, integration is defined as bringing together of parts into a whole. In the economic literature, the term 'economic integration' does not have such a clear-cut meaning. At one extreme, the mere existence of trade relations between independent national economies is considered as a form of economic integration; at the other, it is taken to mean the complete unification of national economies.

Economic integration is defined here as process and as a state of affairs. Considered as a process, it encompasses measures designed to eliminate discrimination between economic units that belong to different national states; viewed as a state of affairs, it represents the absence of various forms of discrimination between national economies.

Economic integration may take several forms that represent various degrees of integration. In a free trade area, tariffs (and quantitative import restrictions) among participating countries are eliminated, but each country retains its own tariffs against non-members. Establishing a customs

union involves, apart from the suppression of intra-area trade barriers, equalizing tariffs on imports from non-member countries.

A common market goes beyond a customs union, inasmuch as it also entails the free movement of factors of production. In turn, an economic union combines the suppression of restrictions on commodity and factor movements with some degree of harmonization of national economic policies, so as to reduce discrimination owing to disparities in these policies. Finally, total economic integration means the unification of economic policies, culminating in the establishment of a supra-national authority whose decisions are binding for the member states.

History

The first important case of economic integration was the German Zollverein in the 19th century, which subsequently led to total economic integration through the unification of the German states with the establishment of the Deutsches Reich. In the 20th century, the creation of the Benelux customs (1948) and subsequently economic (1949) union, comprising Belgium, Luxemburg, and the Netherlands, represented the first step towards European economic integration. It was followed by the establishment of the European Coal and Steel Community (1953) and the European Economic Community or EEC (1958), both comprising Belgium, France, Italy, Luxemburg, the Netherlands, and West Germany.

Austria, Denmark, Norway, Portugal, Sweden, Switzerland, and the United Kingdom founded the European Free Trade Association or EFTA in 1960, with Finland participating first as an associate and later as a full member. In turn, Denmark and the United Kingdom left EFTA and, together with Ireland, entered the European Economic Community in 1968; Greece became a member of the EEC in 1978, and Portugal and Spain joined in 1986.

In Eastern Europe, the Council for Mutual Economic Assistance or CMEA was established in 1948, with the participation of the Soviet Union, Bulgaria, Czechoslovakia, Hungary, Poland, and Romania. Albania and East Germany joined shortly thereafter; subsequently, Cuba and Mongolia became full members while Albania ceased to participate in CMEA activities.

There have been a number of attempts at economic integration in developing countries. Some were to involve the establishment of a free trade area, such as the Latin American Free Trade Association (1960) comprising Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Mexico, Peru, Uruguay, and Venezuela; others were designed to become customs unions, such as the West African Customs Union (1959), including the Ivory Coast, Mali, Mauritania, Niger, Senegal, and Upper Volta. In 1960, the Central American Common Market was established, with Costa Rica, Guatemala, Honduras, Nicaragua, and El Salvador as members; in turn, the East African Common Market, comprising Kenya, Tanzania, and Uganda and subsequently transformed into the East African Economic Community (1967), was designed to become an economic union. None of these attempts has come to fruition, however, as barriers to intra-area trade have not been fully eliminated or have subsequently been restored.

Trade Creation and Trade Diversion

Viner's The Customs Union Issue (1950) was the first important contribution to the theory of economic integration. Viner investigated the impact of a customs union on trade flows and distinguished between the 'trade-creating' and the 'trade-diverting' effects of a union. In the first case, there is a shift from domestic to partner country sources of supply of a particular commodity; in the second case, the shift occurs from non-member country to partner country sources of supply.

Trade creation increases economic welfare, inasmuch as higher-cost domestic sources of supply are replaced by lower-cost imports from partner countries that were previously excluded by the tariff. In turn, trade diversion has a welfare cost since tariff discrimination against non-member countries, attendant on the establishment of the customs union, leads to the replacement of lower-cost sources of supply in

these countries by higher-cost partner country sources.

The net welfare effects of the customs union will depend on the amount of trade created and diverted as well as on differences in unit costs. In a partial equilibrium framework, under constant costs, there will be a welfare gain (loss) if the amount of trade created, multiplied by differences in unit costs between the home and the partner countries, exceeds (falls short of) the amount of trade diverted, multiplied by differences in unit costs between the partner and the non-member countries.

Meade (1955) further considered the effects of a customs union on intercommodity substitution, involving the replacement of domestic products by partner country products (trade creation) and the replacement of products of non-member countries by partner country products (trade diversion). As in the case of substitution among the sources of supply of a particular commodity (production effects), trade creation involves a welfare improvement, and trade diversion the deterioration of welfare, in the event of substitution among commodities (consumption effects).

The separation of production and consumption effects does not imply the absence of interaction between the two. Substitution among sources of supply will affect the pattern of consumption through changes in the prices paid by the consumer. Also, intercommodity substitution will lead to modifications in the pattern of production by changing the prices received by producers.

At the same time, as Lipsey and Lancaster (1956–57) first noted, production and consumption effects – and the theory of customs unions in general – should be considered as special cases of the theory of the second best. Assuming that the usual conditions for a Pareto optimum are fulfilled, free trade will lead to efficient resource allocation while pre-union, as well as the post-union, situations are sub-optimal because tariffs exist in both cases. In the abstract, then, one cannot make a judgement as to whether establishing a customs union will increase or reduce welfare. Nevertheless, a consideration of certain factors may provide a presumption as to the possible direction of the welfare effects of a union.

Factors Influencing the Welfare Effects of a Custom Union

Lipsey (1960) suggested that the welfare effects of a customs union will depend on the relative importance in home consumption of goods produced domestically and imported from non-member countries prior to the establishment of the union. Ceteris paribus, the larger the share of domestic goods and the smaller the share of goods imported from non-member countries, the greater is the likelihood of an improvement in welfare following the union's establishment. Such will be the case since substitution of partner country products for domestic products entails trade creation and their substitution for the products of non-member countries involves trade diversion.

These propositions are consistent with Tinbergen's (1957) conclusion that increases in the size of a customs union will augment the probability of favourable welfare effects; in the limiting case, the customs union includes the entire world, which is equivalent to free trade. Applying the argument that gains are obtained through the enlargement of a union because of increased possibilities for the reallocation of production, it also follows that the gains are positively correlated with increases in the market size of the participating countries (e.g. small countries will gain more from participation in a customs union than large countries).

Viner further considered the implications that differences in production structures among the member countries have for the welfare effects of a customs union. He suggested that the more competitive (the less complementary) is the production structure of the member countries, the greater is the chance that a customs union will increase welfare.

This proposition reflects the assumption that countries with similar production structures tend to replace domestic goods by competing imports from partner countries following the establishment of a customs union, while differences in the production structure within the union lead to substitution of partner country products for lower-cost products originating in non-member

countries (the latter conclusion does not hold if the union includes the low-cost producer).

The welfare effects of a customs union will also depend on transportation costs. Ceteris paribus, the lower are transport costs among the member countries, the greater will be the gains from their economic integration. Thus, the participation of neighbouring countries in a union, with greater possibilities for trade creation across their borders, will offer advantages over the participation of faraway countries that tends to promote trade diversion.

The height of tariffs will further affect the potential gains and losses derived from a customs union. High pre-union tariffs against the future member countries will increase the possibility of trade creation, and hence gains in welfare, following the establishment of the union while low tariffs against non-member countries will reduce the chances for trade diversion. But, these conclusions have little relevance under the application of the most-favoured-nation clause that entails providing equal tariff treatment to all countries before the customs union is established.

Customs Unions vs. Unilateral Tariff Reductions

In the Viner-Meade-Lipsey analysis, participation in a trade-creating customs union was considered as a means to reduce the distorting effects of the country's own tariffs. This argument was carried to its logical conclusion in contributions by Cooper and Massell (1965a) and Johnson (1965) who suggested that participation in a customs union is inferior to the unilateral elimination of tariffs, which leads to greater trade creation without giving rise to trade diversion.

The same authors claimed that the reasons for the establishment of customs unions lie in the gains participating countries may obtain in furthering non-economic objectives, and considered preference for industry as such an objective. They further assumed that this objective can be pursued at a lower cost in the framework of the larger market of a customs union than in the country's own domestic market.

As Johnson noted, the formation of a customs union in the pursuit of the stated objective presupposes that the member countries are at a comparative disadvantage in the production of industrial goods vis-à-vis the rest of the world. Cooper and Massell (1965b) identified such countries with developing countries, further suggesting that the economic planners of these countries are willing to accept some reduction in national income in order to assure increases in industrial production.

The question remains as to why there is a preference for industry. Johnson (1965) expressed the view that such preference may reflect nationalist aspirations and rivalry with other countries; the power of industrial firms and workers to increase their incomes; or the belief that industrial activity involves beneficial externalities. The last point, however, implies that there is no need to introduce non-economic considerations to obtain the Cooper–Mansell–Johnson result; the desirability of a customs union may be established in economic terms, provided that it permits obtaining externalities that cannot be achieved otherwise.

A further question is if unilateral tariff reductions will be superior to a customs union in the absence of a preference for industry or beneficial externalities. The Wonnacotts (1981) showed that this may not be the case if one admits the existence of tariffs in partner and in non-member countries prior to the formation of the customs union.

The elimination of tariffs by partner countries will provide benefits to the home country as it can now sell at a higher price in partner country markets. This gain will be larger the higher is the pre-union tariff in the partner countries and will further be affected by tariffs in the non-member countries. This is because, in selling in partner country markets free of duty, home country producers avoid paying the tariff in non-member countries.

Finally, Cooper and Massell (1965b) noted that a subsidy-union, with each participating country subsidizing its own industrial production, is superior to a customs union. This conclusion follows since the consumption cost of the tariff can be

avoided if the prices of industrial products in the union are maintained at the world market level through subsidies. However, production subsidization may be done by each country individually, with the attendant welfare benefits, without participating in a union.

Multi-country Analysis of a Customs Union

Traditionally, the welfare effects of a customs union were considered from the point of view of a single country. Yet, these effects may differ among member countries, depending on their production structure, location, the height of pre-union tariffs, and other characteristics. In fact, one member country may obtain a gain and another a loss, when any attempt to aggregate gains and losses encounters the well-known difficulties of international welfare comparisons.

The distribution of welfare gains and losses in a customs union will be further affected by changes in the terms of trade. The establishment of a union may give rise to price changes in trade between the member countries, even if the prices at which trade takes place with non-member countries remain unchanged (the case of the 'small' union).

In the more general case, prices in trade with non-member countries will also vary. Now, while trade diversion involves a welfare loss to the member countries of a customs union under unchanged terms of trade, this loss may be offset by a welfare gain due to improvements in the terms of trade attendant on trade diversion. Conversely, whereas under the assumption of unchanged terms of trade the welfare of non-member countries is unaffected by the establishment of a customs union, non-member countries will lose owing to the adverse impact of trade diversion on their terms of trade. This may be interpreted as the result of a shift in the union members' reciprocal demand curve for products originating in non-member countries.

Improvements in the terms of trade thus provide reasons for the establishment of a customs union even in the absence of non-economic objectives and beneficial externalities. Such improvements also favour a customs union over unilateral tariff reductions, which would lead to the deterioration of the terms of trade of the country concerned.

Other things being equal, the larger the union the greater will be its gain, and hence the loss to non-member countries, through terms of trade changes. This is because, ceteris paribus, the larger the union the higher will be the elasticity of its reciprocal demand for foreign products and the lower the elasticity of reciprocal demand on the part of non-member countries for the union's products.

The extent of terms-of-trade effects will further depend on the height of tariffs before and after the establishment of a customs union. As Vanek (1965) first showed, a customs union will not involve a loss to non-member countries, while benefiting its own members, if the union's external tariff level is sufficiently lower than the pre-union tariffs of the member countries.

Vanek's proposition was formulated in a three-country, two-commodity (3×2) model. It has subsequently been extended to a general case, under which compensatory payments to non-member countries were also introduced (Kemp and Wan 1976). At the same time, these propositions indicate a theoretical possibility rather than a likely outcome, since customs unions have shown little inclination to compensate non-member countries for losses attendant upon the union's establishment.

3×3 models represent an intermediate case between 3×2 and $m \times n$ models. They permit introducing a greater number of possible trade patterns, differential tariffs, complementarity and substitution in consumption, with a large number of marginal conditions in production and consumption, as well as intermediate products (Lloyd 1982). The 3×3 model is thus richer in content than the 3×2 model. Despite attempts made at introducing new terminology (Collier 1979), however, adding a third commodity does not appear to have materially affected the basic propositions of customs union theory. This conclusion may also find application to $m \times n$ models.

Free Trade Areas

In a free trade area, maintaining different tariffs among member countries on the products of non-members introduces the possibility of trade deflection. Furthermore, production and investment deflection may occur if one admits trade in intermediate products.

There will be trade deflection if imports enter the free trade area via the member country which applies the lowest tariff. Transportation costs apart, this is equivalent to adopting a tariff equal to the lowest tariff for each commodity in any of the member countries. Under the assumption of unchanged terms of trade, the deflection of trade will increase welfare in the member countries by limiting the extent of trade diversion. Removing this assumption, trade deflection will affect the distribution of welfare between member and non-member countries by reducing the terms of trade gain (loss) for the former (latter).

Production deflection will occur if the manufacture of products containing imported inputs shifts to countries which have lower tariffs on these inputs, because differences in tariffs outweigh differences in production costs. The deflection of production will have unfavourable effects on welfare, since the pattern of productive activity will not follow lines of comparative advantage but rather differences in duties.

The deflection of production may also affect the pattern of investment. Other things being equal, investors will establish factories in countries with lower tariffs on imported inputs. Again, adverse welfare effects will ensue because investments respond to tariff differences rather than to differences in production costs.

The deflection of trade, production, and investment represent unintended effects of free trade areas. To avoid such an eventuality member countries of free trade areas have imposed country of origin rules. These rules limit the freedom of intra-area trade to commodities that incorporate a certain proportion of domestic products or undergo a particular process of transformation in one of the member countries. The application of origin rules limits, but does not entirely eliminate, trade, production and investment deflection in a free trade area. Other things being equal, then, their self-interest would tend to encourage member countries to reduce their own tariffs.

Factor Movements

The deflection of investment may occur within a country or may involve international capital movements. In the first case, it affects the allocation of the country's own capital among industries; in the second case, it influences the international allocation of capital.

The last point leads to the case of common markets where, by definition, the full mobility of factors is assured. Meade (1953) first analysed the welfare effects of the movement of factors of production in an integrated area. He concluded that free factor movement will increase the gains obtained in a union by reducing the relative scarcities of the factors of production. This conclusion reflected the assumption that the conditions for factor price equalization through trade are not fulfilled.

If factors of production were not free to move between member and non-member countries, there will be no welfare loss due to factor movements among member countries to correspond to trade diversion in commodity trade. In the event of such factor movements, however, an analogous case to trade creation and trade diversion occurs if the movement of factors were subject to taxes prior to the establishment of a union and these taxes have been removed among union members. And, in any case, there will be indirect effects on welfare to the extent that factor movements substitute for trade. These effects may involve welfare losses to non-member countries as the newly-established productions substitute for imports from them.

Economies of Scale

Economic integration may lead to lower costs through increases in the volume of plant output. For various types of equipment, such as containers, pipelines, and compressors, cost is a

function of the surface area whereas capacity is related to volume; per unit costs decline with increases in output in the case of bulk transactions as well as for nonproportional activities such as design production planning, research, and the collection and channelling of information; inventory holdings do not need to increase proportionately with output; larger output warrants the application of technological methods that call for the use of specialized equipment or assembly-line production; and large-scale production may be necessary to ensure the optimum use of various kinds of indivisible equipment.

Corden (1972) showed that the traditional concepts of trade creation and trade diversion will be relevant in the case of economies of scale on the plant level but new concepts are added: the cost-reduction effect and the trade-suppression effect. The former refers to reductions in average unit costs as domestic output expands following the establishment of the union; the latter refers to the replacement of cheaper imports from non-member countries by domestic production under economies of scale. In Corden's view, a net benefit is likely to ensue as the cost-reduction effect tends to outweigh the trade-suppression effect.

Plant size and unit costs are not necessarily correlated in the case of multiproduct firms. In such instances, costs may be lowered by reducing product variety through specialization in an integrated area, which permits lengthening production runs for individual products.

The advantages of longer production runs derive from improvements in manufacturing efficiency along the 'learning curve' as cumulated output increases; the lowering of expenses involved in moving from one operation to another that involves the resetting of machines, the shifting of labour, and the reorganization of the work process; and the use of special-purpose machinery in the place of general purpose machinery.

Apart from product or horizontal specialization, there are possibilities for vertical specialization by subdividing the production process among individual establishments in an integrated area. As the sales of the final product increase, parts, components, and accessories may be manufactured in separate plants, each of which enjoys economies of scale, thereby resulting in cost reductions.

Competition and Technological Change

Economic integration will also create the conditions for more effective competition (Scitovsky 1958). By increasing the number of firms each producer considers as his competitors, the opening of national frontiers will contribute to the loosening of monopolistic and oligopolistic market structures in the individual countries. At the same time, there is no contradiction between gains from economies of scale and increased competition, since a wider market can sustain a larger number of efficient units (Balassa 1961).

Greater competition may have beneficial effects through improvements in manufacturing efficiency as well as through technological change. While the former has no place in traditional theory, which postulates the choice of the most efficient production methods among those available to the firm, it may assume considerable importance in countries whose markets have been sheltered from foreign competition.

The stick and the carrot of competition also provides inducement for technological progress in the member countries. In particular, increased competition may stimulate research activity aimed at developing new products and improving production methods. Finally, economic integration may contribute to the transmission of technological knowledge by increasing the familiarity of producers with new products and technological processes originating in the partner countries.

It has been suggested, however, that gains from competition, and from economies of scale, may be obtained through unilateral trade liberalization and that the gains are predicated on the response of economic agents to the stimulus provided by competition (Krauss 1972). While the validity of the second point depends on factors which are particular to each country, the first neglects the gains obtained through the increases in output associated with sales in the markets of partner countries.

Policy Harmonization

Policy differences among the member countries may influence trade flows and factor movements, thereby modifying the welfare effects of economic integration. Industrial policies, social policies, fiscal policies, monetary policies, and exchange rate policies are relevant in this context (Balassa 1961).

Industrial policies may involve granting credit preferences and/or tax benefits across the board or to particular activities. 'Horizontal' policies that are applied across-the-board do not create distortions, unless the conditions under which they are provided favour one activity over another. By contrast, 'vertical' measures are granted to particular activities and thereby introduce distortions, which may counteract the effects of the elimination of intra-area tariffs.

Intercountry differences in social policies will not give rise to distortions, provided that social benefits are financed from the contributions of employers and employees. Nor are these conclusions affected if factor mobility is introduced into the analysis as long as the employees regard the resulting social benefits as part of their compensation.

The situation is different if social benefits are financed from general tax revenue. This case is equivalent to a wage subsidy that favours labour-intensive activities. Correspondingly, differences in the mode of financing social security among the member countries will introduce distortions in resource allocation. This conclusion is strengthened if consideration is given to factor movements that respond to international differences in labour costs.

The elimination of vertical measures of industrial policy and the equalization of the conditions of financing social security will reduce distortions in resource allocation as well as differences in tax burdens among the member countries. Differences in the tax burden may remain, however, owing to national preferences as to the provision of collective goods. The effects of such differences on factor movements will depend on the spending of the tax proceeds. But, there may be 'supply-side' effects, with a lower tax burden providing incentives for work effort and risk taking.

A further question is if, for a given tax burden, intercountry differences in reliance on indirect taxes and income taxes will distort competition. Under the destination principle, indirect taxes are rebated on exports and imposed on imports without such adjustments occurring in regard to income taxes. Nevertheless, distortions in the conditions of competition will not ensue as flexibility in exchange rates will offset differences in rates of indirect taxes.

The application of the origin principle, with indirect taxes levied on production irrespective of the country of sale, in one country and that of the destination principle in another will similarly be offset through exchange rate flexibility. Such will not be the case, however, if cascade-type taxation applied in one country and value added taxation in another, with the former raising the tax burden on industries that go through several stages of fabrication, each of which is subject to tax. Eliminating this source of distortion would necessitate the adoption of value added taxation in all member countries of a union.

While exchange rate flexibility is necessary to offset intercountry differences in systems of taxation, it has been proposed that fixed exchange rates be established following the creation of a union. But such an action is predicated on the coordination – and eventual unification – of monetary and fiscal policies, since otherwise pressures are created for exchange rate changes. The fixity of exchange rate should thus be considered as the final outcome of policy coordination rather than an intermediate step in economic integration (Balassa 1975).

Economic Interpretation of History

Ernest Gellner

Marxism does not possess a monopoly of the economic interpretation of history. Other theories of this kind can be formulated – for instance that which can be found in the very distinguished work of Karl Polanyi, dividing the history of mankind into three stages, each defined by a different type of economy. If Polanyi is right in suggesting that reciprocity, redistribution and the market each defined a different kind of society, this is, in a way, tantamount to saying that the economy is primary, and thus his work constitutes a species of the economic interpretation of history. Nevertheless, despite the importance of Polanyi's work and the possibility of other rival economic interpretations, Marxism remains the most influential, the most important, and perhaps the best elaborated of all theories, and we shall concentrate on it.

One often approaches a theory by seeing what it denies and what it repudiates. This approach is quite frequently adopted in the case of Marxism, where it is both fitting and misleading. We shall begin by adopting this approach, and turn to its dangers subsequently.

Marxism began as the reaction to the romantic idealism of Hegel, in the ambience of whose thought the young Karl Marx reached maturity. This no doubt is the best advertised fact about the origin of Marxism. The central point about Hegelianism was that it was acutely concerned with history and social change, placing these at the centre of philosophical attention (instead of treating them as mere distractions from the contemplation of timeless objects, which had been a more frequent philosophical attitude); and secondly, it taught that history was basically determined by intellectual, spiritual, conceptual or religious forces. As Marx and Engels put it in The German Ideology, 'The Young Hegelians are in agreement with the Old Hegelians in their belief in the rule of religion, of concepts, of an abstract general principle in the existing world' (Marx and Engels 1845–1846, p. 5).

Now the question is – why did Hegel and followers believe this? If it is interpreted in a concrete sense, as a doctrine claiming that the ideas of men determined their other activities, it does not have a great deal of plausibility, especially when put forward as an unrestricted generalization. If it is formulated – as it was by Hegel – as the view that some kind of abstract principle or entity dominates history, the question may well be asked: what evidence do we have for the very existence of this mysterious poltergeist

allegedly manipulating historical events? Given the fact that the doctrine is either implausible or obscure, or indeed both, why were intelligent men so strongly drawn to it?

The answer to this may be complex, but the main elements in it can perhaps be formulated simply and briefly. Hegelianism enters the scene when the notion of what we now call culture enters public debate. The point is this: men are not machines. When they act, they do not simply respond to some kind of push. When they do something, they generally have an idea, a concept, of the action which they are performing. The idea or conception in turn is part of a whole system. A man who goes through the ceremony of marriage has an idea of what the institution means in the society of which he is part, and his understanding of the institution is an integral part of his action. A man who commits an act of violence as part of a family feud has an idea of what family and honour mean, and is committed to those ideas. And each of these ideas is not something which the individual had excogitated for himself. He took it over from a corpus of ideas which differ from community to community, and which change over time, and which are now known as culture.

Put in this way, the 'conceptual' determination of human conduct no longer seems fanciful, but on the contrary is liable to seem obvious and trite. In various terminologies ('hermeneutics', 'structuralism', and others) it is rather fashionable nowadays. The idea that conduct is concept-saturated and that concepts come not singly but as systems, and are carried not by individuals but by on-going historic communities, has great plausibility and force. Admittedly, those who propose it, in Hegel's day and in ours, do not always define their position with precision. They do not always make clear whether they are merely saying that culture in this sense is important (which is hardly disputable), or claiming that it is the prime determinant of other things and the ultimate source of change, which is a much stronger and much more contentious claim. Nonetheless, the idea that culture is important and pervasive is very plausible and suggestive, and Hegelianism can be credited with being one of the philosophies which, in its own peculiar language, had introduced this idea. It is important to add that Hegelianism often speaks of 'Spirit' in the singular; our suggestion is that this can be interpreted as culture, as the spirit of the age. This made it easy for Hegelianism to operate as a kind of surrogate Christianity: those no longer able to believe in a personal god could tell themselves that this had been a parable on a kind of guiding historical spirit. For those who wanted to use it in that way, Hegelianism was the continuation of religion by other means.

But Hegelianism is not exhausted by its sense of culture, expressed in somewhat strange language. It is also pervaded by another idea, fused with the first one, and one which it shares with many thinkers of its period: a sense of historical plan. The turn of the 18th and 19th centuries was a time when men became imbued with the sense of cumulative historical change, pointing in an upward direction – in other words, the idea of Progress.

The basic fact about Marxism is that it retains this second idea, the 'plan' of history, but aims at inverting the first idea, the romantic idealism, the attribution of agency to culture. As the two founders of Marxism put it themselves in The German Ideology (pp. 14–15),

> In direct contrast to German philosophy which descends from heaven to earth, here we ascend from earth to heaven … We set out from real active men, and on the basis of their real life-process we demonstrate the development of the ideological reflexes and echoes of this life-process … Morality, regligion, metaphysics, all the rest of ideology and their corresponding forms of consciousness, thus no longer retain the semblance of independence. They have no history, no development; but men, developing their material production and their material intercourse, alter, along with their real existence, their thinking and the products of their thinking. Life is not determined by consciousness, but consciousness by life.

Later on in the same work, the two founders of Marxism specify the recipe which, according to them, was followed by those who produced the idealistic mystification. First of all, ideas were separated from empirical context and the interests

of the rulers who put them forward. Secondly, a set of logical connections was found linking successive ruling ideas, and their logic is then meant to explain the pattern of history. (This links the concept-saturation of history to the notion of historic design. Historic pattern is the reflection of the internal logical connection of successive ideas.) Thirdly, to diminish the mystical appearance of all this, the free-floating, self-transforming concept was once again credited to a person or group of persons.

If this kind of theory is false, what then is true? In the same work a little later, the authors tell us:

> This sum of productive forces, forms of capital and social forms of intercourse, which every individual and generation finds in existence as something given, is the real basis of . . . the . . . 'essence of man'.. . . These conditions of life, which different generations find in existence, decide also whether or not the periodically recurring revolutionary convulsion will be strong enough to overthrow the basis of all existing forms. And if these material elements of a complete revolution are not present. . . then, as far as practical developments are concerned, it is absolutely immaterial whether the 'idea' of this revolution has been expressed a hundred times already . . . (p. 30).

The passage seems unambiguous: what is retained is the idea of a plan, and also the idea of primarily internal, endogenous propulsion. What has changed is the identification of the propulsion, of the driving force of the transformation. Change continues to be the law of all things, and it is governed by a plan, it is not random; but the mechanism which controls it is now identified in a new manner.

From then on, the criticisms of the position can really be divided into two major species: some challenge the identification of the ruling mechanism, and others the idea of historic plan. As the most dramatic presentation of Marxist development, Robert Tucker's Philosophy and Myth in Karl Marx (1961, p. 123) puts it:

> Marx founded Marxism in an outburst of Hegelizing. He considered himself to be engaged in . . . [an]. . . act of translation of the already discovered truth . . . from the language of idealism into that of materialism. . .. Hegelianism itself was latently or esoterically an economic interpretation of history. It treated history as 'a history of production' . . . in which spirit externalizes itself in thought-objects. But this was simply a mystified presentation of man externalizing himself in material objects.

This highlights both the origin and the validity or otherwise of the economic interpretation of history. Some obvious but important points can be made at this stage. The Hegel/Marx confrontation owes much of its drama and appeal to the extreme and unqualified manner in which the opposition is presented. This unqualified, unrestricted interpretation can certainly be found in the basic texts of Marxism. Whether it is the 'correct' interpretation is an inherently undecidable question: it simply depends on which texts one treats as final – those which affirm the position without restriction and without qualification, or those which contain modifications, qualifications and restrictions.

The same dilemma no doubt arises on the Hegelian side, where it is further accompanied by the question as to whether the motive force, the spirit of history, is to be seen as some kind of abstract principle (in which case the idea seems absurd to most of us), or whether this is merely to be treated as a way of referring to what we now term culture (in which case it is interesting and contentious).

One must point out that these two positions, the Hegelian and the Marxist, are contraries, but not contradictories. They cannot both be true, but they can perfectly well both be false. A world is easily conceivable where neither of them is true: a world in which social changes sometimes occur as a consequence of changes in economic activities, and sometimes as a consequence of strains and stresses in the culture. Not only is such a world conceivable, but it does really rather look as if that is the kind of world we do actually live in. (Part of the appeal of Marxism in its early days always hinged on presenting Hegel-type idealism and Marxism as two contradictories, and 'demonstrating' the validity of Marxism as a simple corollary of the manifest absurdity of strong versions of Hegelianism.) In this connection, it is worth noticing that by far the most influential (and not unsympathetic) sociological critic of Marx is Max Weber, who upholds precisely this kind of

position. Strangely enough, despite explicit and categorical denials on his own part, he is often misrepresented as offering a return to some kind of idealism (without perhaps the mystical idea of the agency of abstract concepts which was present in Hegel). For instance, Michio Morishima, in Why has Japan 'Succeeded'? (1982, p. 1), observes: 'Whereas Karl Marx contended that ideology and ethics were no more than reflections . . . Max Weber . . . made the case for the existence of quite the reverse relationship.' Weber was sensitive to both kinds of constraint; he merely insisted that on occasion, a 'cultural' or 'religious' element might make a crucial difference.

Connected with this, there is another important theoretical difference to be found in Weber and many contemporary sociologists. The idea of the inherent historical plan, which had united Hegel and Marx, is abandoned. If the crucial moving power of history comes from one source only, though this does not strictly speaking entail that there should be a plan, an unfolding of design, it nevertheless does make it at least very plausible. If that crucial moving power had been consciousness, and its aim the arrival at self-consciousness, then it was natural to conclude that with the passage of time, there would indeed be more and more of such consciousness. So the historical plan could be seen as the manifestation of the striving of the Absolute Spirit or humanity, towards ever greater awareness. Alternatively, if the motive force was the growth of the forces of production, then, once again, it was not unreasonable to suppose that history might be a series of organizational adjustments to expanding productive powers, culminating in a full adjustment to the final great flowering of our productive capacity. (Something like that is the essence of the Marxist vision of history.)

If on the other hand the motive forces and the triggers come from a number of sources, which moreover are inherently diverse, there is no clear reason why history should have a pattern in the sense of coming ever closer to satisfying some single criterion (consciousness, productivity, congruence between productivity and social ethos, or whatever). So in the Weberian and more modern vision, the dramatic and unique developments of the modern industrial world are no longer seen as the inevitable fulfilment and culmination of a potential that had always been there, but rather as a development which only occurred because a certain set of factors happened to operate at a given time simultaneously, and which would otherwise not have occurred, and which was in no way bound to occur. Contingency replaces fatality.

So much for the central problem connected with the economic interpretation of history. The question concerning the relative importance of conceptual (cultural) and productive factors is the best known, most conspicuous and best advertised issue in this problem area. But in fact, it is very far from obvious that it is really the most important issue, the most critical testing ground for the economic theory of history. There is another problem, less immediately obvious, less well known, but probably of greater importance, theoretically and practically. That is the relative importance of productive and coercive activities.

The normal associations which are likely to be evoked by the phrase 'historical materialism' do indeed imply the downgrading of purely conceptual, intellectual and cultural elements as explanatory factors in history. But it does not naturally suggest the downgrading of force, violence, coercion. On the contrary, for most people the idea of coercion by threat or violence, or death and pain, seems just as 'realistic', just as 'materialistic' as the imperatives imposed by material need for sustenance and shelter. Normally one assumes that the difference between coercion by violence or the threat of violence, and coercion by fear of destitution, is simply that the former is more immediate and works more quickly. One might even argue that all coercion is ultimately coercion by violence: a man or a group in society which coerces other members by controlling the food supply, for instance, can only do it if they control and defend the store of food or some other vital necessity by force, even if that force is kept in reserve. Economic constraint, it could be argued (as Marxists themselves argue in other contexts), only operates because a certain set of rules is enforced by the state, which may well remain in the background. But economic constraint is in this way parasitic on

the ultimate presence of enforcement, based on the monopoly of control of the tools of violence.

The logic of this argument may seem persuasive, but it is contradicted by a very central tenet of the Marxist variant of the economic theory of history. Violence, according to the theory, is not fundamental or primary, it does not initiate fundamental social change, nor is it a fundamental basis of any social order. This is the central contention of Marxism, and at this point, real Marxism diverges from what might be called the vulgar image possessed of it by non-specialists. Marxism stresses economic factors, and downgrades not merely the importance of conceptual, 'superstructural' ones, but equally, and very significantly, the role of coercive factors.

A place where this is vigorously expressed is Engels's 'Anti-Dühring' (1878):

> . . . historically, private property by no means makes its appearance as the result of robbery or violence. . . . Everywhere where private property developed, this took place as the result of altered relations of production and exchange, in the interests of increased production and in furtherance of intercourse – that is to say, as a result of economic causes. Force plays no part in this at all. Indeed, it is clear that the institution of private property must be already in existence before the robber can appropriate another person's property. . . Nor can we use either force or property founded on force to explain the 'enslavement of man for menial labour' in its most modern form – wage labour. . .. The whole process is explained by purely economic causes; robbery, force, and the state of political interference of any kind are unnecessary at any point whatever (Burns 1935, pp. 267–9).

Engels goes on to argue the same specifically in connection with the institution of slavery:

> Thus force, instead of controlling the economic order, was on the contrary pressed into the service of the economic order. Slavery was invented. It soon became the predominant form of production among all peoples who were developing beyond the primitive community, but in the end was also one of the chief causes of the decay of that system (ibid., p. 274).
>
> Engels a little earlier in the same work was on slightly more favourable ground when he discussed the replacement of the nobility by the bourgeoisie as the most powerful estate in the land. If physical force were crucial, how should the peaceful merchants and producers have prevailed over the professional warriors? As Engels puts it: 'During the whole of this struggle, political forces were on the side of the nobility. . .' (ibid., p. 270).

One can of course think of explanations for this paradox: the nobility might have slaughtered each other, or there might be an alliance between the monarchy and the middle class (Engels himself mentioned this possibility, but does not think it constitutes a real explanation) and so forth. In any case, valid or not, this particular victory of producers over warriors would seem to constitute a prima facie example of the non-dominance of force in history. The difficulty for the theory arises when the point is generalized to cover all social orders and all major transitions, which is precisely what Marxism does.

Engels tries to argue this point in connection with a social formation which one might normally consider to be the very paradigm of the domination by force: 'oriental despotism'. (In fact, it is for this very reason that some later Marxists have maintained that this social formation is incompatible with Marxist theory, and hence may not exist.) Engels does it, interestingly enough, by means of a kind of functionalist theory of society and government: the essential function, the essential role and duty, of despotic governments in hydraulic societies is to keep production going by looking after the irrigation system. As he puts it:

> However great the number of despotic governments which rose and fell in India and Persia, each was fully aware that its first duty was the general maintenance of irrigation throughout the valleys, without which no agriculture was possible (Burns 1935, p. 273).

It is a curious argument. He cannot seriously maintain that these oriental despots were always motivated by a sense of duty towards the people they governed. What he must mean is something like this: unless they did their 'duty', the society in question could not survive, and they themselves, as its political parasites, would not survive either. So the real foundation of 'oriental despotism' was not the force of the despot, but the functional imperatives of despotically imposed irrigation systems. Economic need, as in the case of slavery, makes use of violence for its own ends, but violence itself initiates or maintains nothing. This

interpretation is related to what Engels says a little further on. Those who use force can either aid economic development or accelerate it, or go against it, which they do rarely (though he admits that it occasionally occurs), and then they themselves usually go under: 'Where... the internal public force of the country stands in opposition to economic development... the contest has always ended with the downfall of the political power' (Burns 1935, p. 277).

We have seen that Engels's materialism is curiously functional, indeed teleological: the economic potential of a society or of its productive base somehow seeks out available force, and enlists it on its own behalf. Coercion is and ought to be the slave of production, he might well have said. This teleological element is found again in what is perhaps the most famous and most concise formulation of Marxist theory, namely certain passages in Marx's preface to A Contribution to 'The Critique of Political Economy' (1859):

> A social system never perishes before all the productive forces have developed for which it is wide enough; and new, higher productive relationships never come into being before the material conditions for their existence have been brought to maturity within the womb of the old society itself. Therefore, mankind always sets itself only such problems as it can solve; for when we look closer we will always find that the problem itself only arises when the material conditions for its solution are already present, or at least in the process of coming into being. In broad outline, the Asiatic, the ancient, the feudal, and the modern bourgeois mode of production can be indicated as progressive epochs in the economic system of society (Burns 1935, p. 372).

The claim that a new order does not come into being before the conditions for it are available, is virtually a tautology: nothing comes into being unless the conditions for it exist. That is what 'conditions' mean. But the idea that a social system never perishes before it has used up all its potential is both strangely teleological and disputable. Why should it not be replaced even before it plays itself out to the full? Why should not some of its potential be wasted?

It is obvious from this passage that the purposive, upward surge of successive modes of production cannot be hindered by force, nor even aided by it. Engels, in 'Anti-Dühring', sneers at rulers such as Friedrich Wilhelm IV, or the then Tsar of Russia, who despite the power and size of their armies are unable to defy the economic logic of the situation. Engels also treats ironically Herr Dühring's fear of force as the 'absolute evil', the belief that the 'first act of force is the original sin', and so forth. In his view, on the contrary, force simply does not have the capacity to initiate evil. It does however have another 'role in history, a revolutionary role'; this role, in Marxist words, is midwifery:

> ... it is the midwife of every old society which is pregnant with the new,... the instrument by the aid of which social movement forces its way through and shatters the dead, fossilized, political forms ... (Burns 1935, p. 278).

The midwifery simile is excellent and conveys the basic idea extremely well. A midwife cannot create babies, she can only aid and slightly speed up their birth, and once the infant is born the midwife cannot do much harm either. The most one can say for her capacity is that she may be necessary for a successful birth. Engels seems to have no fear that this sinister midwife might linger after the birth and refuse to go away. He makes this plain by his comment on the possibility of a 'violent collision' in Germany which 'would at least have the advantage of wiping out the servility which has permeated the national consciousness as a result of the humiliation of the Thirty Years War'.

There is perhaps an element of truth in the theory that coercion is and ought to be the slave of production. The element of truth is this: in pre-agrarian hunting and gathering societies, surrounded by a relative abundance of sustenance but lacking means of storing it, there is no persistent, social, economic motive for coercion, no sustained employment for a slave. By contrast, once wealth is systematically produced and stored, coercion and violence or the threat thereof acquire an inescapable function and become endemic. The surplus needs to be guarded, its socially 'legitimate' distribution enforced. There is some evidence to support the view that hunting and gathering societies were more peaceful than the agrarian societies which succeeded them.

One may put it like this: in societies devoid of a stored surplus, no surplus needs to be guarded and the principles governing its distribution do not need to be enforced. By contrast, societies endowed with a surplus face the problem of protecting it against internal and external aggression, and enforcing the principles of its distribution. Hence they are doomed to the deployment, overt or indirect, of violence of the threat thereof. But all of this, true though it is, does not mean that surplusless societies are necessarily free of violence: it only means that they are not positively obliged to experience it. Still less does it mean that within the class of societies endowed with a surplus, violence on its own may not occasionally or frequently engender changes, or inhibit them. The argument does not preclude coercion either from initiating social change, or from thwarting change which would otherwise have occurred. The founding fathers of Marxism directed their invective at those who raised this possibility, but they never succeeded in establishing that this possibility is not genuine. All historic evidence would seem to suggest that this possibility does indeed often correspond to reality.

Why is the totally unsubstantiated and indeed incorrect doctrine of the social unimportance of violence so central to Marxism?

The essence of Marxism lies in the retention of the notion of an historical plan, but a re-specification of its driving force. But the idea of a purposive historical plan is not upheld merely out of an intellectual desire for an elegant conceptual unification of historical events. There is also a deeper motive. Marxism is a salvation religion, guaranteeing not indeed individual salvation, but the collective salvation of all mankind. Ironically, its conception of the blessed condition is profoundly bourgeois. Indeed, it constitutes the ultimate apotheosis of the bourgeois vision of life. The bourgeois preference for peaceful production over violent predation is elevated into the universal principle of historical change. The wish is father of the faith. The work ethic is transformed into the essence, the very species-definition of man. Work is our fulfilment, but work patterns are also the crucial determinants of historical change. Spontaneous, unconstrained work, creativity, is our purpose and our destiny. Work patterns also determine the course of history and engender patterns of coercion, and not vice versa. Domination and the mastery of techniques of the violence is neither a valid ideal, nor ever decisive in history. All this is no doubt gratifying to those imbued with the producer ethic and hostile to the ethic of domination and violence: but is it true?

Note that, were it true, Marxism is free to commend spontaneously cooperative production, devoid of ownership and without any agency of enforcement, as against production by competition, with centrally enforced ground rules. It is free to do it, without needing to consider the argument that only competition keeps away centralized coercion, and that the attempt to bring about propertyless and total cooperation only engenders a new form of centralized tyranny. If tyranny only emerges as a protector of basically pathological forms or organization of work, then a sound work-pattern will on its own free us for ever from the need for either authority or checks on authority. Man is held to be alienated from his true essence as long as he works for extraneous ends: he finds his true being only when he indulges in work for the sake of creativity, and choses his own form of creativity. This is of course precisely the way in which the middle class likes to see its own life. It takes pride in productive activity, and chooses its own form of creativity, and it understands what it does. Work is not an unintelligible extraneous imposition for it, but the deepest fulfilment.

On the Marxist economic interpretation of history, mankind as a whole is being propelled towards this very goal, this bourgeois-style fulfilment in work without coercion. But the guarantee that this fulfilment will be reached is only possible if the driving force of history is such as to ensure this happy outcome. If a whole multitude of factors, economic, cultural, coercive, could all interact unpredictably, there could hardly be any historic plan. But if on the other hand only one factor is fundamental, and that factor is something which has a kind of vectorial quality, something which increases over time and inevitably points in one direction only (namely the augmentation of the productive force of man), then the necessary historical plan does after all have a firm,

unprecarious base. This is what the theory requires, and this is what is indeed asserted.

The general problem of the requirement, ultimately, of a single-factor theory, with its well-directed and persistent factor, is of course related to the problems which arise from the plan that Marxists discern in history. According to the above quotation from Marx, subsequent to primitive communism, four class-endowed stages arise, namely the Asiatic, the ancient, the feudal, and the modern bourgeois, which is said to be the last 'antagonistic' stage (peaceful fulfilment follows thereafter). Marxism has notoriously had trouble with the 'Asiatic' stage because, notwithstanding what Engels claimed, it does seem to exemplify and highlight the autonomy of coercion in history, and the suspension of progress by a stagnant, self-maintaining social system.

But leaving that aside, in order to be loyal to its basic underlying intuition of a guaranteed progression and a final happy outcome, Marxism is not committed to any particular number or even any particular sequence of stages. The factual difficulties which Marxist historiography has had in finding all the stages and all the historical sequences, and in the right order, are not by themselves necessarily disastrous. A rigid unilinealism is not absolutely essential to the system. What it does require (apart from the exclusiveness, in the last analysis, of that single driving force) is the denial of the possibility of stagnation, whether in the form of absolute stagnation and immobility, or in the form of circular, repetitive developments. If this possibility is to be excluded, a number of things need to be true: all exploitative social forms must be inherently unstable; the number of such forms must be finite; and circular social developments must not be possible. If all this is so, then the alienation of man from his true essence – free fulfilment in unconstrained work – must eventually be attained. But if the system can get stuck, or move in circles, the promise of salvation goes by the board. This would be so even if the system came to be stuck for purely economic reasons. It would be doubly disastrous for it if other factors, such as coercion, were capable of freezing it. The denial of any autonomous role for violence in history is the most important, and most contentious, element in the Marxian economic theory of history.

So what the Marxist economic interpretation of history really requires is that no non-economic factor can ever freeze the development of society, that the development of society itself be pushed forward by the continuous (even if on occasion slow) growth of productive forces, that the social forms accompanying various stages of the development of productive forces should be finite in number, and that the last one be wholly compatible with the fullest possible development of productive forces and of human potentialities.

The profound irony is that a social system marked by the prominence and pervasiveness of centralized coercion, should be justified and brought about by a system of ideas which denies autonomous historical agency both to coercion and to ideas. The independent effectiveness both of coercion and of ideas can best be shown by considering a society built on a theory, and one which denies the effectiveness of either.

The social sciences, and economics in particular, separated from moral and political philosophy in the second half of the 18th century when the results of the myriad of intentional actions of people were perceived to produce regularities resembling the laws of a system. Both Physiocratic thought and Smith's *Wealth of Nations* reflect this extraordinary discovery: scientific laws thought to be found only in nature could also be found in society. This extension poses several problems. A serious one refers to the tension of combining individuals' freedom of action with the scientists' desire to discover the systematic aspects of the unintended and quite often unpredictable consequences of human action, that is, the desire to arrive at laws characterized by a certain degree of generality and permanence.

In the history of economic thought this fundamental tension has been solved in different ways. In the 18th century, the mechanistic ideal of the natural sciences, combined with the natural law idea of a harmonious order of nature, determined the way social phenomena were treated. There was a desire to discover the 'natural laws' of economic life and to formulate the natural precepts which rule human conduct.

The classical economists upheld the notion that natural laws are embedded in the economic process as beneficial laws, along with the belief in the existence of rules of nature capable of being discovered. Thus the belief that things could follow the beneficial 'natural course' only in a rationally organized society which it was a duty to create according to the precepts of nature. The economic system is the mechanism by which the individual is driven to fostering the prosperity of society while pursuing his private interest. Hence the automatic operation of the economic system may be combined with freedom of individual action. This is the core of the doctrine of economic harmony. Besides being causal laws of a mechanical type, the laws of nature are providentially imposed norms of conduct. In such a setting it would have been pointless to separate means and ends, since the implementation of natural laws is both an end and a means, and even more pointless to think of a tension between 'explaining' and 'understanding' economic behaviour. Causal and teleological, positive and normative, theoretical and practical started being seen as separate categories only when the economic discourse freed itself from the philosophy of natural law and all its implications.

Post-classical economics set out to be a science of the laws regulating the economic order and of the conditions allowing these laws to operate. It became the basis of a theory that, in Jevons's own terms, proposed to construct a 'social physics'. The view of a social world ordered according to transcendent ends was abandoned in favour of an ideal of objective knowledge of economic phenomena gained through a 'positive' study of the laws that regulate market activities. In so doing, neoclassical 'positive' economics solves the aforementioned tension by extrapolating the theoretical model of natural sciences to economics: economics is to produce the laws of motion similar to those of physics, chemistry, astronomy.

But what is a scientific law and which role do laws play within the logical positivist's perspective adopted by neoclassical economics? Laws provide the foundation of a deductive scientific method of inquiry. According to the deductive–nomological conception of explanation, due to C. Hempel, laws are universal statements not requiring reference to any one particular object or spatio–temporal location. To be valid, laws are constrained neither to finite populations nor to particular times and places; they are, in effect, expressions of natural stationarities. This interpretation of the notion of law provides the so-called covering-law model of explanation with an unquestionably firm inferential foundation. Deductive logic is employed to ensure the truth status of propositions and, since the deductions are (by hypothesis) predicated on true universal statements (laws), the empirical validity of these statements may be ascertained. However, what sort of constraints on economic discourse are

imposed by this positivistic structure? On the one hand this structure constitutes its object; on the other hand it generates specific economic questions together with their method of solution. Following the model of natural sciences and its success in controlling a natural world made up of objects and unvarying relations among them expressed in the form of laws, the neoclassical approach arrives at a study of regularities conceived of as specifying the nature of its objects.

To capture the different interpretations of the notion of law by classical and neoclassical economists let us refer to one of the most famous of economic laws: the law of diminishing returns, also known as the law of variable proportions. Studying agricultural production, Ricardo had noted that different quantities of labour, assisted by certain quantities of other inputs (farm tools, fertilizers, and so on), could be employed on a given piece of land, that is, it was possible to vary the proportions in which land and complex labour (labour assisted by other inputs) are employed. He accordingly arrived at the law which states that production increases resulting from equal increments in the employment of complex labour, while the quantity of land farmed remains constant, will initially be increasing and then decreasing. (To be sure, the first statement of the law is due to the Physiocratic economist Turgot.)

Three points deserve attention. First, Ricardo and classical authors in general offer no formal demonstration of this law. To them, it is basically an empirical law, on which no functional association between output and variable inputs can be built. Second, the classics' use of the law refers to their theories of distribution and development: as the supply of land in the whole system is fixed, sooner or later a point will be reached at which economic growth will come to a halt, notwithstanding any countervailing effects due to technical progress. Finally, the law presupposes a comparative statics framework: the pattern of the marginal products of complex labour refers to different observable equilibrium positions and not to hypothetical or virtual variations.

With the advent of the marginalist revolution, two subtle changes in the interpretation of the law took place. (*a*) The *de facto* elimination of the distinction between the extensive case (the case of the simultaneous cultivation of pieces of land of different fertility) and the intensive case (the application of successive doses of capital and labour to the same piece of land) with an overevaluation of the latter. Classical economists, being interested in the explanation of rent, concentrated on the extensive case; they took also the intensive case into consideration but with many qualifications. Indeed, whereas the various levels of productivity of different qualities of land is a circumstance which may be directly observed in a given situation, the marginal productivity of a given input is related to a virtual increment in output and therefore to a virtual change in the situation. (*b*) The change in the method of analysis – it was preferred to reason in terms of hypothetical rather than observable changes – brought about by the shift of interest towards the intensive margin, supported the thesis of the symmetrical nature of land and other inputs. This in turn favoured the extension of the substitutability between land and complex labour from agricultural production to all kinds of production, including those in which land does not figure as a direct input. It so happened that whereas in classical economics the substitutability between land and complex labour presupposes that simple labour and equipment are strictly complementary, in neoclassical economics this substitutability is applied to all inputs indiscriminately.

However, the neoclassical interpretation of the law poses serious problems. In the first place, there is the problem of justifying, on empirical grounds, the general applicability of the substitution principle. Secondly, and more importantly, in order to allow the substitution of inputs to take place, a certain lapse of time is required during which the required modifications to the productive structure can be made. (It is certainly true that coal can replace oil to provide heating, but before this can happen it will be necessary to change the heating system.) The well-known distinction between the short run and the long run is a partial and indirect way to take the temporal element into consideration. In the short run the plant is fixed by definition. It is therefore the fixed input which, in the neoclassical interpretation of the law, plays the

same role as land in the classical interpretation. Now, neoclassical theory correctly states the law of diminishing returns with respect to the short run; however it is in the long run that the substitutability of inputs becomes actually feasible. One is therefore confronted with a dilemma: the neoclassical interpretation of the law seems to be more plausible in a long-run framework when there exists the necessary time to accommodate input adjustments; on the other hand, fixed inputs cannot, by definition, exist in the long run so that the law of variable proportions cannot be stated in such a context.

This dilemma is the price neoclassical theory has to pay for its interpretation of the law in accordance with the positivistic statute. Indeed, the power of deductive, truth-preserving rules of scientific inference is not purchased without a cost. A school of economic thought which is not prepared to sustain such a cost is the neo- Austrian. The neo-Austrian economists solve what has been called the fundamental tension by arguing economics cannot and should not provide general laws since, by its very nature, it is an idiographic and not a nomothetical discipline. The general target of economics is 'understanding' grounded in *Verstehen* doctrine: by introspection and empathy, the study of the economic process should aim at explaining individual occurrences, not abstract classes of phenomena. It follows that if by a scientific law one should mean a universal conditional statement of type 'for all x, if x is A, then x is B', statements regarding unique events cannot by definition express any regularity for the simple reason that any regularity presupposes the recurrence of what is defined as regular. In the words of L. von Mises, who shares with F. von Hayek the paternity of the neo-Austrian school, what assigns economics its peculiar and unique position in the orbit of pure knowledge '. . . is the fact that its particular theorems are not open to any verification or falsification on the ground of experience . . . the ultimate yardstick of an economic theorem's correctness or incorrectness is solely reason unaided by experience' (von Mises 1949, p. 858).

There is indeed a place for economic 'laws' in the framework of Austrian economics. The familiar 'laws' of economics (diminishing marginal utility, supply and demand, diminishing returns to factors, Say's Law and so on) are seen as 'necessary truths' which explain the essential structure of the economic world but with no predictive worth. In other words, economic laws are not generalizations from experience, as it is the case within the positivistic paradigm, but are theorems which enable us to understand the economic world. It is ironic that Mises' position of radical apriorism joined to Hayek's attack on scientism and methodological monism are completely at variance with the position taken by the father of the Austrian school, Carl Menger (1883), who announced that in economic theories exact laws are defined which are just as rigorous as in fact are the laws of nature.

Between the extreme positions of neoclassical positive economic and neo- Austrian economics are those who, without denying that economics is in search for laws in the same sense in which natural sciences are and that laws perform an explanatory as well as a predictive function, underline that the explicative structure of economics, albeit nomothetical, substantially differs from that of natural sciences. This intermediate position can be traced back to Keynes's (1973) methodology which considers the conditions of truth and universality of the positivistic conception of scientific laws as far too rigid for a discipline such as economics. Two main reasons account for the different epistemological status of laws in natural sciences and in economics. First, the knowledge of economic phenomena is itself an economic variable, that is, it changes, along with the process of its own acquisition, the economic situation to which it refers. The formulation of a new physical law does not change the course of physical processes; it does not influence the truth or falsity of the prognosis. This is not the case in economics where the prognosis, say, that in two years time there will be a boom can cause overproduction and a resulting recession. In turn, this specific aspect is strictly connected to the fact that the object of study of economics possesses an historical dimension. Economics is in time in a way that natural sciences are not. The ensuing mutability of observed regularities is well expressed by Keynes

when he writes, 'As against Robbins, economics is essentially a moral science and not a natural science. That is to say it employs introspection and judgements of value' (1973, p. 297) to which he adds, 'It deals with motives, expectations, psychological uncertainties. One has to be constantly on guard against treating the material as constant and homogenous' (p. 300).

Second, the role played by *ceteris paribus* clauses in natural sciences and in economics is substantially different. The modern economists appeal to the 'other things being equal' clause – which according to Marshall is invariably attached to any economic law – in all those cases where the classical economists were talking of 'disturbing causes'. J.S. Mill's (1836) discussion of inexact sciences is suggestive here:

> When the principles of Political Economy are to be applied to a particular case then it is necessary to take into account all the individual circumstances of that case . . . These circumstances have been called *disturbing causes*. This constitutes the only uncertainty of Political Economy. (1836, p. 300)

Also in natural sciences we find *ceteris paribus* clauses. Indeed, a scientific theory that could dispense with them would in effect achieve perfect closure, which is a rarity. So where lies the difference? The example of the science of tides used by Mill is revealing. Physicists know the laws of the greater causes (the gravitational pull of the moon) but do not know the laws of the minor causes (the configuration of the sea bottom). The 'other things' which scientists hold equal are the lesser causes. So could we conclude that just about all generalizations in both natural sciences and economics express in fact *tendency laws*, in the sense that these 'laws' truly capture only the functioning of 'greater causes' within some domain? Certainly not, since there is a world of difference between the two cases. Galileo's law of falling bodies certainly presupposes a *ceteris paribus* clause, so much so that he had to employ the idealization of a 'perfect vacuum' to get rid of the resistance of air. However, he was able to give estimates of the magnitudes of the amount of distortion that friction and the other 'accidents' would determine and which the law ignored. In other words, whereas in natural sciences the 'disturbing causes' have their own laws, this is not the case in economics where we find tendency statements with unspecified *ceteris paribus* clauses or, if specified, specified only in qualitative terms. In economics it is generally impossible to list all the conceivable inferences implied in a lawlike statement and to replace the *ceteris paribus* clause with precise conditions. So, for example, the law that 'less will be bought at a higher price' is not refuted by panic buying, nor is it confirmed by organized consumer boycotts. No test is decisive unless *ceteris* are really *paribus*.

These remarks help to understand the role acknowledged by Keynes to laws in economic inquiry. Besides general laws, there are also rules and norms which are significant in the explanation of economic behaviour. To Keynes, it makes no sense to reduce all forms of explanation in economics to that of the covering-law model. Indeed, whereas to justify a law one has to show that it is logically derivable from some other more general statements, often called principles or postulates, the justification of rules occurs through the reference to goals and the justification of norms through the reference to values which are not general sentences, but rather intended singular patterns or even ideal entities. Since no scientific law, in the natural scientific sense, has been established in economics, on which economists can base predictions, what are used and have to be used to explain or to predict are tendencies or patterns expressed in empirical or historical generalizations of less than universal validity, restricted by local and temporal limits. Recently, Arrow has amazed orthodox economists when raising doubts about the mechanistically inspired understanding of economic processes: 'Is economics a subject like physics, true for all time or are its laws historically conditioned?' (Arrow 1985, p. 322).

The list of generally accepted economic laws seems to be shrinking. The term itself has come to acquire a somewhat old-fashioned ring and economists now prefer to present their most cherished general statements as theorems or propositions rather than laws. This is no doubt a healthy reaction: for too long economists have been under the nomological prejudice, of positivistic origin, that

the only route towards explanation and prediction is the one paved with laws, and laws as forceful as Newton's laws. Images in science are never innocent: wrong images can have disastrous effects.

Economic Man

Shaun Hargreaves-Heap and Colin G. Clark

Abstract

Economic man 'knows the price of everything and the value of nothing', so said because he or she calculates and then acts so as to satisfy best his or her preferences. The value of these preferences is immaterial. The hypothesis has nevertheless proved remarkably powerful not only in economics but across the social sciences where it has spawned 'rational choice' accounts of many aspects of social life. This ambition has attracted critics both from without and within. The latter have developed, with insights from psychology on how people acquire and use information, a less elegant but arguably more realistic model.

Among the many different portrayals of economic agents, the title of *homo economicus* is usually reserved for those who are rational in an instrumental sense. For example, this is how agency is defined in neoclassical economics. In its ideal type case the agent has complete, fully ordered preferences (defined over the domain of the consequences of his or her feasible actions), perfect information and all the necessary computing power. After deliberation, he or she chooses the action that satisfies their preferences better (or at least no worse) than any other. No questions are raised about the source or worth of preferences, reason focuses on the efficient selection of the means to given ends.

This basic model is then made more sophisticated. The theory of risk allows for the point that an action may have several possible consequences. When preferences are represented via the device of a utility function, the agent assesses his or her expected utility by discounting the utility of each consequence by how likely it is to be the actual one. That requires the agent to have a probability distribution for the consequences, even if only a subjective one. Other refinements include allowance for costs of acquiring information, of processing it and of action. Then there are complexities, illustrated by game theory, when actions of other agents form part of the environment in which the person acts. The basic vision remains, however, one of agents who are rational in the sense that they maximize an objective function subject to constraints (or act 'as if' this were the case).

This vision is not unique to neoclassical economics. For example, Marx's profit- maximizing capitalist fits the same instrumental model of rationality. Institutionalist accounts of, for instance, banks or trade unions often conceive economic bodies as similar unitary rational agents. Nor is the vision confined to any specific motivating desire in agents, like a selfish pleasure-maximizing drive. There is scope for allowing ethical preferences alongside the symptomatic textbook desires for apples and oranges. Agents are, however, regarded as self-interested, in the looser sense that they are moved to satisfy whatever preferences they happen to have. Furthermore, granted that *de gustibus non est disputandum,* this modest base is enough to ground a full-blown social theory on a model of agency which can be exported to other social sciences.

Such a social theory is individualist and contractarian, with a pedigree that includes Hobbes's *Leviathan* and Benthamite utilitarianism. The satisfaction of individual preference, aided by felicific calculation, is what makes the social world go round. Social relations become instrumental, in the sense that they embody exchanges in the service of individual preferences (see Becker 1976). For instance, marriage has been analysed in this spirit as an arrangement to secure the mutual benefit of exchange between two agents with different endowments. Crime has been claimed to occur because calculation of costs and benefits proves it to be the action that maximizes expected utility. Meanwhile, institutions, which feature in elementary microeconomics as constraints on individual choice, become deposits left by earlier transactions, often deliberately so as devices to prevent preferences being frustrated by situations of the Prisoner's Dilemma type. Government policies are explained on the hypothesis that the political arena is also peopled by individuals maximizing expected utility, who form coalitions in support of policies that will secure reelection (see Downs 1957). In short, *homo economicus* morphs into a universal *homo sapiens*.

Such a full-blown social theory may be too ambitious because assumptions that are plausible for simple market transactions become suspect when scaled up. For example, the ideal-type case makes agents, so to speak, transparent to themselves, and does not allow for history occurring behind their backs. Freudians would object to transparency of preferences and Marxians would invoke theories of false consciousness. (Although Marx's capitalists are instrumentally rational, their desire to maximize profit is an alienated one, 'forced' on them by a competitive capitalist system.) Many other social theorists would object to the treatment of norms and social relations as instrumental, on the grounds that norms are prior to preferences. For instance, cultural forms like the rules of orchestral composition are a source of musical preferences rather than a solution to a priori problems of maximizing musical enjoyment. Or, to put this differently, game theory yields too many instances of indeterminacy for an ambitious programme of reducing all social practices to the exercise of instrumental reason by the individual participating agents.

Such objections, of course, need not affect the more modest enterprise of explaining economic transactions within the parameters of social institutions like the market. But even here *homo economicus* has critics. Philosophically, it is not plain that preferences can be taken as given in a sense which makes them impervious to the agent's beliefs about the moral quality of his or her actions. In supposing that only desires can motivate agents, the economist is taking sides in a continuing philosophical dispute between Humeans, who regard reason as the slave of the passions, and Kantians, who make place for the rational monitoring of desire. This dispute surfaces plainly in welfare economics, when it is asked whether all preferences should count equally or whether 'capabilities' are more appropriate for the evaluation of social states than degrees of preference satisfaction, but bears on the elementary model of action too (see Sen 1999).

There are also methodological doubts about the empirical standing of the model. What would falsify the claim that economic agents seek the most effective means to satisfy their preferences? Apparent counter-examples can always be dealt with by treating them as evidence that preferences

have changed or been dismissed through a careful individuation of outcomes. Indeed, since preferences are unobservable, they can be identified only if the correctness of the model is presupposed. In other words, there is room for deeper dispute about the foundations of orthodox microeconomics than is always realized.

Even within economics there are critics. The most substantial attack comes from those who think that perfect information is not a useful limiting case of imperfect information. Granted that there is often no way of calculating the likely marginal costs and benefits of acquiring extra information (short of actually acquiring it), how shall the agent decide rationally when to stop? Simon (1976) uses the question to argue for 'satisficing' models, in place of maximizing ones, and for 'procedural' or 'bounded' rationality. Rationality, he suggests, is a matter of following a procedure that halts with a good solution, and should not be defined in terms of best solutions. While this is a tempting thought, it is not obvious that searching for a 'good' solution is any easier than the best one if 'good' is some kind of second-best version of the 'best'. As a result, 'behavioural economists' have been drawn to the large experimental literature in psychology on how people actually behave and have produced economic models of decision-making that incorporate a variety of psychological processes such as 'self-serving biases', the 'law of small numbers' and 'reference dependence' (see Kahneman 2003). In this way, *homo economicus* has become more psychologically complex and more of an institutional or organizational person than an abstract maximizer.

The rational expectations hypothesis offers a different approach to the information issue. A rational agent who is short of information should not use an information-generating mechanism that gives rise to systematic errors. If errors are systematic, the agent should be able to learn how to eliminate them by amending the mechanism. There is an incentive to do so, because improved estimates of future variables will be profitable. On the face of it this makes rational expectations the natural ally of the pure economic-man models. Economic Man can proceed much as before, in the assurance that inadequate information involves nothing more systematic than 'white noise' and with the benefit of fresh analytic results that flow from a rational expectations hypothesis.

But this is to sidestep the informational problem set earlier, unless one sees how rational agents will learn to remove systematic errors. When there are costs to learning then it may not be rational to expend the effort that achieves a rational expectation. If we set such costs aside, in some simple learning situations a Bayesian updating procedure turns a rational expectations-generating process into an approximation of adaptive expectations, which could be construed as a procedural rule of thumb. But no general rapprochement between maximizing and procedural models of rationality follows. In more general learning situations the rational agent is trying to learn the rational expectations equilibrium relationship between variables – the one which, if used by agents to form their expectations, would reproduce itself in experience (white noise apart). This sounds easy, in that repeated experience of a particular relationship should lead to convergence on accurate parameter estimates. However, ignorance of the rational expectations equilibrium values produces behaviour that departs from those values. So observed values of variables embody a distortion which agents cannot correct without knowing the dimensions of their own ignorance. To know this, however, they would have to know the rational expectations equilibrium values already. To put it as the procedural critics might, learning would be feasible only if there were nothing to learn. The information question has been begged; and the door again opens on to psychology and its rich literature on what people actually do.

Nevertheless, the ideal-type Economic Man remains a powerful model of action not only in neoclassical theories, where insights in comparative statics have been especially notable, but elsewhere too. How powerful it finally is depends, within economics, on what becomes of the informational difficulties and on whether procedural or bounded models can come up with rival results of equal scope and elegance. For the wider social sciences, it offers a tempting analysis of social

behaviour at large both for transactions in other social arenas and for the emergence of the institutions that govern those arenas. But the greater its ambitions, the more serious become the unresolved doubts about the origin of preferences and their relation to norms and institutions.

Economic Organization and Transaction Costs

Steven N. S. Cheung

One important extension of the Coase Theorem states that, if all costs of transactions are zero, the use of resources will be similar no matter how production and exchange activities are arranged. This implies that in the absence of transaction costs, alternative institutional or organizational arrangements would provide no basis for choice and hence could not be interpreted by economic theory. Not only would economic organization be randomly determined; there actually would not be any organization to speak of: production and exchange activities would simply be guided by the invisible hand of the market.

But organizations or various institutional arrangements do exist, and to interpret both their presence and their variation, they must be treated as the results of choice subject to the constraints of transaction costs.

In the broadest sense transaction costs encompass all those costs that cannot be conceived to exist in a Robinson Crusoe economy where neither property rights, nor transactions, nor any kind of economic organization can be found. This breadth of definition is necessary because it is often impossible to separate the different types of cost. So defined, transaction costs may then be viewed as a spectrum of institutional costs including those of information, of negotiation, of drawing up and enforcing contracts, of delineating and policing property rights, of monitoring performance, and of changing institutional arrangements. In short, they comprise all those costs not directly incurred in the physical process of production. Apparently these costs are weighty indeed, and to term them 'transaction costs' may be misleading because they may loom large even in an economy where market transactions are suppressed, as in a communist state.

By definition, an organization requires someone to organize it. In the broadest sense, all production and exchange activities not guided by the invisible hand of the market are organized activities. Thus, any arrangement that requires the use of a manager, a director, a superviser, a clerk, an enforcer, a lawyer, a judge, an agent, or even a middleman implies the presence of an organization. These professions would not exist in the Crusoe economy, and payments for their employment are transaction costs.

When transaction costs are defined to include all costs not found in a Crusoe economy, and economic organizations are defined equally broadly to include any arrangement requiring the service of a visible hand, a corollary appears: all organization costs are transaction costs, and vice versa. That is why during the past two decades economists have striven to interpret the various forms of organizational arrangements in terms of the varying costs of transactions.

Some obvious examples will illustrate the point. A worker in a factory (an organization) may be paid by a piece rate or by a wage rate. If the costs of measuring and enforcing performance (one type of transaction cost) are zero, then either arrangement will yield the same result. But if these costs are positive, the piece-rate contract will more likely prevail if the costs of measuring outputs are relatively low, whereas the wage contract will more likely be chosen if the costs of measuring hours and enforcing performance are low relative to the costs of measuring outputs. As another example, some restaurants (again an organization) measure the quantity of food sold; others serve buffet dinners, allowing customers to eat as much as they please at a fixed price per head. The cost of metering and quantifying food consumption relative to the basic cost of the food will determine which arrangement is chosen. In the total absence of transaction costs, the factory or the restaurant would not exist in the first place, because consumers would buy directly from the input owners who produce the goods and services.

As early as 1937, R.H. Coase interpreted the emergence of the firm (an organization) in light of the costs of determining market prices (transaction costs). When these costs are substantial because of the difficulties of measuring separate contributions by workers and of negotiating prices for separate components of a product, a worker may choose to work in a factory (a firm); he surrenders the right to use his labour by contract and voluntarily submits to direction by a visible hand, instead of personally selling his services or contributions to customers through the invisible hand of the market. The firm is therefore said to supersede the market. As the supersession progresses, the saving in the costs of determining prices will be countered by the rising costs of supervision and of management in the firm. Equilibrium is reached when, at the margin, the cost saving in the former equals the rising cost in the latter.

The firm superseding the market may be regarded as a factor market superseding a product market. If all costs of transactions were zero, the two markets would be inseparable in that a payment made by a customer to the owner of a factor of production would be the same as payment made to a product seller. In such a world it would be a fallacy to speak of the factor market and the product market as coexisting entities.

The presence of transaction costs is a prelude to separate the factor market from the product market. However, in some arrangements, such as the use of certain piece rates, it may become impossible to separate the one market from the other. Therefore, instead of viewing the firm as superseding the market, or the factor market as superseding the product market, it is more correct to view the organizational choice as one type of contract superseding another type. In these terms, the choice of organizational arrangements is actually the choice of contractual arrangements.

When organizational choices are viewed as contractual choices, it becomes evident that it is often impossible to draw a clear dividing line separating one organization from another. Take the firm, for example. It is often the case that the entrepreneur who holds employment contracts (and it is not clear whether it is the entrepreneur who employs the workers or the workers who employ the entrepreneur) may contract with other firms; a contractor may subcontract; a subcontractor may sub-subcontract further; and a worker may contract with a number of ‘employers’ or ‘firms’. If the chain of contracts were allowed to spread, the ‘firm’ might encompass the whole economy. With this approach the size of the firm becomes indeterminate and unimportant. What are important are the choice of contracts and the costs of transactions that determine this choice.

Traditional economic analysis has been confined to resource allocation and income distribution. Contractual arrangements as a class of observations have been slighted in that tradition. In a world complicated by transaction costs, this neglect not only leaves numerous interesting observations unexplained, but actually obscures the understanding of resource allocation and income distribution. The economics of organization or institution or, for that matter, the workings of various economic systems, were never placed in the proper perspectives under the traditional approach. For generations students were told that

various kinds of 'imperfections' were the cause of seemingly mysterious observations: policies were 'misguided', or antitrust specialists were barking up the wrong trees.

The costs of introducing new and more valid ideas must have been enormous. Even today textbooks still discuss marginal productivity theory only with reference to fixed wage and rental payments. Yet economists have known all along that (for labour alone) payments may be in the peripheral forms of piece rates, bonuses, tips, commissions, or various sharing arrangements; moreover, even wage rates may assume a number of forms. Each type of contract implies different costs of supervision, of measurement, and of negotiation, and the form of economic organization, along with the function of the visible hand, changes whenever a different contractual arrangement is chosen.

The choice of contractual arrangements is not, of course, confined to the factor markets. In the product markets, pricing arrangements such as tie-in sales, full-line forcing, or membership fees associated with clubs, may similarly be interpreted in light of transaction costs. Further, business organizations in mergers, franchises, and various forms of integration are now beginning to be viewed as transaction-cost phenomena. Indeed, close inspection of department stores and shopping centres reveals pricing and contractual arrangements between a central agent and individual sellers, as well as among the sellers themselves, which could not be explained by textbook economics.

Transaction costs are often difficult to measure and, as noted earlier, difficult to separate by type. However, the measurement problem can be avoided if only we are able to specify how these costs vary under different observable circumstances, and their different types are separable if viewed in terms of changes at the margin. These two conditions are requisite in the derivation of testable implications for the interpretation of organizational behaviour.

The use of transaction costs to analyse institutional (organizational) choice is superior to three other approaches. One approach would focus on incentives. However, incentives are not in principle observable, and we will do better in deriving testable propositions if the same problem is viewed in terms of the costs of enforcing performance. A second approach adopts risk. However, it is difficult to ascertain how risk is altered under different circumstances. Many risk problems, such as the uncertainty of whether an agreement will be honoured, are also problems of transaction costs, and it is easier to deal directly with those. Finally, some recent advances in transaction-cost analysis have called attention to the costs embodied in dishonesty, cheating, shirking, and opportunistic behaviour. Yet these are loose terms and, whatever they describe, to some extent are always to be found. To the degree that we can identify the particular costs of transactions that promote dishonesty, that shadowy explanation is no longer needed. After all, in what sense can we say a person is 'increasingly dishonest' or 'increasingly opportunistic'?

The transaction-cost approach to analysis of economic organizations can be extended upward from a few participants to the 'government' or even the nation itself. At the lower level, the owners of condominium units almost as a rule form associations with specific by-laws and elect committees to act on matters of common concern, the decisions being determined by majority vote. The transaction costs of ballot voting are less than those of using prices and dollar votes in certain circumstances, and trivial matters may even be delegated to a 'dictatorial' manager to further reduce the cost of voting. Similarly, residents in a particular location may choose to incorporate into a city, selecting their own mayor, with a committee setting up the building codes, hiring firemen and policemen, and deciding other matters of common concern.

Private property rights offer the unique advantage of allowing individual property owners the option of *not* joining an organization. This choice is an effective restraint against the adoption of an organization with higher transaction costs. It is true that a home-owner in a given region may, by majority vote, lose his option of not joining in a city corporation (unlike a worker who, in a free enterprise economy, always has the option of not joining a 'firm'). But with private property

rights the majority vote aims at cost saving, and a reluctant resident may exercise his own judgement by selling his house and moving elsewhere.

Private property rights further reduce transaction costs under competition. An entrepreneur or agent who wants to recruit other resource owners to join his organization must, under competition, offer attractive terms, and this can be achieved only if his organization can effectively reduce transaction costs. On the other hand, the resource owner competing to join an organization will be more inclined to deliver a good performance when at risk of losing his job.

The option of not joining an organization and the cost-reducing function of competition are, of course, restrained when an organization is extended to encompass an entire nation. When citizenship is dictated by birth, the option of not joining is restrained, and competition among nations to recruit members is decidedly less than among organizations within a nation. This relative lack of cost-reducing mechanisms is all the more evident in a communist state, where a citizen does not have the option of choosing an organization within that state.

A communist state may be regarded as a 'superfirm' in which comrades lack the option of not joining. Each worker is assigned to a particular job supervised and directed by the visible hands of comrade officials of varying ranks. In this aspect the communist state is remarkably similar to what Coase calls a 'firm', where workers are told what to do instead of being directed by market prices. But the lack of market prices in the communist state is not due to the costs of determining prices; rather, in the absence of private property rights market prices simply do not exist, and visible supervision by a hierarchy ranking becomes the remaining alternative to chaos.

The transaction costs of operating an organization are necessarily higher in a communist state than in a free enterprise economy, due to the lack of option of not joining and the lack of competition both to recruit members among organizations and to induce members to perform well.

If the transaction costs of operating organization were zero, resource allocation and income distribution would be the same in a communist state as in a free enterprise state: consumer preferences would be revealed without cost; auctioneers and monitors would provide freely all the services of gathering and collating information; workers and other factors of production would be directed free of cost to produce in perfect accord with consumer preference; each consumer would receive goods and services in conformity with his preferences; and the total income received by each worker, as determined costlessly by an arbitrator, would equal his marginal productivity plus a share of the rents of all resources other than labour, according to any of a number of criteria costlessly agreed upon. But such an ideal situation is obviously not to be found.

We therefore conclude that the poor economic performance of a communist state is attributable to the high transaction costs of operating that organization. Under the postulate of constrained maximization, the communist state survives for the same reason that any 'inefficient' organization survives: namely, the transaction costs of *changing* an organizational (institutional) arrangement are prohibitive. Such costs include those of obtaining information about the workings of alternative institutions, and of using persuasive or coercive power to alter the status of the privileged groups whose incomes might be adversely affected by the institution of a different form of economic organization.

Economic Sanctions

Jeffrey J. Schott

Abstract

Economic sanctions are tools of statecraft used to achieve a broad range of foreign policy goals by threat or deployment of coercive measures such as trade embargoes, asset freezes, or withholding of development aid. Throughout the post-war era, the United States and other countries frequently have imposed economic sanctions, even though they have contributed only infrequently to foreign policy successes. Globalization has made the exercise of economic coercion increasingly complex, but has not obviated the utility of sanctions as part of the foreign policy arsenal.

Economic sanctions are tools of statecraft used to influence the behaviour of foreign countries by the threat or actual withdrawal of trade and sources of finance. Traditional means of coercion include trade embargoes, withholding development assistance, and asset freezes. The objective is to confront a foreign country with a choice: either bear the cost of lost trade and finance, or change policies to comply with the demands of those imposing the sanctions (the sender countries). Projecting power through economic coercion is deemed more forceful than diplomatic reproach yet less drastic than military intervention. In practice, economic measures generally are deployed as part of a broader programme of foreign policy responses encompassing diplomatic entreaties, covert or quasi-military intrusions, and threat of or preparation for military action.

Countries impose sanctions in pursuit of a variety of foreign policy goals. Historically, economic sanctions have preceded and then accompanied military conflict. The oil embargo of Japan was a prelude to the Second World War in the Pacific; so, too, were the United Nations' sanctions against Iraq following its invasion of Kuwait in 1990. Obviously, sanctions are part and parcel of 'hot wars' that sever economic ties between the combatants; but they are also prevalent in 'cold war' episodes, where the goal is to impair military capabilities through denial of weapons and dual-use technologies (for example, post-war sanctions against the Soviet Union and its satellites under the auspices of the Consultative Group and Coordinating Committee for Multilateral Export Controls, or CoCom, and efforts to blunt the development of nuclear weapons in Iran and North Korea). In addition, sanctions have sought to impede or reverse military incursions across borders (for example, the League of Nations effort to get Italy to withdraw from Abyssinia in 1936) and between warring factions within a country (the sad recent history of several West African states).

Not all sanctions episodes respond to or presage military actions. Many post-war cases have been advanced to counter other types of aberrant behaviour such as state sponsored terrorism, proliferation of weapons of mass destruction, or

human rights abuses. In these cases, sender countries impose sanctions in an effort to redress foreign outrages, to deter emulation by others (the rationale in most anti-proliferation cases), and to punish the target regime for its misdeeds (for example, the US grain embargo after the Soviet invasion of Afghanistan in 1989). In a number of cases, sanctions pursue the goal of regime change *sotto voce* – whether the target is Moammar Gaddafi in Libya, Kim Jong-il in North Korea, or the Afrikaaners in South Africa. Sanctions that portend regime change obviously meet stauncher resistance than those that seek narrow changes in governance by the target government.

Do Sanctions 'Work'?

Foreign policy ventures seldom yield unambiguous results. Gauging the effectiveness of sanctions involves a combination of quantitative method and intuition, and often requires subjective evaluation of incomplete results. Sanctions alone seldom are sufficient to change foreign practices, but they can *contribute* to the achievement of policy goals in conjunction with other instruments of statecraft, if properly designed and implemented. That is easier said than done.

Sanctions are blunt policy instruments; they are better at impairing economic performance over time than at inflicting surgical strikes on target countries. Senders that expect immediate gratification often tire of the effort, especially if the sanctions impose significant costs on their own firms and workers. Moreover, when sanctions are hard hitting, it is difficult to avoid innocent victims within the target country and in neighbouring states; in such cases, the debilitating effect of sanctions often results in substantial suffering among the civilian population. Humanitarian exemptions from the sanctions designed to soften the blow to the general public invariably weaken the economic impact of the sanctions and muddy the policy signal to the target regime. To be sure, such loopholes in the sanctions net are important both on moral grounds and to maintain the cohesion of the coalition of sender countries, but the loopholes are prone to abuse (witness the scandalous operation of the United Nations' oil-for-food programme, which was supposed to channel Iraqi oil export revenues to humanitarian assistance) and reduce the economic pressure to comply with the sender's demands.

Almost all sanctions leak; targeted countries can evade the full thrust of the economic restrictions by redirecting trade and finance to non-sanctioning states or by engaging in clandestine operations. Countries seeking economic or political influence with the target regime often conspire to evade the sanctions; the Cold War period was replete with examples of 'Black Knight' countries coming to the rescue of targeted regimes with aid to offset the impact of sanctions imposed by the United States or the Soviet Union. Smugglers still outwit even the most comprehensive embargoes – witness the billions of dollars earned by Saddam Hussein, the former Iraqi president, from illicit oil exports during the period of 'comprehensive' UN sanctions against Iraq. For a price, targeted regimes can still procure goods, services and technologies; the profit motive seems to be an irresistible force regardless of region or culture!

That said, sanctions have contributed to a few notable successes in the post-war era, including the collapse of the apartheid regime in South Africa and the renunciation of terrorism by President Gaddafi in Libya. Hufbauer et al. (2007) found success – measured by the partial fulfillment or better of policy goals – in more than a quarter of the almost 200 sanctions episodes documented in the 20th century. (The third edition of this comprehensive study of economic sanctions contains updated policy analysis and case studies, and an extensive bibliography. See also Baldwin 1985, for an examination of the tools of economic statecraft, and Martin 1992, for analysis of the use of multilateral economic sanctions.) Most of these cases, however, involved relatively modest demands on the target country. When the stakes are high, resistance by the target regime stiffens. Accordingly, most high-profile sanctions cases – like those seeking to oust President Castro in Cuba or to deter support for terrorism and the development of nuclear weapons by the ayatollahs in Iran – have been abject failures.

Can Sanctions Be Effective in an Era of Rampant Globalization?

Economic sanctions traditionally have been the domain of big powers, acting unilaterally or as part of a broader international coalition. Until recently, the big powers controlled the trade lanes and purse strings of international commerce, and held a near monopoly on advanced technologies. Since the mid-1980s, however, the success of post-war economic development, spurred in part by the spread of technological innovation, has eroded the franchise of the big powers and created alternative sources of goods, technology and capital for countries targeted by economic sanctions. Simply put, globalization has made it much harder to design an effective sanctions policy.

In addition, global politics are now more complex than in the period of East–West rivalry. Former allies differ regarding strategies and priorities for using sanctions to deal with regional trouble spots. For example, Europe is more vulnerable than the United States to an interruption of energy supplies from the Middle East, and thus is less willing to constrain oilfield development and to take actions that risk political retaliation. Similarly, China and Japan are highly dependent on imported energy and thus sensitive to sanctions against Iran and other oil – producing states.

Globalization also has contributed to the decentralization of power, allowing smaller countries – especially those rich in energy resources – to provide offsetting assistance to blunt the economic impact of sanctions. But the influence of globalization goes beyond the realm of state-to-state intervention; terrorism, for example, now operates in a stateless domain of sleeper cells and territories outside of governmental control linked through informal financial and telecommunications networks. For that reason, sanctions policies increasingly seek to target individuals and corporations as well as governmental bodies, and to favour financial measures to interdict inter-bank electronic transfers in addition to the more traditional controls on trade, investment and development assistance.

In sum, economic sanctions continue to play a major role in international relations. However, the familiar goals of economic coercion now must be pursued through measures adapted to the changing conditions in global markets. The use of economic sanctions needs to be reconsidered and revamped, but not abandoned.

Economic Science and Economics

Henry Sidgwick

The terms ‘economy’ and ‘economic’ or ‘economical’, are now used chiefly in two meanings, which it is well to distinguish clearly; since, though divergent in their history, they are liable to fusion, and therefore in some degree to confusion.

‘Economy’ originally meant, in Greek, the management of the affairs of a household, especially the provision and administration of its income. But since both in the acquisition and in the employment of wealth it is fundamentally important to avoid waste either of labour or of its produce, ‘economy’ in modern languages has come to denote generally the principle of seeking to attain, or the method of attaining, a desired end with the least possible expenditure of means; and the words ‘economy’, ‘economic’, ‘economical’, are often used in this

sense, even without any direct relation to the production, distribution, or consumption of wealth. Thus we speak of 'economy of force' in a mechanical arrangement without regard to its utility, and of 'economy of time' in any employment whether productive of wealth or not.

On the other hand, as there is an obvious analogy between the provision for the needs of a state and the provision for the needs of a household, 'political economy', in Greek, came to be recognized as an appropriate term for the financial branch of the art or business of government. It is found in this sense in a treatise translated as Aristotle's in the 13th century; and so, when, in the transition from medieval to modern history, the question of ways and means obtrusively claimed the attention of statesmen, 'political economy' was the name naturally given to that part of the art of government which had for its aim the replenishment of the public treasury, and – as a means to this – the enrichment of the community by a provident regulation of industry and trade. And the term retained this meaning till the latter part of the 18th century without perceptible change – except that, towards the end of this period, the enrichment of the people came to be less exclusively regarded from the point of view of public finance, and more sought as a condition of social well-being.

But in the latter part of the 18th century, under the influence primarily of the leading French 'Économistes' or 'Physiocrats' – Quesnay, De la Rivière, and others - the conception of political economy underwent a fundamental change, in consequence of a fundamental change in the kind of answer which these thinkers gave to the question 'how to make a nation wealthy'. The physiocrats proclaimed to France, and through France to the world, that a statesman's true business was not to *make* laws for industry and trade in the hope of increasing wealth; but merely to ascertain and protect from encroachment the simple and immutable laws of nature, under which the production of wealth would regulate itself in the best possible way if governments would abstain from meddling. A view broadly similar to this, but less extreme, and, partly for this reason, more directly influential, was expounded in Adam Smith's *Wealth of Nations*. Instead of showing the statesman how to 'provide a plentiful revenue or subsistence for the people' – which was one of the two main objects of political economy, according to the traditional view – Adam Smith aims at showing him how nature, duly left alone, tends in the main to attain this end better than the statesman can attain it by governmental interference. Accordingly, so far as the widespread influence of Adam Smith's teaching went, that branch of the statesman's art which aimed at 'providing a plentiful revenue for the people' tended almost – though not altogether – to shrink to the simple maxim of *laisser faire*: leaving in its place a scientific study of the processes by which wealth is produced, distributed, and exchanged, through the spontaneous and partly unconscious division of labour among the members of human society, independently of any governmental interference beyond what is required to exclude violence or fraud. A part, indeed, of the old art of political economy – that which aimed at 'supplying the state with a revenue sufficient for the public service' – remained indispensable to the statesman; but it was held that this traditional art required to be renovated by being rationally based on the doctrines of the new-born science just described. It is, then, this scientific study of the department of social activity that most writers on the subject now primarily mean by the term 'political economy': such part of the old governmental art so called, as the doctrine of the new science is held to admit, being commonly regarded as 'applied political economy'. In consequence of this change the adjective 'economic', instead of the too cumbrous 'politico-economic', has come to denote the matters investigated by the science of political economy, and the propositions and arguments relating to them.

By thinkers and duly-instructed students this distinction between 'science' and 'art' – between the study of 'what is' and the study of 'what ought to be' – is usually regarded as simple and clear; and accordingly when such persons speak of the 'laws of political economy' they mean not rules by which the process of the social production and distribution of wealth *ought* to be governed, but general relations of co-existence and sequence among phenomena of this class, ascertained by a scientific study of this process as it actually takes place.

This distinction, however, has been found difficult to establish in common thought: even well-educated persons still occasionally speak of the 'laws of political economy' as being 'violated' by the practice of statesmen, trades-unions, and other individuals and bodies. It is partly in order to prevent this confusion that the terms 'economic science' and 'economics' have recently come more and more into use, as a preferable alternative for political economy, so far as it is the name of a science. As to the scope of this science – it would be generally agreed that it is a branch of a larger science, dealing with man in his social relations; that it is to an important extent, but not altogether, capable of being usefully studied in separation from other branches of this science; and that it is mainly concerned with the social aspect – as distinct from the special technical aspect – of such human activities as are directed towards the production, appropriation, and application of the material means of satisfying human desires, so far as such means are capable of being exchanged. It would also be generally agreed that the method of economic science is partly deductive, partly inductive and historico-statistical. But to attempt a more precise determination of its method and scope, and especially of its relation to the art or system of practical rules which should guide the action of governments or private individuals in economic matters, would require us to enter into questions of a highly controversial kind; which will be more conveniently discussed when we come to deal with the older and wider term Political Economy.

Economic Sociology

Richard Swedberg

Abstract

The term 'economic sociology', used primarily by sociologists, is defined as the application of sociological concepts and methods of analysis to economic phenomena. Founded by Durkheim, Weber, and Simmel, and continued by Schumpeter and Polanyi, it began to flourish in the mid-1980s around the notion that economic actions are embedded in personal networks. The concept of networks and other concepts and perspectives from 'new economic sociology' facilitate the analysis of topics like the links between corporations and between firms, job search, production markets, finance markets, insurance markets, industrial markets, consumption, and ethnic entrepreneurship. Its long-term impact on economics remains uncertain.

The first recorded use of the term 'economic sociology' is in a 1879 work by Stanley W. Jevons; and it is clear from the context that Jevons viewed economic sociology as part of the overall enterprise of economics rather than as an area belonging to another social science, such as sociology. Today, in contrast, the term 'economic sociology' is used primarily by sociologists, and they define it as *the application of sociological concepts and methods of analysis to economic phenomena.* While it is definitely possible to treat the great concern with institutions in New Institutional Economics, for example, as a kind of economic sociology, the reader is referred to the entry for

this topic for this type of analysis. Similarly, while Gary Becker at times has referred to his extension of the economic model to non-economic topics as 'economic sociology', the reader is similarly referred to the entry for his work.

Here, the first section, on classical economic sociology, is followed by sections on more recent economic sociology. This way of proceeding not only follows the general development of the field of economic sociology but is often how economic sociology is taught today, since the classics play a somewhat different role in economic sociology (as in sociology itself) to that in economics. In brief, while sociologists are trained through work with the classics as well as modern material, today's economists read the classics primarily when they study the history of their discipline.

Classical Economic Sociology

The work of Karl Marx (1818–83) can be seen as a type of economic sociology, in the sense just mentioned. More generally, Marx closely linked classical economic categories, such as value, price and capital, to distinctly social categories, such as class, work and relations of production. Nevertheless, Marx has played a marginal role in economic sociology as an academic enterprise – except as a catalyst and inspiration for a number of scholars, including Max Weber and Joseph Schumpeter.

Modern academic sociology is generally regarded as having three founders – Max Weber, Emile Durkheim and Georg Simmel – all of whom were interested in the economy. Georg Simmel (1858–1918), who pioneered sociology in Germany, wrote on the sociological role of money, competition and trust in the economy (Simmel 1900; 1908). He closely linked different types of money to different types of social authority, and also attempted to show how money is linked to the element of relativism in modern society. Competition, he argued, releases the energy of all participants to the benefit of the public, whereas in a conflict combatants are pitted against each other and block each other's efforts. Trust, finally, is central to the economy as well as society at large; without trust, the economy as well as society would collapse.

Emile Durkheim (1858–1917), unlike Simmel, attempted to institutionalize economic sociology, partly by encouraging some of his students to specialize in this field. Durkheim's own most important contribution to economic sociology can be found in his doctoral study of the division of labour, which contains a sharp critique of the argument in Adam Smith's *The Wealth of Nations* (Durkheim 1893). According to Durkheim, while Adam Smith had seen the significance of division of labour exclusively from the perspective of the creation of wealth, he had neglected its importance for the cohesion of society. More precisely, Smith had failed to realize that the primary function of the division of labour in modern society is to tie people together: people who do very different things need each other, and this is also what gives cohesion to modern society.

The most sustained effort to lay a solid theoretical foundation for economic sociology and also to carry out empirical studies can be found in the work of Max Weber (1864–1920) (Swedberg 1998). While Weber is famous for *The Protestant Ethic and the Spirit of Capitalism* (1905), it is less well known that his work is part of a more general attempt to develop a new academic field that would complement economic history and economic theory, namely, economic sociology.

At first Weber carried out empirical and historical studies with this goal in mind, and of these *The Protestant Ethic* is by far the best known (but see also Weber 1909; 1895). Weber's thesis, which holds that a certain type of religion ('ascetic Protestantism') had helped to create the mentality of modern capitalism in the 16th and 17th centuries ('rational capitalism'; Weber 1905), has led to a heated debate. Most commentators have found Weber's thesis unconvincing, but it should be emphasized that the debate is still going on with as much fervour as in the early 20th century (see, for example, Marshall 1982).

The heart of Weber's economic sociology is to be found in *Economy and Society*, a work that was incomplete when Weber died. It is here, for example, that Weber set out his well-known typology of

capitalism: political capitalism, traditional capitalism and rational capitalism. While the former two have existed for thousands of years, rational capitalism has emerged only in modern times and in the West. While traditional capitalism is non-dynamic and centred around small enterprises involving trade and the exchange of money, political capitalism is profit-making that either takes place through the state or under its direct protection, as in imperialism. Rational capitalism, in contrast, gets its name from the strong element of conscious and methodical calculation: the activities of the firm are carried out with the help of accountants and a trained staff; similarly, the activities of the state bureaucracy (including in the legal system) are predictable and rational. All of this makes possible a truly dynamic and revolutionary form of capitalism, according to Weber.

Economy and Society also contains a serious attempt by Weber to develop the central theoretical categories of economic sociology (Weber 1914, pp. 63–211). The basic unit of analysis is 'economic social action', which differs from economic action in economic theory by partly being determined by its social dimension. Economic social action is defined by Weber as behaviour that is (*a*) invested with meaning, (*b*) aimed at utility and (c) *oriented to another actor.* Utility is what makes the action 'economic'; and Weber's definition of 'social' is to be found in the formula 'orientation to another actor'. The emphasis on meaning explains why Weber's sociology is called an interpretive sociology; his economic sociology was to be a form of *interpretive economic sociology.*

Weber then proceeds to economic relationships in which two actors orient their actions to one another. These relationships can be either open or closed; and there is a general tendency for open economic relationships to become closed when there are not enough resources to go round. Economic organizations are defined as closed social relationships of a certain type; there also has to be a staff. Economic systems, finally, can be oriented either to profit-making (as in capitalism) or to the provision for a household (as in socialism or earlier non-market economies). Weber also discusses a host of other topics, including trade, money, division of labour and different ways of appropriation.

After the Classics

While the founding fathers of sociology were all interested in economic sociology and promoted it, the topic did not become popular among sociologists until the mid- 1980s with the emergence of so-called 'new economic sociology'. The reason for this is not clear, but may well have been a strong sense among sociologists that the economists were better equipped to deal with economic topics. In any case, very little work on economic sociology was produced between 1920 and the mid-1980s.

There were, however, a few exceptions. For one thing, sociologists did discuss topics relating to the economy, even if they did so under labels other than 'economic sociology'. One example is industrial sociology, which saw as its main task to analyse situations when people work in groups, in the factory as well as the office. An important research result is that workers develop norms in a number of areas, including what is seen as the maximum effort. Those who breach these norms are punished (for example, Whyte 1955).

Three individuals who all made important contributions to economic sociology also appeared during the period after the classics: Joseph Schumpeter, Karl Polanyi and Talcott Parsons. According to Schumpeter (1885–1950), economics should be a broad science ('social economics') and encompass four areas: economic theory, economic history, economic statistics and economic sociology (Schumpeter 1954, pp. 12–24). Schumpeter did work in each of these fields, including economic sociology. According to Schumpeter, economic sociology deals with institutions, while economic theory deals with economic mechanisms. Schumpeter's three most famous essays in economic sociology deal with the issues of social class in economic life, the role of taxation ('fiscal sociology') and imperialism (Schumpeter 1991). Schumpeter thought highly of these essays and they are all considered minor classics today.

But one can also find elements of economic sociology in some of Schumpeter's non-sociological writings. This goes for the famous analysis of entrepreneurship in *Theory of Economic Development,* not least the element of resistance from the environment that the entrepreneur usually confronts (Schumpeter 1934). Similarly in *Capitalism, Socialism and Democracy*, we find a sociological portrait of contemporary capitalism. The US economy was doing very well, according to Schumpeter, but its institutions were decaying (Schumpeter 1942).

Like Schumpeter, Karl Polanyi (1886–1964) came from the Austro-Hungarian Empire and ended his life on the American continent. Like Schumpeter, he wrote a famous book on capitalism – *The Great Transformation* – and contributed to the economic sociology of his days (Polanyi 1957). It is to Polanyi that we owe the term 'embeddedness', even if he used it in his own, very political sense: all economies had been embedded in politics and religion before the advent of capitalism, and were disembedded by the traumatic 'great transformation'. The political task of the day, in other words, was to re-embed the economy into political and human values.

Polanyi covered historical distances with great ease and was as much at home in ancient Babylonia as in 19th-century Britain or 20th-century United States. The scope of his knowledge about the economy is also reflected in one of his most useful sets of categories: the concepts of reciprocity, redistribution and exchange (for example, Polanyi 1971). In a kinship situation, for example, reciprocity may be used as a way of distributing resources. A political centre, like the state, would in contrast redistribute resources; and a market distributes resources through exchange. Most economic systems draw on each of these three ways of distributing resources, with their corporate sectors ('exchange'), state sectors ('redistribution') and household sectors ('reciprocity').

Talcott Parsons (1902–1979) had begun his career as an economist, only to switch to sociology, since he thought that utilitarian thought was unable to properly capture the structure of modern society. Parsons argued for a general systems perspective in social theory, and suggested in *Economy and Society* (together with Neil Smelser) that the economy should be conceptualized as a sub-system of the general system of society (Parsons and Smelser 1956). Just as each society has to have a distinct goal ('Polity') and a value-system ('Latent-Pattern-Maintenance'), it also has to adapt to nature and reality ('Economy'). While it is part of society, the economy is also its own society, with a 'polity', 'latent-pattern-maintenance', and so on.

New Economic Sociology

Around the mid-1980s American sociologists suddenly started to become interested in economic sociology, and it is this development that is generally known as 'new economic sociology'. One article in particular operated as a catalyst in this process, and that is Mark Granovetter's 'Economic action and social structure: the problem of embeddedness' (1985). Its central argument is that all economic actions are embedded in personal networks, and it is this quality that brings them into the sociologist's domain. While this message was important enough in itself, the article's implicit or subliminal message that sociology had neglected a whole area of social life which lent itself to sociological analysis, namely, the economy, also explains its great impact. Since sociological skills had not been applied to economic problems, sociologists might also be able to solve a number of important puzzles that the economists had failed to do, according to Granovetter.

Since the mid-1980s economic sociology has advanced steadily, and it is now fully institutionalized in the United States. It is routinely taught in sociology departments in all the major universities and also has a strong presence among the major journals of the profession. The American Sociological Association has a special section for economic sociology; a number of readers have been published as well as a huge handbook (Smelser and Swedberg 1994; 2005).

Economic sociology is becoming increasingly popular and accepted in Europe as well, though in

a somewhat different form than in the United States, which is only natural given the various national traditions in sociology. While interesting contributions can be found in many European countries, it is especially in France that one can find highly original contributions that stand up well to international competition (for England, see for example Dodd 1994; for Scotland, MacKenzie 2003; for Germany, Beckert 2004; for Italy, Trigilia 2002; and for Sweden, Aspers 2001).

The three key figures in French economic sociology are Pierre Bourdieu, Luc Boltanski and Michel Callon (see also the works of Lebaron 2000, and Steiner 2005). Bourdieu (1930–2002) has, among other things, analysed consumption in an innovative manner in his celebrated study *Distinction* (1986); he has also sketched a whole programme for economic sociology, drawing on his three key concepts of habitus, field, and different types of capitals (Bourdieu 1979; 2005). Luc Boltanski has contributed to the discussion of modern capitalism through an important study of class formation and also co-authored a provocative volume on 'the new spirit of capitalism' (Boltanski 1987; Boltanski and Chiapello 1999). And Michel Callon (1998) has introduced the so-called theory of performativity or the idea that economic theory may be as successful as an explanatory approach for the simple reason that it analyses phenomena that it has helped to create in the first place.

The number of studies in economic sociology (books and articles) amounts to several thousand by now, which makes it hard to summarize its achievements. One way to convey a sense of this literature, however, would be to discuss the methods that are being used to gather and analyse data as well as some of the most important topics. That economic sociology indeed has a distinctive profile that sets it off from mainstream economics emerges very clearly from a discussion of these two themes.

The data that is being used in economic sociology has often been put together by the analyst, and it is considerably less common than in mainstream economics to draw on official data of the type that is produced by government agencies. One example is historical studies in economic sociology, as illustrated by Bruce Carruther's *City of Capital* (1996). The focus in this work is the emergence of one of the world's first financial markets, and the author draws heavily on various primary and secondary sources. In particular, Carruthers succeeds in showing that early trade in shares often followed party lines; that is, sellers were reluctant to trade with political opponents.

Comparative studies are long-standing in economic sociology and have also been popular in new economic sociology. In one of these, *Forging Industrial Policy*, Frank Dobbin (1994) compares the ways in which the railroad industry developed in the 19th century in the United States, Britain and France. The author shows that industrial policy has largely mirrored the general political culture in its approach to solving problems in each of these three countries. In the United States, there has been scepticism towards the state and reliance on the corporations; in France, the state has been the central actor; and in Britain there has been an attempt to protect the individual firm from competition as well as from interventions from the state. Dobbin claims to have found that there is no one best way of doing things. Rather, people generalize from how they themselves do things and proclaim this to be the universally rational way to proceed.

Economic sociologists also draw on ethnography and participant observation, two methods that allow the researcher to handle huge amounts of empirical detail and to approach things from the perspective of the actors. Michael Burawoy (1979), for example, worked as a shop steward in order to better understand how workers interact and deal with the demands of their work (especially boredom); and Mitchel Abolafia (1996; 1998) passed an examination as a stockbroker in order to better understand what goes on in various stock and bond exchanges.

By far the most significant single method used by economic sociologists today, however, is that of networks. This is a very flexible tool, which allows for quantification and therefore goes well with a large number of research tasks. It has been used, for example, to analyse the links that exist between corporations by virtue of having the same

individual on their boards (so-called interlocks). Through the resultant system of communication, various ways of doing things may be diffused. The so-called poison pill (a measure against hostile takeovers) has, for example, been shown to diffuse quickly among corporations linked by common board members (Davis 1991). That links between corporations are not to be understood exclusively in terms of instrumental actions may be exemplified by the fact that, when a board member resigns or dies, he or she is only replaced in something like half of the cases (Palmer 1983).

Using networks is also a popular way in economic sociology to approach collaboration between corporations as well as the relationship between firms and their customers and suppliers (see, for example, Gulati and Gargiulo 1999). The area where it has been most successful, however, may well be the labour market; and here the classic study is Mark Granovetter's *Getting a Job* (Granovetter 1974). While one may have thought that the most important source of assistance for a person seeking a job is that's person's closest friends and family ('strong ties'), in fact it is his or her more casual contacts ('weak ties'), whose number depends on how many jobs a person has had. The reason for this 'strength of weak ties' is simply that, whereas one's 'strong ties' all share the same information, 'weak ties' can provide access to new and varied information, including information about job opportunities.

In European economic sociology an attempt has also been made to expand the notion of networks to include not only people and organizations in the category of actors but also objects (so-called actor-network-theory; see, for example, Law and Hassard 1999). That objects can be actors in the conventional sense of this term is no doubt wrong; the weaker claim that objects can be part of networks is, however, more interesting. One may, for example, see a machine as a link between people, some objects may be used for communication between people, and so on – and all this can affect the structure of the network. More generally, the advocates of actor-network-theory also argue that the traditional approach of economists and sociologists tends totally to ignore the role that objects play in the economy and to focus exclusively on actions, social relations and the like. The perspective that argues for including objects in the analysis is usually referred to as 'materiality'.

When it comes to the topics that are often analysed, new economic sociologists have first and foremost tried to focus on economic institutions as opposed to phenomena situated at the boundary of, say, religion and the economy or politics and the economy. The reason for this has been a desire to take on truly 'economic' topics and go beyond the old division of labour between economics and sociology, when the former dealt with the economy and the latter with society minus the economy. As examples of this is the interest among contemporary economic sociologists in markets and corporations, which have attracted a large number of studies.

One type of study has attempted to develop a general model for markets that differs sharply from the standard economic model of the perfect market. The most prominent example of this is the work of Harrison White (1981; 2002) on so-called production markets, by which he roughly means industrial markets. Production markets, it is argued, differ from so-called exchange markets primarily because their participants have permanent roles as either sellers or buyers and do not switch between these two roles as is common in financial markets.

According to White, the typical production market holds about a dozen actors who closely follow what the other actors are up to. Markets come into being, White argues, precisely because economic actors position themselves in relation to the products of other actors. Prices are not set through demand and supply but by producers relating the revenue of their goods to the volume that is being sold. Individual markets, finally, are connected to each other in giant networks, either 'upstreams' (suppliers) or 'downstreams' (customers).

A number of studies of financial markets have also been carried out, and here the work of Donald MacKenzie is outstanding (for example, MacKenzie 2003; MacKenzie and Millo 2003). MacKenzie has picked up from Callon the theme of performativity, and he uses it, for example, in his

analysis of trade in options. The pricing of options was very difficult, the argument goes, until Black, Scholes and Merton suggested a solution for which the latter two would win the Nobel Prize in 1997. While this formula covers most cases with much precision, according to MacKenzie it does not cover all – and this was to have important consequences. Since this fact was not well understood, however, and since economic reality was mistaken for how it was portrayed in finance theory (performativity), there have been cases in which people were unprepared for what was happening (as in the case of Long-Term Capital Management). MacKenzie traces this development and also shows how actors have tried to protect themselves against exceptional cases by keeping a margin against the price predicted according to the Black–Scholes–Merton formula.

Economic sociologists have suggested several new ways to approach consumer markets. Viviana Zelizer (1979), for example, has analysed the growth of the market in life insurance in the United States and shown how the idea of putting a price on a human life initially attracted hostility, for religious reasons. But as people moved into the cities and religion had to adjust to new circumstances, a different view of life insurance emerged. Zelizer has recently also started to look at consumption among children, both how children are socialized into becoming consumers and the ways in which they themselves relate to objects and goods in their environment (Zelizer 2005).

DiMaggio and Louch (1998) have attempted to use networks to analyse consumption. While it is well known that people will turn to others in their surroundings to find out where to buy something, and which merchants, traders and so on are reliable ('search embeddedness'), DiMaggio and Louch examine situations in which people approach someone in their personal network in order to buy something ('within-networks exchange'). As it happens, this is quite common, especially infrequent purchases of the type that involve legal services, home repair maintenance and the buying of a car or a home.

The number of studies in economic sociology that deal with corporations is very great, but a few studies nonetheless stand out. One of these is Mark Granovetter's pioneering 1994 article on business groups. Against R.H. Coase, Granovetter argues that it is not so much the existence of the individual firm that needs to be explained but the common phenomenon of groups of firms. In many countries, such as India, South Korea and Japan, these business groups control large parts of the economy, but have not received the scholarly attention that they deserve. The impact of business groups in the United States is not clear from Granovetter's work, except that US antitrust legislation has ruled out some common forms of this phenomenon.

The business groups that Granovetter studies lend themselves to a networks approach, and so do the corporations that Ronald Burt (1983) has analysed in his study of US industrial markets. Each firm, according to Burt, can be conceptualized as situated at the centre of a network in which there are a number of competitors, suppliers and customers. The fewer competitors there are, the more suppliers, and the more customers, the more the corporation is characterized by 'structural independence'. And with more structural independence comes more profit, as Burt shows.

The emphasis on corporations in interaction, as opposed to the single corporation, is also obvious in another landmark study in economic sociology, *Regional Advantage* by AnnaLee Saxenian (1994). Following Alfred Marshall in analysing industrial districts, Saxenian carries out a comparative study of the computer industry during the post-war period in Silicon Valley and the area around Route 128 in Boston. Silicon Valley has clearly overtaken Route 128 during recent decades, and the reason for this, according to Saxenian, has to do with the nature of the interaction in the two regions. While in Route 128 the corporations are loath to cooperate, rely on banks for finance, and prosecute employees who switch to competitors, in Silicon Valley there is plenty of cooperation, finance comes from venture capital firms, and employees are free to switch as they like. A much more decentralized and flexible form of entrepreneurship, in brief, has emerged in Silicon Valley.

Saxenian's fascination with entrepreneurship is shared by many economic sociologists. While

she argues that a radical decentralized industrial region represents the best conditions for entrepreneurship, there exist other perspectives as well. Granovetter, for example, argues that entrepreneurs often come from those parts of the social system which are far away from the controlling centre (for example, Granovetter 2005). While this may be termed a theory of peripheral entrepreneurship, Granovetter suggests several other situations that are favorable to entrepreneurship. An entrepreneur may, for example, be someone who crosses a social boundary in society and thereby becomes the first to unite resources from two otherwise separated regions (for example, Granovetter 1995). On immigration, Granovetter also points out that some ethnic groups that are not entrepreneurial in their country of origin may be highly entrepreneurial in their new country because they often leave parts of the extended family behind (Granovetter 1995). This means that they do not have to provide jobs for their relations or share their wealth with relatives.

Economic sociologists have been very active in studying ethnic entrepreneurship, (for example, Light 2005). Ethnic entrepreneurs, for example, often have to overcome the fact that their initial market consists of their countrymen ('the ethnic market'), and that they will have to go beyond this market if they are to expand. In many cases they have become entrepreneurs simply because they have no other way of making a living ('forced entrepreneurship').

Economic sociologists have also emphasized the collective nature of entrepreneurship and attempted to explode the myth of the creative Schumpeterian individual. One important example of this can be found in the research by Rosabeth Moss Kanter (1983) on entrepreneurship within the corporation, so-called intrapreneurship. Through a combination of ethnographic studies and survey research, Kanter has attempted to show the conditions under which it is possible to put together creative and entrepreneurial groups in modern corporations. Someone has to suggest the creation of such groups and provide them with resources and legitimacy. The group also has to be defended from outside intervention while it operates, internal conflicts have to be solved, and so on. According to Kanter, this type of group is common among modern corporations.

While economic sociologists have been unable to present a general theory of entrepreneurship, it is nonetheless clear that a number of insights have been accumulated. Economic sociologists are also expanding their work into such topics as social entrepreneurship and the diffusion of courses among business schools (for example, Swedberg 2000).

Concluding Remarks

Economic sociology is currently in a very active phase of its development, and all signs indicate that this trend will continue. Economic sociologists are also gradually expanding their range of topics of study. There has recently, for example, been an attempt to introduce law into the analysis, and some economic sociologists are trying to formulate a position on the relationship between the economy and technology. Some economic sociologists are also in the process of investigating the role of emotions in the economy; and there is a growing number of studies of gender and the economy. What all of this adds up to, again, is a steady growth of studies in economic sociology and a confirmation that economic sociology is established as a distinct and accepted area of sociology. But it remains to be seen whether economic sociology will be able to make inroads into economics itself and gain respect from economists, along the lines of, say, behavioural economics.

Marginal analysis is actually only a particular case of a more general theory, the theory of surpluses and the economy of markets, which, if considered first, facilitates the discussion of the equimarginal principle.

The General Theory of Surpluses and the Economy of Markets: Fundamental Concepts and Theorems

To simplify the exposition, it is assumed that one good (U), enters all preference and production functions, and that its quantity can vary continuously. Except for the hypothesis of continuity with respect to this good (U), the discussion in this first part is free of any restrictive hypothesis of continuity, differentiability or convexity for the goods (V),. . .,(W) considered, and the preference indexes and production functions. (For an exposition of the following theory in the case where no one good plays a particular role, see Allais 1985, Section II, pp. 139–41.)

Structural Conditions

The needs of every unit of consumption, individual or collective, can be entirely defined by considering a preference index

$$I_i = f_i(U_i, V_i, \ldots, W_i) \tag{1}$$

increasing as it passes from a given situation to one it finds preferable. Every quantity V_i is counted positively if it refers to a consumption, negatively if it refers to a service supplied.

The set of feasible techniques for a unit of production j can be represented by a condition of the form

$$f_j(U_j, V_j, \ldots, W_j) \geq 0$$

where every quantity V_j is considered as representing a consumption or an output depending on whether it is positive or negative.

The extreme points corresponding to the boundary between possible and impossible situations represent states of maximum efficiency for the production unit considered. They may be represented by the condition

$$f_j(U_j, V_j, \ldots, W_j) = 0. \tag{2}$$

The function f_j may be called the production function. It is defined up to any transformation which leaves its sign unchanged.

From a technical point of view, maximum efficiency implies quite specific conditions. If, for instance, one considers a production technique $A = A\ (X, Y,..., Z)$ and if n production units are technically preferable to a single one, we should have (Allais 1943, pp. 187–8; 1981, pp. 319–22)

$$\sum_j A(X_j, Y_j, \ldots, Z_j) > A\left[\sum_j X_j, \sum_j Y_j, \ldots, \sum_j Z_j\right]. \tag{3}$$

In the opposite case we have

$$A\left[\sum_j X_j, \sum_j Y_j, \ldots, \sum_j Z_j\right] > \sum_j A(X_j, Y_j, \ldots, Z_j). \tag{3*}$$

An industry is referred to as differentiated if the use of distinct production units is technically more advantageous than the concentration of all production operations into a single production unit. It is called non-differentiated in the opposite case. Conditions (3) and (3*) are two particular illustrations of differentiation (Allais 1943, p. 637).

From inequality (3) it is possible to show that the whole production function of a differentiated industry is asymptotically homogeneous. In this case ($n \gg 1$) there is quasihomogeneity (Allais 1943, pp. 201–6; 1974b).

Distributable Surplus Corresponding to a Given Modification of the Economy

The distributable surplus σ_u relative to a good (U) and to a realizable modification of the economy which leaves all preference indexes unchanged is defined as the quantity of that good which can be released following this shift (Allais 1943, pp. 610–16). The surplus considered here differs essentially from the concepts of consumer surplus as normally considered in the literature (for example, Samuelson 1947, pp. 195–202; Blaug 1985, pp. 355–70; Allais 1981, pp. 297–8, and 1985, nn. 12–13).

Let us consider an initial state $(\mathscr{E}_1)$ characterized by consumption values U_i, V_I,...,W_i and U_j, V_j,..., W_j (positive or negative) of the different units of consumption and production. We have

$$\Sigma_i U_i + \Sigma_j U_j = U_0;$$
$$\Sigma_i V_i + \Sigma_j V_j = V_0; \ldots; \Sigma_i W_i + \Sigma_j W_j = W_0 \tag{4}$$

where U_0, V_0,..., W_0 designate available resources. Let $(\delta\mathscr{E}_1)$ be a feasible modification of $(\mathscr{E}_1)$ characterized by finite variations δU_i, δV_i,..., δW_i, δU_j, δV_j,..., δW_j, and let

$$(\mathscr{E}_2) = (\mathscr{E}_1) + \delta(\mathscr{E}_1)$$

represent the new state.

According to (4) we naturally have

$$\sum_i \delta V_i + \sum_j \delta V_j = 0$$

for every good (U), (V),..., (W). From (2) we also have for every unit of production j

$$f_j(U_j + \delta U_j, V_j + \delta V_j, \ldots, W_j + \delta W_j) = 0.$$

According to (1) the preference indexes become

$$I_i + \delta I_i = f_i(U_i + \delta U_i, V_i + \delta V_i, \ldots, W_i + \delta W_i).$$

The δI_i can be positive, zero, or negative.

Let us now define a third state $(\mathscr{E}_3)$ by the condition that by the modification $-\delta\sigma_{ui}$ of just the quantities $U_i + \delta U_i$ all the preference indexes return to their initial values.

We then have the conditions

$$f_i(U_i + \delta U_i - \delta\sigma_{ui}, V_i + \delta V_i, \ldots, W_i + \delta W_i) = f_i(U_i, V_i, \ldots, W_i). \tag{5}$$

The state $(\mathscr{E}_3)$ can be termed 'isohedonous' with the state $(\mathscr{E}_1)$. In passing from $(\mathscr{E}_1)$ to $(\mathscr{E}_3)$ the quantity

$$\delta\sigma_u = \sum_i \delta\sigma_{ui} \tag{6}$$

of the good (U) is released, as all the units of consumption find themselves again in situations which they consider equivalent, since their preference indexes return to the same values (Allais 1943, pp. 637–8).

The surplus $\delta\sigma_u$ has been released during the passage from $(\mathscr{E}_1)$ to $(\mathscr{E}_3)$. It may then be considered that in the situation $(\mathscr{E}_1)$ this surplus was both realizable and distributable. It may further be considered that in passing from $(\mathscr{E}_1)$ to $(\mathscr{E}_2)$, it has in effect been distributed.

The distributable surplus thus defined covers the whole economy, but this definition can be used for any group of agents. It is necessary only to consider the functions f_i and f_j and the resources relating to this group in the preceding relations.

Any exchange system, with the corresponding production operations it implies, is deemed 'advantageous' when a distributable surplus is achieved and distributed, so that the preference index of any consumption unit concerned increases. If an exchange and production system is advantageous, there must be at least one system of prices which allows it, the prices used by each pair of agents being specific to them. The distribution of the realized surplus between agents is determined by the system of prices used in the exchanges between them.

Conditions of Equilibrium and Maximum Efficiency

In essence all economic operations of whatever type may be considered as reducing to the search for, the achievement of, and the distribution of surpluses. Thus stable general economic equilibrium exists if, and only if, in the situation under consideration, there is no realizable surplus, which means

$$\delta\sigma_u \leq 0 \tag{7}$$

for all feasible modifications of the economy (Allais 1943, pp. 606–12).

In such a situation the distributable surplus is zero or negative for all possible modifications of the economy compatible with its structural relations, and it is impossible to find any set of prices that would permit effective bilateral or multilateral exchanges (accompanied by the implied production operations) which are advantageous to all the agents concerned.

A situation of maximum efficiency can be defined as a situation in which it is impossible to improve the situation of some people without undermining that of others, i.e. to increase certain preference indices without decreasing others. The set of states of maximum efficiency represents the boundary between the possible and the impossible (Fig. 1).

From those definitions of the situations of maximum efficiency and stable general economic equilibrium, it follows, with the greatest generality and without any restrictive hypothesis of continuity, differentiability or convexity, except for the common good (U), that:

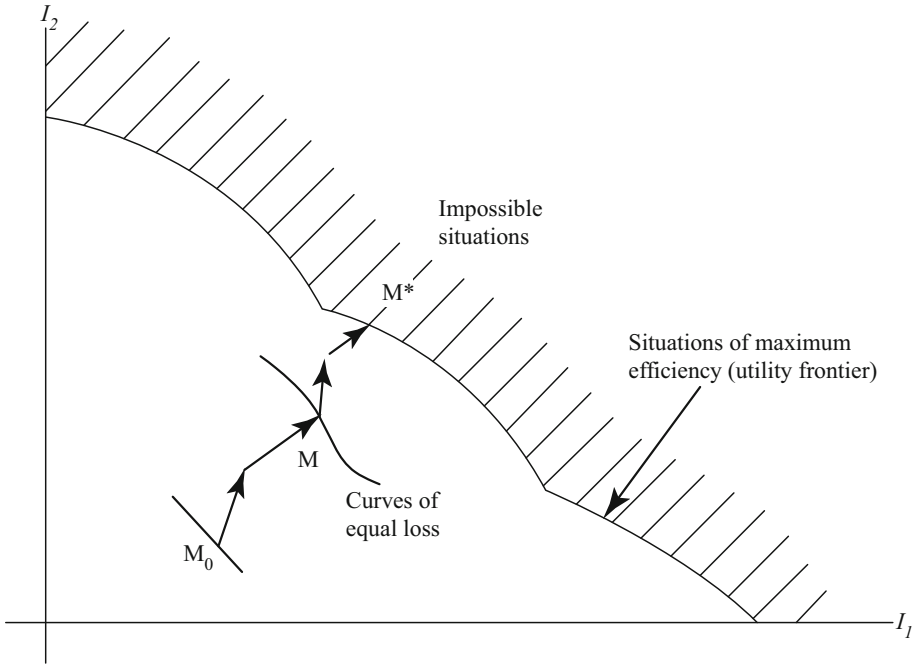
> Any state of stable general economic equilibrium is one of maximum efficiency (*First theorem of equivalence*). Any state of maximum efficiency is one of stable general economic equilibrium (*Second theorem of equivalence*).

Since there can be no stable general economic equilibrium if there is any distributable surplus, every state of stable general economic equilibrium is a state of maximum efficiency. Conversely, if there is maximum efficiency, there is no realizable surplus which could be used to increase at least one preference index without decreasing the others, and consequently, every state of maximum efficiency is a state of stable general economic equilibrium.

Because of the theorems of equivalence, the terms 'conditions of stable general economic equilibrium' and 'conditions of maximum efficiency' are used interchangeably below.

The Dynamic Process of the Economy: Decentralized Search for Surpluses

In their essence all economic operations, whatever they may be, can be thought of as boiling down to the pursuit, realization and allocation of distributable surpluses. The corresponding



Economic Surplus and the Equimarginal Principle, Fig. 1 Process of dynamic evolution. Illustrative diagram

model is the Allais model of the economy of markets (1967), defined by the fundamental rule that every agent tries to find one or several other agents ready to accept at specific prices a bilateral or multilateral exchange (accompanied by corresponding production decisions) which will release a positive surplus that can be shared out, and which is realized and distributed once discovered. Thus the evolution of the market's economy is characterized by the condition

$$\delta I_i \geq 0$$

for every consumption unit.

Since in the evolution of an economy of markets surpluses are constantly being realized and allocated, the preference indexes of the consumption units are never decreasing, at the same time as some are increasing. This means that for a given structure, that is to say, for given preferences, resources, and technical know-how, the working of an economy of markets tends to bring it nearer and nearer to a state of stable general economic equilibrium, hence a state of maximum efficiency (Fig. 1), which is the third fundamental theorem.

Naturally such evolution takes place only if sufficient information exists about the actual possibilities of realizing surpluses.

To any given initial situation whatsoever, assumed not to be a situation of equilibrium, there corresponds an infinite number of possible equilibrium situations, each corresponding to a particular path and each satisfying the general condition that no index of preference should take on a lower value than in the initial situation (Fig. 1).

Economic Loss

The loss σ_u^* which is associated with a given situation is defined as the greatest quantity of the good (U) which can be released in a transformation of the economy for which all the preference indexes remain unchanged (Fig. 1) (Allais 1943, pp. 638–49).

It is a well determined function

$$\sigma_u^* = F[I_1, I_2, \ldots, I_n, U_0, V_0, \ldots, W_0] \quad (8)$$

of the preference indexes I_i and of the resources V_0 which characterize this situation. The loss σ_u^* is an

indicator of inefficiency, and $-\sigma_u^*$ an indicator of the efficiency of the economy as a whole.

The loss is minimum and nil in every state of maximum efficiency, and positive in every feasible situation which is not a state of maximum efficiency. It decreases in any modification of the economy, whereby some preference indexes increase, others remaining unchanged, or whereby some surpluses are released with no decline in some preference indexes.

Paths to States of Economic Equilibrium and Maximum Efficiency

Since the preference indices I_i are continuous functions of the quantities U_i of the common good (U), the boundary between the possible and the impossible situations in the hyperspace of preference indexes is constituted by a continuous surface. On this surface the loss σ_u^* is nil. This representation allows an immediate demonstration by simple topological considerations of propositions whose proof would otherwise be very difficult. (The paternity of this representation has been unduly attributed to P. Samuelson 1950, but it was in fact published for the first time in Allais 1943, and systematically used by Allais in later years especially 1945 and 1947; see Allais 1971, n.11, p. 385; and 1974a, n.18, pp. 176–7.)

For every feasible situation which is not a state of maximum efficiency, represented by a point such as M_0, there are an infinity of realizable displacements M_0M enabling a situation of maximum efficiency M^* to be approached, such that all the preference indexes have greater values than in the initial situation M_0.

Figure 1 presents an illustration of the process of dynamic evolution by releasing and sharing out of surpluses during which the loss σ_u^* is constantly decreasing (Allais 1943, 1974b, and 1981, p. 121).

The Changing Structure of the Economy

As psychological patterns vary, as techniques are improved, or as new resources are discovered (or existing resources depleted), the set of situations of maximum efficiency relative to the indexes of preference constantly undergoes change over time. Consequently, situations of equilibrium and maximum efficiency are never reached, and what is really important is to determine the rules of the game which must be applied to come constantly closer to them as rapidly as possible. At a given time t, if information is sufficient and if the adjustments are sufficiently rapid, the point representing the economy will never be very far from the maximum efficiency surface of that time t.

General Comment

An economy of markets can be defined as one in which the agents – consumption, production, and arbitrage units – coexist and are free to undertake any exchange transaction or production operation which can result in rendering some distributable surplus available. The principle of the market economy is that any surplus realized is shared among the operators involved. How the surpluses achieved are shared out depends on the specific systems of prices used in the exchanges between the agents concerned. The prices used are always specific to the exchange and production operations considered and there is never a unique system of prices used in common by all the agents.

Diagrammatic representation like that of Fig. 1 reveals clearly three basic facts:

1. There is an infinity of situations of maximum efficiency corresponding to a given initial situation characterized by some distribution of property.
2. To each situation of maximum efficiency there corresponds a final distribution of property.
3. This final distribution depends on the initial situation and the distribution of surpluses in the course of the transition.

Thus there is a very strong interdependence between the point of view of efficiency corresponding to the discovery and realization of surpluses and the ethical point of view corresponding to their sharing.

In any event, since only what is produced can be shared, the incentive stemming from the partial or total appropriation of the surpluses by the various agents appears as a fundamental factor for the functioning of the economy of markets.

On the general theory of surpluses and the economy of markets in the general case, and on the fundamental theorems see Allais (1943, pp. 112–77; 181–211; 604–56; 1967, § 8–65; 1968a, vol. 2; 1968b, 1971, 1974a, 1981, pp. 27–48; 1985).

The Equimarginal Principle

Continuity and Differentiability

The preceding definitions and theorems are very general and do not make any hypothesis of continuity, derivability or convexity, except the hypothesis of continuity for the common good (U).

We now assume in addition only that all the quantities and functions considered are continuous and that all functions have first and second order derivatives, the following developments being totally independent of any hypothesis of general convexity.

From the sign conventions adopted earlier it follows that for any *i, j* and *V*

$$f'_{iv} = \partial f_i/\partial V_i \geq 0,\ f'_{jv} = \partial f_j/\partial V_j \geq 0.$$

The second partial derivatives are written

$$f''_{ivw} = \partial^2 f_i/\partial V_i \delta W_i, \quad f''_{jvw} = \partial^2 f_j/\partial V_j \delta W_j\,.$$

In the following, the symbol $\overline{d^2 g}$ represents the second differential

$$\overline{d^2 g} = \sum_U^W g''_{v^2} \mathrm{d}V^2 + 2 \sum_{U,V} g''_{vw} \mathrm{d}V\,\mathrm{d}W$$

of a function $g(U, V, \ldots, W)$ when all parameters in that function are taken as independent, while the symbol $\overline{d^2 g}_u$ represents what this second differential becomes after du has been replaced by its expression derived from

$$\mathrm{d}g = \sum_U^W g'_v \mathrm{d}V = 0$$

(Allais 1968a, vol. 2, pp. 77–8; 1973b, pp. 151–5; 1981, pp. 688–9).

Convexity and Concavity

The local properties of diminishing or increasing marginal returns are related to local conditions of convexity or concavity. Convexity is defined as follows:

Ordinal fields of preference A field of choice is said to be convex in the whole space (postulate of general convexity) if, at all points of the field, the condition

$$I(M_0) \leq I(M_1)$$

entails

$$I(M_0) \leq I(M)$$

with

$$M = \lambda M_0 + (1 - \lambda) M_1 0 < \lambda < 1.$$

There is local convexity at M_0 if this condition is satisfied only for

$$|\mathrm{M_0 M_1}| < \varepsilon$$

where ε is a given positive number.

When differentiability is assumed local convexity implies.

$$\overline{d^2 f_{iu}} \leq 0 \quad \text{for} \quad \mathrm{d}f_1 = 0\,.$$

Fields of production A field of production is said to be convex over the whole space (postulate of general convexity) if, for any two possible points M_0 and M_1, the centre of gravity defined by the relation

$$M = \lambda M_0 + (1 - \lambda) M_1$$

is likewise a possible point for.

$$0 < \lambda < 1.$$

Local convexity obtains at M_0 if the preceding condition is satisfied only for

$$|M_0 M_1| < \varepsilon$$

where ε is a given positive number.

When differentiability is assumed, local convexity implies

$$\overline{d^2 f_{iu}} \leq 0 \quad \text{for} \quad \mathrm{d}f_1 = 0 \cdot$$

In fact there is no production operation that does not begin by providing increasing marginal returns, and it is only beyond a certain threshold that diminishing marginal returns are observed. That is a general physical law of nature (Allais 1943, pp. 193–5; 1968a, vol. 2, pp. 68–96; 1971, pp. 362–4; 1974a, pp. 153–7). Similarly it can be considered as an introspective datum that psychological returns begin by increasing but in the end always decrease beyond certain threshold values. That is a general psychological law (Allais 1968a, vol. 2, pp. 109–38; 1971, pp. 360–2; 1974a, pp. 153–5). These are two fundamental properties of fields of choice and production. They rule out the postulate of general convexity which is generally accepted in the contemporary literature.

Generation of Distributable Surplus

Consider any economic state $(\mathscr{E})$ and a realizable modification $(\delta\mathscr{E})$ such that all the preference indexes I_i remain constant (isohedonous modification). Let the conditions of constancy of these indexes and the conditions corresponding to the production functions be written in the same general form

$$g_k(U_k, V_k, \ldots, W_k) = 0 \tag{9}$$

where U_k, V_k,..., W_k represent the consumption of both consumption and production units. By convention, any quantity V_k, if positive, represents consumptions, either by a consumption or a production unit. For any production or consumption unit, any parameter V_k, if negative, represents production of a good or a service.

Let $\mathrm{d}U_k$, $\mathrm{d}V_k$,..., $\mathrm{d}W_k$, be the first order differentials of the variations δU_k, δV_k,..., δW_k of consumptions U_k, V_k,..., W_k in the displacement $(\delta\mathscr{E})$. From (9), we have

$$g'_{ku}\mathrm{d}U_k + g'_{kv}\mathrm{d}V_k + \cdots + g'_{kw}\mathrm{d}W_k = 0. \tag{10}$$

Let δV_{kl} be the quantity of (V) received by the consumption or the production unit k from the consumption or production unit l. By definition, we have

$$\delta V_k = \sum_{k \neq 1} \delta V_{kl} \tag{11}$$

$$\delta V_{lk} = -\delta V_{kl}. \tag{12}$$

Assuming that the displacement $(\delta\mathscr{E})$ is such that

$$\sum_k \delta V_k = 0, \ldots, \sum_k \delta W_k = 0. \tag{13}$$

Let

$$\varepsilon^k_{v,u} = g'_{kv}/g'_{ku}. \tag{14}$$

The ratio $\varepsilon^k_{v,u}$ is the coefficient of marginal equivalence (or marginal rate of substitution) of goods (V) and (U) for agent k (Allais 1943, pp. 609–10, and 617–21).

From (10) and (14) we have the relation (15)

$$\mathrm{d}U_k = -\left[E^k_{vu}\mathrm{d}V_k + \cdots + E^k_{wu}\mathrm{d}W_k\right] \tag{15}$$

between the first order differential $\mathrm{d}U_k$, $\mathrm{d}V_k$,..., $\mathrm{d}W_k$.

If $\mathrm{d}U_k$ is positive, agent k receives a quantity $\mathrm{d}U_k$ to within the second order. If $\mathrm{d}U_k$ is negative, agent k supplies a quantity $-\mathrm{d}U_k$ to within the second order.

From the condition (13), it follows that the displacement considered releases a global distributable surplus

$$\delta\sigma_u = -\sum_k \delta U_k$$

representing the excess of the quantities supplied over the quantities received of good (U) whose first order differential is

$$\delta\sigma_u = -\sum_k \mathrm{d}U_k.$$

From (11) and (15)

$$\mathrm{d}U_k = -\sum_{v}^{w}\left[\varepsilon_{vu}^{k}\sum_{\substack{k,l\\k<l}}\mathrm{d}V_{kl}\right]$$

and from (12), we have (Allais 1952c, p. 31; 1968a, vol. 2, p. 174; 1981, p. 88)

$$\mathrm{d}\sigma_u = \sum_{v}^{w}\sum_{\substack{k,l\\k<l}}\left(\varepsilon_{vu}^{k} - \varepsilon_{kl}^{l}\right)\mathrm{d}V_{kl}. \tag{16}$$

According to definitions (5) and (6) $\mathrm{d}\sigma_u$ is the first differential of the global distributable surplus $\delta\sigma_u$ released in the displacement considered. For all economic agents the unit of value is defined by condition $u_k = u = 1$. The marginal values v_k,..., w_k of goods (V),. . ., (W) for unit k are defined with respect to the u_k by the relations

$$\frac{g'_{ku}}{u_k} = \frac{g'_{kv}}{v_k} = \cdots = \frac{g'_{kw}}{w_k} \tag{17}$$

$$u_k = u = 1. \tag{18}$$

Under the adopted sign convention, all the v_k are positive. We have from (14) and (18)

$$\varepsilon_{vu}^{k} = v_k \tag{19}$$

and relation (16) is written

$$\mathrm{d}\sigma_u = \sum_{v}^{w}\sum_{\substack{k,l\\k<l}}(v_k - v_l)\mathrm{d}V_{kl} \tag{20}$$

where v_k and v_l are the marginal values of good (V) for units k and l. This summation covers all agents, both consumption and production units. It can thus be seen that all the differences between the marginal values in the situation $\mathscr{E}$ can give rise to the release of potential surpluses which can be released and distributed.

The meaning of relation (20) is immediate. Thus if $v_k > v_l$ the relative value of good (V) is higher for agent k than for agent l. The transfer of a positive quantity $\mathrm{d}V_{kl}$ of good (V) from agent l to agent k therefore creates an additional positive value

$$\mathrm{d}\sigma_{ukl} = (v_k - v_l)\mathrm{d}V_{kl}.$$

If in this 'isohedone' transformation surpluses are released, all positive, they can be distributed in such a way as to increase all preference indexes. In such a modification of the economy, the maximum distributable surplus diminishes, and the point representing the economic situation considered moves closer to the surface of maximum efficiency in the hyperspace of preference indexes. Naturally, for this condition to obtain, the corresponding exchanges and the changes of the consumptions and productions they imply in the production system, must effectively occur.

Psychological Values and Marginal Psychological Values

Naturally, the v_k are only marginal values for the agents. The psychological values v_i^* of the consumption V_i of a subject i is defined by the relation

$$f_i\left(U_i + v_i^* V_i, 0, \ldots, W_i\right) = f\left(U_i, V_i, \ldots, W_i\right)$$

where $v_i^* V_i$ is the sum he would accept to receive to offset the drop in his consumption V_i to zero. The unit value v_i^* is generally much higher than the marginal value v_i corresponding to relations (17), (18) and (19).

In any event, a consumption is only advantageous when its psychological value is higher than its marginal value, because, if this were not so, it would be in the subject's interest to reduce his consumption V_i.

Conditions of Stable General Economic Equilibrium and Maximum Efficiency of the Economy

From condition (7) it follows that the necessary and sufficient condition for a situation $(\mathscr{E})$ to be of stable equilibrium and maximum efficiency is that the distributable surplus $\delta\sigma_u$ defined by (5) and (6) be negative or zero for every feasible modification $(\delta\mathscr{E})$, that is every modification that is compatible

with the constraint conditions, that is, the structural relations of the economy (2) and (4) above.

Condition (7) implies the two conditions (Allais 1943, p. 612)

$$\mathrm{d}\sigma_u = 0 \,(\text{first order condition}) \tag{21}$$

$$\mathrm{d}^2\sigma_u \leq 0 \,(\text{second order condition}) \tag{22}$$

for any realizable and reversible modification ($\delta\mathscr{E}$) in which the expressions of $\mathrm{d}\sigma_u$ and $\mathrm{d}^2\sigma_u$ represent the first and second differential of $\delta\sigma_u$.

Thus we have according to (21) and (22) using the above notations

$$\mathrm{d}\sigma_u = \sum_i \mathrm{d}\sigma_{ui} = \sum_i \mathrm{d}I_i / I'_{iu} = 0 \tag{23}$$

$$\mathrm{d}^2\sigma_u = \sum_i \frac{\overline{\mathrm{d}^2 f_{iu}}}{f'_{iu}} + \sum_j \frac{\overline{\mathrm{d}^2 f_{ju}}}{f'_{ju}} \leq 0 \quad \text{for} \quad \mathrm{d}\sigma_u = 0\,. \tag{24}$$

Actually, and according to relation (20), the first order condition (23) implies that when the quantities V_k are not nil, all the marginal values v_k are equal to a same value v and a same system of prices u, v,..., w *then exists for all the agents k concerned*, *such that.*

$$\frac{g'_{ku}}{u} = \frac{g'_{kv}}{v} = \cdots = \frac{g'_{kw}}{w}. \tag{25}$$

These equalities condense the general equimarginal principle into a single formulation. They express the fact that in a situation of equilibrium and maximum efficiency, the psychological (or objective) value v_k of the last dollar is the same, for any agent (consumption or production unit), whatever use it is put to.

For the quantities V_k which are nil (terminal equilibria), we necessarily have

$$v_k \leq v$$

since, if this were not true, the operator's interest would be to increase V_k from the value $V_k = 0$; he could indeed do this because of the existence of other operators who are in a situation of tangential equilibrium for good (V).

The second order condition (24) holds whether or not the $\mathrm{d}f_i$ are equal to zero. It is only subject to the constraint (21). If we consider only the modifications of the economy involving units k and l, condition (24) is written

$$\mathrm{d}^2\sigma_u = \frac{\overline{\mathrm{d}^2 f_{ku}}}{f'_{ku}} + \frac{\overline{\mathrm{d}^2 f_{lu}}}{f'_{lu}} \leq 0 \quad \text{for} \quad \mathrm{d}\sigma_{uk} + \mathrm{d}\sigma_{ul} = 0$$

shows that when in a situation of maximum efficiency consumption or production units consume (or produce) the same goods, one unit at most is in a situation of local concavity, that is, in a situation of marginal increasing returns (Allais 1968a, pp. 196–9; 1974a, n.125, p. 184; 1981, p. 65).

Consequently, when maximum efficiency obtains, most operators are in a situation of local convexity and marginal decreasing returns. However, this condition cannot be interpreted as meaning that all fields of choice and production are convex everywhere, this hypothesis being totally contradicted by observed data.

When local convexity obtains for a consumption unit, its index of preference is effectively at a maximum, subject to the budgetary constraint, equilibrium prices being taken as given. Similarly, if local convexity obtains for a production unit, the unit's income is effectively at a maximum, equilibrium prices again being taken as given. However, these two principles, which in any case could be valid only for a situation of maximum efficiency, cannot be considered as corresponding in all cases to optimum behaviour, and they cannot be taken to be of general value. As a matter of fact and for instance, if, in a situation of maximum efficiency, a production unit is in a situation of local concavity, its income is minimum, the equilibrium prices being considered as given.

Conditions (25) and (24) show the total symmetry of the implications of the psychological and technical structures of the economy.

Approximate Value of the Economic Loss Corresponding to the Non-equality of Marginal Values in the Neighbourhood of a Situation of Maximum Efficiency

The integration of Eq. (20) along a path leading to a state of maximum efficiency leads to the following approximate estimate to within third order accuracy of the global loss involved in the initial situation (relation 8)

$$\sigma_u^* \sim \frac{1}{2u} \sum_{v} \sum_{\substack{k,l \\ k<l}} (v_k - v_l)\delta V_{kl}^*. \qquad (26)$$

In this relation, the quantities $v_k - v_l$ represent the differences of marginal values in the initial state considered, and the δV_{kl}^* are the quantities of the good (V) received by operator k from operator l in the transition from the initial to the final state. Relation (26) is of the broadest generality, and holds whatever the initial state (Allais 1952a, pp. 31–2, n. 8; 1968a, vol. 2, p. 207; 1981, p. 110).

Its simplicity is really extraordinary in view of the complexity of the concept it represents, namely the maximum of the distributable surplus for all the modifications which the economy can undergo while leaving the preference indexes unchanged.

In the neighbourhood of a situation of maximum efficiency, the $(v_k - v_l)$ and δV_{kl}^* are of the first order quantities, where as the loss σ_u^* is only of the second order. However, since the δV_{kl}^* are of the first order, the variations δI_i of the preference indexes are also of the first order. As a result, and for instance, in the neighbourhood of a situation of maximum efficiency, taxes have major first order effects on the distribution of income but only second order effects on the efficiency of the economy.

On the theoretical foundations of the equimarginal principle, see Allais (1943, pp. 604–56, 1945, 1952a, pp. 28–32; 1967, 1968a, vol. 2, 1971, 1973a, 1973b, 1974a, 1974b, 1981 and 1986). Illustrative models: Allais (1943, Annexe I, pp. 4–24; 1945, pp. 57–69). On its extension see: cases of perfect and imperfect foresight: Allais (1943, pp. 343–84; 1947, pp. 23–228; 1964, 1967, 1968a, vol. 2). Illustrative models: (1947, pp. 631–771). Capitalistic optimum theory: Allais (1947, pp. 179–228; 1962, 1963). Demographic optimum theory: Allais (1943, pp. 749–85). Case of risk: Allais (1952b). Application of marginal analysis to transport: Allais (1964 and 1987). For a general overview on the meaning, limits, generalizations, and history of the equimarginal analysis see Allais (1987).

General Overview

Theory of Surpluses and Marginal Analysis

As a matter of fact a single relation, the relation (20) (or the equivalent relation (16)) condenses the whole marginal approach as it has developed for over a century. Subject only to the hypotheses of continuity and derivability implied by any marginal theory, it applies in all cases, and its simplicity is really extraordinary.

It also shows that equilibrium and maximum efficiency can obtain only when all marginal values are equal, which is the equimarginal principle.

The equimarginal principle was discovered first by Gossen (1854), and rediscovered, broadened and introduced independently into economics by Jevons (1871), Menger (1871) and Walras (1874–7). In the following years numerous new developments of the principle have been presented by their immediate successors, especially by Edgeworth (1881), Irving Fisher (1892) and Vilfredo Pareto (1896–1911). Particularly striking illustrations of the role of differences in marginal equivalences are Ricardo's theory of comparative costs (1817) and Dupuit's theory of economic losses (1844–53).

This principle corresponds to the outcome of the dynamic process of the economy induced by differences in marginal equivalences. According to Irving Fisher (1892), with whose judgement I agree fully, 'No idea has been more fruitful in the history of economic science.' Its applications

and generalizations dominate all economic analysis in real terms.

From the foregoing a double conclusion emerges: the classical theory of marginal equivalences is irreplaceable to make understandable the underlying nature of all economic phenomena; the general theory of surplus, of which classical marginal theory is only a special case, allows one to extend the propositions of marginal analysis to the most general case of discrete variations and indivisibilities.

As important as the analysis of the conditions of general equilibrium and maximum efficiency may be, the analysis of the dynamic processes which enable surpluses to be generated from a given situation is much more important. From this point of view the analyses by Dupuit, Jevons, Edgeworth, Pareto, and the marginal school and its predecessors in general, appear much more realistic than the contributions which rest only upon the consideration of Walras's general model of equilibrium.

In fact, what is really important is not so much the knowledge of the properties of a state of maximum efficiency as the rules of the game which have been applied to the economy effectively to move nearer to a state of maximum efficiency.

The decentralized search for surpluses is truly the dynamic principle from which a thorough and yet very simple conception of the operation of the whole economy can be derived. Whereas in the market economy model the search for efficiency is essentially focused on the determination of a certain set of prices, the analysis of the model of the economy of markets is based on the search for potential surpluses and their realization. Not only is the economy of markets model much more realistic than the market economy model while lending itself to much simpler proofs, but also these proofs are not subordinated to any restrictive assumptions relating to continuity, differentiability of functions, or convexity. All of economic dynamics is reduced to a single principle: the search for and realization of potential surpluses, which leads to the minimization of loss for the economy as a whole.

On all these points see especially: Allais (1971 and 1974a).

The Tendencies of the Contemporary Literature

From Walras on, the literature became progressively – and unduly – concentrated on equilibrium analysis which, however interesting it could be, is less so than the analysis of the processes by which the economy tends at any time towards situations of equilibrium which in fact are never reached.

Today there is a tendency to neglect the dynamic marginal approach based on the consideration of differences in marginal equivalences; and in the name of a so-called rigour it has been replaced by new theories. A fortiori, the general theory of surpluses which generalizes marginal analysis is simply ignored. This development, which in reality, and despite the too-widely held belief to the contrary, represents an immense step backward, basically stems from the unquestioning acceptance of 'established truths' taught by the dominant 'establishments', whose only real basis is their incessant repetition.

As a matter of fact the guiding principles of the contemporary theories descending from Walras: the adoption of the market economy model; the hypothesis that a common price system applicable to all operators prevails at each instant; the assumption of general convexity; and the exaltation of mathematical formalism of the theory of sets to the detriment of conformity with actual facts, constitute an impediment to any genuine progress in analysis of the economy in real terms.

The essential difference between the market economy model and the model of the economy of markets is that, in the latter, the exchanges leading to equilibrium take place successively at different prices, and that, at any given moment, the price sets used by different operators are not necessarily the same. Whereas in the first model the final situation is determined totally by the initial situation, which correspondingly plays a privileged role without any real justification, in the second the final situation depends both on the

initial situation and the path taken from it to the final situation (Fig. 1).

Whereas the market economy model postulates perfect competition and a large number, if not an infinity, of operators, the model of the economy of markets applies just as well to the cases of monopoly as to the cases of competition.

Not only is the market economy model unrealistic, but it also gives rise to considerable mathematical difficulties when an attempt is made to demonstrate the above three fundamental theorems. Whether differential calculus or set theory is used, the theorems can only be demonstrated under extremely restrictive conditions, and the difficulties they imply are, from an economic standpoint, completely artificial, for they arise solely from the unrealistic nature of the model used. Paradoxically, whereas these restrictive assumptions are totally unrealistic, most of the theoretical difficulties encountered disappear, as shown above, once they are discarded.

The market economy approach leads to imposing on any economic model, for it to be considered satisfactory, conditions which actually apply to a particular model, which are generally not fulfilled in reality, and for which, at all events, no rigorous justification can be found.

By departing from the great tradition of marginal theory and by adopting an unrealistic model and unrealistic assumptions, the contemporary theories, purely mathematical, have doomed themselves to sterility as regards the understanding of reality.

On the contemporary theories see especially: Samuelson (1947), Arrow (1968), Debreu (1959 and 1985), Blaug (1979 and 1985), Arrow and Hahn (1971), Hutchison (1977, pp. 62–97 and 161–70), Woo (1985), and Allais (1952b, 1968b, 1968e, 1971, 1974a, and 1981).

Economic Theory and the Hypothesis of Rationality

Kenneth J. Arrow

In this paper, I want to disentangle some of the senses in which the hypothesis of rationality is used in economic theory. In particular, I want to stress that rationality is not a property of the individual alone, although it is usually presented that way. Rather, it gathers not only its force but also its very meaning from the social context in which it is embedded. It is most plausible under very ideal conditions. When these conditions cease to hold, the rationality assumptions become strained and possibly even self-contradictory. They certainly imply an ability at information processing and calculation that is far beyond the feasible and that cannot well be justified as the result of learning and adaptation.

Let me dismiss a point of view that is perhaps not always articulated but seems implicit in many writings. It seems to be asserted that a theory of the economy must be based on rationality, as a matter of principle. Otherwise, there can be no theory. This position has even been maintained by some who accept that economic behaviour is not completely rational. John Stuart Mill (1848, bk. 2, ch. 4) argued that custom, not competition, governs much of the economic world. But he adds that the only possible theory is that based on competition (which, in his theories, includes certain elements of rationality, particularly shifting capital and labour to activities that yield higher returns); 'Only through the principle of competition has political economy any pretension to the character of science', ([1848] 1909, p. 242).

Certainly, there is no general principle that prevents the creation of an economic theory based on hypotheses other than that of rationality. There are indeed some conditions that must be laid down for an acceptable theoretical analysis of the economy. Most centrally, it must include a theory of market interactions, corresponding to market clearing in the neoclassical general equilibrium theory. But as far as individual behaviour is concerned, any coherent theory of reactions to the stimuli appropriate in an economic context (prices in the simplest case) could in principle lead to a theory of the economy. In the case of consumer demand, the budget constraint must be satisfied but many theories can easily be devised that are quite different from utility maximization. For example, habit formation can be made into a theory; for a given price-income change, choose the bundle that satisfies the budget constraint and that requires the least change (in some suitably defined sense) from the previous consumption bundle. Though there is an optimization in this theory, it is different from utility maximization; for example, if prices and income return to their initial levels after several alterations, the final bundle purchased will not be the same as the initial. This theory would strike many lay observers as plausible, yet it is not rational as economists have used that term. Without belabouring the point, I simply observe that this theory is not only a logically complete explanation of behaviour but one that is more powerful than standard theory and at least as capable of being tested.

Not only is it possible to devise complete models of the economy on hypotheses other than rationality, but in fact virtually every practical theory of macroeconomics is partly so based. The price- and wage-rigidity elements of Keynesian theory are hard to fit into a rational framework, though some valiant efforts have been made. In the original form, the multiplier was derived from a consumption function depending only on current income. Theories more nearly based on rationality make consumption depend on lifetime or 'permanent' income and reduce the magnitude of the multiplier and, with it, the explanatory power of the Keynesian model. But if the Keynesian model

is a natural target of criticism by the upholders of universal rationality, it must be added that monetarism is no better. I know of no serious derivation of the demand for money from a rational optimization. The loose arguments that substitute for a true derivation, Friedman's economizing on shoe leather or Tobin's transaction demand based on costs of buying and selling bonds, introduce assumptions incompatible with the costless markets otherwise assumed. The use of rationality in these arguments is ritualistic, not essential. Further, the arguments used would not suggest a very stable relation but rather one that would change quickly with any of the considerable changes in the structure and technology of finance. Yet the stability of the demand function for money must be essential to any form of monetarism, not excluding those rational expectations models in which the quantity theory plays a major role.

I believe that similar observations can be made about a great many other areas of applied economics. Rationality hypotheses are partial and frequently, if not always, supplemented by assumptions of a different character.

So far, I have argued simply that rationality is not in principle essential to a theory of the economy, and, in fact, theories with direct application usually use assumptions of a different nature. This was simply to clear the ground so that we can discuss the role of rationality in economic theory. As remarked earlier, rationality in application is not merely a property of the individual. Its useful and powerful implications derive from the conjunction of individual rationality and the other basic concepts of neoclassical theory – equilibrium, competition, and completeness of markets. The importance of all these assumptions was first made explicit by Frank Knight (1921, pp. 76–79). In the terms of Knight's one-time student, Edward Chamberlin (1950, pp. 6–7), we need not merely pure but perfect competition before the rationality hypotheses have their full power.

It is largely this theme on which I will expand. When these assumptions fail, the very concept of rationality becomes threatened, because perceptions of others and, in particular, of their rationality become part of one's own rationality. Even if there is a consistent meaning, it will involve computational and informational demands totally at variance with the traditional economic theorist's view of the decentralized economy.

Let me add one parenthetic remark to this section. Even if we make all the structural assumptions needed for perfect competition (whatever is needed by way of knowledge, concavity in production, absence of sufficient size to create market power, etc.), a question remains. How can equilibrium be established? The attainment of equilibrium requires a disequilibrium process. What does rational behaviour mean in the presence of disequilibrium? Do individuals speculate on the equilibrating process? If they do, can the disequilibrium be regarded as, in some sense, a higher-order equilibrium process? Since no one has market power, no one sets prices; yet they are set and changed. There are no good answers to these questions, and I do not pursue them. But they do illustrate the conceptual difficulties of rationality in a multiperson world.

Rationality as Maximization in the History of Economic Thought

Economic theory, since it has been systematic, has been based on some notion of rationality. Among the classical economists, such as Smith and Ricardo, rationality had the limited meaning of preferring more to less; capitalists choose to invest in the industry yielding the highest rate of return, landlords rent their property to the highest bidder, while no one pays for land more than it is worth in product. Scattered remarks about technological substitution, particularly in Ricardo, can be interpreted as taking for granted that, in a competitive environment, firms choose factor proportions, when they are variable, so as to minimize unit costs. To be generous about it, their rationality hypothesis was the maximization of profits by the firm, although this formulation was not explicitly achieved in full generality until the 1880s.

There is no hypothesis of rationality on the side of consumers among the classicists. Not until John Stuart Mill did any of the English classical economists even recognize the idea that demand

might depend on price. Cournot had the concept a bit earlier, but neither Mill nor Cournot noticed – although it is obvious from the budget constraint alone – that the demand for any commodity must depend on the price of all commodities. That insight remained for the great pioneers of the marginalist revolution, Jevons, Walras, and Menger (anticipated, to be sure, by the Gregor Mendel of economics, H.H. Gossen, whose major work, completely unnoticed at the time of publication [1854], has now been translated into English [1983]). Their rationality hypothesis for the consumer was the maximization of the utility under a budget constraint. With this formulation, the definition of demand as a function of all prices was an immediate implication, and it became possible to formulate the general equilibrium of the economy.

The main points in the further development of the utility theory of the consumer are well known. (1) Rational behaviour is an ordinal property. (2) The assumption that an individual is behaving rationally has indeed some observable implications, the Slutsky relations, but without further assumptions, they are not very strong. (3) In the aggregate, the hypothesis of rational behaviour has in general noimplications; that is, for any set of aggregate excess demand functions, there is a choice of preference maps and of initial endowments, one for each individual in the economy, whose maximization implies the given aggregate excess demand functions (Sonnenschein 1973; Mantel 1974; Debreu 1974; for a survey, see Shafer and Sonnenschein 1982, sec. 4).

The implications of the last two remarks are in contradiction to the very large bodies of empirical and theoretical research, which draw powerful implications from utility maximization for, respectively, the behaviour of individuals, most especially in the field of labour supply, and the performance of the macroeconomy based on 'new classical' or 'rational expectations' models. In both domains, this power is obtained by adding strong supplementary assumptions to the general model of rationality. Most prevalent of all is the assumption that all individuals have the same utility function (or at least that they differ only in broad categories based on observable magnitudes, such as family size). But this postulate leads to curious and, to my mind, serious difficulties in the interpretation of evidence. Consider the simplest models of human capital formation. Cross-sectional evidence shows an increase of wages with education or experience, and this is interpreted as a return on investment in the form of foregone income and other costs. But if all individuals are alike, why do they not make the same choice? Why do we observe a dispersion? In the human capital model (a particular application of the rationality hypothesis), the only explanation must be that individuals are not alike, either in ability or in tastes. But in that case the cross-sectional evidence is telling us about an inextricable mixture of individual differences and productivity effects. Analogously, in macroeconomic models involving durable assets, especially securities, the assumption of homogeneous agents implies that there will never be any trading, though there will be changes in prices.

This dilemma is intrinsic. If agents are all alike, there is really no room for trade. The very basis of economic analysis, from Smith on, is the existence of differences in agents. But if agents are different in unspecifiable ways, then remark (3) above shows that very few, if any, inferences can be made. This problem, incidentally, already exists in Smith's discussion of wage differences. Smith did not believe in intrinsic differences in ability; a porter resembled a philosopher more than a greyhound did a mastiff. Wage differences then depended on the disutilities of different kinds of labour, including the differential riskiness of income. This is fair enough and insightful. But, if taken seriously, it implies that individuals are indifferent among occupations, with wages compensating for other differences. While there is no logical problem, the contradiction to the most obvious evidence is too blatant even for a rough approximation.

I have not carried out a scientific survey of the uses of the rationality hypothesis in particular applications. But I have read enough to be convinced that its apparent force comes only from the addition of supplementary hypotheses. Homogeneity across individual agents is not the only auxiliary assumption, though it is the deepest. Many

assumptions of separability are frequently added. Indeed, it has become a working methodology to start with very strong assumptions of additivity and separability, together with a very short list of relevant variables, to add others only as the original hypotheses are shown to be inadequate, and to stop when some kind of satisfactory fit is obtained. A failure of the model is attributed to a hither to overlooked benefit or cost. From a statistical viewpoint, this stopping rule has obvious biases. I was taught as a graduate student that data mining was a major crime; morality has changed here as elsewhere in society, but I am not persuaded that all these changes are for the better.

The lesson is that the rationality hypothesis is by itself weak. To make it useful, the researcher is tempted into some strong assumptions. In particular, the homogeneity assumption seems to me to be especially dangerous. It denies the fundamental assumption of the economy, that it is built on gains from trading arising from individual differences. Further, it takes attention away from a very important aspect of the economy, namely, the effects of the distribution of income and of other individual characteristics on the workings of the economy. To take a major example, virtually all of the literature on savings behaviour based on aggregate data assumes homogeneity. Yet there have been repeated studies that suggest that saving is not proportional to income, from which it would follow that distributional considerations matter. (In general, as data have improved, it has become increasingly difficult to find any simple rationally based model that will explain savings, wealth, and bequest data.)

The history of economic thought shows some other examples and difficulties with the application of the rationality hypothesis. Smith and the later classicists make repeated but unelaborated references to risk as a component in wage differences and in the rate of return on capital (e.g., Mill [1848] 1909, pp. 385, 406, 407, 409). The English marginalists were aware of Bernoulli's expected-utility theory of behaviour under uncertainty (probably from Todhunter's *History of the Theory of Probability*) but used it only in a qualitative and gingerly way (Jevons [1871] 1965, pp. 159–60; Marshall 1920, pp. 842–3). It was really not until the last 30 years that it has been used systematically as an economic explanation, and indeed its use coincided with the first experimental evidence against it (see Allais 1979). The expected-utility hypothesis is an interesting transition to the theme of the next section. It is in fact a stronger hypothesis than mere maximization. As such it is more easily tested, and it leads to stronger and more interesting conclusions. So much, however, has already been written about this area that I will not pursue it further here.

Rationality, Knowledge, and Market Power

It is noteworthy that the everyday usage of the term 'rationality' does not correspond to the economist's definition as transitivity and completeness, that is, maximization of something. The common understanding is instead the complete exploitation of information, sound reasoning, and so forth. This theme has been systematically explored in economic analysis, theoretical and empirical, only in the last 35 years or so. An important but neglected predecessor was Holbrook Working's random-walk theory of fluctuations in commodity futures and securities prices (1953). It was based on the hypothesis that individuals would make rational inferences from data and act on them; specifically, predictability of future asset prices would be uncovered and used as a basis for current demands, which would alter current prices until the opportunity for gain was wiped out.

Actually, the classical view had much to say about the role of knowledge, but in a very specific way. It emphasized how a complete price system would require individuals to know very little about the economy other than their own private domain of production and consumption. The profoundest observation of Smith was that the system works behind the backs of the participants; the directing 'hand' is 'invisible'. Implicitly, the acquisition of knowledge was taken to be costly.

Even in a competitive world, the individual agent has to know all (or at least a great many)

prices and then perform an optimization based on that knowledge. All knowledge is costly, even the knowledge of prices. Search theory, following Stigler (1961), recognized this problem. But search theory cannot easily be reconciled with equilibrium or even with individual rationality by price setters, for identically situated sellers should set identical prices, in which case there is nothing to search for.

The knowledge requirements of the decision may change radically under monopoly or other forms of imperfect competition. Consider the simplest case, pure monopoly in a one-commodity partial equilibrium model, as originally studied by Cournot in Cournot 1838. The firm has to know not only prices but a demand curve. Whatever definition is given to complexity of knowledge, a demand curve is more complex than a price. It involves knowing about the behaviour of others. Measuring a demand curve is usually thought of as a job for an econometrician. We have the curious situation that scientific analysis imputes scientific behaviour to its subjects. This need not be a contradiction, but it does seem to lead to an infinite regress.

From a general equilibrium point of view, the difficulties are compounded. The demand curve relevant to the monopolist must be understood *mutatis mutandis*, not *ceteris paribus*. A change in the monopolist's price will in general cause a shift in the purchaser's demands for other goods and therefore in the prices of those commodities. These price changes will in turn affect by more than one channel the demand for the monopolist's produce and possibly also the factor prices that the monopolist pays. The monopolist, even in the simple case where there is just one in the entire economy, has to understand all these repercussions. In short, the monopolist has to have a full general equilibrium model of the economy.

The informational and computational demands become much stronger in the case of oligopoly or any other system of economic relations where at least some agents have power against each other. There is a qualitatively new aspect to the nature of knowledge, since each agent is assuming the *rationality* of other agents. Indeed, to construct a rationality-based theory of economic behaviour, even more must be assumed, namely, that the rationality of all agents must be *common knowledge*, to use the term introduced by the philosopher David Lewis (1969). Each agent must not only know that the other agents (at least those with significant power) are rational but know that each other agent knows every other agent is rational, know that every other agent knows that every other agent is rational, and so forth (see also Aumann 1976). It is in this sense that rationality and the knowledge of rationality is a social and not only an individual phenomenon.

Oligopoly is merely the most conspicuous example. Logically, the same problem arises if there are two monopolies in different markets. From a practical viewpoint, the second case might not offer such difficulties if the links between the markets were sufficiently loose and the monopolies sufficiently small on the scale of the economy that interaction was negligible; but the interaction can never be zero and may be important. As usually presented, bargaining to reach the contract curve would, in the simplest case, require common knowledge of the bargainer's preferences and production functions. It should be obvious how vastly these knowledge requirements exceed those required for the price system. The classic economists were quite right in emphasizing the importance of limited knowledge. If every agent has a complete model of the economy, the hand running the economy is very visible indeed.

Indeed, under these knowledge conditions, the superiority of the market over centralized planning disappears. Each individual agent is in effect using as much information as would be required for a central planner. This argument shows the severe limitations in the argument that property rights suffice for social rationality even in the absence of a competitive system (Coase 1960).

One can, as many writers have, discuss bargaining when individuals have limited knowledge of each other's utilities (similarly, we can have oligopoly theory with limited knowledge of the cost functions of others: see, e.g., Arrow 1979). Oddly enough, it is not clear that limited knowledge means a smaller quantity of information than complete knowledge, and optimization

under limited knowledge is certainly computationally more difficult. If individuals have private information, the others form some kind of conjecture about it. These conjectures must be common knowledge for there to be a rationality-based hypothesis. This seems to have as much informational content and to be as unlikely as knowing the private information. Further, the optimization problem for each individual based on conjectures (in a rational world, these are probability distributions) on the private information of others is clearly a more difficult and therefore computationally more demanding problem than optimization when there is no private information.

Rational Knowledge and Incomplete Markets

It may be supposed from the foregoing that informational demands are much less in a competitive world. But now I want to exemplify the theme that perfect, not merely pure, competition is needed for that conclusion and that perfect competition is a stronger criterion than Chamberlin perhaps intended. A complete general equilibrium system, as in Debreu (1959), requires markets for all contingencies in all future periods. Such a system could not exist. First, the number of prices would be so great that search would become an insuperable obstacle; that is, the value of knowing prices of less consequence, those of events remote in time or of low probability, would be less than the cost so that these markets could not come into being. Second, markets conditional on privately observed events cannot exist by definition.

In any case, we certainly know that many – in fact, most – markets do not exist. When a market does not exist, there is a gap in the information relevant to an individual's decision, and it must be filled by some kind of conjecture, just as in the case of market power. Indeed, there turn out to be strong analogies between market power and incomplete markets, though they seem to be very different phenomena.

Let me illustrate with the rational expectations equilibrium. Because of intertemporal relations in consumption and production, decisions made today have consequences that are anticipated. Marshall (1920, bk 5, chs 3–5) was perhaps the first economist to take this issue seriously. He introduced for this purpose the vague and muddled concepts of the short and long runs, but at least he recognized the difficulties involved, namely, that some of the relevant terms of trade are not observable on the market. (Almost all other accounts implicitly or explicitly assumed a stationary state, in which case the relative prices in the future and between present and future are in effect current information. Walras (1874, lessons 23–25) claimed to treat a progressive state with net capital accumulation, but he wound up unwittingly in a contradiction, as John Eatwell has observed in an unpublished dissertation. Walras's arguments can only be rescued by assuming a stationary state.) Marshall in effect made current decisions, including investment and savings, depend on expectations of the future. But the expectations were not completely arbitrary; in the absence of disturbances, they would converge to correct values. Hicks (1946, chs 9–10) made the dependence of current decisions on expectations more explicit, but he had less to say about their ultimate agreement with reality.

As has already been remarked, the full competitive model of general equilibrium includes markets for all future goods and, to take care of uncertainty, for all future contingencies. Not all of these markets exist. The new theoretical paradigm of rational expectations holds that each individual forms expectations of the future on the basis of a correct model of the economy, in fact, the same model that the econometrician is using. In a competitive market-clearing world, the individual agent needs expectations of prices only, not of quantities. For a convenient compendium of the basic literature on rational expectations, see Lucas and Sargent (1981). Since the world is uncertain, the expectations take the form of probability distributions, and each agent's expectations are conditional on the information available to him or her.

As can be seen, the knowledge situation is much the same as with market power. Each agent has to have a model of the entire economy to preserve rationality. The cost of knowledge, so emphasized by the defenders of the price system

as against centralized planning, has disappeared; each agent is engaged in very extensive information gathering and data processing.

Rational expectations theory is a stochastic form of perfect foresight. Not only the feasibility but even the logical consistency of this hypothesis was attacked long ago by Morgenstern (1935). Similarly, the sociologist Robert K. Merton (1957) argued that forecasts could be self-denying or self-fulfilling; that is, the existence of the forecast would alter behaviour so as to cause the forecast to be false (or possibly to make an otherwise false forecast true). The logical problems were addressed by Grunberg and Modigliani (1954) and by Simon (1957, ch. 5). They argued that, in Merton's terms, there always existed a self-fulfilling prophecy. If behaviour varied continuously with forecasts and the future realization were a continuous function of behaviour, there would exist a forecast that would cause itself to become true. From this argument, it would appear that the possibility of rational expectations cannot be denied. But they require not only extensive first-order knowledge but also common knowledge, since predictions of the future depend on other individuals' predictions of the future. In addition to the information requirements, it must be observed that the computation of fixed points is intrinsically more complex than optimizing.

Consider now the signalling equilibrium originally studied by Spence (1974). We have large numbers of employers and workers with free entry. There is no market power as usually understood. The ability of each worker is private information, known to the worker but not to the employer. Each worker can acquire education, which is publicly observable. However, the cost of acquiring the education is an increasing function of ability. It appears natural to study a competitive equilibrium. This takes the form of a wage for each educational level, taken as given by both employers and workers. The worker, seeing how wages vary with education, chooses the optimal level of education. The employer's optimization leads to an 'informational equilibrium' condition, namely, that employers learn the average productivity of workers with a given educational level. What dynamic process would lead the market to learn these productivities is not clear, when employers are assumed unable to observe the productivity of individual workers. There is more than one qualitative possibility for the nature of the equilibrium. One possibility, indeed, is that there is no education, and each worker receives the average productivity of all workers (I am assuming for simplicity that competition among employers produces a zero-profit equilibrium). Another possibility, however, is a dispersion of workers across educational levels; it will be seen that in fact workers of a given ability all choose the same educational level, so the ability of the workers could be deduced from the educational level ex post.

Attractive as this model is for certain circumstances, there are difficulties with its implementation, and at several different levels. (1) It has already been noted that the condition that, for each educational level, wages equal average productivity of workers is informationally severe. (2) Not only is the equilibrium not unique, but there is a continuum of possible equilibria. Roughly speaking, all that matters for the motivation of workers to buy education are the relative wages at different educational levels; hence, different relations between wages and education are equally self-fulfilling. As will be seen below, this phenomenon is not peculiar to this model. On the contrary, the existence of a continuum of equilibria seems to be characteristic of many models with incomplete markets. Extensive non-uniqueness in this sense means that the theory has relatively little power. (3) The competitive equilibrium is fragile with respect to individual actions. That is, even though the data of the problem do not indicate any market power, at equilibrium it will frequently be possible for any firm to profit by departing from the equilibrium.

Specifically, given an equilibrium relation between wages and education, it can pay a firm to offer a different schedule and thereby make a positive profit (Riley 1979). This is not true in a competitive equilibrium with complete markets, where it would never pay a firm to offer any price or system of prices other than the market's. So far, this instability of competitive equilibrium is a

property peculiar to signalling models, but it may be more general.

As remarked above, the existence of a continuum of equilibria is now understood to be a fairly common property of models of rational market behaviour with incomplete information. Thus, if there were only two commodities involved and therefore only one price ratio, a continuum of equilibria would take the form of a whole interval of price ratios. This multiplicity would be non-trivial, in that each different possible equilibrium price ratio would correspond to a different real allocation.

One very interesting case has been discussed recently. Suppose that we have some uncertainty about the future. There are no contingent markets for commodities; they can be purchased on spot markets after the uncertainty is resolved. However, there is a set of financial contingent securities, that is, insurance policies that pay off in money for each contingency. Purchasing power can therefore be reallocated across states of the world. If there are as many independent contingent securities as possible states of the world, the equilibrium is the same as the competitive equilibrium with complete markets, as already noted in Arrow (1953). Suppose there are fewer securities than states of the world. Then some recent and partly still unpublished literature (Duffie 1985; Werner 1985; Geanakoplos and Mas-Colell 1986) shows that the prices of the securities are arbitrary (the spot prices for commodities adjust accordingly). This is not just a numéraire problem; the corresponding set of equilibrium real allocation has a dimensionality equal to the number of states of nature.

A related model with a similar conclusion of a continuum of equilibria is the concept of 'sunspot' equilibria (Cass and Shell 1983). Suppose there is some uncertainty about an event that has in fact no impact on any of the data of the economy. Suppose there is a market for a complete set of commodity contracts contingent on the possible outcomes of the event, and later there are spot markets. However, some of those who will participate in the spot markets cannot participate in the contingent commodity markets, perhaps because they have not yet been born. Then there is a continuum of equilibria. One is indeed the equilibrium based on 'fundamentals,' in which the contingencies are ignored. But there are other equilibria that do depend on the contingency that becomes relevant merely because everyone believes it is relevant. The sunspot equilibria illustrate that Merton's insight was at least partially valid; we can have situations where social truth is essentially a matter of convention, not of underlying realities.

The Economic Role of Informational Differences

Let me mention briefly still another and counter-intuitive implication of thoroughgoing rationality. As I noted earlier, identical individuals do not trade. Models of the securities markets based on homogeneity of individuals would imply zero trade; all changes in information are reflected in price changes that just induce each trader to continue holding the same portfolio. It is a natural hypothesis that one cause of trading is difference of information. If I learn something that affects the price of a stock and others do not, it seems reasonable to postulate that I will have an opportunity to buy or sell it for profit.

A little thought reveals that, if the rationality of all parties is common knowledge, this cannot occur. A sale of existing securities is simply a complicated bet, that is, a zero-sum transaction (between individuals who are identical apart from information). If both are risk averters, they would certainly never bet or, more generally, buy or sell securities to each other if they had the same information. If they have different information, each one will consider that the other has some information that he or she does not possess. An offer to buy or sell itself conveys information. The offer itself says that the offerer is expecting an advantage to himself or herself and therefore a loss to the other party, at least as calculated on the offerer's information. If this analysis is somewhat refined, it is easy to see that no transaction will in fact take

place, though there will be some transfer of information as a result of the offer and rejection. The price will adjust to reflect the information of all parties, though not necessarily all the information.

Candidly, this outcome seems most unlikely. It leaves as explanation for trade in securities and commodity futures only the heterogeneity of the participants in matters other than information. However, the respects in which individuals differ change relatively slowly, and the large volume of rapid turnover can hardly be explained on this basis. More generally, the role of speculators and the volume of resources expended on informational services seem to require a subjective belief, at least, that buying and selling are based on changes in information.

Some Concluding Remarks

The main implication of this extensive examination of the use of the rationality concept in economic analysis is the extremely severe strain on information-gathering and computing abilities. Behaviour of this kind is incompatible with the limits of the human being, even augmented with artificial aids (which, so far, seem to have had a trivial effect on productivity and the efficiency of decision making). Obviously, I am accepting the insight of Herbert Simon (1957, chs 14, 15), on the importance of recognizing that rationality is bounded. I am simply trying to illustrate that many of the customary defences that economists use to argue, in effect, that decision problems are relatively simple break down as soon as market power and the incompleteness of markets are recognized.

But a few more lessons turned up. For one thing, the combination of rationality, incomplete markets, and equilibrium in many cases leads to very weak conclusions, in the sense that there are whole continua of equilibria. This, incidentally, is a conclusion that is being found increasingly in the analysis of games with structures extended over time; games are just another example of social interaction, so the common element is not surprising. The implications of this result are not clear. On the one hand, it may be that recognizing the limits on rationality will reduce the number of equilibria. On the other hand, the problem may lie in the concept of equilibrium.

Rationality also seems capable of leading to conclusions flatly contrary to observation. I have cited the implication that there can be no securities transactions due to differences of information. Other similar propositions can be advanced, including the well-known proposition that there cannot be any money lying in the street, because someone else would have picked it up already.

The next step in analysis, I would conjecture, is a more consistent assumption of computability in the formulation of economic hypotheses. This is likely to have its own difficulties because, of course, not everything is computable, and there will be in this sense an inherently unpredictable element in rational behaviour. Some will be glad of such a conclusion.

Economic Theory of the State

R. Jessop

The basic forms, social functions, institutional boundaries and legitimating principles of states vary across historical epochs and also differ among specific regimes in the same epoch. This makes it difficult (some would even say impossible) to develop a theory which applies to all states – whether in general or simply in their economic aspects. This entry limits itself to some economic aspects of the capitalist state.

The Capitalist Type of State

Capital accumulation has occurred under the most divergent state forms, but not all state forms are equally supportive of capital accumulation. Various attempts have been made to construct theoretically an ideal type of state which is both possible and particularly appropriate under capitalism without claiming, however, that this 'capitalist type of state' exists always and everywhere in capitalist societies. Among other characteristics of this state form, three institutional features are worth noting here: it has an effective monopoly of coercive power, its resources are purchased with money derived from taxation, and its activities are subject to the rule of law. Each of these features is not only compatible with but also potentially supportive of the capitalist economic order.

Firstly, the state is able to monopolize coercion because capital appropriates the surplus labour of

workers through the wage-relation rather than through extra-economic compulsion. This monopoly is also functional since it prevents particular economic agents from using direct force to subvert the free play of market forces. Secondly, state resources can be purchased because capitalism involves generalized commodity production and money mediates the exchange of all commodities (including labour-power). The state should raise monetary taxation because it cannot meet its reproduction needs by selling its own output, and cannot expropriate them forcibly only from those who happen to produce them without undermining the formal equality and property rights which underpin capitalism. Thirdly, the rule of law can exist because capitalism presupposes the formal freedom and equality of all economic agents. Only if it exists can such agents rely on a stable and impartial legal and political environment for their long-term economic activities.

These three institutional traits of the state facilitate capital accumulation. But they are neither logically nor historically necessary; nor, where they occur, do they guarantee accumulation. This is not simply because economic factors themselves engender recurrent crises within capitalism. There are also distinct political reasons. These are rooted in the institutional form of the state and in the struggles which occur around the nature and purposes of state power. To take only three examples. The institutional separation between the state and economy is crystallized above all in the state's legitimate coercive monopoly and its incarnation of national-popular unity vis-à-vis the antagonistic private interests of civil society. This means that the state has the political and ideological capacities to disturb as well as to promote capital accumulation. Nor does the tax form have any self-evident limits. It can produce fiscal crises and/or disproportions between state expenditure and the requirements of capital accumulation. Thirdly, because the rule of law implies formal neutrality towards particular economic agents, it is correspondingly inadequate as a steering mechanism. But more purposive, ad hoc, discretionary interventions can produce bureaucratic overload and also disrupt the labour process and capitalist market forces. Whether such problems occur depends not only on the form of the state and its integration into the circuit of capital but also on the changing balance of political forces.

Economic Aspects of the Capitalist State

Nowhere are economic systems self-reproducing, self-regulating and self-sufficient. They always depend on other institutional systems and the contingent support of non-economic forces. The capitalist state clearly has a key role in securing such institutional preconditions; and it is also the nodal site for political support. This does not mean, however, that one can enumerate a set of essential economic functions which must be performed by the capitalist state. Indeed, paraphrasing Max Weber's more general comment on the modern state, one could say: there are no economic activities which capitalist states have not at some time undertaken and none which they undertake invariably and exclusively. In particular the capitalist state is neither confined to producing 'public goods' nor is it the sole producer of such goods. Instead, even if certain broad developmental tendencies can be identified, its precise economic activities are always conjunctural. They are always influenced, furthermore, by political and ideological as well as economic factors.

Economic Periodization of the Capitalist State

The structural relations between state and economy and the forms of state intervention typically vary across time as well as nations. This has encouraged attempts at periodization. Although labels vary, four phases are often identified: mercantilism, liberal capitalism, (simple) monopoly capitalism and late (or state monopoly) capitalism. Without necessarily endorsing these attempts at periodization, the basic features of each stage can be presented as follows.

Under mercantilism state power is used to establish the dominance of the capital relation

and market forces. This is the period of primitive accumulation and capitalist manufacture and is associated historically with the absolutist state. Once this dominance is secured, a liberal phase is said to follow. This involves the nightwatchman state which is restricted to securing the general external conditions of production and has no significant directly economic role. The third phase is linked to the dominance of monopoly capital and the rise of imperialism. In this stage the state serves to regulate the economic dominance of monopoly capital, assumes an active role of managing the economic and political relations between organized capital and the labour movement, and also employs extra-economic coercion abroad in inter-imperialist competition. Next comes the state monopoly capitalist stage. State management of the domestic economy through taxation, state credit, public enterprise and/or the so-called military-industrial complex now have an increasingly important role; the welfare state system and collective consumption become central to the reproduction of labour-power and to political management; and international and transnational state organizations have a key role in managing the world economy. Not all national economies have experienced all four stages and much depends on the timing of their capitalist development and on their place within the international division of labour.

Such changes in the state's economic role also involve reorganizing its overall institutional form. Growing state intervention is typically associated with the strengthening of the executive at the expense of the legislative branch, the rise of functional (as opposed to territorial) representation closely tied to the administration, the increased importance of the state economic apparatus and the growing dominance of economic criteria within non-economic departments, and the decline of the substantive rule of law (as opposed to the simple maintenance of legal forms) in favour of more discretionary forms of intervention. Thus the growth of state economic intervention leaves neither the economy nor the state unchanged. The circuit of capitals is socialized through the state and the state is reorganized to reflect economic needs (cf. Poulantzas 1978).

Explanations for the Economic Role of the State

Various explanations have been offered for the state's assumption of economic functions and for their general developmental tendencies. Broadly speaking these comprise two main groups: explanations which focus on the essential structure and laws of motion of capitalism and explanations which focus on the social relations which obtain between class forces. Included among the former are explanations which emphasize the inability or failure of individual capitals, market forces or the law of value to secure all the institutional and economic conditions needed for capital accumulation. These conditions are frequently said to include: (a) 'general external conditions' such as bourgeois law or a formally rational monetary system; (b) public goods such as fire services, sea walls or statistical services which facilitate production in all branches; and (c) material factors productively consumed in all or most branches, such as labour-power or energy supplies. The more 'class-theoretical' explanations focus either on the state's instrumentalization by particular (capitalist) class interests and/or on its relatively autonomous role in managing the balance of class forces both within the economic sphere and in society more generally. In turn the relative strength of class forces is sometimes attributed to changes in the mode of production and sometimes to broader social and political factors ranging from unionization to wars.

The reasons advanced for increasing state intervention can be used to illustrate such arguments. Some theorists highlight changes in the forces of production (e.g their increasing socialization, growing capital intensity or lengthening turnover time of capital). Others emphasize changes in the relations of production (e.g. the shift from absolute to relative surplus value, growth of monopoly capital, increased importance of banking or financial capital, the internationalization of production, or changing forms of economic crisis). Yet others have stressed an increased importance of the tendency of the rate of profit to fall. Whatever reasons are advanced, however, the same conclusion is drawn. In the

course of capital accumulation there is a growing need for state intervention to socialize the forces of production (e.g. infrastructural provision, manpower training, technological innovation) and/or the relations of production (e.g. state credit, economic management or collective consumption) to compensate for the failures of market forces and competition adequately to coordinate and integrate the circuit of capital. Whilst such explanations often identify important structural changes in capitalism, they do not provide a satisfactory explanation for the political response to such changes. Nor does an emphasis on the mediating role of class struggle help much here unless attention is paid to the full range and forms of political forces.

The General Limits to State Intervention

There has been considerable interest in the limits as well as the reasons for state intervention. Again we find both general explanations and arguments relating to various stages of intervention. The following factors are frequently cited here: (a) the exclusion of the state from the heart of the production process – which means it must react *a posteriori* to events it cannot directly control or engage in ineffective *a priori* planning; (b) its tendency to respond to economic problems and crises in terms of surface appearances (e.g. inflation, unemployment, trade deficits) which have no obvious or consistent relationship to the real course of capital accumulation – which means that state policies often have limited or perverse effects; (c) the inherent limitations of law and money as steering mechanisms for a constitutional tax-state – since both mechanisms operate at a distance from real economic agents and processes; (d) the contradictions involved in the expansion of non-commodity forms of provision – they may promote capital accumulation but they also withdraw money from the circuit of capital, they can promote fiscal crises, and they suggest that the commodity form is neither natural nor necessary; and (e) the *sui generis* interests of state managers which can conflict with the supposed needs of capital. Most of these difficulties are aggravated by the co-existence of an effective world economy and a multiplicity of nation-states.

Political and Ideological Complications

The state's economic role is always affected by its other tasks. These include its own organizational reproduction, maintaining domestic political order and territorial integrity, and defining and interpreting national unity. Thus economic policies are typically inserted into more general political strategies and influenced by political and ideological struggles. This affects the inputs, 'withinputs' and outputs of the state system.

On the input side economic needs must be translated into political demands through whatever organizational and institutional channels are available; and they must be coupled with political values and legal norms which are often only indirectly relevant to economic considerations. Within the state system it is the balance of political forces which determines how these economic demands are expressed in economic policies. This will vary with the individual forms of policy production (e.g. bureaucratic, purposive programming, participation, delegation to professionals) and with the manner in which some basic unity is imposed on the state's manifold activities. Each mode of policy-production contains its own limitations; moreover, problems of internal unity often preclude the flexible responses needed for economic management. All this is aggravated because political forces are generally most immediately concerned with other political forces and only indirectly with the economic sphere. Accordingly, it is the political repercussions of economic events and crises which matter more than their inherent economic form or substance. Finally, the outputs of the state are generally mediated in and through its own forms of intervention which operate at one or more removes from the real economy.

Even the increasingly dominant state economic apparatus must operate in this environment and it is also prey to muddling through, administrative inertia, political pressures and ideological

thinking. State-owned industries and central banks typically operate in a political environment which shapes their economic activities and distinguish them from private industrial or financial enterprises. In general, state intervention reflects the balance among all political forces and these extend well beyond the classes, fractions and strata defined by the circuit of capital. This helps to explain the incoherence of economic policies and the difficulties of rational economic planning.

Indeed the state's current expanded role involves two double-binds: the one economic, the other political. Firstly, when the state intervenes to alleviate structural economic crises, it must substitute its own policies for the purgative effects of market-mediated reorganization. Thus it typically changes the forms in which economic crises operate rather than eliminating them and even internalizes such crises within the state. Here they can take such forms as fiscal crises, legitimacy crises, representational crises, crises of internal unity and crises of governmental effectiveness or overload. But, since the state's role has now become vital for accumulation, it cannot solve economic crises simply by withdrawing or refusing to intervene. At best it can reorganize how it intervenes. Moreover, in so far as economic crises are seen to follow from such withdrawal, refusal or reorganization, they can also precipitate new forms of political crisis. Secondly, in attempting to resolve crises on behalf of capital, it faces a political dilemma. If its crisis-management deliberately favours one fraction of capital at the expense of others, it is liable to aggravate economic problems for capital as a whole and to weaken its own legitimacy. But even if it succeeds in winning support for policies in the collective interests of capital, it cannot thereby avoid favouring some capitals more than others. This will modify the balance of forces and could disturb the initial alliance which sustained such policies.

Further Research

A general economic theory of the capitalist state is impossible because national economies and nation-states are too varied and because economic issues are always influenced by non-economic factors. But a theoretically informed account of the economic aspects of particular capitalist states is certainly possible. In this context it would be worth exploring the following issues. What forms are taken by the institutional separation of the state from the economic realm and what do these forms imply for the nature and limits of state intervention? How can one identify the collective interests of capital when these are always overdetermined by contingent political and ideological factors and when alternative paths and strategies are followed in different national economies? What difference do the various forms of political representation and intervention make to the economic role of the state in capitalist societies? What scope is there for international state organizations to regulate or manage economic crises? In answering such questions one must recognize that, despite the above-mentioned limitations to the state's capacities to manage capitalism, some states and regimes are more successful than others. This suggests the need for much more detailed historical analyses and for taking seriously the 'political' moment of political economy.

Economic War

P. J. D. Wiles

Economic war constitutes all economic measures taken, before, during or instead of a military war, to harm an enemy. Compare protectionism, which is all the measures taken to 'defend' the national economy. These latter are often precisely the same measures. The subjective perception of how they do defend our own long-run economic interests is very often incorrect, and always controversial: for free trade lies at the root of Western economics. By contrast there is little theory about economic war, and (or so?) most of the measures taken seem by common admission well fitted to their time and place.

In view of the paucity of 'embargological' writing this entry must be of a frankly introductory character. First, it is well to establish some key definitions:

Embargo – a state's (or alliance's) prohibition to all its (their) citizens to sell to, or buy from, a named party, even when the price is right. An embargo is not an act of military war, and one on imports is little different from protectionism, except that its motive is to harm the foreign seller not benefit his domestic competitor.

Blockade – the prohibition by a state upon third states to trade with the second state, its enemy; a blockade must be enforced by military means and so is an act of war, possibly even against third states.

Both embargoes and blockades normally list specific goods and services. Note that the embargo of a sufficiently wide alliance is as good as a blockade, but is still no act of war.

Boycott – an embargo, usually popular or informal, on purchases alone. Typically the state machine is not involved, but some social group.

Contraband – goods on such a list that a third state tries to smuggle through a blockade.

Sanctions – the League of Nations' word for its members' punishment of an aggressor by a combined official blockade (the wording of Article 16 is vague in all original and amended versions, so the word 'blockade' is a little strong).

*Transport stranglehold*s – when one country's transport system monopolizes, or nearly so, access to another. The great case recently is Mozambique over Southern Rhodesia (the Beira railway, see below). A near case used to be the Arab League's use of the Suez Canal against Israel.

Black List – when the state imposing an embargo (or blockade) seeks to enforce it by a secondary embargo directly on specific firms within a third (capitalist) country, that are 'violating' the original embargo as they are of course entitled by international law and the law of their own state. The Arab League runs such a blacklist. The USA enforces its stricter view of CoCom in the same way. Communist enterprises are of course 'unblacklistable' – apart from their states.

Hostile Planner – the external authority who intervenes in the market (his, ours or the world's) in order to do us harm. This concept is necessary to remind us that interventions are not always benevolent. However, just as those of the friendly (and so mainly internal) planner may be mistaken and so maleficent, those of the hostile planner may be mistaken and so beneficient.

Bottleneck effect – when an unsubstitutable import is successfully embargoed, and some activity must, at least in the short run, be shut down.

CoCom – the Co-ordinating Committee of the NATO powers plus Japan, Australia and New Zealand. Administers an embargo of militarily significant industrial products. Is consultative only, each member remaining sovereign.

Dual Use – services like rail freight and goods like special steel and aero engines have dual military and civilian use. Thus an embargo on military goods *must* hit some civilian ones. Economic war has a very long history indeed. Its variety is best appreciated by considering its first in the Mercantilist era. In the 17th and 18th centuries the state was broadly proto-Keynesian. It sought to expand the quantity of money, in order to increase employment, encourage development and – above all – collect a gold stock in case of war. Economic war was the normal condition of Mercantilist international relations, interrupted only by military war. Although it certainly had military implications, it was not, as in the 20th century, a sign of extreme hostility or easily distinguished from mere protectionism.

But how does a bankless state acquire money? If, as was normal, it had no gold or silver mines and could not steal any in its colonial conquests it could only run a balance of payments surplus. This would not only bring in money, it would also set off the foreign-trade multiplier – a concept dimly perceived but not analysed; i.e. the new money would not be hoarded. So trade was a zero-sum game – the international division of labour dates only from Smith – and indeed a war of all against all in search of gold. Therefore one embargoed imports and encouraged exports, for one's own good. In peace time one did this *contra mundum*, in wartime one concentrated on one's enemy, doing oneself good and him harm all at once. Exporting to the enemy (except technology) was very patriotic, since it harmed him. Even military supplies were allowed (British cloth for the Grande Armée), though not actual arms. This was all an essentially monetary, not an input/output, view of economic war.

Banks and paper money added to but did not modify these policies, notably in the Napoleonic Wars. Paper money was regarded with extreme suspicion – a sign of national weakness even if convertible, since clearly the authorities had already failed to gather enough gold for all purposes. So we add to our goals the destruction of the enemy's convertibility. When Pitt went off gold it was a Napoleonic victory, due to France's superior exports (of wheat). The nature of this victory was that it was a blow to the morale of an enemy with a weak balance of payments. Drained externally of the means of internal payment, Pitt was faced with severe unemployment in Yorkshire, and a budget deficit if he wished to do something about it (in the absence of an existing and functioning welfare state). He therefore went off gold and printed the money – a defeat all in itself.

Let us jump to the 19th century, during which 'embargology' declined as free trade doctrine spread, and the notion spread that war is an epiphenomenon on the real, freely trading, peaceful, liberal, capitalist, democratic world of the planetary economy. In such an environment, where also in practice few wars were fought between major powers, there was no incentive even to consider economic measures short of war.

The 20th century has not forgotten the 19th, and it is only shamefacedly that it has reverted to the practice of the 17th and 18th centuries. Not accidentally protectionism has grown back too, but the two are not mixed up as under Mercantilism. All modern states have banks and paper money, and the monetary peculiarities of late Mercantilism have dropped away. With the welfare state and fiscal/monetary policy the modern state can sufficiently mitigate external crises to retain domestic political stability. Inconvertibility and inflation will not alter its warlike stance. Economic war has therefore – again very rationally – become an input–output matter, though the state of our enemy's gold reserve continues to be a preoccupation since gold is fungible into any input.

But the main change, surely due to 19th century example, is that economic war is no longer waged for economic ends (make him economically weaker so that I can be economically stronger, trade being a zero-sum game), but only for 'political' ends (make him economically weaker

so that I can be militarily stronger). We may even infer that civilization has advanced: dirtly tricks are no longer played by states merely for civilian gain. Let us examine a few examples of the new, more purely military economic war.

In the simplest case a specific export is embargoed to the enemy. If it is not a finished good, like a weapon, but an input (e.g. special steel) or both (e.g. refined petrol), our enemy must shut down some activity because of the bottleneck effect. This is the main weapon of modern economic war. If, however, his gold reserve is low and his balance of payments strained we may also embargo his exports, quite in general. This will force him to cut an import of his choice, and so suffer a mild bottleneck.

The practical complications are illuminating. Should the USA embargo the sale of wheat to the USSR, or should France embargo the purchase of Soviet gas? Provided that France does not become dependent on this gas (e.g. above five per cent of all fuel consumption) she clearly has a better economic case for doing what she prefers. For the USA, wheat relieves a serious and immediate bottleneck: that of fodder, leading to the immediate slaughter of Soviet livestock.

By a simple and well tried 'iteration', the livestock slaughter first raises, then lowers the supply of meat, the great crucial consumer good shortage that has already lead to very serious rioting and many deaths (Novocherkassk, 1962), not to mention a huge consumer subsidy. For comparison, in 1801 Britain imported French wheat to avoid a serious food shortage and despite Mercantilist doctrine. The mad Tsar Paul suggested a wheat embargo, this being his period of alliance with France. But that would have been to embargo an export, so everyone pointed out that he was only the mad Tsar Paul. Napoleon, of course, supported by current doctrine, had no qualms about his export. Anyway had not low farm prices contributed to the Vendée? Similarly Reagan fears, or feared, low farm prices, and brought Carter's wheat embargo to an end.

Yet again, wheat is a perfectly competitive commodity, and so much less suitable to be embargoed (though sometimes easy enough to blockade). In fact under President Carter the USSR bought wheat from Argentina instead. But the price was higher, the docking facilities worse and the delay considerable. All this imposed external costs the USSR, while USA, selling elsewhere in the world, had very minor external losses. Her losses were internal, indeed mainly only transfers, embarrassing the government but not much impoverishing the people: price support outlays, storage costs and electoral shifts.

Nevertheless it is part of the conventional wisdom of modern 'embargology' to count as far as possible in physical terms. The embargo deprived USSR of scarcely any bushels of wheat, so it is accounted a failure. The notion of a discriminatory export tax, of depressing the enemy's terms of trade, has achieved no recognition: the intellectual world of modern economic war is one of input-output and, seemingly, fixed co-efficients Mercantilism knew better. Even the export of money itself (long-term loans) is not taxed, but simply subjected to administrative control. But it has eventually been agreed, among the NATO powers, no longer to subsidize loans to Warsaw Pact countries; i.e. not to operate export credit guarantees in favour of even non-embargoed exports. At least, like machinery, large long-term loans are not perfectly competitive and so much easier to control.

If Mercantilism knew little about foreign lending, it knew as well as we do about technology transfer. Technology, like gold itself, was an exception: it must never be exported. For with better technology 'we' beat 'them', both in war and in the exportation of ordinary goods and services. In modern times technological levels differ much more, and the subject has become more important. Although no one country has a monopoly, the advanced have become very advanced, and it has become much more difficult to absorb their output; their active help is needed. There has also grown up an unduly sharp distinction between civilian and military technology – as if dual use were inconceivable. Moreover, military R&D bulks much larger in the total.

It was the beginning of the end of Mercantilism when David Hume declared that, In opposition to his narrow and malignant opinion, I will venture to assert, that the increase of riches and commerce

in any one nation, instead of hurting, commonly promote (sic) the riches and commerce of all its neighbours; and that a state can scarcely carry its trade and industry very far, where all the surrounding states are buried in ignorance, sloth and barbarism (*Three Essays*... II: *On the Jealousy of Trade*, Josiah Tucker's edn, London 1787, first page).

Economic war contributes much less than nothing if we only want to prosper. In the circumstances of the Cold War, the sole long-term economic war that the world now knows, this is clearly still true, but irrelevant. The great question is purely, will this new political system – opposed to 'us' on principle, and both expecting and working for 'our' total defeat – become more friendly just because it is richer? Or will it spend the extra resources on yet more arms?

The political aims of an economic war are seldom clear. Do we want (i) to incapacitate our enemy, (ii) to dissuade him, or (iii) much more ambitiously, to change his policy and aims? And with which economic instruments should we proceed in each case? In the absence of good theory modern political leaders enter upon economic war in permanent ignorance and temporary passion; their Mercantilist predecessors were far better served.

Case (iii) is bimodal. It includes, as a valid 'offensive' tactic, bringing the enemy into our group, transferring technology to him, lending him money at a discount and so enriching him: 'stab with a sausage'. In a basically economic analysis we need only say, this is absolutely correct, and the best policy by far, but only if it is sure to work, and within reasonable time. If not, case (iii) means, bimodally, that very severe measures indeed are appropriate: conversion through fear.

Case (ii) implies short slaps on the wrist, with valid threats of worse to come. It implies that we have *some* ability to change policy, at least in small matters, and are therefore prepared to 'fine-tune' our measures and to agree with each other on tactics.

Case (i) implies despair over ultimate friendship, and accepts a 'peace that is no peace' as a long-term goal: the establishment of military superiority by permanently slowing up the enemy's economic growth, without fine-tuning. One cannot after all fine-tune so diverse and fractious a coalition as the CoCom.

Modern economic war concerns mainly military and dual-use goods. This is an unnecessary restraint: if our enemy can make wheat with difficulty and rifles with ease we should deprive him of wheat. The logic is irrefragable in Case (iii) strategies, indeed hard to beat in Case (ii). Lipstick, therefore, is a highly strategic commodity if our enemy taxes it heavily and his comparative cost situation makes its production for any reason expensive for him. The concentration of embargoes in military goods serves however a good electoral purpose; ordinary people do not understand the lipstick argument but do agree that we should not deliver weapons (a not wholly correct proposition!).

Do the initiators of economic warfare always fail in their aims? This is often stated these days, by those who wish to end the CoCom and widen embargoes and with it (unilaterally) the Cold War against USSR. There is, however, no truth in 'always'; at most one can say, politicians initiate military war with far more thought, and it is not the fault of economic war, but of those who wage it, that its record is so spotty.

We list the main disputed or forgotten incidents since 1919:

1935–6. League of Nations sanctions against Italy, on the occasion of her Abyssinian aggression. Excessive moderation shown: neither oil imports nor use of the Suez Canal embargoed, but these were the only two serious bottlenecks. Reasons: fear of war in Mediterranean, and of Fascist-Nazi alliance.

1940. Anglo-American partial embargo on oil for Japan. Japanese general staff estimate military action will shortly become impossible. Pearl Habor results. This catastrophe for the initiators shows, at any rate, the effectiveness of their threat.

1976. Ian Smith, leader of the illegal white government of Southern Rhodesia, was forced to

go to the negotiating table with his black enemies by Samora Machel's closure of the Beira railway. In power since 1974, Machel had hesitated because of the huge loss of invisible earnings. The effect of this was to divert all traffic to the South African network, which is about five times as far to the sea, and so very expensive; overloading it was also very unpopular with the South African government (but to South African pressure was added greater guerrilla activity). So the success of the Mozambican embargo redeemed the failure of the British. The latter was of course grossly mis-conceived. Even if better administered it could not have worked before the Portuguese Revolution.

The beginning of East-West Détente in 1970 merits longer treatment. First Brezhnev offered the German Treaty, then the Helsinki Declaration and then, more informally, the emigration of Jews. These were, in their original form, substantial concessions, and the quid pro quo was to be technology transfer, and access to Western capital markets. In 1972 the deal was in place: the frontiers of West Berlin were recognized, the European Security Conference had begun (to end in 1975 with the Helsinki Declaration on human rights, communications, etc.), and the Jews were coming out.

But in the same year, 1972, Senator Jackson boasted during elections too much of how he had literally bargained the loans against the emigration. Sheer pride forced Brezhnev to hold back his emigrant Jews and the deal turned sour. This however does not alter the fact that the original détente was made possible by the US embargoes on technology and capital: the very Soviet political concessions basic to the earlier Détente, which the Western enemies of CoCom and the renewed Cold War wish to bring back, were themselves the product of the relaxation of the still earlier embargoes.

Economic war against South Africa since about 1946 has been, until September 1985, mainly a matter of private boycott; except that the Communist powers have embargoed her (save Mozambique, which is much more dependent than upon Southern Rhodesia; and the USSR which has co-operated in the international diamond duopoly). Ideologically motivated private groups in the advanced capitalist democracies have refused to buy this or that export; but since they have never fully controlled any enterprises this has affected only consumer goods. States have embargoed the sale of weapons and police equipment (except Israel and Brazil). All this is standard stuff – and was very ineffective.

Much more novel was the 'extra-territorial' use of shareholder power. Much as the US government forces its firms to boycott Swedish firms that have been blacklisted for ignoring CoCom, so have ideological groups of shareholders forced enterprises with branches in South Africa to raise black wages above the market level, recognize black unions and even to evade local laws. This has been achieved more by bad publicity than by serious voting blocks at shareholders' meetings. The role of the churches, both as shareholders and as propagandists, has been considerable. Such interference is known as extra-territoriality: the state (Sweden or South Africa) on whose territory the enterprise produces or sells, or the trade union organizes, loses the degree of control over events that is normal in a capitalist state owing to foreign bodies with their own political will. This is not the case if it has merely to deal with a profit seeking headquarters abroad. Non-profit seekers are much more formidable, once in full control.

Disinvestment runs clean contrary to this. Anti-Apartheid campaigners have divided into pragmatists wishing to use such little powers as extra-territoriality confers, and extremists wishing to keep, above all, their hands clean. Disinvestment is no weapon at all against a company that does not want to borrow more, and the refusal to recognize this simple fact shows us again at what a low intellectual level economic war is ordinarily discussed. But disinvestment has a corollary of very great potency indeed: the refusal to buy new issues. This refusal rubs off on the bonds and bills of the South African government. It

was of course the disinvestment controversy, and the spreading of the consciousness of what Apartheid really means, that made conservative Western banking circles refuse to 'put together a package' during the debt crisis of September 1985, turning them into a sort of moralized IMF. It will be observed that the more monetary, Mercantilist view of economic war has lost little validity.

Let us conclude with a mixed bag of applications of economic theory, for war and trade have many parallels:

(a) small countries are seldom in a position to make economic war, but are ideal victims of it:
(b) even large ones are not often well placed. Countries should form alliances, or coalitions as one says in oligopoly theory.
(c) even before size comes factor endowment. To be the monopolist of a raw material is great, but to possess an irreplaceable transport artery is still greater. And factor endowment is always largely historical chance.
(d) trade unions make economic war and throw up many parallels.
(e) to a most curious extent there is little notion of compensation for the losses caused to one's side by economic war. Once's image is of rich corporations losing small sums by not selling, or delaying the sale of, high technology. So the issue only arises domestically when small enterprises (e.g. farmers) are hit. As to international burden sharing, say with CoCom, the diplomacy of it would be horrendously complicated and divisive. But could not Britain have subsidized Mozambique, already in 1975, to close the Beira railway?

Economics in Belgium

Guido Erreygers

Abstract

There is no single Belgian school of economics, but a number of Belgian economists have made significant contributions, including Adolphe Quetelet, Ernest Solvay, Léon Dupriez, Paul Van Zeeland, Gaston Eyskens, Étienne Sadi Kirschen, Robert Triffin and Jacques Drèze.

Keywords

Belgium; De Man Plan; De Molinari, Gustave; Drèze, Jacques; European Economic Association; Free trade; Quetelet, Adolphe; Triffin, Robert

JEL Classifications

Although no genuine Belgian school of economics has ever emerged, except perhaps in the second half of the 20th century, Belgian economists have made original and significant contributions to the discipline and played a major role in the creation of a European community of economists.

Before the First World War

When Belgium gained independence in 1830, economics as a scientific discipline virtually did not exist in the country. By the middle of the 19th century, however, most universities were offering courses on economic subjects, economists began forming associations, and international cooperation was actively pursued. Throughout the 19th century French economic thought was undoubtedly the main source of inspiration for economists working in Belgium, but British, German and Dutch economic schools were also influential. Another characteristic of that period was the

strong separation along ideological lines, with little interaction between Catholic economists, mainly associated to the Catholic University of Louvain, on one side, and liberal and socialist economists, associated to the Free University of Brussels and the State Universities of Ghent and Liège, on the other. The ideological divide is clearly visible in the rather biased account of the history of economic thought in 19th-century Belgium published by Michotte (1904).

Although not in the first place known as an economist, the polymath Adolphe Quetelet (1796–1874) needs to be mentioned for his path-breaking contributions with regard to the use of statistics in the social sciences. He introduced the notion of the 'average man', which in economics influenced the work of both the German Historical School and William Stanley Jevons (Mosselmans 2005). A fine example of pioneering statistical research is provided by the household surveys of Édouard Ducpétiaux (1804–1868), whose data were used by Ernst Engel to derive relationships between consumption and income.

Not surprisingly, many Belgian economists considered themselves to be part of the liberal family. The first generation of liberal economists is probably best represented by Charles De Brouckere (1796–1860), who combined careers in politics, academics and business. Together with Adolphe Le Hardy de Beaulieu (1814–1894), the Italian émigré Giovanni Arrivabene (1787–1881) and others, he founded a Belgian association of free-traders (Erreygers 2001). The main accomplishment of the association was the organization of the Congrès des Économistes in September 1847 in Brussels, the very first international conference of economists attended predominantly by ardent free-traders, and also by Karl Marx and Friedrich Engels. The next generation of liberal economists was headed by Gustave De Molinari (1819–1912), who advocated an extreme libertarian form of liberalism, opposing virtually any form of government intervention. Some consider him to have laid the foundations of free-market anarchism, also known as anarchocapitalism (Hart 1981–2). Although he spent much of his time in France, where he was for a long time editor of the *Journal des Économistes*, he played a very active role in Belgium. He founded and edited *L'Économiste Belge*, animated the Société Belge d'Économie Politique, and managed to breathe new life into the free-trade movement, both nationally and internationally (Van Dijck 2008). In many of these initiatives he found a fellow-traveller in Charles Le Hardy de Beaulieu (1816–1871), who published several textbooks on economics. It must be added, however, that few Belgian economists shared De Molinari's extreme view of liberalism.

In the second half of the 19th century Émile De Laveleye (1822–1892) was the country's most prominent economist. This prolific writer covering a wide area of topics had been strongly influenced by the French philosopher and Christian socialist François Huet, who taught at the University of Ghent. De Laveleye's economic publications included work on the origins and varieties of property rights, on bimetallism and on socialist doctrines. He was professor of political economy at the University of Liège, and authored an often reprinted textbook on economics. He considered his views to be close to those of John Stuart Mill and the German Historical School. Although very much appreciated by his contemporaries – he built up an impressive international network of colleagues and correspondents – his contributions lost most of their influence soon after he died.

At that time the wealthy industrialist Ernest Solvay (1838–1922), founder of the chemical firm Solvay & Cie, started to turn his attention to social and economic issues. He was convinced that a change of the monetary system (replacing the system based on metallic money by a pure-credit system which he called 'social comptabilism') combined with a sweeping reform of taxation (replacing all existing taxes by taxes on gifts and bequests, with rates increasing with the number of transfers) would provide the clue to solving society's problems (Erreygers 1998; Boianovsky and Erreygers 2005). Solvay, a prominent liberal, worked on these issues in close collaboration with leading socialist economists such as Hector Denis (1845–1913) and Émile Vandervelde (1866–1938). Their monetary

propositions led to a debate with Léon Walras, who saw a great similarity with his own views. On a more practical level, Solvay influenced economics in Belgium through his generous funding of various institutions associated to the University of Brussels, the most important of which are the Institut de Sociologie and the École de Commerce Solvay (now Solvay Business School). These institutions allowed economists such as Émile Waxweiler (1867–1916), Maurice Ansiaux (1869–1943) and Boris Chlepner (1890–1964) to do research.

Socialist doctrines found responsive audiences in Belgium, partly as the result of the rapid industrialization, but also because of the presence of exiles such as Karl Marx and Joseph Proudhon. The Saint-Simonians and Fourierists attracted scores of young intellectuals. This created a fertile ground for such figures as Hippolyte Colins de Ham (1783–1859), who proposed to provide all adults with a capital endowment, Joseph Charlier (1816–1896), who launched the idea of an unconditional basic income, and César De Paepe (1842–1890), who tried to bridge the gap between the Marxists and the anarchists (Cunliffe and Erreygers 2001).

At the University of Louvain economics had a decidedly Catholic profile in the 19th century. Charles Périn (1815–1905) and Victor Brants (1856–1917) both aimed at developing a social economics in accordance with the doctrine of the Church, along the lines of Le Play.

The Interwar Period

After the end of the First World War fellowships offered by the Commission for Relief in Belgium and the Belgian American Educational Foundation gave many talented economics students the opportunity to spend at least one year in the United States. This was the case with Léon Dupriez (1901–1986), Paul Van Zeeland (1893–1973) and Gaston Eyskens (1905–1988), who combined their studies at the University of Louvain with stays in respectively Harvard, Princeton and Columbia. As a result Belgian economics gradually obtained a more American character and the University of Louvain became much more prominent in economic research (Maes and Buyst 2005).

Dupriez introduced to Belgium the statistical business cycle techniques used by Harvard University. He became the driving force of the Institut des Sciences Économiques (later renamed Institut de Recherches Économiques et Sociales, IRES), founded in 1928 at the University of Louvain. Van Zeeland, who had joined the National Bank of Belgium as head of its research department, made a swift career in the bank and was soon considered as one of the country's leading economic experts. In the troubled political and economic climate of the 1930s he was twice prime minister of governments of 'national unity'. With the scientific backing of IRES, Van Zeeland successfully devalued the Belgian currency in 1936. The Van Zeeland governments also included the socialist Hendrik De Man (1885–1951), who in 1933 had proposed an ambitious 'Labour Plan' (also known as the 'De Man Plan') as a way out of the economic depression. His project, which was intensively discussed and had broad support in Belgium and in other countries, involved state planning of the economy and a technocratic way of governing.

A few isolated attempts were made to introduce a more mathematical approach in economics. The most ambitious project was that of Bernard Chait (1893–1957), an engineer and businessman who was in close contact with Jan Tinbergen and François Divisia. In his 1938 Ph.D. thesis he constructed a general mathematical theory capable of explaining business cycle movements, but he failed to convince economists of its usefulness (Erreygers and Jolink 2007).

After the Second World War

In the first half of the 20th century economics gained increasing recognition as a mature scientific discipline. Universities created special

schools and separate faculties for economic sciences, and several economics journals were launched. In the northern part of the country Dutch gradually replaced French as the language of instruction. Both the Universities of Brussels and Louvain were eventually split into Dutch-speaking and French-speaking universities.

As early as the 1930s Gaston Eyskens had become the leading figure of the Dutch-speaking section of economists at the University of Louvain. In the years after the war he seemed to be more receptive to the ideas of Keynes than the leading figure on the French-speaking side, Léon Dupriez, who favoured a laissez-faire approach and resisted to the introduction of Keynesian macroeconomic policies. The tension between the Dutch-speaking and French-speaking section at the university led to the foundation, in 1955, of a separate Dutch-speaking research institute at the University of Louvain, the Center for Economic Studies. The Center provided scientific backing for various economic reforms adopted under Eyskens's period as prime minister of Belgium (1958–61, 1968–72). Eyskens also took the initiative to create a government planning bureau (Buyst et al. 2005).

At the University of Brussels Étienne Sadi Kirschen (1913–2000) was the main agent of change in the 1950s. After having worked at the Office of European Economic Cooperation in Paris, he organized a team which estimated the first national accounts for Belgium. In 1957 Kirschen and his collaborators founded the Département d'Économie Appliquée, better known under its acronym DULBEA, the economic research institute of the University of Brussels. It constructed the first input–output table for Belgium. In close cooperation with Tinbergen, who lectured at the University of Brussels in the 1960s, Kirschen emphasized policy-oriented research based on quantitative methods, as exemplified in the ambitious threevolume *Economic Policy in our Time* (1964) by an international team of economists led by Kirschen (Sirjacobs 1997).

A few Belgian economists emigrated and made a career abroad. The most striking case is that of Robert Triffin (1911–1993), who initially studied at the University of Louvain. Having obtained his Ph.D. at Harvard, he worked for the Fed and the International Monetary Fund (IMF) – under its first director, the former Belgian Finance Minister Camille Gutt (1884–1971) – and in 1951 became professor of economics at Yale University. He made himself a reputation by pointing out a crucial weakness of the Bretton Woods system (later known as the Triffin dilemma) and arguing for a fundamental reform of the international monetary system. He was an influential economic adviser to key players in the European economic and monetary integration process; he returned to Belgium in the 1970s (Maes and Buyst 2005). A less well-known émigré is Raymond De Roover (1904–1972), who after his studies at the Antwerp Catholic business school decided to specialize in economic history. He earned his Ph.D. at the University of Chicago, and was later appointed as professor in Boston and New York. His work on early banking in Bruges and Florence made him a leading specialist on late medieval economic history and thought.

Probably the most important development in Belgian economics after the Second World War was initiated by a man who decided not to stay in the United States after completing his Ph.D. thesis. In 1966 the Center for Operations Research and Econometrics (CORE) was founded in Louvain. This was very much the achievement of Jacques Drèze (b. 1929), a student of the University of Liège who thanks to a fellowship of the Commission for Relief in Belgium went to the United States and obtained a Ph.D. at Columbia. After his return to Belgium he was appointed at the University of Louvain, where he rapidly replaced Dupriez as the dominant figure of the economics faculty, but he kept close contacts with his American colleagues, especially at Northwestern and Chicago, where he was visiting professor in the 1960s. The creation of CORE marked the adoption of a decidedly American style of doing research. From the outset CORE was meant as an interdisciplinary research institute, bringing together specialists in econometrics, statistics, operations research, game theory and

(mathematical) economics. Thanks to grants from the Ford Foundation and other institutions, it created a stimulating environment for research and offered fellowships to both Ph.D. students and established researchers. CORE was unique not only because it brought together Dutch-speaking and French-speaking economists from the University of Louvain, but also because Drèze managed to get the econometricians of the University of Brussels involved in the project. Moreover, from the very beginning CORE opened itself to the world: it hired the Dutch econometrician Anton Barten (b. 1930), established strong links with other European institutions focusing on quantitative economics, and welcomed American and other foreign scholars as fellows (Maes and Buyst 2005).

The University of Brussels and CORE played a major role in the creation of the *European Economic Review* and the European Economic Association. The *European Economic Review* was founded in 1969 by the European Scientific Association for Medium and Long Term Economic Forecasting (ASEPELT), of which Kirschen was the driving force. His younger colleagues Jean Waelbroeck (b. 1927) and Herbert Glejser (b. 1938), both of the University of Brussels, were the founding editors. In 1985 Waelbroeck and three other Belgian economists, Jean Jaskold Gabszewicz (b. 1936), Louis Phlips (b. 1933) and Jacques-François Thisse (b. 1946), all affiliated to CORE, took the initiative to launch the European Economic Association. Drèze was elected as the first president.

Drèze's contributions to economics are extensive, covering uncertainty, general equilibrium theory, macroeconomics, econometrics and much more (Dehez and Licandro 2005). He is by far the most influential Belgian economist of the second half of the 20th century. Besides those already mentioned, other important Belgian economists include Claude d'Aspremont (b. 1946), Paul De Grauwe (b. 1946), Mathias Dewatripont (b. 1959), Pierre Pestieau (b. 1943), Jean-Philippe Platteau (b. 1947) and Gérard Roland (b. 1954). It is remarkable that the top of the economics profession remains very much dominated by French-speaking economists.

Economics Libraries and Documentation

P. Sturges

Libraries for a discipline are formed and characterized by that discipline. It is quite easy for a visitor to recognize that a library is for scientists or for humanists or for social scientists just by a glance at the types of books, periodicals and other material on the shelves. Libraries for economists reflect the distinctive and changing sources and documentation of economics, which are in turn products of changes in the discipline itself. As economists have successively widened the scope of their enquiries and added weapons to their methodological armoury, so the types of material they have needed to consult have multiplied. As the immediate communication of their results has become more and more pressing, so the types of publication they have favoured have evolved in response. The library providing effective service to an econometrician today would have been as irrelevant to a 17th-century mercantilist as the literature of econometrics would have been incomprehensible. This article will deal with economics libraries in their natural context of economics documentation.

The first economics collections were in the private libraries of 17th- and 18th-century scholars. Adam Smith, renowned for his forgetfulness and carelessness in dress, was able to defend himself with the claim that at least 'I am a beau in my books'. In fact the majority of his 3000 titles were in the miscellaneous topics a gentleman scholar might have been expected to cultivate, with only about 100 directly on economic topics. Nevertheless, his economic method was a book-based one, using material from his predecessors and building it into his own system. About 100 authors are quoted in the *Wealth of Nations* (1776), though not always by name. By Smith's day there was already a large monograph literature the economist could draw on in several languages: pamphlets advocating trading schemes, tracts on farm management, alarming arguments on the growth or decline of population, accounts of particular industries, countries, cities, etc. The first economists wrote in monograph form too, either the pamphlet directed at some particular case or instance, or, from the 18th century onwards, the full length treatise summing up a whole theory of economics. Such was to remain the pattern of economics publishing until the later 19th century.

Not all economists relied on published sources; Malthus and others travelled widely in search of facts which they blended with information derived from extensive reading. There were other economists like Ricardo, whose theorizing worked outwards from his own inner store of business experience and personal insights, for whom access to a library was of less significance. An economist whose method did rely on books was usually forced to be a collector himself since libraries well-stocked with suitable publications were few. The 19th-century British economist, Richard Jones, in the laborious progress of his treatise on *Rent* (1831) made frequent calls on the kindness of his friend William Whewell to provide him with books from the 'Public Library' (in fact the predecessor of Cambridge University Library). As a country clergyman with little money for book buying and in comparative isolation from access to libraries, it was a difficult assignment for him to develop a theory of rent based on worldwide evidence. Indeed, as the complexity and specialization of the economics discipline grew during the 19th century it became less and less possible for an economist to function away from well-stocked libraries.

One reason for the increased dependence was the question of priority. As the literature of economics grew, so did the possibility of the prior publication of a supposed original idea. W.S. Jevons, for instance, developed and published his marginal utility theory in virtual isolation from other ideas on the topic. His subsequent realization that Menger and Walras had arrived at the same theoretical point in the same year of 1871 was disturbing, but as a voracious collector of economics literature he began to appreciate that there were also predecessors,

most notably Hermann Heinrich Gossen, whose work published in 1854, needed to be acknowledged. It was becoming clear in various inescapable ways that the economist needed a library. Great general libraries such as that of the British Museum, could and still can provide much for the economist. Karl Marx, for instance, laboured there to great effect for years, and was able to display an encyclopedic knowledge of the relevant literature as a result. Nevertheless, by the end of the 19th century, the discipline was ready for specialized economics libraries.

Estimates of the numbers of practising economists at a given time are even today fraught with problems of definition. However, it is fairly safe to say that until the end of the 19th century and the early 20th century brought the creation of schools and faculties of economics in the universities of Europe and North America, and governments and business began to hire people with the degrees awarded by these institutions, practising economists were very few in number and more significantly were thinly scattered geographically. A few, most notably Smith himself but others such as Jean-Baptiste Say, were professors in faculties of law or other marginally related disciplines. Most were first and foremost otherwise employed: as a businessman like Ricardo, an official like J.S. Mill, a clergyman like the abovementioned Richard Jones, an engineer like Dupuit, or a landowner like von Thünen. Libraries to serve such a scattered and heterogenous group were not practical. With the rise of Cambridge as a centre of economics excellence in the second half of the 19th century, the creation of the London School of Economics in 1895, and the emergence of great faculties of economics at Harvard, Columbia and Chicago by the beginning of the 20th century in the USA, there were for the first time concentrations of economics teachers, researchers and students, whose needs gave rise to specialized economics libraries.

The source materials that such libraries might stock were multiplying fast. The business world was the chief generator of publications of use to economists. Journals from many countries in specific fields such as mining, insurance and banking, prospectuses and annual reports of railway companies, histories of firms or industries, biographies of businessmen, documents from international fairs and exhibitions, all burgeoned during the 19th century. For the first time, governments became significant publishers of economics-related literature: British Parliamentary Papers and United States Congressional Documents began to appear with increased volume and regularity almost immediately the 19th century began. In other countries the quantity, if not the regularity, of government publications also increased swiftly as the century progressed. Much of their content was statistical; and the US Census of 1790 and the British Census of 1801 were milestones in the practice of number gathering. Statistical societies, such as that of London (founded 1825, now the Royal Statistical Society) arose to take advantage of this material and in the process created a new layer of publication which economists could exploit.

The growth of economics as a discipline not only brought about the multiplication of materials but also created a need for more immediate channels of communication. The monograph which had been the chief avenue of publication for so long, began to lose some of its importance to the periodical. During the 19th century, economists had written for the great literary reviews, for general interest magazines, for newspapers, and for the one or two specialized publications such as the *Economist*. It was only after 1886, however, when the *Quarterly Journal of Economics* was founded by Harvard University, followed quite swiftly by the Royal Economic Society's *Economic Journal* (1891) and Chicago's *Journal of Political Economy* (1892), that there was a serious rival medium for economic writings. When the *American Economic Review* joined them in 1911, a main core of prestigious journals was taking shape, and the nature of the communication of economic ideas was completely altered. The need to convince a publisher of the validity and interest of one's ideas, or alternatively to publish at one's own expense, was replaced by interaction with an editor or editorial board drawn from one's peers. The possibility of quite swift and direct communication of one's ideas, even on highly technical matters, was opened up. Economics publication

became more focused and more isolated from public debate.

This rich growth of sources permitted economists to build more and more elaborate structures of argument and evidence. W.S. Jevon's perilous but gallant attempts to link cyclical commercial fluctuations back through the business statistics to agricultural yields, to weather data, and finally to sunspot activity in a chain of causality, was just a particularly bold exploitation of the wealth that was becoming available. Even a collector of books as enthusiastic as Jevons could not reasonably hope to acquire materials of the number and type required for work of this kind. It is no coincidence that Jevons was an enthusiastic member of the Library Association (UK) and published papers on the topic of libraries. Whilst the 18th-century or early 19th-century economist urgently needed to be a collector of books, an economist of the late 19th and early 20th century like F.Y. Edgeworth needed to own hardly any books and could rely on libraries entirely.

The economics libraries which were created to cope with the growing need of economic researchers for specialized materials were, in the first place, historical collections designed to allow the reconstruction of past theory and the recovery of past knowledge. Two of the greatest have their roots in the personal collecting of one man. H.S. Foxwell (1849–1936) bridged the age of the great amateur collectors and that of specialised professional libraries. He amassed two great collections during a lifetime of acquisition carried on at a level of bibliomania. His first collection, sold in 1901 to the Goldsmiths Company, is now the basis of London University Library's Goldsmiths' Collection. His second collection, begun immediately the Goldsmiths sale had put his finances to rights, was sold in 1929 to Harvard Business School, which took possession on Foxwell's death to form the Kress Library. Kress is in turn now only part of the Baker Library of Harvard Business School.

Other great academic libraries also follow this pattern of a core historical collection alongside a fast-growing and fast-changing current collection. Columbia University, with its Seligman Collection, Johns Hopkins with the Hutzler Collection (assembled by Jacob Hollander) and the University of Illinois with its Hollander Collection, show a similar pattern. In Britain, the historical riches of Goldsmiths' are complemented within the London University system by the London School of Economics' British Library of Political and Economic Science, founded in 1896. Other parts of the world also have libraries of similar scope – Japan, for instance, where the Menger, Schumpeter and Burt Franklin collections of Hitotsubashi University provide a basis of old economics material to underpin its modern collections. With business history now an accepted discipline in graduate business schools in North America, the older titles in these libraries' core collections are attracting renewed attention from researchers.

Other types of economic research library have grown up in the 20th century to supplement the provisions of the academic libraries. Departments of Government and their associated agencies are the most common alternative source of economics materials. In the USA in particular, excellent libraries of this type are numerous; the US Department of Commerce Library, founded in 1913, for instance, has extensive collections including much statistical material, and agricultural economics material is one of the chief strengths of the National Library of Agriculture, originally established as the Department of Agriculture Library in 1862. The Federal Trade Commission, the Treasury, the Federal Reserve System Board of Governors, and other US Government agencies have fine economics libraries. The Library of Congress too, in its Social Science Reading Room, gives access to an enormous wealth of economics material. Other countries also have government economics libraries, the UK Board of Trade Library being one particularly fine example. International organizations also support economics collections; the International Labour Organisation (ILO) in Geneva, maintains an extremely large library, accessible via a computerized retrieval system. The Chambre de Commerce et d'Industrie Library in Paris is an example of a large, modern economics library supported by a trade association. The greatest economics collection in the public library sector is that of the New York Public Library, whose

Economic Division has since 1919 produced the weekly *Bulletin of the Public Affairs Information Service*, the foremost index to the world's English language literature in the related fields of economics, finance, business, labour and public affairs.

Only a comparatively few libraries have the resources to devote the necessary attention to the full potential range of material required by economists and the techniques that will permit its efficient acquisition and retrieval. The Library of the Instituts für Weltwirtschaft in Kiel, Federal Republic of Germany, regarded by many as the premier economics library in the world, has been able to do this consistently since its foundation in 1914. Its catalogue of persons gives access to material not only via authors of books, articles and chapters, editors of books, symposia and journals, writers of prefaces and introductions, but also to material whose subject is a person or persons connected with economics. Its title catalogue includes not merely books, but also annual reports, serials, newspapers, collections, and the corporate bodies, congresses and conferences which publish material. The subject catalogue has geographical entries in addition to conventional subject headings. Cross reference cards are hardly ever needed, for as many copies of the full entry card as are necessary are entered in the relevant places in the catalogue. The work of the library is largely in the hands of professional economists whose subject expertise ensures the accuracy of subject cataloguing. Because the provision of good catalogues is never enough to ensure that the user obtains documents that relate to his interests, Kiel like many other special libraries alerts users to pertinent new acquisitions. Mark Perlman (1973) has justly called its methods 'the acme of the traditional approach to economics literature retrieval'.

In addition to dealing with the complexities of the multiplying sources for economic research, libraries have had to come to terms with yet another shift in the forms of economic communication. The urgency to establish the priority of ideas or to publish research before it becomes obsolete has placed strains on book and journal publishing with which they have been unable to cope. The average lag between submission of an article and its publication in a journal has increased over the years, and the maximum wait may be in excess of two years. This is despite the introduction of submission fees intended to reduce the number of submissions to some journals, the growth in the number of specialized journals and the introduction of a journal, *Economics Letters*, specifically designed to ensure swift publication of material. Academic monograph publishing is currently under the severest financial strains, with spiralling costs leading to higher price per copy to the consumer, with consequently reduced numbers of sales driving the unit cost up still further. In their editorial decisions, therefore, publishers are putting increasing weight on the market value of proposed titles.

The solution to this problem has been the increasing use of semi-published forms usually referred to as working papers. This form of distribution for an individual paper, reproduced by some inexpensive method and circulated via the writer's own institution's mailing list, causes confusion and distress to some librarians. Some libraries only acquire working papers if they are free, many do not catalogue them, some bind them in series, others do not. Some libraries avoid them altogether because of the difficulties they cause, and in the conviction that anything worthwhile which appears as a working paper will eventually be published in more permanent form. This is a serious disservice to economic scholarship. Roy Harrod (1969) said 'Mimeographed essays issued in advance of publication, if any, by the research unit of one university to the professors of other universities all over the world have come to constitute the main matter for reading, at least among theoretical economists.' Indeed, some of the difficulty of knowing all the writings of an economist as distinguished as the Norwegian Ragnar Frisch stems from the fact that he published so frequently in working paper form. The collection of working papers at Warwick University Library. (UK), their published *Economics Working Papers Bibliography* and their microform service are a major contribution to this problem area.

In the last quarter of the 20th century, the forms of source material for the economist have begun to challenge the service capacities of traditional

librarianship. Most particularly, published statistics are no longer adequate for the purposes of many economists: they are out-of-date when published; they are in summary rather than comprehensive form; and they require recording in computerized form so that they can be arranged, shuffled and manoeuvred into revealing forms by the researcher. The electronic publication of statistics, making them available originally in computerized form, is growing rapidly. Increasingly, economic research depends on access to suitable computer hardware, availability of programmes which will perform the required tasks, and tapes of the data, rather than on books or other paper formats. To some extent this trend tends to exclude the library from the research process, but that is not necessarily always the case.

The issue of whether an economics library should merely confine itself to searching bibliographic databases on behalf of its economist clients or whether it should go further in identifying and making available numeric databases, has already begun to be explored, for instance in the Economics Library of the Ministry of Agriculture Fisheries and Food in the UK (O'Sullivan 1982). The Baker Library at Harvard has long been involved with the acquisition of computerized data bases, but now has professional staff members who are also actively involved in reviewing, publicising, and manipulating numerical databases. What is more, to add the exploitation of numerical databases, whether commercial, such as the many provided by Evans Economics, Inc. (EEI), or government created, such as the US Bureau of Labor Statistics' LABSTAT, or the various services of the Bureau of Economic Analysis, to the functions of a library which is already managed by computerized systems often does not seem like a major problem. The availability of statistics in published or database form, the relative costs, types of series available in the alternative forms, the compatibility of computerized data with the systems available to the economist, are undeniably difficult issues. However, librarians in their new roles as information specialists are proving themselves capable of lending invaluable assistance to their clients with this type of material.

The potential of computerized systems for the swift transmission of information is likely to be further exploited. Electronic mail, for instance, already permits the flexible exchange of messages, long or short, amongst individuals or groups, by users of computer systems linked by telephone lines. The potential of electronic mail for the almost instant communication of research findings amongst a group of interested experts, an 'invisible college', is obvious. The electronic journal, which is at present being developed at a number of centres, seems likely to be an answer to the problem of the chronic pressure on economics journals. The electronic journal exists originally as a database controlled by an editor. Authors send their 'manuscripts' to the editor on-line from wherever their computer is located, the text can be refereed, edited and amended on-line, and then the subscribers read the journal on-line, printing out text on demand. The journal can be altered daily if new material is received and old material can be relegated to storage files. Within a group of specialists, united by the necessary machinery and associated financial arrangements, accurate, easily modified information can be available in a form more swift and convenient than any previously used. This new communication medium need not necessarily circumvent specialized libraries, which in future might actually provide facilities for such operations, for instance in the archiving of material from the electronic journal.

With their computer expertise, their staffs of specialists, and their vested interest in the storage and dissemination of information, there are very obviously roles which libraries are developing in the management of electronic information systems. Though there seems little indication of the large-scale return to conventional library-based scholarship in economics prophesied by Harry Johnson (1977), a total disregard of the value of historic and rare books collections already existing should not be contemplated. No discipline can safely neglect its past and it is to be hoped that economics libraries will cherish their treasures for the use of the minority of scholars whose approach is more reflective and retrospective. Nonetheless, the cutting edge of economics librarianship in the 21st century seems likely to be

as different from that of the 20th or the 19th as will be its forms of documentation, and indeed the economics discipline which generates them.

Economics of Franchises

Roger D. Blair and Jessica S. Haynes

Abstract

Franchising, which is common in many advanced economies, is a contractual form of vertical integration. This article examines the economic rationale for choosing franchising over vertical integration. It also examines the influence of the franchisor's ability to maximize its own profit.

Keywords

Distribution systems; Franchisee; Franchising; Franchisor; Royalties; Vertical integration

Franchising is a contractual form of vertical integration. A manufacturer, for example, produces a product that must be distributed to consumers. The manufacturer can perform the distribution function itself through a chain of retail outlets it owns and operates. When a manufacturer both produces and distributes its product, the firm is vertically integrated by ownership. The manufacturer can then control the retail promotion, customer service, pricing, product availability, delivery and other relevant decisions at the distribution stage. It does this through internal managerial decisions designed to maximize the overall profit of the firm. But this is not the only way to organize the production and distribution of the firm's output. Instead of having a network of its own distributors, it can license independent firms to perform the distribution function. These licensees are termed franchisees, and the distribution system is called a franchise system. The manufacturer then engages in a contractual form of vertical integration. The franchise contract gives the franchisee the right to distribute the manufacturer's product, but also allows the manufacturer to control retail promotion, customer service, resale prices (minimum or maximum), and a host of other things that are important to the manufacturer, who is now a franchisor. But if franchising is just a contractual form of vertical integration, what is the rationale for franchising?

Rationale for Franchising

Brands provide information to consumers in a mobile society, and so reduce search costs.

When a consumer visits a branded outlet, there are supposed to be no surprises – pleasant or otherwise. Thus, local residents go to Roger's Ribs and Jessica's Java while visitors go to Sonny's Barbecue and Starbucks. The consumer's increased reliance on brand names has resulted in the development of chains of retail outlets. Chains benefit from lower costs as a result of economies of bulk purchasing and economies of scale in production, new product development, and promotion. In principle, all of the retail outlets could be corporately owned and managed, but many of the resulting chains are organized as franchises.

Franchising permits specialization that may lead to higher overall profits. The franchisor is the innovator who specializes in developing the brand, exploiting economies of scale in production and promotion, and negotiating with vendors on behalf of the chain. The franchisees bring their entrepreneurial spirit to their locations. They also contribute their knowledge of the local market. The result is a synergistic effect which increases potential profits (Caves and Murphy 1976). Franchising succeeds because it allows each party to do what it does best. Further, franchise contracts deliberately organize this relationship to give the franchisor and franchisee incentives to work in tandem to increase revenues.

Types of Franchise

Although the lines drawn are somewhat arbitrary, franchising can be divided into *traditional* franchising and *business format* franchising. Traditional franchising is used by a manufacturer to distribute its product through distributors (the franchisees) that are specifically licensed to do so. Traditional franchising is found in several industries: automobiles, beer, gasoline, ice cream, and soft-drink bottling to name a few. Business format franchising involves the use of the franchisor's brand, trademark and trade dress, and distinctive way of supplying goods and services to the consumer. In this case, the franchisor develops and promotes the concept while the franchisees implement the concept and carry out local production and distribution. The 'quick serve restaurant' sector is a good example. with familiar names such as the US-based chains McDonald's, Pizza Hut, Subway and Taco Bell. There are many other sectors in business format franchising including accounting services, automobile servicing, health and fitness, hotels and motels, and real estate.

Franchisor Compensation in Traditional Franchising

Traditional franchisors sell products to their franchisees which are resold to consumers. The franchisor earns its profit on these sales to franchisees. The extent to which franchising is a good substitute for vertical integration depends on two critical factors: the market structure in distribution and the relative efficiency of franchisees versus employee-managers. Assuming that franchisees are neither more nor less efficient than employee-managers, a manufacturer will earn the same profit whether it performs the distribution function itself or franchises the distribution. Its profit will be the same because the cost of performing the distribution function will be in the same in either case. If franchisees are more efficient than employee-managers, then distribution costs will be lower, retail demand will be higher, or both. This will improve the manufacturer's profit, due to increased sales to the franchisees.

If there is monopoly at the distribution stage, the market structure is one of successive monopoly. Assuming equal efficiency, the manufacturer will prefer vertical integration rather than franchising. Compared with the case of competitive distribution, successive monopoly results in double marginalization, which leads to lower output and higher price. The manufacturer's profits are reduced below the level that would result from vertical integration because double marginalization reduces the derived demand for the product.

These ill effects can be offset with other contractual provisions such as maximum resale price constraints, minimum quantity standards and price advertising (Blair and Esquibel 1996). If these are effective, they should eliminate the

exercise of downstream monopoly power and improve the manufacturer's profits.

Things are more complicated when franchisees are more efficient than employee-managers. The effect of the increased efficiency is to shift the derived demand to the right. This, of course, tends to improve the manufacturer's profits. The exercise of monopoly power by the franchise, however, tends to decrease the manufacturer's profits. The net effect cannot be determined on a priori grounds. Presumably, when a manufacturer expects the net effect to be positive, franchising is selected.

Franchisor Compensation in Business Format Franchising

Business format franchisors do not sell products to their franchisees for resale. Instead, they provide a concept, a brand, and a distinctive way of doing business. Business format franchisors have many ways of charging their franchisees for using the licence: initial franchise fees, sales revenue royalties, output royalties, rent and sales of necessary inputs, to name a few.

Nearly all franchisors include franchise fees in their contracts. These fees are structured as either initial or periodic lump-sum payments, with the initial form being far more prevalent. Blair and Lafontaine (2005, p. 61) found that 99.2 percent of all franchisors use initial franchise fees. In principle, both forms allow the franchisor to capture the maximum profit available under vertical integration, provided that the franchisee can obtain all inputs at competitive prices. To realize this level of profit, the franchisor sets the initial franchise fee or the present value of the periodic payments equal to the present value of the stream of future operating profits that will be generated by the franchisee. This, in turn, will allow the franchisee to earn only a competitive return on its investment.

As in traditional franchising, the efficiency of the franchisees relative to employee-managers contributes to the level of profits the franchisor can obtain. If franchisees are more efficient, this will increase the franchisor's profit because franchisees will bid up the franchise fee until it is equal to the stream of future operating profits.

Although theoretically feasible, franchise fees generally are not set at such a high level. This is predominantly a result of the uncertainty surrounding future market conditions, future interactions between the parties, as well as franchisees' wealth constraints. Often franchise fees just cover the start-up costs of opening a new franchise location.

Franchisors can also extract revenue by charging franchisees royalties, based on either a percentage of their sales revenue or a fixed fee on output sold. Sales revenue royalties are the more prominent of the two forms and the second most utilized charge by franchisors, next to initial franchise fees (Blair and Lafontaine 2005, p. 66).

As long as the franchisee can acquire all inputs at competitive prices and a competitive market exists among local franchisees, the franchisor can extract the optimum level of profits with royalties. In the case of sales revenue royalties, the franchisor achieves this outcome by setting the royalty rate equal to the ratio of the difference between the profit maximizing price and marginal cost to the profit maximizing price. This rate will result in a post-royalty price equal to the franchisees' marginal cost. The royalties collected will be precisely equal to the maximum profits that vertical integration would yield.

Again, franchisees' efficiency relative to employee-managers impacts these profits and the decision to franchise. If the franchisees are more efficient, then the franchisor will earn more profit due to the increase in sales revenue. If instead the employee-manager is more efficient, then the company will choose vertical integration.

If the franchisee has local monopoly power, however, the franchisor will be unable to attain the maximum level of profit through a sales royalty. The ability to exert local market power makes price endogenous for franchisees and allows them to factor sales revenue royalties into output decisions. Therefore, no sales revenue royalty will allow the franchisor to capture the amount of profit available through vertical integration. An equivalent analysis holds for output-based royalties (Blair and Kaserman 1980). Output-based royalties, however, make little sense in business

format franchises because there are often too many products to make tracking outputs feasible.

Another way in which franchisors obtain revenue is through input requirements. In many business format franchise systems, the franchisees are required to buy inputs from the franchisor. For example, a pizza franchisee may be required to buy pizza dough and sauces from the franchisor. If the franchisor charges its franchisees prices above the competitive level, these tying arrangements provide an alternative way of extracting the profit that vertical integration would provide (Blair and Kaserman 1978). Again, however, this result holds only when there is competition among the franchisees; otherwise, the higher input prices cause distortions that reduce overall profits.

Choosing to Franchise

The choice of franchising ultimately depends on whether it is more profitable than vertical integration. This, in turn, depends on the structure of the particular market and the efficiency of franchisees relative to employee-managers. The less competitive the downstream market structure, the less attractive franchising becomes. But the more efficient franchisees are, the more attractive franchising becomes. The choice of whether and how to franchise will therefore vary from chain to chain.

Economics of Online Recruitment

Catherine Thomas

Abstract

Online recruitment describes hiring workers who were initially selected via the Internet. The practice is now widespread, with a majority of US jobseekers undertaking some online job search activity. The online intermediaries that allow employers and employees to connect with each other, leading to online recruitment, vary in scope. They range from websites that provide information about workers or openings, thereby facilitating search ('job boards' or 'job search engines') to websites that both provide information and enable employers and employees to interact online during the hiring process ('online labour markets'). A subset of online labour markets also provides an infrastructure that allows for online management of the work process and payment systems.

This article describes the development of intermediaries that govern online recruitment and the communications technology that has shaped the course of that development. It presents data collected from various sources about the extent and growth of online recruitment. It then discusses some of the features of online recruitment that are of interest for general economic research. These features include online labour market search and matching processes; supply and demand in online labour markets; the implications of online hiring for remote work where output can be delivered electronically; and the increased availability of data about labour market transactions in online settings.

Job Boards and Job-Search Engines

The Internet allows employers and employees to communicate prior to an employment contract in a variety of ways. The common feature of online recruitment intermediaries is that they provide the institutional framework, or infrastructure, that permits this communication. The first main way in which they facilitate communication is to make employers aware of potential employees, and vice versa. In the early 1990s, along with the development of the Internet came organisations that allowed employers to post online descriptions of job vacancies and allowed prospective employers to search those listings. Websites that perform this function are commonly referred to as 'job boards'. Some sites also allow workers to post their résumés online to bring them to the attention of recruiters. While recruitment via these sites is initiated online, the jobs that are filled via this recruitment channel span many types of work and a broad range of sectors in the traditional offline economy.

Early job boards ranged from being quite generalist in the type of work posted to being very specialised. Large corporations were some of the first recruiters to adopt online technology in their hiring processes, purchasing technology from specialised software providers but performing the intermediation functions of managing applications in-house. As early as 2001, 90% of large US corporations were recruiting via the internet (Cappelli 2001), with the corporate homepage often providing a 'careers' link for prospective applicants. Large newspapers also put their classified section's job listings online, and non-profit organisations such as the US military began to operate online recruitment services. During the late 1990s, in tandem with the Internet boom, a handful of online job-search engines grew to prominence in this industry. These include Indeed, CareerBuilder, Monster.com, HotJobs and SimplyHired. Some of these job boards (such as LinkUp, Indeed and SimplyHired) are metasearch engines, which means that they aggregate job postings from other boards, an activity known as 'scraping' or 'wrapping'. While these large websites are broad in scope, there are also many industry-specific sites. One example is the IT industry site DICE.com.

Many Internet job-search engines also provide additional services that assist in employer and employee search. Most of the large sites are continually evolving, offering job-seekers and potential employers increasingly sophisticated tools. For example, Monster.com – now the world's largest recruitment website, with over 1.3 million resumes being posted globally each month (Monster.com 2012) – offers workers tools including skills analysis, cover letter and résumé-writing tips, and career management services such as employer comparisons and salary and benefits analysis. In 2012, Monster launched BeKnown, a professional networking application on Facebook, to allow employers to manage their online recruitment activities.

Online search dominates job-seeking activity in the USA and in other developed countries. Jansen et al. (2005) estimated that by 2005, more than 52 million Americans had performed online job searches. By 2010, a group of the largest

online recruiters had 51.1 million visitors per month among them (comScore 2010). In 2012, 99% of the Fortune 1000 firms had purchased services from or utilised job postings on Monster.com. The Monster Employment Index (MEI), a survey measure available on the Monster.com website, tracks changes in online recruitment activity over time and across different industry sectors in the USA, Canada, Europe and India, by gathering and summarising data from a large representative selection of career web sites and online job listings.

Online Labour Market Platforms

Intermediaries have also arisen to facilitate the online recruitment of workers whose output can be delivered electronically and they look very different from the search engines described above. When the work can be done remotely, the ability to recruit workers online has an even greater transformational effect on recruitment activities because, while traditional labour markets are segmented across geographical boundaries and by distance, online labour markets for remote work can match employers and employees across the world. Blinder and Krueger (2009) estimate that up to 25% of US jobs can be offshored, made possible, in part, by electronic product delivery.

Websites that assist employers in finding workers to deliver electronic output began to emerge in the late 1990s and early 2000s. While these websites function as platforms that facilitate search, they also provide infrastructure that allows employers to oversee the different stages of the employment process. Website functions include hiring, project/work management, payment management and API (application programming interface). These services reduce the trade frictions associated with hiring and managing a single remote worker, as well as the barriers to the coordination of multiple remote workers. Horton (2010) refers to these platform websites as 'Online Labour Markets' (OLMs) and describes them as having three common features: (1) Labour is exchanged for money within the platform. As such, there are two parties involved in each transaction, and these platforms differ from online tools that deliver content without payment, such as Wikipedia and Linux. (2) Output is delivered electronically. (3) The allocation of labour is determined and payments for services are conducted within the platform. Horton then divides the OLMs that have these three features into two categories: 'spot' OLMs and 'contest' OLMs.

Spot OLMs allow employers and employees to contract with each other regarding a specific piece of work, at a given price, or for a specified length of time. The work contracted ranges from data entry, to website optimisation, to discrete programming tasks. Large intermediaries in this category include oDesk.com, ELance, RentACoder and Guru. Amazon's Mechanical Turk (AMT) is an example of a spot OLM that offers a slightly different set of services, providing employers with the opportunity to hire a large temporary workforce online to perform wide-ranging tasks. This platform is often used both as an experimental site for research (where the human response is of interest in itself) and for commercial tasks in which humans are more effective than computers (for example, identifying objects in a photograph or transcribing audio recordings).

Data on the total number of employees and postings on each of these sites are relatively sparse. A 2009 report estimates that ten of the largest platforms had over 2.3 million registered workers at that time, although these workers are likely to overlap across sites (SmartSheet 2009). The types of tasks performed via spot online labour market platforms range from small, automated tasks with low pay, to simple projects, to relatively complex integrated tasks. Examples include: finding a set of email addresses or prices; writing a product review; designing a website or a presentation; programming software; or developing an algorithm. The tasks span services and solutions that are built on top of Micro Tasks platforms (such as often found on AMT) or technology-assisted relationship management on top of project management (as offered by oDesk).

The second category of online labour market platforms comprises 'contest' websites. The

employer–employee relationship on contest OLMs functions differently from that in spot markets, in that firms requiring certain electronic output post a competition for that output and invite submissions on the website. Workers who wish to enter the competition undertake the work, and buyers either select a winner or opt not to do so. Intermediaries of this type include CrowdSpring, 99Designs, GeniusRocket and LogoTournament.

Technological and organisational advances within these platforms have led to the globalisation of the labour market for this type of work. The employers demanding these types of labour services are often located in different countries from where the most efficient potential employees can be found, and employers can recruit large numbers of foreign workers with the required skills within these sites. As an illustration, in June 2010, over 60% of the revenues paid for online work in oDesk.com came from employers located in the USA, while workers located in the USA accounted for less than 15% of the revenues. The country accounting for the largest share of revenues earned was India, at almost 30%. A majority of transactions on this website span international borders, and employers regularly employ workers in different countries simultaneously.

In addition, the flexibility provided in these virtual workplaces allows for labour market participation among groups of domestic and foreign workers that previously had limited employment opportunities. The discrete nature of jobs, the variation in job duration, and the worker's ability to perform independent work, perhaps at irregular hours, make part-time online work possible for them. The online workforce includes large groups of students, for example.

Employer–Employee Matching and Wage Determination in Online Labour Markets

Because labour market outcomes are one key determinant of individuals' economic activity, economists devote much time to understanding how labour markets work (Rogerson et al. 2005). The growing prevalence of recruitment in online labour markets is, hence, of great interest to researchers because the longstanding and important questions about all labour markets are paralleled in online settings. In addition, the contrast between offline and online labour markets is, in itself, revealing about frictions that exist in all labour markets.

In particular, economists study labour market efficiency, motivated by several key empirical facts. One critical question is why it is that unemployment often exists at the same time as unfilled job vacancies. Another central question involves the way in which wage levels are set for individual workers in employment: why is it that similar workers earn persistently different wage rates? For example, Mortensen (2003) finds that observable characteristics typically explain no more than 30% of observed wage variation in traditional labour markets. These two facts each suggest that trade frictions in labour markets prevent these markets from clearing at an equilibrium wage rate that reflects the interaction of competitive demand and supply. As noted by Rogerson et al. (2005, p. 960), the empirical evidence suggests that 'there is simply no such thing as a centralised market where buyers and sellers of labour meet and trade at a single price, as assumed in classical equilibrium theory'.

Labour market economists have shown that introducing employer and employee search to labour market models can generate theoretical predictions that mirror observed outcomes in these markets. Much of this research has its origins in work done by the winners of the 2010 Nobel Prize in economic science, Peter Diamond, Dale Mortensen and Christopher Pissarides. These models typically consider a forward-looking individual's job-search problem – the decision of whether to look for a job based on expected future wages and the likelihood of finding a job, as well as job-search costs and any benefits from remaining unemployed. Similarly, an employer's problem about whether to post a job and search for a worker can be modelled as a function of the probability of finding a worker, the value of finding a worker to accept the job, the

expected wage that it would cost the employer, and any search costs that would be incurred. Petrongolo and Pissarides (2001) survey early matching work in labour markets, and discuss how various models differ in the wage determination process, matching function, and in the other assumptions made.

Online recruitment is generally thought to lower the costs associated with job search, in comparison to offline labour markets. When employers can browse the résumés of hundreds or thousands of potential hires that have all been screened as possessing relevant qualifications and experience for the job, it is much easier to become informed about candidates. In addition, many intermediaries lower the costs of contacting the workers, and some even facilitate employer–-employee contracting. This can all be done in front of computers from remote locations. Most models of search and matching predict that lower search costs increase match efficiency and, depending on the structure of the model, often also increase the productivity of the resulting employment matches. Both these effects increase economic output and have the potential to transform a whole range of labour market outcomes, including wages, job duration, aggregate unemployment and aggregate productivity.

Online recruitment, especially in online labour market platforms, is also changing the nature of the bargaining game between employers and workers that determines workers' wages. In traditional models of labour markets, wages are often modelled as the outcome of Nash Bargaining over the surplus generated by the transaction, relative to each party's outside option and bargaining power. One implication of the increased ease of search and matching in online markets could well be that the outside options for employers and employees, as well as their relative bargaining powers, are different than in offline markets. It could be that a given employer, when searching online rather than offline, has a choice between larger numbers of potential hires that are closer substitutes and who have fewer valuable outside options. For a given worker, on the other hand, the ability to search online may increase his or her access to potential employment opportunities. The overall consequences for the wage determination process are likely to depend on the nature of the job posting and the set of skills required in the job, as well as the matching function in the online labour market in question.

Online Labour Supply and Demand

While lower search costs in online recruitment are predicted to increase the efficiency of labour market outcomes for a given set of employers and employees, it is also likely that lower costs will affect the number and type of workers applying for jobs. As the costs of applying for jobs fall, the number of applicants for any one job is predicted to increase, and employers may find that having many more applicants makes it harder and more costly to find a good fit among the candidates. In particular, online applicant profiles tend to contain lots of information described by Autor (2001) as 'low bandwidth', meaning that the information is not helpful to employers in distinguishing between candidates. In online markets, employers have less of the 'high bandwidth' information that can be more easily gathered during inperson meetings and that allows employers to determine the quality of the match for each potential candidate.

Perhaps more importantly, in addition to increasing the number of applicants, when employers solicit applications, the composition of workers applying for jobs may change. When it is costly to apply, workers with private information about their own suitability for the job will apply only if the probability of their being hired, which is increasing in their fit, is sufficiently high. When application costs fall, candidates who judge themselves to be less well suited to the job will choose to apply, increasing the problems associated with adverse selection (Akerlof 1970). Autor (2001) forecasts that this adverse selection of lower-quality – or worse-fit – applicants into the set of candidates for any given job could work to offset efficiency gains from lower search costs. There is some empirical evidence that is consistent with the presence of adverse selection in several online markets. Among the largest OLM platforms, a large share of posted jobs are never

filled despite attracting large numbers of applications, suggesting that distinguishing between candidates remains a costly undertaking for recruiters in these markets.

However, low search costs and more competition among workers (leading to lower wages) are also likely to bring employers into the market and affect the number and type of jobs that employers post. A 2009 report by Smartsheet.com comments that many buyers of online labour services are individual employers or small companies with one-off projects and limited in-house resources. Often, the work done online via online recruitment would have been infeasible to staff through traditional labour markets. This includes tasks such as image tagging, transcription and other large volume tasks that can be completed online at relatively low cost.

Additional Features of Interest in Online Recruitment for Electronically Delivered Work

In markets where adverse selection threatens to lead to market unravelling, efficiency can be increased through the development of costly signalling mechanisms (Spence 1973). In online labour markets, it is possible that good-quality workers might find it worthwhile to agree to work at a very low wage until their type is revealed. High future wages would compensate for the cost of sending this signal only for those workers who are subsequently revealed, on the job, to be high quality. Employers, then, would be able to distinguish good-quality from bad-quality workers by offering low initial wages. In practice, however, there is some evidence that current online labour market institutions are unable to facilitate the costly signalling required to separate good from bad workers. While workers with no established reputation often bid to work at very low hourly wages, there is still unemployment among these workers and, at the same time, job postings go unfilled. One potential explanation is that hiring online workers incurs costs for employers in addition to the wages paid in any transaction, and the wages paid to workers cannot fall to levels that are low enough to induce employers to hire a worker of unknown quality. For instance, workers typically cannot bid to work for negative wages on OLMs. Some online labour market platforms are developing alternative mechanisms that allow the quality of inexperienced workers to be credibly revealed. For example, Stanton and Thomas (2012) show that inexperienced workers affiliated with the small organisations in oDesk.com called outsourcing agencies are high-quality workers. Affiliation is associated with greater employment success on the site, which suggests that affiliation acts as a credible signal of quality.

When work is undertaken remotely by workers recruited online, employers might be particularly concerned about moral hazard. For example, when the work undertaken requires a worker to have access to proprietary systems and data, an employer takes on the risk that this information will be expropriated. There are also the more standard concerns about the possibility of worker shirking on the job. The largest online labour markets have been able to develop an institutional context that discourages worker moral hazard or, at least, insures employers against it. Most OLMs operate dispute resolution systems – tending to favour the employer – and monitoring systems that reduce contractual incompleteness. Many have wellfunctioning employer feedback systems that allow workers to build valuable reputations in the marketplace and increase incentives for good performance on the job.

The low observed wages, especially in online labour market transactions between employers in developed economies and workers in low-wage countries, have led to public debate about whether these marketplaces constitute 'digital sweatshops' (Zittrain 2009). There is concern that firms hire remote workers in online markets to engage in cross-border institutional arbitrage, allowing employers to avoid their local labour market regulations. It is, however, not clear that this view is held by the workers on these sites. In his 2011 paper, Horton surveys workers on AMT and finds that they perceive online employers to be slightly fairer and more honest than offline employers.

One final issue that arises as a consequence of the growth in online recruitment for work that can be delivered electronically is that the need for physical concentration of the workforce is greatly reduced. A distributed workforce that spans the confines of a traditional workplace may also render traditional organisational hierarchies redundant. Some managerial roles that involve coordinating teams and processing information may be replaced by online communications technology. By facilitating online remote work, it is likely that developments in online recruitment have consequences for how firms are structured and for the way in which economic activity is undertaken, in general, in the global economy.

Data Availability About Market Transactions

Overall, then, online recruitment opens up new channels of communication that can be characterised as reducing search costs and affecting the bargaining power of each party, perhaps making labour supply more competitive. In labour economics, both the matching function and the bargaining function are central in determining labour market outcomes (and, thus, individual and economy-wide economic outcomes). But, in addition to changing the nature of these functions, online recruitment offers unprecedented access to micro-level data about the recruitment process that will allow the nature of these functions to be studied in much greater detail. Precisely because interactions happen electronically, at arm's length, data on the nature of these interactions can be stored and retrieved by researchers *ex post*.

As an example, it is now possible to determine the profiles that employers choose to view, how long they look at each profile, and whom they choose to contact. In OLMs, researchers can observe entire employment histories for workers and entire hiring histories for employers. In some cases, these websites collect data on the bargaining process over wages, along with both employers' and employees' outside options, as revealed by other job offers or potential hires. One remaining drawback is that firms and workers cannot generally be easily tracked across different markets. With access to all these data, it becomes feasible to observe the impact of policy experiments at a level of detail that is not practical in offline labour markets. Nonetheless, the extent to which any inferences drawn are externally valid, for example, in offline labour markets, would depend, however, on the experiment in question. Researchers should bear in mind that the type of jobs (and the type of workers) on online sites are a selected sample from the overall labour market.

Economics, Definition of

Roger E. Backhouse and Steven Medema

Abstract

Economics is difficult to define unambiguously, many definitions having been proposed as the subject has evolved. Definitions are *ex post* constructions, even rationalizations, but they can nonetheless influence what economist do and how they set about doing it. This article considers the main definitions from the late 18th century to the present, pointing out some of the ways in which changing views reflect and have influenced changes in the subject.

Keywords

Cameralism; Economic science; Economics imperialism; Economics, definition of; Institutional design; Marshall, As; Mill, J. S; Operations research; Political economy; Rational choice; Robbins, L. C; Samuelson, P. A; Scarcity; Steuart, Sir J; Value judgements

The definition of economics has evolved significantly over time, influenced by and influencing the focus of economic study. The definition often attributed to Jacob Viner, 'economics is what economists do', reflects the difficulty of providing an unambiguous definition. The problem, of course, is that definitions of the field are proposed *ex post* in an attempt to impose order upon a body of work that has grown up as economists have sought to tackle diverse practical and intellectual problems. Viner's statement suggests that there is no need for a tight, specific definition of the subject, which may explain the tendency of economists blithely to ignore definitions, and hence to not analyse them in detail, except sporadically. However, definitions of the subject do have effects through influencing what economists choose to study and the methods they think legitimate for analysing them.

The root of the word 'economics' lies in the Greek *οίκονομία*, meaning the management of a household, as in Xenophon's *Οίκονομικος*, written around 400 BC. In the 18th century, the idea of efficiently providing for the wants of a household was extended to the nation as a whole, under the heading 'political economy', the term first used for the discipline that later became economics. The first systematic English-language book on the subject was James Steuart's *An Inquiry into the Principles of Political Oeconomy* (1767, p. 16). Though Steuart made an analogy between 'providing for all the wants of a family, with prudence and frugality' and doing the same for the state, there was a difference, for the ruler of the state could not direct people in the way that the head of a household was able to do. This had the consequence that,

> The great art therefore of political oeconomy is, first to adapt the different operations of it [the state] to the spirit, manners, habits and customs of the

> people; and afterwards to model these circumstances so, as to be able to introduce a set of new and more useful institutions. (Steuart 1767, p. 16)

No doubt influenced by German Cameralism, Steuart saw institutional design as lying at the heart of political economy. This usage was followed by Adam Smith, who saw political economy as 'a branch of the science of a statesman or legislator' with two objects: providing the people with 'plentiful revenue or subsistence' and providing the state with enough revenue to provide public services (Smith 1776, p. 428).

Many of the classical economists, however, disagreed with the focus on policy, arguing that political economy was concerned with the laws that govern the production, distribution and consumption of wealth, the clearest example of this being Jean Baptiste Say, whose major work (1803) is *Traité d'économie politique, ou simple exposition de la manière dont se forment, se distribuent et se consomment les richesses* (A treatise on political economy, or a simple account of the way in which wealth is formed, distributed and consumed). This definition formed the basis for Nassau Senior's *Outline of the Science of Political Economy* (1836) in which he argued that the science was based on four propositions, the first and most important of which was 'That every man desires to obtain additional Wealth with as little sacrifice as possible' (Senior 1836, p. 26).

Neither of these definitions was acceptable to John Stuart Mill, whose 'On the Definition of Political Economy; and the Method of Investigation Proper to It', first published in 1836, was the last of his *Essays on Some Unsettled Questions of Political Economy* (1844). To define political economy as the rules for making a nation rich was to confuse 'art' and 'science'. However, it was not enough to define it as the laws relating to the production and use of wealth, for these included many physical laws that lay outside its remit. He thus favoured a more limited definition: 'The science which treats of the production and distribution of wealth, so far as they depend upon the laws of human nature' or 'The science relating to the moral or psychological laws of the production and distribution of wealth' (Mill 1844, p. 318). Mill went on to argue that even this definition was too broad, for political economy related only to man in society.

The most significant challenge to this definition of political economy as, loosely, the science of wealth, came from Alfred Marshall, who offered the well-known definition:

> Political Economy or Economics is a study of mankind in the ordinary business of life; it examines that part of individual and social action which is most closely connected with the attainment and with the use of the material requisites of wellbeing. (Marshall 1890, p. 1)

This definition is significant not so much for changing the name of the discipline to economics as for its focus on the study of mankind. For Marshall, as for many of his generation, the evolution of human character was of crucial importance: it was important to study actual human behaviour, but it was important, especially in the longer run, to consider how activities and consumption served to influence character and hence behaviour. Wants could not be taken as given but depended on activities.

In these discussions there was, as Neville Keynes pointed out, an ambiguity in the use of the word 'economic'. On the one hand it referred to attaining an end 'with the least possible expenditure of money, time and effort' (Keynes 1891, pp. 1–2) whilst on the other hand it was used as an adjective corresponding to the noun, wealth. The economists who laid most emphasis on the first of these were the Austrians – Carl Menger and his successors – who focused on economizing behaviour. It was his familiarity with this literature that led Lionel Robbins to deny originality for his much-quoted definition, 'Economics is the science which studies human behaviour as a relationship between ends and scarce means which have alternative uses' (Robbins 1932, p. 16). Robbins's definition put scarcity and choice at the centre of economic analysis. He emphasized that 'any kind of human behaviour' that demonstrates the scarcity aspect falls within the scope of economics, and that there are 'no limitations on the subject-matter of Economic Science' beyond involving 'the relinquishment of other desired alternatives' (choice) (1932, p. 17).

The significance of this definition lies in its analytical nature: instead of defining economics in terms of its subject matter, it defines it as an aspect of behaviour. In spite of Robbins's claim that he was simply describing professional practice, the initial reaction of the profession to his definition of economics, at least as it surfaced in academic journal articles and introductory textbooks (where the definition of economics was primarily discussed), was negative (for a detailed discussion, see Backhouse and Medema 2007). Throughout the 1930s and 1940s, textbook writers continued to define economics in terms more reminiscent of Mill and Marshall than Robbins, in that, even where reference was made to scarcity, this was frequently qualified: economics was described as a social science concerned with the study of wealth, of earning a living or a study of the system of free enterprise. Robbins's choice-based definition was seen as too wide, and needed to be restricted so as to rule out matters that did not come within the 'traditional' boundaries of economics. The acceptance of the Robbins definition came piecemeal. First, scarcity came to be stressed as important to the subject. The first edition of Paul Samuelson's *Economics* (1948), undoubtedly the leading textbook in the post-war period, captures well the qualified attitude with which the Robbins definition was approached. Samuelson explained that economics was about scarcity, for 'the American way of life' required more resources than were available, but he chose to define the subject in terms of 'what', 'how' and 'for whom' – that is, as concerning the production and consumption of goods and services. There is nothing here that is inconsistent with Robbins, but this approach was equally consistent with a more traditional approach. Books such as George Stigler's *Theory of Price* (1946), which adopted the Robbins definition, laid great stress on both scarcity and choice, but others carefully refrained from doing so.

It was only in the late 1950s and 1960s that the use of Robbins's definition became widespread. By the late 1960s, Samuelson's *Economics* was claiming that economists agreed on 'a general definition something like the following':

> Economics is the study of how men and society *choose*, with or without the use of money, to employ *scarce* productive resources, which could have alternative uses, to produce various commodities over time and distribute them for consumption, now and in the future, among various people and groups in society. (Samuelson 1967, p. 5).

However, support for this was still not universal. For Richard Lipsey, whose *Introduction to Positive Economics* was one of the most successful rivals to Samuelson's *Economics*, scarcity was '*one of* the basic problems encountered in *most* aspects of economics', not the entire subject (Lipsey 1963/71, p. 50). Economics also dealt with questions related to failure to achieve a point on the production possibility frontier, such as explaining unemployment, which could not be reduced to problems of scarcity.

The move by Robbins to define economics as an aspect of behaviour made it just a short step to defining economics in terms of a method – that of rational choice-which could be applied not simply to production and consumption choices, but to all of human behaviour. This move was encouraged by the tendency, in the aftermath of the Second World War, to see economics though the lens of operations research, as social engineering, in which optimization techniques were central and game theory played a significant role. It has also been argued that this move towards emphasising rational choice had ideological attractions during the Cold War. During the 1960s, economics became increasingly conceived as the 'science of choice', without reference to a particular social domain, even, at times, without reference to scarcity: the subject could encompass non-market as well as market activities. The work of Theodore Schulz and Gary Becker on human capital, James Buchanan, Anthony Downs and Gordon Tullock on political processes, and Becker on discrimination and on crime and punishment laid foundation for what came to be called 'economics imperialism', the application of economics to fields including politics, law, history, and sociology. These theoretical moves were reinforced by advances on the empirical side, where the techniques developed by, for example, James Heckman and Daniel McFadden for analysing

cross-section data sets on individuals and households were used to investigate phenomena, such as non-marital fertility, that lie outside the traditional domain of economics as concerned with market behaviour.

Robbins's definition of economics in terms of the allocation of scarce resources remains the most widely cited definition of the subject, but it has never commanded universal assent. Though scarcity can be defined in such a way as to make it true, there have always been significant numbers of economists who have considered that it does not encompass all aspects of their discipline and that qualifications or extensions are required. These result in definitions closer to those found in the 19th-century literature, focusing on phenomena such as the production and distribution of wealth. At the other end of the spectrum, there are economists for whom rational choice is more fundamental than scarcity. To this extent, then, there is no universally agreed upon definition of the subject.

The reason this does not present a problem is that economists can proceed with their work irrespective of how their subject is defined. Definitions of fields generally come only after the field is established; as fields change, so definitions change. Despite this, however, definitions can matter. As Mill recognized, questions of method and definition are linked. The clearest example of this is Robbins, who sought to derive all the main propositions of economics from the premise of scarcity. His definition, therefore, was the basis for claiming that economic theory was central to economics – that it was far more important than Marshall had believed it to be. Also significant was his reference to economic science, for the word science is far from neutral. Robbins had argued that value judgements, including those necessary to make interpersonal welfare comparisons, did not come within the scope of economic science, but belonged instead to the realm of 'political economy'. In claiming this, he was arguably attempting to clarify the status of economists' arguments, for, as he later made very clear, offering any advice on economic policy requires such value judgements. Thus if economics includes policy advice it must encompass more than economic science as Robbins defines it. However, such is the prestige of 'science' that Robbins's definition caused many economists to try to dispense with value judgements altogether, even in welfare economics. An exercise in clarification (and no doubt a critique of certain views of the subject) thus had the effect of significantly narrowing the subject. Attempting to define economics thus was not and is not simply a descriptive exercise; it has consequences for what economists do, and how they go about doing it.

Economies and Diseconomies of Scale

Joaquim Silvestre

Conceptual Issues

Definitions

We consider the unit costs of producing a (single or composite) output under a given technology (no technical change). We say that there are *economies* (or *diseconomies*) *of scale* in some interval of output if the average cost is decreasing (or increasing) there. This definition focuses on economies and diseconomies of a technical character. It is sometimes extended to cover business activities other than production (such as marketing, financing, training: see Scherer 1980).

Note that, in the case of a composite output, the proportions among the goods produced are kept constant. (A different notion, that of 'economies of scope' contemplates variations in cost as the output mix varies.) The definition of cost may, on the other hand, imply that the input proportions are adjusted in order to minimize expenditures. A related idea is that of returns to scale: here both the output and input proportions are kept fixed, and one compares the amount of (the simple or composite) output $f(x)$ produced by a given input vector x with the amount produced by vector λx, for $\lambda > 1$. *Increasing* (or *decreasing*, or *constant*) *returns to scale* are said to prevail if $f(\lambda x)$ is greater than (or smaller than, or equal to) $\lambda f(x)$. Under some conditions (see, e.g., Fuss and McFadden 1978, p. 48) increasing (or decreasing) returns to scale are equivalent to economies (or diseconomies) of scale.

If f is a strictly concave function and $f(0) \geq 0$, or if f is homogeneous of degree less than one, then decreasing returns to scale prevail. Conversely, homogeneity of degree greater than one is a sufficient condition for increasing returns to scale.

Internal and External Economies and Diseconomies

It is sometimes useful (see, e.g., section, "Perfect Competition as Price Taking Behaviour" below) to consider economies of scale that appear only at the aggregate level and not at the level of the individual firm. For example (see Chipman 1970) let there be two firms with cost functions $C_j(y_j) = k_j y_j$, $j = 1, 2$. Firm j treats k_j as a parameter, and in this sense its technology displays constant returns to scale. But suppose that k_j actually depends on the amount of output of the other firm, say $k_j = [y_i]^{\beta}$. Then the aggregate cost is $[y_2]^{\beta} y_1 + [y_1]^{\beta} y_2$. We have *external economies* if $\beta < 0$ and *external diseconomies* if $\beta > 0$.

Explaining Diseconomies and Economies of Scale

We consider diseconomies first. Decreasing returns imply that duplicating *all* inputs yields less than twice the amount of output. But an exact clone of a production process that exhaustively lists all factors of production should give exactly the same output. The failure to double the output suggests the presence of an extra input, not listed among the arguments in the production function, that cannot be duplicated. This idea goes back to Ricardo's rent as based on the impossibility of duplicating agricultural land of a given quality. Alternatively, the extra input can be interpreted as managerial skill.

Consider (see McKenzie 1959) a strictly concave production function $f(x)$, where x is an L-dimensional input vector. One can associate to it a constant returns to scale technology with $L + 1$ inputs $F(x; z)$ and a fixed level of the extra input, say $z = 1$, such that $f(x) = F(x; 1)$, i.e., f describes the amounts of output obtainable by varying the first L inputs when the 'managerial skill' is kept at the constant level $z = 1$. To this end, define $F(x; z) = zf(x/z)$. It is easy to check that F is quasiconcave and homogeneous of

degree one, i.e., constant returns to scale. Moreover, competitive profits can be viewed as the competitive reward to the 'managerial skill' (at $z = 1$, $z(\partial F/\partial z) = f(x) - \nabla f(x) \cdot x$).

A similar notion can be applied to the case of external diseconomies of scale: the extra input can then be identified with a common pool resource (say, clean water), available in a limited amount. Conversely, the extra public input may be created by the activity of the industry (say, information or specific training of the labour pool): this will generate external economies of scale.

We turn now to internal economies of scale. Koopmans (1957) reviews some controversies on this issue and remarks (p. 152 fn.3), 'I have not found one example of increasing returns to scale where there is not some indivisible commodity in the surrounding circumstances.' The following ideas have appeared in the literature.

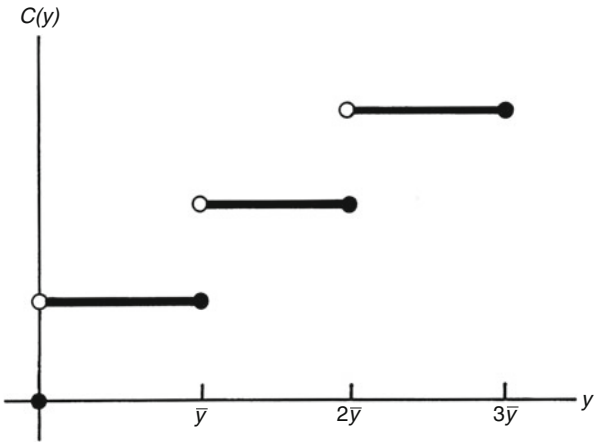
(a) *Indivisible input.* Assume for instance that the only input is some specific capital good (a machine, plant, ship or pipeline) which is indivisible in the sense that it becomes useless if physically divided. It has a given maximal capacity $\bar{y}$, but it can be underutilized to produce amounts of output less than $\bar{y}$. Then $C(y)$ looks like Fig. 1, and there are economies of scale in each of the intervals $[0, \bar{y}\,]$, $[\bar{y}, 2\bar{y}\,]$,K, $[(n-1)\bar{y}, n\bar{y}\,]$, K.

(b) *Set-up cost.* Take the only input to be labour time and assume that a certain amount of time has to be spent in preparation for the task (the set-up cost can be given several interpretations, as time spent in: (1) concentrating and getting psychologically ready for the task; (2) learning how to do it; (3) preparing the tools needed). Once the set-up cost is paid, the amount of output is proportional to the extra labour spent. This looks like Fig. 2, where increasing returns to scale prevail. Set-up costs can here be viewed as a form of indivisibility: 'readiness' (or 'information' or 'preparation') is indivisible: a 'half-ready' worker is useless.

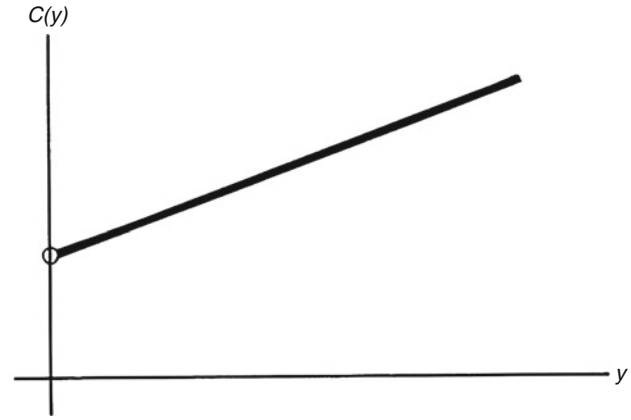
(c) The above examples can be extended to more than one capital good (or type of set-up cost). Consider, for instance, pipelines ten miles long. Only metal sheet is used in their production: the amount needed is proportional to the radius of the pipeline. Output y (flow of oil between two points ten miles apart) is proportional to the section area, a quadratic function of the radius. A pipeline of a given radius is indivisible, but one can build pipelines of any radius. The cost function looks like Fig. 3. The vertical coordinate can be interpreted as the minimal dollar outlay of a firm that buys pipelines and sells y, or as the amount of the input 'square yards of metal sheet' used by a vertically integrated firm that produces its own pipelines and sells output y.

(d) Adam Smith's division of labour. The *Wealth of Nations* attributes to the 'division of labour' the increase in output per worker. The main argument seems to be based on the set-up costs of (b) above. Smith's notion is related

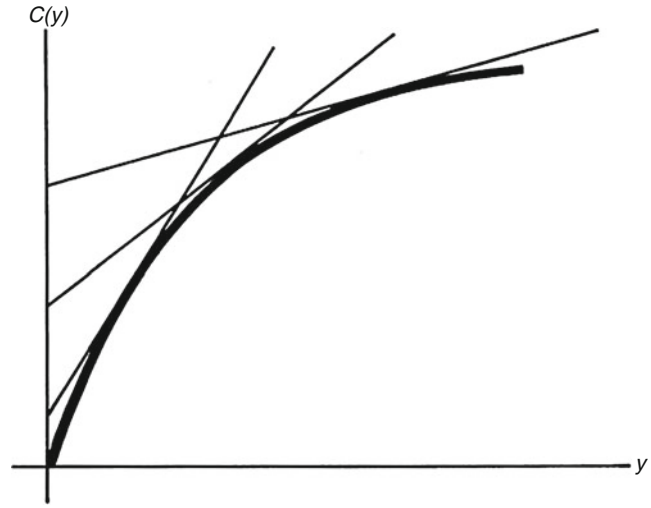
Economies and Diseconomies of Scale, Fig. 1



Economies and Diseconomies of Scale, Fig. 2



Economies and Diseconomies of Scale, Fig. 3



to another fundamental idea: the Ricardian gains from specialization and trade. But, in Arrow's (1979) words, 'the Ricardian idea of specialization lacks some characteristics of the Smithian; in Ricardo's system the abilities to produce are given. In Smith's view, specialization is more a matter of deliberate choice.'

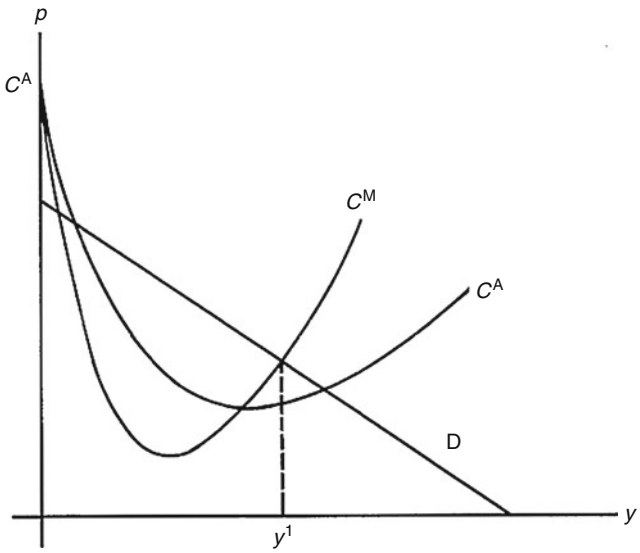
Economies of Scale and Market Structure

Perfect Competition as Price Taking Behaviour

A perfectly competitive firm is often defined as one that faces a horizontal demand curve. It is clear that, as long as $C(0) = 0$, no such firm can be at equilibrium at a level of output at which the average cost faced by the firm is decreasing.

This in particular implies that competition cannot prevail under the presence of internal economies of scale at all levels of output. The argument allows for economies of scale which are external to the competitive firm. (But the *laissez-faire* equilibrium will then typically be suboptimal.) The idea of constant (or increasing) average cost at the firm level but of decreasing average cost at the aggregate level (industry economies of scale) did play an important role in the controversies on the compatibility between economies of scale and competition (see Chipman 1965). This idea is illustrated in the example of section, "Internal and External Economies and Diseconomies"

Economies and Diseconomies of Scale, Fig. 4



above: the reader is referred to Chipman (1970) for a rigorous study.

We now focus on internal economies. Let the market demand curve be as in Fig. 4 where the average and marginal curves of a typical firm are also drawn. This situation does not *per se* violate the price taking rule: one could have, for instance, a single price taking firm operating at y^1. But such a combination of demand and cost does not fit well with the idea of perfect competition.

First, it is graphically clear that at most two firms may operate in this market. But it is then unrealistic to assume that each firm will take the market price (or the price charged by the other firm) as given.

Second, with two firms the aggregate supply curve would look like the discontinuous curve in Fig. 5, where supply at no price equals demand. Difficulties with the existence of competitive equilibrium will in general appear as soon as the average cost is somewhere decreasing.

These difficulties become more severe when considering unrestricted entry (with identical cost curves for all incumbents and entrants), a natural attribute of perfect competition: it is then required that at a 'long run' equilibrium no potential entrant have incentives to enter. But if potential entrants are themselves price takers, a long-run equilibrium implies zero profits, and typically none will exist if the cost curves are U-shaped. The entry model of Baumol et al. (1982) faces the same existence difficulties.

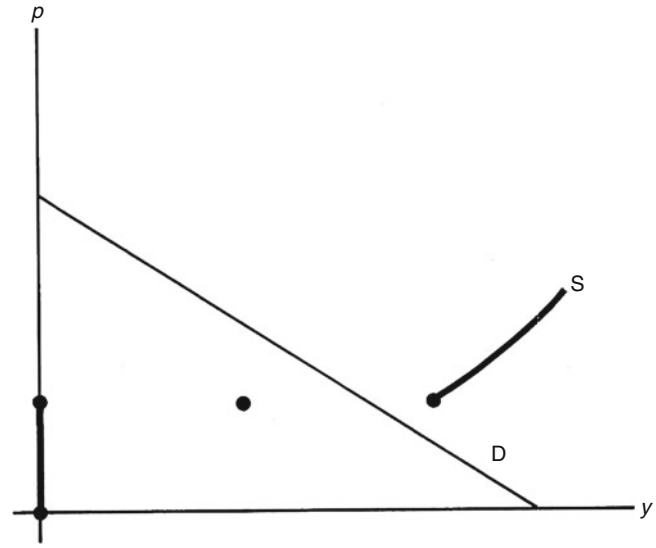
Explaining the Number of Firms

The previous discussion suggests that imperfect competition will prevail under economies of scale. On the other hand, one would expect the number of firms in an industry to be inversely related to the degree of scale economies relative to the extent of the market. Novshek's (1980) approach yields a rigorous version of this idea. Novshek considers a model of Cournot oligopoly with free entry where potential entrants adopt themselves the Cournot conjecture that active firms will keep their output constant (as proposed by Bain 1956; Sylos-Labini 1962).

An example will illustrate Novshek's method. Consider a market where the aggregate (inverse) demand is given by $p = a - b\,Y$. The number of firms in the industry is not given, but all firms, incumbent or potential, have access to the same cost function: $C(y) = g + cy$. The positive parameter g is a set-up cost: the larger g, the stronger the economies of scale. Similarly, the larger a or the smaller b, the larger the extent of the market.

Write $\hat{y}(n) = (a - c)/(n + 1)b$. This is the output of a firm at the (unique and symmetric) Cournot equilibrium for n active firms. For this

Economies and Diseconomies of Scale, Fig. 5



to be a Novshek (or Long-run Cournot) Equilibrium we require that: (a) the price be not less than average cost; this is a *no exit* condition. (b) No potential entrant has incentives to enter, i.e., $a - b(n\hat{y}(n) + y) \leq c + g/y$ for all $y > 0$: this is a *no entry* condition.

It can be checked that (a) and (b) impose lower and upper bounds on the number of firms n^* that can prevail at a Novshek Equilibrium. The no exit condition implies that $n^* + 1 \leq (a - c)/\sqrt{(bg)}$, and the no entry condition implies that $n^* + 1 \geq (1/2)(a - c)/\sqrt{(bg)}$. The expression $(a - c)/\sqrt{(bg)}$ can be viewed as an index of the 'extent of the market relative to the scale economies', since it is increasing in a and decreasing in b and g. Both bounds increase with this index, and in this sense the number of firms in an industry increases with it.

Perfect Competition as a Limit

Section, "Perfect Competition as Price Taking Behaviour" above discussed the existence difficulties that appear when production functions are not concave. These difficulties, serious for competitive equilibrium, are attenuated when considering noncompetitive equilibria: existence results for general equilibrium models can be found in Arrow and Hahn (1971) and Silvestre (1977, 1978). We focus now on partial equilibrium markets of the Novshek type (as in section, "Explaining the Number of Firms" above, but perhaps with U-shaped costs). Consider a sequence of such markets each with the same technology but with increasing size of the consumer sector (say, the parameter b of section, "Explaining the Number of Firms" above tends to zero). Equilibria turn out to exist at least for all but a finite number of markets in such a sequence.

Moreover, the equilibria of such a sequence converge to an optimal state (zero welfare loss) where the price equals the marginal cost. Such a limiting state can motivate an alternative definition of a (long-run) competitive equilibrium: this approach has the virtue of providing a justification (from the noncooperative, Cournot viewpoint) of the price taking postulate (see Mas-Colell 1980, 1981).

The convergence to long-run competitive equilibrium obtains both in the case of U-shaped cost curves and in the case of everywhere decreasing average costs (see Guesnerie and Hart 1985). This suggests a certain degree of compatibility between increasing returns and competition, in the sense that if the economy is sufficiently large, the price will be approximately equal to marginal cost in either case (even when price taking behaviour is ruled out). But Guesnerie and Hart also show that

the per capita welfare loss tends to zero much more rapidly in the U-cost case. Thus, in their words, 'there remains a sense in which everywhere increasing returns do cause greater problems for the competitive model than do increasing returns which are eventually exhausted' (p. 541).

Normative Analysis

Consider a commodity that is produced with economies of scale and that is sold in a market at a uniform price. Efficiency requires that price be equal to marginal cost. But the marginal cost is lower than the average cost. Hence, efficient pricing requires that the producing firm suffer losses. This is a basic obstacle to efficiency under increasing returns to scale. (When the commodity is not easily transferable among buyers efficiency can sometimes be achieved by means of price discrimination or nonlinear pricing schedules.)

One institutional arrangement that can in principle resolve the conflict is the public ownership of the firm. The firm can then be instructed to set prices equal to marginal costs and be subsidized for the resulting losses (see Hotelling 1938). This motivates the concept of Marginal Cost Pricing Equilibrium (see Guesnerie 1975; Beato 1982), an extension of the notion of general competitive equilibrium where firms with increasing returns to scale must follow the marginal cost pricing rule instead of profit maximization. Any efficient allocation can be attained as a marginal cost pricing equilibrium for some redistribution of income. But setting prices equal to marginal cost only guarantees the first order conditions for efficiency, not sufficient here. Thus, one should not expect that all marginal cost pricing equilibria will be efficient. A weaker desideratum is the existence of at least one efficient marginal cost pricing equilibrium compatible with a given income distribution. This turns out to obtain in some special cases (e.g., when there is a representative consumer) but not in general (see Guesnerie 1975; Brown and Heal 1979, 1980; Beato and Mas-Colell 1985).

There are, on the other hand, practical obstacles to the achievement of efficiency by a publicly owned firm. First, the absence of a profit maximization target may reduce the incentives for cost minimization. Second, the implied redistribution from taxpayers to buyers may be ethically objectionable if, say, only the wealthy are buyers. Or the public firm may find itself legally or politically constrained to break even, because it may in practice be hard to distinguish the losses mandated by marginal cost pricing from those caused by mismanagement. First best efficiency is then unattainable.

An interesting second best problem for a publicly owned or regulated firm with economies of scale is the following one (see Ramsey 1927; Boiteux 1956). Let the firm be constrained to break even, and let it sell the same commodity in two separate markets. Efficiency would require setting the prices in both markets equal to the (common) marginal cost, but this violates the break-even constraint. The second best solution requires charging different prices: the market with less elastic demand is charged a higher price.

Economy as a Complex System

Alan Kirman

Abstract

Complex systems are composed of particles or agents which interact directly with each other. The rules for this interaction may be very simple and may not reflect the sort of rationality associated with standard economic models. Interaction is not through some exogenously given market, nor does it depend on the complicated reasoning involved in game theory. A complex system exhibits emergent aggregate properties as it organizes itself, and these can explain important phenomena such as bubbles, herding behaviour, and segregation. In each case the aggregate state of the economy or market could not be predicted from the average behaviour of the individuals.

Introduction

The term 'complex system' has been widely used in science and many different definitions have

been given. Frequently, rather than give a definition of such a system, scientists have fallen back on certain characteristics that these systems exhibit. For example, emergence, self-organization, synergetics, collective behaviour, and non-equilibrium have all been cited in this regard. It is useful at the outset to make the distinction between 'complexity' and 'complex system'. The former involves a number of ideas which are important in economics and which are inherited from computer science but which will not be dealt with here. In particular, the notion of computational complexity, as it applies to decision-making or to the computation of equilibria or of dynamic programming problems is central to certain aspects of economic theory. However, here the discussion will turn on the idea of the economy as a complex, adaptive, evolving system. For economists the first real incarnation of this approach was with the introduction of deterministic chaos. The idea of complex dynamic behaviour, which would not explode or cycle or converge to a steady state, was fascinating for a science long dominated by the ideas of convergence to a static equilibrium or to a steady state. Jean-Michel Grandmont (1985) developed a simple model of 'business cycles' involving the 'tent map', which gave rise to such chaotic behaviour. Apart from the idea of the complicated dynamics involved, it was clear that the fact that a small perturbation in the initial conditions governing such a process could produce radically different trajectories was also of great intellectual interest. Two important innovations were involved. Firstly, there was the idea that the economy should be thought of as a truly dynamic system and that the initial conditions of such a system might play a key role. Secondly, there was the idea that there might be no continuity in the dependence on those initial conditions and that small changes might radically influence the trajectory of the system; hence the famous allusion to the influence of the fluttering of a butterfly's wing on the world's weather. These two aspects led economists to focus their attention on deterministic chaos. Yet in making such a close link between complexity and chaos, economists may have lost sight of the broader implications of complexity for the analysis of economic systems.

To see why this is so, consider what sort of systems are referred to as 'complex' in other disciplines. Typically they have some, or all, of the following characteristics:

- The agents are heterogeneous and interact directly with each other.
- The interaction and the information of agents are 'local'.
- The agents' behaviour is governed by simple 'rules of thumb'.
- The aggregate behaviour of the system is not that of an 'average' or representative agent.
- This aggregate behaviour 'emerges' from the complicated interaction between the individuals.

To someone who has not studied theoretical economics, all of these characteristics might seem rather intuitive as features of an economy. Yet they are very different from the traditional view. In that view, the economy is a system in which the only interaction is through the market. By this it is meant that agents react to signals from some central authority such as an auctioneer. In some way the central prices adjust so as to coordinate the activities of the agents. The system adjusts in this way until the activities are coordinated – for example, in a market economy, until aggregate demand for all products is equal to the aggregate supply of those products. Once this is achieved, the signals will not change and no agent has an incentive to modify his behaviour and to deviate from this 'equilibrium state'.

This description reveals another important feature of the collective model. No agent takes account of any influence that he might have on the outcome of the system. Many economists will react to this description by arguing that models of 'imperfect competition' abound, and in these models agents take into account the impact of their actions on the state of the system and know that other agents do the same.

This brings us to a second view of the economy, that based on game theory. Here all agents take account of the reciprocal impacts of their

actions and know that all the other agents do the same. This view is very different from the basic model of the economy. However, it is also very different from that of a complex system, since it attributes unlimited calculating capacity and depth of reasoning to the agents.

The vision of the economy as a complex system falls between these two approaches. It requires neither the central coordinating mechanism of the competitive market, nor the analytically sophisticated players of game theory.

A good comparison might be between, on the one hand, an economy organized as a set of markets that are open simultaneously, each with an auctioneer and, on the other, an ants' nest. In the former there are structured central price-giving mechanisms, and the actors gradually reveal their willingness or non-willingness to pay until the goods are allocated efficiently. In the latter, the individuals pursue their own different activities and react to each other and to outside stimuli. The system organizes itself but there is no central mechanism for achieving such organization. No one would think of trying to describe the activity of an ants' nest by examining the behaviour of the 'representative ant' yet many would describe the allocation of effort and resources as 'efficient'.

The sort of system that could be described as complex in the sense outlined above can be physical or biological or social. A typical reaction to the use of physical or biological analogies in economics or other social sciences is that social systems are populated by individuals that have intentions and undertake purposeful activity, while the other systems are composed of purposeless molecules or particles. It is therefore argued that the sort of analysis that can be applied to the other systems is not pertinent to the analysis of economic systems. This reasoning does not stand up to close inspection. If individuals follow well-defined rules and their interaction is well specified, the simple models that are used in physical and biological models can be applied. Precisely why the individuals should follow these rules is a different question.

Why is the complex systems approach of particular interest currently to economists? Economic theory has recently been attacked on two fronts. The first is the problem of aggregation: how is the behaviour of the economic system related to that of the individuals that make it up? The second is the question of why individuals behave as they do. The answer to the first question is simple but undermines much of modern macroeconomics that is based on the idea that the behaviour of the aggregate can be treated as the behaviour of an individual. Yet what is known is that the standard model of a system composed of isolated individuals each solving his own maximizing problem does not allow one to treat the system as an individual. (This is not the place to enter into the details of this assertion but the basic argument is given in Kirman 1992, and stems from the results of Sonnenschein, Mantel and Debreu). The second question is that posed by behavioural economics that questions the idea of the isolated maximizing individual. Ideas from Simon (1957) onwards have suggested that individuals reason in a limited and local way. Experiments, observation, and examination of the neural processes utilized in making decisions all suggest that *homo economicus* is not an accurate or adequate description of human decision making. (For a good survey of the relevant literature, see Rabin 1998).

All of this suggests that one might want to take a very different view of how the economy functions. In particular, the notion of a complex system as used in many parts of science seems to correspond well to an intuitive vision of the economy. Just as in an ants' nest individuals perform tasks without having any idea of the behaviour of the system, individuals in an economy go about their business and achieve a remarkable degree of coordination. Take a simple example that of bees in a hive. The tasks for house bees are varied but temperature control is one of the important duties. When the temperature is low, bees cluster to generate heat for themselves, but when it is high some of them fan their wings to circulate air throughout the hive. The general hive temperature required is between 33° and 36°C, while the brood chamber requires a constant heat of 35°. Honey has to be cured in order to ripen, and this also requires the help of circulating air. According to Crane (1999), 12 fanning bees positioned across a hive entrance 25 cm wide can produce an air flow amounting to

50–60 litres per minute. This fanning can go on day and night during the honey-flow season. Honeybees' wings beat 11,400 times per minute, thus making their distinctive buzz.

What is the lesson here for us? The typical economist's response to this phenomenon would be to consider a representative bee and then study how its behaviour responds to the ambient temperature. This would be a smooth function of temperature, wing beats going up or down with the temperature. Yet this is not what happens at all. Bees have different threshold temperatures and they are either on (beating at 11,400 beats per minute) or off. As the temperature rises more bees join in. Thus collectively with very simple 1, 0 rules the bees produce a smooth response. This sort of coordination, with each agent doing something simple, can only be explained by having a distribution of temperature thresholds across bees. Aggregation of individuals with specific local and differentiated behaviour produces smooth and sophisticated aggregate behaviour.

Nobody would argue that, in social systems, all coordination is achieved by simple interaction. Markets make a powerful contribution to economic coordination. Yet the important question is not whether such mechanisms exist, but how they come into being and develop and modify their rules. As already explained, the idea that the existence of such markets facilitates the allocation of resources is clear and generally accepted. What is not so clear is that the abstract idea of a market governed by centralized prices which are adjusted to equilibrate the market has any descriptive value. The idea of markets and networks of communication and transactions as emergent and changing phenomena is much more persuasive.

Considering the economy in this light is far from a new idea. When Adam Smith discusses the 'invisible hand' some of these notions are apparent, Pareto's work contains some of these ideas and Hayek is perhaps he who was closest to this vision. Schelling in his *Micromotives and Macrobehavior* (1978) clearly foresaw the role of self-organization. A recent development of these ideas had an introduction on the formal level by Foellmer (1974), who adopted the basic Ising model. He posited a system in which individuals were situated in space and whose preferences were dependent on those around them. This dependence was stochastic, that is, the probability of having certain preferences depended on the preferences of an individual's neighbours. If all the preferences are independently drawn, then one can determine the expected values of the equilibrium prices. However, if the interdependence of the individuals is too strong, this is no longer true. The 'law of large numbers' no longer applies. There is no easy transition from the micro to the macro level by simple averaging.

Foellmer's contribution was left to one side for a long time. However, the complexity approach to economics took on new life with the work at the Santa Fe Institute of a number of economists, physicists and other scientists such as Arthur, Bak, Blume, Durlauf, Geanakoplos, and Holland. A good picture of this sort of work can be found in *The Economy as an Evolving Complex System* (Anderson et al. 1988) and the two additional volumes that followed it (Arthur et al. 1997; Blume and Durlauf 2006).

The emphasis on the increasing 'socialization' of economics, which is intrinsic to models of interacting agents, permits one to introduce the influence of neighbours and groups on individual behaviour. Such an approach is standard in sociology and anthropology but has remained a very thinly populated field in economics. A good survey of this work is to be found in Durlauf and Young (2001).

One important part of the research on complex systems in economics has been that on *agent-based* models. Here the idea is to look at a set of linked individuals whose behaviour is influenced by and which influences their neighbours, and to simulate the dynamics of that interaction. Perhaps the best-known early example of this was Axelrod's work on the Prisoner's Dilemma, which is summarized in Axelrod (1997). He started from a series of tournaments. The strategies used for these were those that individuals proposed for a repeated Prisoner's Dilemma game. These strategies were then played against each other in a series of tournaments and the winning strategy turned out to be 'tit for tat', which is basically cooperative.

Axelrod was concerned that those who had entered his tournament had already anticipated the strategies that would be proposed by others. To overcome this he ran simulations in which new strategies were introduced into the pool of existing strategies. To do this he assigned existing strategies randomly to his artificial agents and then modified them using a 'genetic algorithm'. (For an introduction to the theory and use of genetic algorithms see Mitchell 1996). The set of strategies thus evolved in two ways. After the strategies had played against each other a new generation with more of the successful strategies was created. To these were also added new strategies generated by mutations and crossovers from the current population. After a while reciprocating strategies – that is, strategies which respond to cooperation with cooperation but which defect in the face of defection – took over, giving high payoffs. Here we have a selection process working on strategies that evolved rather than were consciously chosen. The behaviour of this basic but complex system – indeed, Axelrod refers to himself as a complexity scientist – led to the evolution of interesting aggregate characteristics. In this context it is also interesting to look at the work of Lindgren (1991), who also allowed the evolution of the strategy pool and generated periods of stability in which one strategy dominated, followed by periods of instability as the population was invaded by another strategy. This corresponds to the idea of 'punctuated equilibria' introduced into evolutionary theory by Eldredge and Gould (1972).

The notion of evolution, which can also be interpreted in the human or social context as adaptive learning, is important here. We can think of selection among a population of automata endowed with single strategies or of the idea that individuals learn to use more successful strategies.

Phase Transitions

Recalling the characterization of complex systems given above, it is worth considering a few examples.

In complex systems governed by local interactions, it may be the case that as a result of some perturbation there is a major change in aggregate behaviour. This is an important idea which is central to *statistical mechanics*. The idea here is that local interaction can generate a rapid transition from one 'phase' to another of an economic system and, more importantly, that one cannot simply apply the 'law of large numbers' to evaluate the impact of stochastic shocks. An example of this is provided by Bak et al. (1993), who consider a model of 'self-organized criticality' to describe an economy composed of a large number of productive units, each supplying a limited number of customers and, in turn, each supplied by a limited number of suppliers; both customers and suppliers are located near the productive unit.

The graph outlining the location of productive units is a cylindrical lattice. In other words, each production unit is supplied by the firms above it on a vertical line and supplies the customers next to it on a horizontal line. The demand for each final good producer is characterized by stochastic fluctuations, which affects the variability of orders received by the suppliers. Such orders (and shocks) are locally and vertically correlated, as every final producer is supplied by the two upstream firms situated a line up along the network representing the productive system. In such a context, characterized by local interaction, Bak et al. (1993) prove that, if individual costs are non-convex, the aggregation of small independent individual shocks may lead to large aggregate fluctuations in the productive system, breaking therefore the law of large numbers. These small shocks do not cancel each other out but are amplified by their interaction. Thus fluctuations at the aggregate level cannot be explained by reducing the whole model to one of an individual.

Coordination: The Schelling Model

Now let us pursue the discussion of the relationship between aggregate and individual behaviour. One of the important features of complex systems is that the system can coordinate on a solution which could not be predicted from a careful analysis of

the average or typical individual. In other words, patterns at the aggregate level can emerge as the individuals in an economy or market interact with each other. The emergence of such aggregate patterns cannot be forecast from the specification of the individual characteristics. A good example of this was provided by Tom Schelling at the end of the 1960s (for a summary see Schelling 1978). He introduced a model of segregation involving local interaction, in the sense that peoples' utility depends on the race of their neighbours. He showed that, even if people have only a very mild preference for living with neighbours of their own colour, as they move to satisfy their preferences complete segregation will occur.

The basic model is very simple. Take a large chess board, and place a certain number of black and white counters on the board, leaving some free places. A counter prefers to be on a square where half or more of the counters in his Moore neighbourhood, (the eight squares around him) are of its own colour (utility 1) to the opposite situation (utility 0). From the counters with utility zero, one is chosen at random and moves to a preferred location. This model, when simulated, yields complete segregation even though people's preferences for being with their own colour are not strong. Indeed, the result holds when individuals are happy even when more than half of their neighbours are of a colour different from their own. This result was greeted with surprise and has generated a large literature.

In fact, this result is not surprising and some simple physical theory (see Vinkovic and Kirman 2006), can explain the segregation phenomenon. Numerous variants on Schelling's original model have been developed. In particular, the form of the utility function used by Schelling, the size of neighbourhoods, the rules for moving, and the amount of unoccupied space have all been studied (see Pancs and Vriend 2007, for a survey). The physical model encompasses all of these variants.

An attempt to provide a formal structure has been made by Pollicott and Weiss (2001). They however, examine the limit of a Laplacian process in which individuals' preferences are strictly increasing in the number of like neighbours. In this situation it is intuitively clear that there is a strong tendency to segregation. Yet Schelling's result has become famous because the preferences of individuals for segregation were not particularly strong. The model is of interest because it illustrates the emergence of an aggregate phenomenon which is not directly foreseen from individual behaviour and because it concerns an important economic problem, that of segregation.

The physical analogue to Schelling's model, developed in Vinkovic and Kirman (2006), exhibits three features of the resultant segregation. The first is the organization of the system into 'regions' or clusters, each containing individuals of only one colour. Second, it explains the shape of the frontier between the regions. Lastly, in the case where several clusters of one colour may form it allows one to analyse the size distribution of the clusters.

The basic idea is simple. Think of utility as the negative of energy. Particles with high energy in the physical system correspond to individuals with low utility in the social system. Where are the unhappy or high-energy individuals to be found? Clearly they are individuals on the frontiers of clusters. Those within clusters of their own colour are happy and have no possibility of increasing their utility by moving. Those on the frontier, on the other hand, are in contact with those of the other colour and there may be too many of the latter. In this case these individuals correspond to particles with high energy. A physical system with these characteristics will seek to minimize its energy. The energy is highest on the frontier between clusters. Thus the way for the system to minimize its energy is to reduce the length of these frontiers. It will achieve this by organizing itself into clusters, and the shape and size of these clusters will depend on the precise variant of the model. In the original model the system will organize itself into two giant clusters, each composed of individuals of one colour. If we only allow people to move to currently free places, then the number of these will be important for the outcome. If there are not enough, the system will 'freeze' with many small clusters. If, on the other hand, individuals can swap places the system will segregate, but there will be perpetual movement within it. Thus, a simple physical

model generates the result obtained by Schelling and, furthermore, shows how the form of the segregation depends on the exact version of the model. (For a discussion of the emergent properties of the Schelling model see emergence).

The 'El Farol Bar'

Another interesting example of emergent coordination is that provided by Brian Arthur (1994) in his 'El Farol Bar' problem. The simple model that he develops and which has been taken up by many physicists under the name of 'the minority game' shows how individuals using rules -of thumb can come to coordinate in a way which yields a satisfactory social outcome even though no individual had any such intention. The idea is that the bar can hold 100 people. Being at the bar with fewer than 60 people is, by common consent, better than staying at home. However once attendance goes over 60 the bar becomes too crowded and home is the preferable alternative. The question then is how people will decide whether to go to the bar. Suppose that they all reason strategically. In this case they must decide in function of what their neighbours will decide. Thus, to anticipate whether there will be more than 60 people at the bar they must reflect on the strategies employed by the others. However, they must also take into account that the others are doing the same and know that the others know that they know that they are behaving in this way. This leads to an infinite regress that poses logical problems for the foundations of such game-theoretic reasoning. Rather than attribute such calculating capacities to his agents, Brian Arthur imagined that each was endowed with a set of forecasting rules based on previous attendance at the bar. Given his set of rules the individual chooses that rule which has forecast best up to the present, 'best' meaning the forecast that has the smallest sum of squared prediction errors, for example. Now, each agent uses, as information, just the attendance observed at the bar, and updates in consequence. There is no coordinating mechanism, yet the model quickly settles to the 'equilibrium' solution with 60 people at the bar with occasional small deviations. Furthermore, each agent receives a fixed number of forecasting rules, some of which may be rather stupid. Nevertheless, coordination is achieved at the aggregate level.

Some things about this model are worth noting. It is not guaranteed that all agents will learn to forecast correctly; some may persist in erroneous forecasts. The way in which the model is set up means that whenever attendance goes to 61 many people are unhappy, which is not the case when it goes to 59. This asymmetry does not prevent the achievement of collective coordination, however. Thus, the relation between satisfactory performance at the aggregate level and satisfaction at the individual level is tenuous. While many may find this example intriguing, one might enquire as to how it can be directly applied to economic problems. An interesting answer is to be found in a book by some Oxford physicists who specialize in complex systems and who apply the model to financial markets (see Johnson et al. 2003, pp. 81–136).

Financial Markets

This brings us to another important example, that of financial markets. Models of economies with interacting agents in the spirit of complex systems may, as we have just seen, be able to show how certain aggregate coordination may emerge. They may also help us to analyse some of the observed features of markets which normal economic analysis has difficulty explaining. For example, one of the major problems with the standard model of financial markets is that they do not reproduce certain well-established stylized facts about empirical price series. In standard models, where there is uncertainty about the evolution of prices, the usual way of achieving consistency is to assume that agents have common and 'rational' expectations. Yet, if agents have such common expectations, how can there be trade? Indeed there are many 'no trade' theorems for such markets. How, then, do we deal with the fact that the volume of trade on financial markets is very important and that agents do, in fact, differ in their opinions and forecasts and that this is one

of the main sources of such trade? There is also an old problem of 'excess volatility,' that is, prices have a higher variance than the returns on the assets on which they are based. One answer is to allow for direct interaction between agents other than through the market mechanism. Models reminiscent of the Ising model from physics have been used to doing this. For example, one might suggest that individuals may change their opinions or forecasts as a function of those of other agents. In simple models of financial markets such changes may be self-reinforcing. If agents forecast an increase in the price of an asset and others are persuaded by their view, the resultant demand will drive the price up, thereby confirming the prediction. However, the market will not necessarily 'lock on' to one view for ever. Indeed, under certain rather reasonable assumptions, if agents make stochastic rather than deterministic choices, then it is certain that the system will swing back to a situation in which another opinion dominates. The stochastic choices are not irrational, however. The better the results obtained when following one opinion, the higher is the probability of continuing to hold that opinion.

Such models will generate swings in opinions, regime changes and 'long memory', all of which are hard to explain with standard analysis. An essential feature of these models is that agents are wrong for some of the time, but whenever they are in the majority they are essentially right. Thus they are not systematically irrational. (For examples of this sort of model see, Lux and Marchesi 1999; Brock and Hommes 1997; and Kirman and Teyssiere 2005, and for a recent survey, De Grauwe and Grimaldi 2006). Thus the behaviour of the agents in the market cannot correctly be described as 'irrational exuberance', in the well-known words of Alan Greenspan, Chairman of the Board of Governors of the Federal Reserve from 1987 to 2006.

Economists faced with this sort of model are often troubled by the lack of any equilibrium notion. The process is always moving; agents are neither fully rational nor systematically mistaken. Worse, the process never settles down to a particular price even without exogenous shocks. Suppose that we accept this kind of model: can we say anything analytic about the time series that result? If we consider some of these models, for certain configurations of parameters they could become explosive. There are two possible reactions to this. Since we will never observe more than a finite sample, it could well be that the underlying stochastic process is actually explosive, but this will not prevent us from trying to infer something about the data that we observe. Suppose, however, that we are interested in being able, from a theoretical point of view, to characterize the long-run behaviour of the system. In particular, if we treat the process as being stochastic and do not make a deterministic approximation, then we have to decide what, if anything, constitutes an appropriate long-run equilibrium notion. Such a concept provides an answer to those who consider that complex systems, by their nature, are not amenable to formal analysis. Foellmer et al. (2005), examined the sort of price process discussed here and produced some analytical results characterizing the process. Furthermore, they provided a long-run equilibrium notion that is not the convergence to a particular price vector.

If prices change all the time, as they will do in an evolving complex system, how may one speak of 'equilibrium'? The idea is to look at the evolving distribution of prices and to try to characterize its long-run behaviour. Foellmer et al. (2005) examined the process governing the evolution of asset prices and the profits made by traders, and gave conditions under which it is ergodic, that is, the proportion of time that the price takes on each possible value converges over time and that the *limit distribution* is unique. (For a discussion of the mathematical background, see ergodicity and nonergodicity in economics). This means that, unlike the 'anything can happen' often associated with deterministic chaos, in the long run the price and profits process does have a well-defined structure.

Conclusion

To view the economy as a complex system implies a fundamental rethinking of theoretical

economics. The basic idea is that of a decentralized system with no central source of signals, whose aggregate behaviour cannot be reduced to that of an individual. Furthermore, the individuals are endowed with local information and interact directly with each other, and their behaviour can be characterized by simple rules. Such a vision is far from new in economics. Its origins can be traced back at least to Adam Smith and a long chain of economists leads from him to Hayek and Simon, who preceded the developments described here. The most recent contributions borrow heavily from other disciplines such as statistical physics and the appearance of 'econophysics' represents a shift from the path that led from classical mechanics to axiomatic mathematical models as the basic paradigm of economic theory. This sort of approach has already allowed economists to analyse problems such as contagion, neighbourhood effects, financial bubbles, and herding behaviour, none of which fits well into the standard economic framework. In addition, many of the features that are imposed on standard models emerge as a result of the interaction between agents (see emergence).

Perhaps, most importantly, looking at economies in this way provides a very different and more intuitive vision of the economy as a vast interactive system whose aggregate properties reflect the self-organization of the system and its continual adaptation. However, entrenched ideas die hard and it remains to be seen whether Steven Hawking's prediction that the 21st century will be the 'age of complexity' will hold true for economics.

Econophysics

J. Barkley Rosser Jr.

Abstract

Econophysics, a term neologized only in 1995, refers to physicists studying economics problems using conceptual approaches from physics. Certain ideas are emphasized, especially the ubiquity of scaling laws in distributions of financial returns, income and wealth, firm sizes, city sizes, and other economic phenomena. However, economists have been using many of these techniques since much earlier, and the influence of ideas from physics on economics dates as far back as 1801 at least. Arguably, if economics successfully absorbs the most useful of this work, 'econophysics' may cease to exist.

According to Bikas Chakrabarti (2005, p. 225), the term 'econophysics' was neologized in 1995 at the second Statphys-Kolkata conference in Kolkata (formerly Calcutta), India, by the physicist H. Eugene Stanley, who was also the first to use it in print (Stanley 1996). Mantegna and Stanley (2000, pp. viii–ix) define 'the multidisciplinary field of econophysics' as 'a neologism that denotes the activities of physicists who are working on economics problems to test a variety of new conceptual approaches deriving from the physical sciences'.

The list of such problems has included distributions of returns in financial markets (Mantegna 1991; Levy and Solomon 1997; Bouchaud and Cont 1998; Gopakrishnan et al. 1999; Sornette and Johansen 2001; Farmer and Joshi 2002), the distribution of income and wealth (Drăgulescu and Yakovenko 2001; Bouchaud and Mézard 2000; Chatterjee et al. 2005), the distribution of economic shocks and growth rate variations (Bak et al. 1993; Canning et al. 1998), the distribution of firm sizes and growth rates (Stanley et al. 1996a, b; Takayasu and Okuyama 1998; Botazzi and Secchi 2003), the distribution of city sizes (Rosser 1994; Gabaix 1999), and the distribution of scientific discoveries (Plerou et al. 1999; Sornette and Zajdenweber 1999), among other problems, all of which are seen at times not to follow normal or Gaussian patterns that can be described fully by mean and variance. The main sources of conceptual approaches from physics used by the econophysicists have been from models of statistical mechanics (Spitzer 1971), geophysical models of earthquakes (Sornette 2003), and 'sandpile' models of avalanches, the latter involving self-organized criticality (Bak 1996). An early physicist to assert the essential identity of statistical methods used in physics and the social sciences was Majorana (1942).

A common theme among those who identify themselves as econophysicists is that standard economic theory has been inadequate or insufficient to explain the non-Gaussian distributions empirically observed for various of these

phenomena, such as 'excessive' skewness and leptokurtotic 'fat tails' (McCauley, 2004). With their sense of creating and developing a new science based on physics that is superior to the older conventional economics, many of the econophysicists have focused their publishing efforts in physics journals, notably *Physica A*, *Physical Review E*, and *European Physical Journal B*, to name some of the most frequently used ones, along with the general science journal *Nature* and some more clearly multidisciplinary journals such as *Quantitative Finance*. However, increasingly some of the econophysicists have begun to publish jointly with economists, with some of these papers appearing in economics journals as well. This should not be surprising in that the emergence of econophysics followed fairly shortly after the influential interactions and discussions that occurred between groups of physicists and economists at the Santa Fe Institute (Anderson et al. 1988; Arthur et al. 1997), with some of the physicists involved in these discussions also becoming involved in the econophysics movement.

Now we come to a great curiosity and irony in this matter: some of the main techniques used by econophysicists were initially developed by economists (with many others developed by mathematicians), and some of the ideas associated with economists were developed by physicists. Thus, in a sense, these efforts by physicists resemble carrying coals to Newcastle, except that it must be admitted that many economists either forgot or never knew of these issues or methods. This is true of the most canonical of such models, the Pareto distribution.

The Empirical Focus on Scaling Laws (Power Laws)

If there is a single issue that unites the econophysicists it is the insistence that many economic phenomena occur according to distributions that obey scaling laws rather than Gaussian normality. Whether symmetric or skewed, the tails are fatter or longer than they would be if Gaussian, and they appear to be linear in figures with the logarithm of a variable plotted against its cumulative probability distribution. They search for physics processes, most frequently from statistical mechanics, that can generate these non-Gaussian distributions that obey scaling laws.

The canonical (and original) version of such a distribution was discovered by the mathematical economist and sociologist, Vilfredo Pareto, in 1897. Let N be the number of observations of a variable that exceed a value x with A and α positive constants. Then

$$N = Ax^{-\alpha}. \tag{1}$$

This exhibits the scaling property in that

$$\ln(N) = \ln A - \alpha \ln(x). \tag{2}$$

This can be generalized to a more clearly stochastic form by replacing N with the probability that an observation will exceed x. Pareto formulated this to explain the distribution of income and wealth, and believed that there was a universally true value for α that equalled about 1.5. More recent studies (Clementi and Gallegati 2005) suggest that it is only the upper end of income and wealth distributions that follow such a scaling property, with the lower ends following the lognormal form of the Gaussian distribution that is associated with the random walk, originally argued for the whole of the income distribution by Gibrat (1931).

The random walk and its associated lognormal distribution is the great rival to the Pareto distribution and its relatives in explaining stochastic economic phenomena. It was only a few years after Pareto did his work that the random walk was discovered in a Ph.D. thesis about speculative markets by the mathematician Louis Bachelier (1900), five years prior to Einstein using it to model Brownian motion, its first use in physics (Einstein 1905). Although the Paretian distribution would have its advocates for explaining stochastic price dynamics (Mandelbrot 1963), the random walk would become the standard model for explaining asset price dynamics for many decades, although it would be asset returns that would be so modelled rather than asset prices

themselves directly as Bachelier did originally. As a further irony, it was a physicist, M. F. M. Osborne (1959), who was among the influential advocates of using the random walk to model asset returns. It was the Gaussian random walk that would be assumed to underlie asset price dynamics when such basic financial economics concepts as the Black–Scholes formula would be developed (Black and Scholes 1973). If we let p be price, R be the return due to a price increase, B be debt, and σ be the standard deviation of the Gaussian distribution, then Osborne characterized the dynamic price process by

$$dp = Rpdt + \sigma pdB. \quad (3)$$

Meanwhile, a variety of efforts were made over a long time by physicists, mathematicians and economists to model a variety of phenomena using either the Pareto distribution or one its relatives or generalizations, such as the stable Lévy (1925) distribution, prior to the clear emergence of econophysics. Alfred Lotka (1926) saw scientific discoveries as following this pattern. George Zipf (1941) would see city sizes as doing so. Benoit Mandelbrot (1963) saw cotton prices doing so and was inspired to discover fractal geometry from studying the mathematics of the scaling property (Mandelbrot 1983, 1997). Ijiri and Simon (1977) saw firm sizes also following this pattern, a result more recently confirmed by Axtell (2001).

Economists Doing Econophysics?

Also, economists would move to use statistical mechanics models to study a broader variety of economic dynamics prior to the emergence of econophysics as such. Those doing so included Hans Föllmer (1974), Lawrence Blume (1993), Steven Durlauf (1993), William Brock (1993), Duncan Foley (1994) and Michael Stutzer (1994), with Durlauf (1997) providing an overview of an even broader set of applications. However, by 1993 the econophysicists were fully active even if they had not yet identified themselves by this term.

While little of this work explicitly focuses on generating outcomes consistent with scaling laws, it is certainly reasonable to expect that many of them could. It is true that the more traditional view of efficient markets with all agents possessing full information rational expectations about a single stable equilibrium is not maintained in these models, and therefore the econophysics critique carries some weight. However, many of these models do make assumptions of at least forms of bounded rationality and learning, with the possibility that some agents may even conform to the more traditional assumptions. Stutzer's (1994) reconciles the maximum entropy formulation of Gibbsian statistical mechanics with a relatively conventional financial economics formulation of the Black–Scholes options formula, based on Arrow–Debreu contingent claims (Arrow 1974). Brock and Durlauf (2001) formalize heterogeneous agents socially interacting within a utility maximizing, discrete choice framework. Neither of these specifically generates scaling law outcomes, but there is nothing preventing them from doing so potentially.

While some econophysicists seek to integrate their findings with economic theory, as noted above many seek to replace conventional economic theory, seeing it as useless and limited. An irony in this effort is that it has been argued that conventional neoclassical economic theory itself was substantially a result of importing 19th-century physics conceptions into economics, with not all observers approving of this (Mirowski 1989). The culmination of this effort is seen by many as being Paul Samuelson's *Foundations of Economic Analysis* (1947), whose undergraduate degree was in physics at the University of Chicago. Samuelson himself noted approvingly that Irving Fisher's 1892 dissertation (1926) was partly supervised by the pioneer of statistical mechanics, J. Willard Gibbs (1902), and as far back as 1801 Nicholas-François Canard conceived of supply and demand ontologically being contradicting 'forces' in a physics sense. So the interplay between economics and physics has been going on for far longer and is considerably more complicated than is usually conceived.

Related Trans-disciplinary Movements

Curiously but unsurprisingly given the tremendous attention given to the new econophysics movement, it has spawned imitators since 2000 in the form of *econochemistry* and *econobiology*, although these have not had nearly the same degree of development. The former term is the title of a course of study established at the University of Ulm by Barbara Mez-Starke, and was used to describe the work of Hartmann and Rössler (1998) at a conference in 2002 in Urbino, Italy (see also Padgett et al. 2003, for a more recent effort). The latter term first appeared in Hens (2002), although McCauley (2004, pp. 196–9) dismisses it as not a worthy competitor for econophysics. Nevertheless, there has long been a tradition among economists of advocating drawing more from biology for inspiration than from physics (Hodgson 1993), going back at least as far as Alfred Marshall's famous declaration that economics is 'a branch of biology broadly interpreted' (Marshall 1920, p. 637), even as Marshall's actual analytical apparatus arguably drew more from physics than from biology.

In any case, one trend we can expect for some time is an increase in coauthoring between economists and physicists within the area of econophysics (Lux and Marchesi 1999; Li and Rosser 2004). Very likely we shall eventually see the more useful ideas of econophysics coming to be absorbed into economics proper. As that comes to pass, it may also come to pass that the separate and distinct movement we now know as econophysics will cease to exist and will be forgotten, just as most economists do not think about the physics roots of standard neoclassical economic theory today.

The son of Sir Robert Eden, F.M. Eden was educated at Oxford, gaining a Master's degree in 1789. A co-founder of the Globe Insurance Company, he published in 1797 the three volumes of his investigation into the conditions of the labouring poor, *The State of the Poor*. This work was perhaps the most detailed appraisal of social legislation and its actual workings that had appeared, and the findings provided ample material for ensuing debate on the best form of dealing with poverty and pauperism. In the years that followed Eden wrote a number of pamphlets on related issues.

The greater part of *The State of the Poor* records Eden's findings relating to the actual conditions prevailing in the parishes of England. Stimulated by the high prices prevailing in 1794–5, Eden initially set out to study the condition of the poor, but later extended this to the labouring classes. He encountered at times great resistance from local parish authorities, but despite this he was able to gather a considerable amount of information on wage levels, diet and prices. This was linked to an appraisal of the nutritional value of available foodstuffs, such that it was possible to arrive at some kind of comparative assessment of levels of poverty and want. It emerged from his empirical findings that the actual conditions and treatment of the poor varied greatly from parish to parish, this in part reflecting the patchwork of legislation that had grown up over the years in relation to the pauper and the workless. He argued however that existing legislation implied a policy of support for the indigent, and that in general a civilized society had an obligation to make such provision.

Edgeworth as a Statistician

Stephen M. Stigler

Francis Edgeworth was the leading theorist of mathematical statistics of the latter half of the 19th century, though his influence was diminished by the difficulty of his exposition. He is most frequently remembered today for his work on the

Edgeworth Series, but in fact he touched on nearly every sphere of modern statistics, from the analysis of variance to stochastic models, to multivariate analysis, to the asymptotic theory of maximum likelihood estimates, to inventory theory. In some areas such as correlation, his work was decisive in the development of all that followed.

Edgeworth's first purely statistical work was published in 1883, when he began a series of papers examining the methods, rationale and philosophical foundations of probability and its application to the analysis of observational data. Most of this work appeared in the *Philosophical Magazine, Mind*, or the *Journal* of the London (later the Royal) Statistical Society. Between 1883 and 1890 he published over 30 separate papers on a wide selection of statistical topics; these works are best viewed as the tracks left by a first-rate mind as it took an excursion through territory that had already been explored. He found much that was new, but his principal occupation re-examining past works, particularly those of Laplace, to see how they might be used in social science. A major (and under appreciated) accomplishment of this period was Edgeworth's explanation of how simple significance tests could be used to compare averages. The mathematical technique was not new, but the conceptual framework was subtly different from that of the early astronomers, and while Edgeworth's (1885b) explanation may today seem elementary, it had a lasting widespread impact. In subsequent work (Edgeworth 1885c; Stigler 1978) he developed what might now be viewed as an analysis for an additive effects model for a two-way classification, and he was sensitive to the effect non-normality or serial dependence could have upon the procedures.

Edgeworth's main orientation in his inferential work was Bayesian, and he presented both philosophical and mathematical investigations of this approach. To Edgeworth, a prior distribution was based in a rough way upon experience. A uniform prior was often justified because, Edgeworth observed, we do not find a pattern in nature that tends to favour one set of values for its constants over another set. Edgeworth tempered this with a realization that inferences would frequently not be very sensitive to the prior specification (Edgeworth 1885a). When evaluating the significance of differences, however, Edgeworth reverted to a sampling theory viewpoint. One of his 1883 works includes a derivation of Student's *t*-distribution as the posterior distribution for a normal mean. From 1890 to 1893 Edgeworth, reacting to work by Galton, gave the first fully developed mathematical examination of correlation and its relation to the multivariate normal distribution (Edgeworth 1892a, b). Edgeworth showed how the constants of a multivariate normal distribution could be expressed in terms of pairwise correlation coefficients (and hence how the conditional expectation of one variable given others could be expressed in terms of correlation coefficients), and he investigated how a correlation coefficient could be estimated from data. His work gave what may be the earliest version of what has come to be called Pearson's product moment estimate (or Pearson's *r*). Incidentally, it was Edgeworth who coined the term 'coefficient of correlation', as Galton had used 'index'.

Edgeworth's work on correlation had an immense influence upon Karl Pearson, and through him upon all 20th-century work on this topic. In the 1890s, Edgeworth's statistical work became increasingly occupied by a competition with Karl Pearson as to who could best model skew data. Pearson, with his family of skew curves that included gamma distributions and a scheme (the method of moments) for selecting a curve within this family, is generally conceded to have won the contest. Edgeworth at one time or another tried three different approaches. One of these (the 'method of translation', or fitting a normal curve to transformed data) has become popular in more recent times. Another (fitting separate half-normal curves to the left and right sides of the distribution) has been largely forgotten. The third was based upon what we now call the Edgeworth Series. The essence of Edgeworth's approach was to generalize the central limit theorem by the inclusion of correction terms, terms that appeared in the derivation of the distribution of sums but which became negligible if the number of terms in the sum was large. The idea was that skew distributions found in nature

were skew because they were aggregates of relatively small numbers of non-normal components. Edgeworth was thus taking a theoretical approach, one that he felt was more appealing than Pearson's more ad hoc approach. The Edgeworth Series was foreshadowed in his work as early as 1883 (when he found it as a series solution to the heat equation), but the full development came later (Edgeworth 1905), and the labour he put into it after 1895 was immense, and largely unrewarded. His attempts to provide a methodology for fitting the series to data attracted few followers, Arthur Bowley being the only important one. Bowley's brave attempt to explain the method in his assessment of Edgeworth's work (Bowley 1928) was only marginally more readable than Edgeworth's own many efforts on this. Ironically, later statisticians (notably Harold Cramér, see Cramér 1972) have found that Edgeworth's mode of arranging correction terms was far superior to alternatives proposed by Bruns, Gram and Charlier, and the Edgeworth Series has become an important technique for approximating sampling distributions (rather than data distributions, as Edgeworth had intended).

In addition to these major themes, Edgeworth's work abounds in minor nuggets. The largest of these may be a series of papers in 1908–9 that we can now recognize as containing the germ of a proof of the asymptotic efficiency of maximum likelihood estimates. In a contentious 1935 meeting of the Royal Statistical Society this work was pointed out to R.A. Fisher by Bowley as an unacknowledged predecessor, although it seems doubtful that it had any influence on Fisher (see Pratt 1976). Of more importance was Edgeworth's work on index numbers and on the theory of banking. While his work on index numbers is more properly treated with his economic work, it is worth noting here that he was a pioneer in the application of probability to the analysis and choice of index numbers. In regard to banking, based upon statistical considerations, he promulgated in 1888 the rule that the reserves of a bank need only be proportional to the square root of its liabilities (Edgeworth 1888).

In all Edgeworth's work one is constantly coming upon minor, often paradoxical observations (see for example, Stigler 1980) that reveal the depth of his understanding, the subtlety of his thoughts, and a grasp of mathematics that seems quite at odds with his lack of formal training in the subject. Edgeworth was an independent thinker upon statistical matters, though he was perhaps the earliest to appreciate and follow up on Galton's innovative concepts of regression and correlation. Edgeworth's most important influence was upon Karl Pearson, though Pearson was chary in his recognition of this influence. Taken together, Galton, Edgeworth and Pearson shaped modern statistics to a greater degree than any other individual or group before R.A. Fisher. Edgeworth's works on statistics number at least 75, and it is rare to find one that is self-contained. Bowley (1928) made an attempt to summarize all of Edgeworth's statistical work, and he gave a bibliography of most of it. Stigler (1978, 1986) gives a more recent assessment, and comments upon different aspects of Edgeworth's work can be found in papers by Kendall (1968, 1969) and Pratt (1976).

Edgeworth Price Cycles

Michael D. Noel

Abstract

Edgeworth price cycles refer to an asymmetric pattern of prices that result from a dynamic pricing equilibrium among competing oligopolists. The resulting time series takes on a sawtooth shape – many small price decreases interrupted only by occasional large price increases. Maskin and Tirole (Econometrica 56(3): 571–599, 1988) formalized the theory, and later extensions were provided by Eckert (International Journal of Industrial Organization 21(3): 151–170, 2003) and Noel (Journal of Economics and Management Strategy 17(2): 345–377, 2008). Edgeworth price cycles are the leading theory for explaining the asymmetric price cycles that appear in many US, Canadian, Australian and European retail gasoline markets (e.g. Noel (Review of Economics and Statistics 89(2): 324–334, 2007a), Eckert (Canadian Journal of Economics 35(1): 52–77, 2002), Doyle et al. (Energy Economics 32(3): 651–660, 2010), Wang (Journal of Political Economy 117(6): 987–1030, 2009b)). While the gasoline cycles continue to generate public concern with claims of collusion often raised, the current evidence favours Edgeworth price cycles being the result of stronger competition and the source of lower retail gasoline prices.

Introduction

Edgeworth price cycles refer to an asymmetric pattern of prices that is generated by a dynamic pricing equilibrium among competing oligopolists under certain simple assumptions. Most notably, the oligopolists are assumed to compete in prices, follow Markov strategies, and face relatively high price elasticities for their good. The time series of market prices under this equilibrium takes on a sawtooth shape, with many small price decreases interrupted only by occasional large price increases. The asymmetric price pattern is repeated over and over, even in the absence of any supply or demand shocks.

Edgeworth price cycles are the leading theory behind the asymmetric price cycles that appear in many retail gasoline markets around the world. First observed in some US cities in the 1960s, they have become commonplace in many US, Canadian, Australian and European retail gasoline markets (e.g. Noel (2007a), Eckert (2002), Doyle et al. (2010), Wang (2009b)) and visually are very similar to the theoretical cycles. A single cycle is often a week or two long with amplitude up to about 10% of the price.

Two waves of literature examine these cycles empirically. The first investigates the cause of the retail gasoline price cycles. The near consensus in the literature is that the cycles are Edgeworth price cycles. The location and shape of the cycles and the behaviour of different types of firms along the cycles support the Edgeworth price cycles theory.

The second wave of literature examines the welfare effects of the cycles relative to a stable price equilibrium. The literature is young, but the results currently favour the conclusion that the price cycles are indicative of stronger competition and the source of lower prices for consumers.

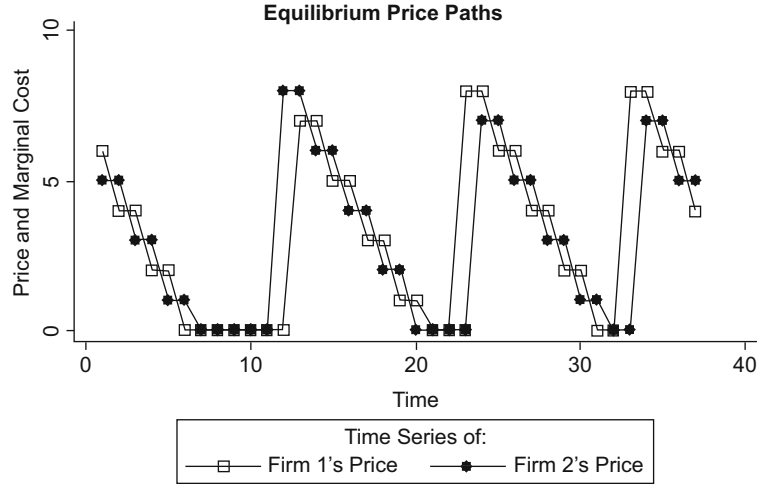
The Theory of Edgeworth Price Cycles

The notion of a competitively driven, dynamic, asymmetric price cycle dates back to Edgeworth (1925). Edgeworth was a strong critic of the Cournot model and argued that when marginal costs were increasing (or firms were capacity constrained in the extreme case), prices in oligopolistic competition would not be stable as in Cournot's model. Instead, they would change continually along an asymmetric price cycle.

Firms would undercut one another to gain market share until prices were low enough that one firm could profitably raise the price and serve the residual demand left over from the capacity constrained firm. Interestingly, Edgeworth considered his cycle a disequilibrium, as the notion of equilibrium was then equated to stable prices.

The seminal theory paper on Edgeworth price cycles is by Maskin and Tirole (1988), who gave the cycles their name. Maskin and Tirole assume two identical and infinitely lived firms with high discount factors that sell homogeneous goods and compete in prices. Firms are restricted to using Markov strategies, which in this context means that a firm's pricing decision depends only on the price of the other firm currently in effect. Demand is constant and costs are zero. Maskin and Tirole show that in this setting two possible types of Markov perfect equilibria could result. The first generates stable prices over time, while the second results in asymmetric price cycles – that is, Edgeworth price cycles – in equilibrium.

Figure 1 shows firm prices in a cycling equilibrium. The mechanism operates as follows. Starting from prices relatively high above marginal cost, firms alternately and repeatedly undercut one another's price by the smallest possible amount. Because the goods are identical, this is sufficient to fully steal total market demand. Undercutting continues until prices fall all the way to marginal cost (zero in this example). At that point, there is no gain from lowering prices further, but there is a gain from raising them. If one firm were to raise its price to a much higher level, the other firm would surely respond with a higher price too, just slightly undercutting that of the first firm. As a result, when prices are at marginal cost, firms play a war of attrition, each mixing between a higher price and maintaining the marginal cost price. Eventually, one firm relents by restoring its price to a high level, the other follows, and a new round of undercutting



Edgeworth Price Cycles, Fig. 1 Theoretical Edgeworth cycle

begins. The cycle repeats over and over even in the absence of cost and demand shocks.

The theory of Edgeworth price cycles is the leading theory for explaining the asymmetric price cycles found in retail gasoline markets. However, not all of its assumptions are well suited to retail gasoline. Retail gasoline is not perfectly homogeneous, marginal costs are not constant, there are more than two firms, and so on. To address this, Noel (2008) extends the model to allow for fluctuating costs, capacity constraints, product differentiation, triopoly situations, and other extensions. Noel shows that Edgeworth price cycles are robust when product differentiation or capacity constraints are not too strong. Noel also shows that cycles are robust to triopoly, but now with challenges in the form of false starts. These occur when the first firm to increase price abandons its high price altogether, after waiting too long for others to follow. Since false starts make it more costly for a firm to be the first to raise its price, the cycle peak and trough prices move lower and average prices fall from increased competition. In another important extension, Eckert (2003) showed that if firms share the market very unequally at equal prices (interpretable as the case of asymmetrically sized firms), Edgeworth price cycles are more likely.

Empirical Evidence of Edgeworth Price Cycles

An early criticism of the theory, dating back to at least Nichol (1935), was that the model failed to predict the experience of any known real-world markets. There has also been very limited success in generating Edgeworth cycles in laboratory experiments (Leufkens and Peeters 2008).

This all changed when – with the availability of new high-frequency and station-specific datasets – asymmetric retail price cycles were discovered in gasoline markets in many countries in the 1990s and 2000s. As of 2010, cycles have been observed in many retail gasoline markets in the USA, Canada, Australia, Norway, Germany and Belgium, with other discoveries sure to come. (Cycles had been detected in a few US cities in the late 1960s and early 1970s, but they received little attention from economists at the time and then disappeared from view for thirty more years.) Recently, inverted asymmetric price cycles have also been found in keyword advertising auctions at leading search engines (inverted because competition is among buyers instead of sellers) (Zhang 2005).

The first generation of studies in the literature sought a cause for the empirical asymmetric cycles, and the results of that literature strongly point to Edgeworth price cycles (to name a few: Castanias and Johnson (1993), Lewis and Noel (in press), Lewis (2009a, b), Doyle et al. (2010), in US retail gasoline markets; Noel (2007a, b, 2009, 2010a), Eckert (2002, 2003), Eckert and West (2004), Atkinson (2009) in Canada; Wang (2009a, b) in Australia; and Zhang (2005) in Internet auction markets). One opposing view is that of Foros and Steen (2008), who examine Norway and argue that the cycles there, although similar to those in other countries, are possibly a form of pure collusion.

The first known publication that noted asymmetric price cycles in retail gasoline was Allvine and Patterson (1974), who showed cycles in several US cities in the late 1960s and early 1970s. Castanias and Johnson (1993) reported summary statistics on the cycles in Los Angeles area and noted the resemblance between those cycles and the then newly published Maskin and Tirole (1988) theory article. In Los Angeles, a single cycle lasted about one to two months with an amplitude of roughly 25% of the price.

The first full-length scientific papers were written about Edgeworth cycles in Canada, where most large cities experienced price cycles beginning from at least the late 1980s. The cycles ranged from weekly up to bimonthly in duration and longer. Eckert (2003) showed that price volatility in retail gasoline prices in Canadian cities were consistent with the general predictions of his extension of the Edgeworth cycle model.

Noel (2007a) specifically modelled the asymmetric price movements in Canadian cities and found that a greater market share of aggressive independent firms resulted in cycles that were *faster*, *taller* and *less* asymmetric, consistent

with the theory. Noel (2007b) examined station-specific data in Toronto, Canada, and showed that behaviours of differently sized firms were also consistent with the theory. Large refiner-retailers tended to lead price increases, and smaller independents tended to lead price decreases. The duration of cycles in Toronto averaged a week and the amplitude was about 8% of the price. Atkinson (2009) found similar results with high-frequency price data in Guelph, Canada.

Retail gasoline price cycles were rediscovered in dozens of US cities in the early 2000s, although it is uncertain how long they existed prior to that. The cycles were weekly in most cities but biweekly in a few. Lewis (2009a, b) support that the cycles in the Midwest US are Edgeworth price cycles. The amplitude of the cycles averaged 7% of the retail price. Doyle et al. (2010) present further evidence that cycles were more likely with more large, price-aggressive independents, consistent with their extension of the theory.

In major Australian cities and many smaller ones, retail gasoline price cycles were weekly in duration, except in Perth where they were sometimes biweekly. Wang (2009a) estimates especially high cross price elasticities in Perth, consistent with the theory, and Wang (2009b) shows that the pattern of price increases among the leading firms is consistent with the use of mixed strategies, as predicted in a symmetric Edgeworth price cycles model.

Foros and Steen (2008) examine the cycles in Norway which share the characteristics of cycles elsewhere. They offer the opposing view that the Norwegian cycles may be a pure collusion story on the basis that the large price increases occur in a short window on late mornings and early afternoons on Mondays. While there is no direct evidence of widespread collusion in Norway or elsewhere, isolated instances of individual dealers colluding with one another can occur in cycling markets, just as they can in non-cycling markets (see Wang (2008) for the case of Ballarat, Australia, and Erutku and Hildebrand (2010) for the case of four towns in Quebec, Canada).

Edgeworth price cycles have not been well understood in many circles and the large sweeping price increases understandably raise antitrust scrutiny. The second wave of the Edgeworth price cycles empirical literature examines the impact that cycles have on price and welfare.

Most important and difficult is the question of how markups rise and fall with the presence of Edgeworth cycles. Noel (2002) shows that in Canada markups within the same city in a nearby time period (i.e. controlling for time–city effects) were one cent lower just after cycles began compared with before. The consumer gain of cycling in his sample cities is CDN$48 million per year. Doyle et al. (2010) show that in the USA, markups in cycling cities are one to two US cents per gallon lower than in non-cycling cities, controlling for market structure and other observables. Wang (2009b), however, finds that prices were 1.8 cents lower when cycles temporarily ceased in the four months after the passing of the 24 hour price change pre-notification law in Perth, Australia. Noel (2010b) notes it would not be unusual for prices to temporarily fall in such a situation, as firms jostle for position and generate a string of false starts as they adjust to the new notification requirements.

Lewis (2009a) and Lewis and Noel (in press) argue for another pro-competitive aspect to Edgeworth price cycles – that they more effectively anchor prices to wholesale costs over the long run. In non-cycling markets, the well-known rockets and feathers phenomenon is that prices rise quickly after a cost increase but fall slowly after a cost decrease (Borenstein et al. 1997). Noel (2009) and Eckert (2003) even show that in cycling markets, the presence of the asymmetric cycle can generate or magnify such an effect. However, compared to non-cycling markets, in cycling markets the cycles are effective in returning prices to costs at every trough. Lewis (2009a) shows that retail gasoline prices in US markets with Edgeworth price cycles fell much more quickly in the months after Hurricane Katrina than those cities without, for a relative gain of US$1.33 million per 100,000 people. Lewis and Noel (in press) look more comprehensively at 72 US cities and show that cost shocks are passed through two to three times faster in cities with Edgeworth price cycles than in cities

without, substantially reducing the rockets and feathers welfare loss relative to non-cycling cities.

Noel (2010a) argues for another hidden benefit of Edgeworth price cycles. Very simple purchase timing strategies can allow price elastic consumers in Toronto to easily reduce their gasoline expenditures by 4% relative to purchasing at random times. The gain would be even greater in other markets (e.g. Norway or Australia) where cycle troughs are even more easily predictable. Firm price reoptimization in response to large numbers of consumers timing the cycles could limit the gain, of course, but as the Australian experience shows, the cycles remain active and strong even when there is significant consumer awareness of them.

The greater implication of Noel (2010a) is that to the extent that consumers use purchase timing strategies that are not observed by the researcher, the benefit of Edgeworth price cycles is understated. This is because when consumers can time purchases to periods of lower prices during cycles, the more economically relevant measure of *quantity-weighted* prices is likely to be lower than the unweighted average price in markets with cycles, but the same in markets without. A comparison of average quantity-weighted prices under periods of cycling and non-cycling would then reveal a greater price advantage to consumers in markets with Edgeworth price cycles.

Conclusion

Edgeworth price cycles are asymmetric price cycles generated from equilibrium behaviour in a game of oligopolistic price competition. Firms repeatedly steal market demand from one another by undercutting down to marginal cost. Firms then sequentially increase prices back to the top of the cycle and begin undercutting again.

The empirical literature strongly favors the asymmetric price cycles in retail gasoline markets being generated by an Edgeworth price cycles process. While research continues, the weight of the current evidence also points to the conclusion that Edgeworth price cycles are indicative of stronger competition. They benefit consumers with lower and more efficient prices relative to the less controversial stable price equilibrium.

The literature on Edgeworth price cycles continues to grow. An obvious direction for future work is to search for and uncover additional examples of Edgeworth price cycles outside of retail gasoline. Further extensions to the theory can help guide this search, and conversely the findings of the search can suggest new extensions to the theory to help identify the factors most critical to cycle generation. Finally, the welfare effects of Edgeworth price cycles have only recently begun to be understood. An important direction of future research would be to study and quantify these effects further, with obvious and important antitrust and policy implications.

Abstract

Edgeworth was a major figure in the development of neoclassical economics, and one of its most original theorists, making a wide range of lasting contributions. After describing his approach to economics, this article discusses his early work in moral philosophy, which had a strong influence on his economics. His important contribution to the theory of exchange, focusing on indeterminacy and the role of the number of traders, is examined. His later work on monopoly, international trade and taxation are then briefly discussed.

Biographia

Francis Ysidro Edgeworth (1845–1926) was born in Edgeworthstown in County Longford, Ireland. The background into which he was born was dominated by the 'larger than life' figure of his grandfather Richard Lovell Edgeworth (1744–1817), whose life was documented in a two-volume memoir (1820) by his oldest daughter, the famous novelist Maria Edgeworth (1767–1849). Richard Lovell's many scientific and mechanical experiments were helped by his strong association with the Lunar Society of Birmingham, whose members included Watt, Bolton, Wedgwood, Priestley, Darwin and Galton. In addition, Maria's scientific acquaintances included Davy, Humboldt, Herschel, Babbage, Hooker and Faraday. The marriage of F. Y. Edgeworth's cousin Harriet Jessie Edgeworth (daughter of Richard Lovell's seventh and youngest son Michael Pakenham, 1812–1881) to Arthur Gray Butler provided links with another large and eminent academic family. These connections extend even further since A. G. Butler's sister, Louisa Butler, married Francis Galton, a cousin of Charles Darwin.

Richard Lovell's sixth son, and 17th surviving child, was Francis Beaufort Edgeworth (1809–1846), who met his wife, Rosa Florentina Eroles, the daughter of a Spanish refugee from Catalonia and then aged 16, while on the way to Germany to study philosophy; they married within three weeks in 1831. F. Y. Edgeworth was their fifth son. With his family background and his knowledge of French, German, Spanish and Italian, Edgeworth had wide international sympathies. On the family background, see Butler and Butler (1927) and for a full-length treatment of Edgeworth's work, see Creedy (1986).

Edgeworth was educated by tutors in Edgeworthstown until the age of 17, when in 1862 he entered Trinity College Dublin to study languages. In 1867 Edgeworth entered Exeter College, Oxford, but after one term transferred to Magdalen Hall. He transferred to Balliol in 1868, where in Michaelmas 1869 he obtained a first in Literae Humaniares. He was called to the bar in 1877, the same year in which his first book, *New and Old Methods of Ethics,* was published. Edgeworth applied unsuccessfully for a professorship of Greek at Bedford College, London, in 1875, but later lectured there on English language and literature for a brief period from late 1877 to mid-1878. He had earlier lectured on logic, mental and moral sciences and metaphysics to prospective Indian civil servants, at a private institution run by a Mr. Walter Wren. In 1880 he applied for a chair of philosophy, also unsuccessfully, but began lecturing on logic to evening classes at King's College London. Soon after the publication of his second book, *Mathematical Psychics,* in 1881, he applied for a professorship of logic, mental and moral philosophy and political economy at Liverpool. Testimonials for two of Edgeworth's applications were given by Jevons (see Black 1977, V, pp. 98, 145) and Marshall.

Edgeworth had to wait until 1890 until he obtained a professorial appointment: this was at King's College London, where he succeeded Thorold Rogers in the Tooke Chair of Economic Science and Statistics. In the next year, 1891, he again succeeded Rogers, this time to become Drummond Professor and Fellow of All Souls' College, Oxford, a position he held until his

retirement in 1922. Edgeworth therefore finally settled in Oxford at the age of 46 in what was to become one of the most illustrious British chairs in economics. At the same time he became the first editor of the *Economic Journal.* He was editor or co-editor from its first issue until his death. He was supported by Henry Higgs from 1892 to 1905, when the latter became the Prime Minister's Private Secretary, with further assistance provided at a later stage by Alfred Hoare. Keynes was a co-editor for 15 years. After a tremendously creative period of the late 1870s and 1880s, Edgeworth had become firmly established as the leading economist, after Marshall, in Britain.

In addition to his work in economics, Edgeworth began a series of statistical papers in 1883. He was President of section F of the British Association in 1889, a position he held again in 1922. Edgeworth's work on mathematical statistics played an increasingly important role. Indeed, of about 170 papers which he published, approximately three-quarters were concerned with statistical theory. He became a Guy Medalist (Gold) of the Royal Statistical Society in 1907 and was President of the Society during 1912–1914. His main contributions to statistics concern work on inference and the law of error, the correlation coefficient, transformations (what he called 'methods of translation'), and the 'Edgeworth expansion'. The latter, a series expansion which provides an alternative to the Pearson family of distributions, has been widely used (particularly since the work of Sargan 1976) to improve on the central limit theorem in approximating sampling distributions. It has also been used to provide support for the bootstrap in providing an Edgeworth correction. Edgeworth's work in probability and statistics has been collected by McCann (1996). His third and final book was *Metretike*: *or the Method of Measuring Probability and Utility* (1887). These contributions are not examined here; see Bowley (1928) and Stigler (1978).

Approach to Economics

A dominant characteristic of Edgeworth's approach to economics is that it is mathematical, characterized by an original use of techniques, although he does not appear to have received a formal training in mathematics. However, he came to economics from moral philosophy. The central question of distributive justice, rather than simply the application of mathematics, dominated his attitude towards economics. His main argument was that mathematics provided powerful assistance to 'unaided' reason, and could check the conclusions reached by other methods. Thus:

> He that will not verify his conclusions as far as possible by mathematics, as it were bringing the ingots of common sense to be assayed and coined at the mint of the sovereign science, will hardly realise the full value of what he holds, will want a measure of what it will be worth in however slightly altered circumstances, a means of conveying and making it current. (1881, p. 3)

Edgeworth's approach contrasts sharply with that of Marshall. The contrast between Edgeworth and Marshall was neatly summarized by Pigou as follows:

> During some thirty years until their recent deaths in honoured age, the two outstanding names in English economics were Marshall ... and Edgeworth... Edgeworth, the tool-maker, gloried in his tools . . . Marshall, on the other hand, had what almost amounted to an obsession for hiding his tools away. (Pigou and Robertson, 1931, p. 3)

Although both men turned to economics from mathematics and moral philosophy, Marshall generally used biological analogies, and was concerned with developing maxims. In contrast, Edgeworth generally used mechanical analogies, and was more concerned with developing theorems.

In the 1880s and 1890s the deductive method encountered a great deal of criticism, especially from the 'Historical School' of economists. Edgeworth's defence of the deductive method often involved showing how other economists had advocated its use. His interest in the natural sciences often led him to make comparisons with scientific laws, and especially to show that the physical sciences also relied on abstraction and approximation.

Edgeworth argued carefully that the assumptions used in economics are often untestable, and he therefore took precautions against the

accusation of 'plucking assumptions from the air'. He was conscious of the fact that the difficulty is in making the crucial abstractions which make the particular problem under consideration tractable, but which are not question begging. His attitude to many a priori assumptions was directly related to his approach to statistical inference. In *Mathematical Psychics,* for example, he referred to 'the first principle of probabilities, according to which cases about which we are equally undecided ... count as equal' (1881, p. 99). This was then transferred to economics. The appropriate assumption was that all feasible values, say, of elasticities, were equally likely, until evidence is obtained. Hence, 'There is required, I think ... in order to override the a priori probability, either very definite specific evidence, or the consensus of high authorities' (1925, ii, pp. 390–391). This also illustrates Edgeworth's attitude to authority and his many allusions to the views of other leading economists. Price (1946, p. 38) referred to his frequent 'reference to authority for . . . support of tentative opinion waveringly advanced'.

Edgeworth was also prone to stress negative results. For example, in discussing taxation, where the criterion of minimum sacrifice does not alone provide a simple tax formula, he stated:

> Yet the premises, however inadequate to the deduction of a definite formula, may suffice for a certain negative conclusion. The ground which will not serve as the foundation of the elaborate edifice designed may yet be solid enough to support a battering-ram capable of being directed against simpler edifices in the neighbourhood. (1925, p. 261)

Edgeworth's position as editor of the *Economic Journal* enabled him to combine both his critical attitude and his appetite for a wide range of reading. He contributed 32 book reviews, and in sending books to other reviewers he would include 'apposite remarks on particular points in the text' (Bowley 1934, p. 123). These reviews should also be placed beside his 17 reviews in the Academy, and 131 articles in the original *Palgrave's Dictionary of Political Economy.* Furthermore, Edgeworth's later articles in the *Economic Journal,* such as those on international trade and on taxation, took the form of extended commentaries on contemporary work.

Early Work in Moral Philosophy

Before turning to economics, Edgeworth published a brief note in *Mind* in 1876, and his first (privately printed) book on New and Old Methods of Ethics in 1877. The description by Keynes of Edgeworth's first book could just as well be applied to his other two books:

> Edgeworth's peculiarities of style, his brilliance of phrasing, his obscurity of connection, his inconclusiveness of aim, his restlessness of direction, his courtesy, his caution, his shrewdness, his wit, his subtlety, his learning, his reserve –all are there full-grown. Quotations from the Greek tread on the heels of the differential calculus. (Keynes, 1972, p. 257)

The main focus of this early work, strongly influenced by the great Cambridge philosopher Henry Sidgwick (1838–1900), was to examine in detail the implications of utilitarianism for the optimal distribution of resources. Edgeworth's special and original contribution was to apply advanced mathematics to this problem. Edgeworth's approach was dominated by his utilitarianism, but the influence of contemporary psychological research and the impact of evolutionary ideas can also be traced. Both aspects led to explicit consideration of differences between individuals and changes which take place over time.

Edgeworth was also influenced by the major fierce debates in the last half of the 19th century between egoism, evolutionism, idealism, intuitionism, and of course utilitarianism. His brand of utilitarianism became extremely eclectic, and embraced the majority of the above principles (except for those of the Hegelian idealists) while regarding utilitarianism as the 'sovereign principle'. His note in *Mind* discussed Matthew Arnold's views of Joseph Butler, who had examined egoism at great length. Arnold had argued that Butler's term 'self love' should be interpreted to mean 'the pursuit of our temporal good'. However, Edgeworth argued that egoism and utilitarianism could be subsumed under the same principle. He believed Butler to be saying, 'duty and interest are perfectly coincident; for the most part in this world, but entirely and in every

instance, if we take in the future and the whole' (1876, p. 571).

Edgeworth generally distinguished between 'impure' and 'pure' utilitarianism. In the latter case individuals are assumed to be concerned with the welfare of society as a whole. The former case in fact corresponds more closely with a 'short term' version of egoism. Economic exchange can usefully be analysed in terms of 'jostling egoists', but he believed that ultimately individuals would evolve to become pure utilitarians. A reason for believing that individuals would make such a transition was later to be developed by Edgeworth in the form of his contractarian justification of utilitarianism as the appropriate principle of distributive justice.

Edgeworth's early utilitarianism was influenced by his wide knowledge of work in experimental psychology. In his books of 1877 and 1881 there are many references to the work of Delboeuf, Fechner, Helmholtz, Weber and Wundt. These references occur in the context of discussing the nature of utility functions and, although Edgeworth at this time was not aware of the earlier work of Jevons, the same range of psychological work was also important to Jevons. Edgeworth in 1877 explicitly suggested, in connection with Fechner, that an additive form would not be appropriate.

A further aspect, of Edgeworth's utilitarianism is his attitude towards authority. An important issue for early utilitarians involved the nature of inductive evidence about the consequences of acts. Most people cannot know the full consequences of their acts, so that rules of moral conduct must be followed (in contrast with intuitionism where individuals are assumed to have immediate consciousness of moral rules). In arriving at such rules, the opinions of highly regarded individuals are taken to be credible though it may not be possible to show conclusively that they are 'correct'. Edgeworth argued, for example, that 'we ought to defer even to the undemonstrated dicta and opinions of the wise, who have a power of mental vision acquired by experience' (1925, ii, p. 149).

Edgeworth defined the problem of determining the optimal utilitarian distribution as follows: 'given a certain quantity of stimulus to be distributed among a given set of sentients . . . to find the law of distribution productive of the greatest quantity of pleasure' (1877, p. 43). In treating this problem mathematically Edgeworth used Lagrange multipliers, without any explanation, and concluded that, 'unto him that hath greater capacity for pleasure shall be added more of the means of pleasure' (1877, p. 43). In using Lagrange multipliers Edgeworth was also careful to discuss possible complications, referring to the possibility of multiple solutions and explicitly discussing corner solutions and inequality constraints.

Further complexities were then examined, where Edgeworth emphasized that utilitarianism implies equality of the 'means of pleasure' only under a special set of assumptions, and in the general case the prescribed solution will be some form of inequality. In dealing with the distribution of effort, he argued not surprisingly that most work should be provided by those most capable of providing it. In a yet more general treatment of the problem, Edgeworth used the calculus of variations, but again provided the reader with virtually no help in following his mathematical argument. Edgeworth's analysis of the utilitarian optimal distribution was continued in his paper on 'The Hedonical Calculus' (1879), which was later reprinted as the third part of *Mathematical Psychics.*

Early Work in Economics

The turning point in Edgeworth's work was his introduction to Jevons in 1879 by a mutual friend James Sully, who in 1878 moved to Hampstead, where Edgeworth had lodgings in Mount Vernon and where Jevons also lived; see Sully (1918, pp. 180, 223). His first knowledge of Marshall came from Jevons, who 'highly praised the then recently published Economics of Industry' (in Pigou 1925, p. 66). Edgeworth became interested in the problem of the indeterminacy of the rate of exchange, arising from the existence of only a small number of transactors. This led rapidly to Edgeworth's second and most important

book *Mathematical Psychics*: *An Essay on the Application of Mathematics to the Moral Sciences* (1881), which was clearly written in a state of considerable enthusiasm for his new subject. This slim volume of 150 pages was known only to a small group of experts. Marshall's review began, 'this book shows clear signs of genius, and is a promise of great things to come' (Whitaker 1975, p. 265). Jevons began by stating that 'whatever else readers of this book may think about it, they would probably all agree that it is a very remarkable one' (1881, p. 581). It was not until the middle of the 20th century that many of its central ideas began to be more fully appreciated.

Part 1 of *Mathematical Psychics* (1881, pp. 1–15) was devoted mainly to a justification of the use of mathematics in economics where precise data are not available. There is probably no other 'apology' in the whole of economic literature which compares with Edgeworth's plea for the application of mathematics. For example, when considering individual utility maximization:

> Atoms of pleasure are not easy to distinguish and discern; more continuous than sand, more discrete than liquid; as it were nuclei of the just-perceivable, embedded in circumambient semi-consciousness. We cannot count the golden sands of life; we cannot number the 'innumerable smile' of seas of love; but we seem to be capable of observing that there is here a greater, there a less, multitude of pleasure-units; mass of happiness; and that is enough. (1881, pp. 8–9)

Great stress was placed on comparison with Lagrange's 'principle of least action' in examining the overall effects produced by the interactions among many particles. The connection with Edgeworth's analysis of competition, involving interaction among a large number of competitors to produce a determinate rate of exchange, is central here. The fact that in the natural sciences so much could be derived from a single principle was important for both Jevons and Edgeworth. But Edgeworth took this to its ultimate limit in arguing that the comparable single principle in social sciences, that of maximum utility, would produce results of comparable value. Referring to Laplace's massive work, *Mécanique Céleste,* he suggested that:

> 'Mécanique Sociale' may one day take her place along with 'Mécanique Celeste' [sic], throned each upon the double-sided height of one maximum principle, the supreme pinnacle of moral as of physical science … the movements of each soul, whether selfishly isolated or linked sympathetically, may continually be realising the maximum energy of pleasure, the Divine love of the universe. (1881, p. 12)

Jevons's work in the *Theory of Political Economy* involved the application of very basic mathematics and of psychological research to the analysis of exchange in competitive markets. In addition to this direct stimulus, Edgeworth was also influenced by an anonymous review of Jevons's book in the *Saturday Review* (1871).

The crucial development following Edgeworth's contact with Jevons was not simply the realization that mathematics could be used to examine equilibrium in exchange. Rather, it was that in his analysis Jevons explicitly assumed, through his 'law of indifference', that all individuals take the equilibrium prices as given, that is, outside their control. In using this law as 'one of the central pivots of the theory', Jevons stated that, 'there can only be one ratio of exchange of one uniform commodity at any moment' (1871, p. 87). His theory was explicitly limited to the static equilibrium conditions. He deliberately excluded the role of the number of competitors from his analysis via the awkward notion of the 'trading body', following correspondence with Fleeming Jenkin (1833–1885), who raised the question of indeterminacy with just two traders; see Black (1977, iii, pp. 166–78). Jenkin could not see why two isolated individuals should accept the price-taking equilibrium, whereas Jevons wished to consider the behaviour of two typical individuals in a large market.

In a section on 'Failure of the Laws of Exchange', Jevons discussed cases in which some indeterminacy would result. His most notable example was of house sales, where it was suggested that indeterminacy would result from the discrete nature of the good being exchanged. The *Saturday Review* article took exception to this, suggesting that indeterminacy 'is really owing in our opinion to the assumed absence of competition' (see Black 1981, p. 157). The stress

on indeterminacy was also influenced by Marshall's discussion of wage bargaining: Edgeworth (1881, p. 48 n.1) referred to Thornton's comparison of the determination of prices in Dutch and English auctions, and cited Alfred and Mary Paley Marshall's joint book on the *Economics of Industry* (1879).

It was this gap in Jevons's analysis that Edgeworth set out to fill. His achievement was to show the conditions under which competition between buyers and sellers, through a barter process, leads to a 'final settlement' which is equivalent to one in which all individuals act independently as price takers. As he later stated (1925, p. 453), 'the existence of a uniform rate of exchange between any two commodities is perhaps not so much axiomatic as deducible from the process of competition in a perfect market'.

Exchange and Contract

Having argued that 'the conception of Man as a pleasure machine may justify and facilitate the employment of mechanical terms and Mathematical reasoning in social science' (1881, p. 15). Edgeworth moved on to the analysis of the 'economical calculus', the starting point of which was the assumption that 'every agent is actuated only by self-interest' (1881, p. 16).

In modern economic analysis the analytical tools invented by Edgeworth in 1881, such as the indifference map and the contract curve, are now used in a vast range of contexts. They were introduced by Edgeworth to examine the nature of barter among individuals. He wanted to see if a determinate rate of exchange would be likely to result in barter situations where it is assumed only that individuals wish to maximize their own utility, considered solely as a function of their own consumption. With full knowledge of individuals' utility functions, and their initial endowments of goods, would it be possible to work out a 'determinate' rate of exchange at which trade would take place? Edgeworth's direct statement of the problem is as follows:

> The PROBLEM to which attention is specially directed in this introductory summary is: How far contract is indeterminate – an inquiry of more than theoretical importance, if it show not only that indeterminateness tends to [be present] widely, but also in what direction an escape from its evils is to be sought. (1881, p. 20)

Edgeworth began his analysis of this problem by taking the simplest case of two individuals exchanging fixed quantities of two goods. The basic framework is that described by Jevons, where the first individual holds all of the initial stocks of the first good, and the second individual holds all the stocks of the second good. He wrote the utility functions of each individual in terms of the amounts exchanged rather than consumed, using the general utility function ('utility is regarded as a function of the two variables, not the sum of two functions of each', 1881, p. 104). He then immediately defined the contract curve and indifference curves, in that order.

In the sentence which follows Edgeworth's introduction of the general utility function, he raised the question of the equilibrium which may be reached with 'one or both refusing to move further'. In barter the conditions of exchange must be reached by voluntary agreement, or contract, between the two parties, and of course it is fundamental that no egoist would agree to a contract which would make him worse off than before the exchange. The question thus concerns the nature of the settlement reached by two contracting parties. He immediately answered that contract supplies only part of the answer so that 'supplementary conditions . . . supplied by competition or ethical motives' are required, and then wrote the equation of his famous contract curve (1881, pp. 20–1).

The problem of obtaining the equilibrium values of x and y which, 'cannot be varied without the consent of the parties to it' was stated as follows: 'It is required to find a point (x, y) such that, in whatever direction we take an infinitely small step, $[U_A]$ and $[U_B]$ do not increase together, but that, while one increases, the other decreases' (1881, p. 21). The locus of such points 'it is here proposed to call the contract-curve'. Edgeworth's alternative derivations of the contract curve

involved the movement, from an arbitrary position, along one person's indifference curve; 'motion is possible so long as, one party not losing, the other gains' (1881, p. 23). He thus used the Lagrange multiplier method of maximizing one person's utility subject to the condition that the other person's utility remains constant.

In the diagram drawn by Edgeworth (1881, p. 28) he did not use a box construction. Furthermore the only indifference curves shown fully were those which each individual is able to reach in isolation, and which therefore specify the limits beyond which each is not prepared to move. Also part of the offer or reciprocal demand curves of each individual were drawn on the same diagram, although they were not defined until ten pages later.

After presenting the results for the two-person two-good case, Edgeworth (1881, p. 26) examined the contract curve in the case where three individuals exchange three goods, stated that it is given by the 'eliminant', and then gave three lines of three sets of partial derivatives. In fact, the contract curve in this context is defined by $\left|\frac{\partial U_i}{\partial x_j}\right|$, where $\frac{\partial U_i}{\partial x_j}$, is the marginal utility of person i with respect to good j, but Edgeworth did not use the modern notation for determinants and did not set the Jacobian equal to zero. This early use of determinants in economics would probably have confused many of his readers.

The Problem of Indeterminacy

The concepts of indifference curves and the contract curve therefore help to specify a range of 'efficient exchanges' of goods between individuals. The essential feature of the analysis from Edgeworth's point of view is precisely that there is a range rather than a unique point: 'the settlements are represented by an indefinite number of points' (1881, p. 29). At any particular settlement, the rate of exchange is expressed simply in terms of the amount of one good which is given up in order to obtain a specified amount of the other good. Hence the existence of a range of efficient contracts means that the rate of exchange is 'indeterminate'. The rate of exchange achieved in practice will thus depend to a large extent on bargaining strength. It was this result which led Edgeworth to make his often quoted remark that 'an accessory evil of indeterminate contract is the tendency, greater than in a full market, towards dissimulation and objectionable arts of higgling' (1881, p. 30).

Edgeworth argued that his analysis of indeterminacy in contract between two traders could be applied to a very wide variety of contexts. In particular, the tendency of large groups to form 'combinations', as in the case of trade unions and employers' associations, would serve to increase the extent of indeterminacy. The general applicability of his analysis of contract and indeterminacy was summarized by Edgeworth as follows:

> What it has been sought to bring clearly into view is the essential identity (in the midst of diversity of fields and articles) of contract; a sort of unification likely to be distasteful to those excellent persons who are always dividing the One into the Many, but do not appear very ready to subsume the Many under the One. (1881, p. 146; Plato's expression 'the one in the many' was later used by Marshall as the motto for his 1919 book on *Industry and Trade*.)

Having shown the possibilities of indeterminacy, Edgeworth then went on to show how 'the escape from its evils' requires either competition or arbitration.

Competition and the Number of Traders

The central question which Edgeworth was trying to resolve in the second part of *Mathematical Psychics* was that of the conditions necessary to remove the indeterminacy which exists in the case of barter between two traders. The question naturally arises as to the extent to which this indeterminacy is the result of the absence of competition in the simple two-person market. Edgeworth thus quickly moved on to the introduction of further traders.

In Edgeworth's earlier problem of two traders exchanging two goods, the definition of a range of

efficient exchanges (along the contract curve) is of course analytically separate from the question of whether or not two isolated traders would actually reach a settlement on the contract curve. However, these two aspects were not clearly separated by Edgeworth because at the beginning of his analysis he introduced his stylized description of the process of barter: this is the famous 'recontracting' process. Edgeworth did not wish to assume that individuals initially have perfect knowledge. Instead, he supposed that, 'There is free communication throughout a normal competitive field. You might suppose the constituent individuals collected at a point, or connected by telephones – an ideal supposition, but sufficiently approximate to existence or tendency for the purposes of abstract science' (1881, p. 18). The knowledge of the other traders' dispositions and resources could be obtained by the formation of tentative contracts which are not assumed to involve actual transfers, and can be broken when further information is obtained. Edgeworth introduced this in typical style:

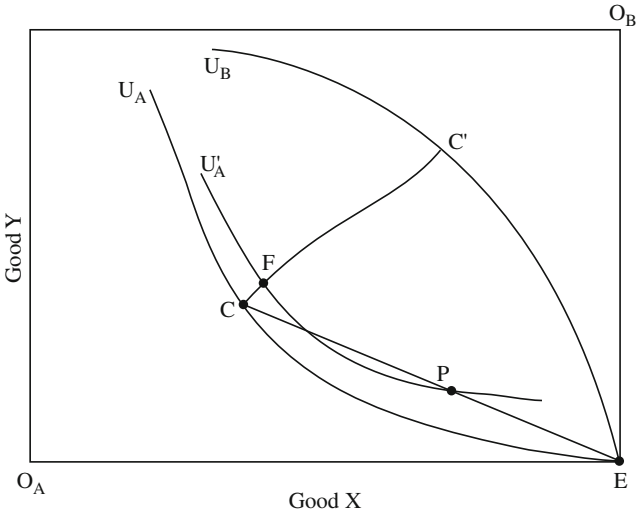
> 'Is it peace or war?' asks the lover of 'Maud', of economic competition, and answers hastily: it is both, pax or pact between contractors during contract, war, when some of the contractors without the consent of others recontract. (1881, p. 17; the allusion here is to Alfred Tennyson's poem *Maud*: *A Monodrama,* part 1, verse VII.)

An important role of the recontracting process is thus to disseminate information among traders. It allows individuals who initially agree to a contract, which is not on the contract curve, to discover that an opportunity exists for making an improved contract according to which at least one person gains without another suffering.

However, the real importance of the recontracting process lies in the fact that it allows for Edgeworth's analysis of the role of the number of individuals in a market. With numerous individuals, the recontracting process makes it possible to analyse the use of collusion among some of the traders. Individuals are allowed to form coalitions in order to improve bargaining strength. Recontracting enables the coalitions to be broken up by outsiders who may attract members of a group away with more favourable terms of exchange.

Edgeworth's analysis was extremely terse and the following discussion does not therefore follow his own presentation. The analysis begins by introducing a second person A and a second person B. The new traders are assumed to be exact replicas of the initial pair, with the same tastes and endowments. This simplification is useful because the dimensions of the Edgeworth box and the utility curves are identical for each pair of traders. Hence, it enables the same diagram to be used as in the case when only two traders are considered in isolation. Two basic points can be stated immediately. First, in the final settlement all individuals will be at a common point in the Edgeworth box. Second, the settlement must be on the contract curve. The first point arises because if two individuals have identical tastes then their total utility is maximized by sharing their resources equally. It is useful to consider other types of contract which will eventually be broken, in order to illustrate the way in which the introduction of additional traders provides a role for some kind of competitive process.

The major question at issue is whether the range of indeterminacy along the contract curve is reduced by the addition of these traders. Consider Fig. 1 and suppose that when A_1 and B_1 are trading independently of A_2 and B_2, trader B_1 has all the bargaining power and is able to appropriate all the gains from trade by pushing A_1 to the limit of the contract curve at point C. Suppose also that the same applies to A_2 and B_2. If the two pairs of traders are then able to communicate with each other, A_2 can now simply refuse to trade with B_2 at C. With no transaction costs, A_2 was previously indifferent between trading at C and consuming at the endowment point, E. This endowment position is effectively the 'threat point' of the As: it is the position in which they would find themselves if the bargaining process were to break down. But A_2 no longer needs to remain in isolation after refusing to trade with B_2, and instead can trade with A_1, after A_1 has traded with B_1 at C and has therefore obtained some of good Y. The two As can share their stocks of X and Y equally, arriving at point P; such an equal division maximizes their total utility.



Edgeworth, Francis Ysidro (1845–1926), Fig. 1 Two pairs of traders

By reaching point *P,* halfway between *C* and *E,* the convexity of the indifference curves implies that they are both better off than anywhere on the no-trade indifference curve. The two As would be on a higher common indifference curve, and thus better-off, if they could consume at a point along the *CPE* which is to the north-west of point *P* However, they do not have enough resources to move beyond the halfway point *P.*

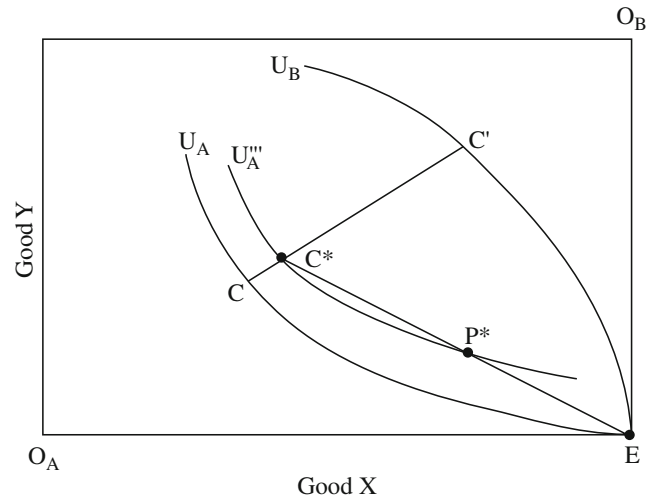
Trader B_2, who has been isolated, cannot prevent such a bargain. Thus B_1 is at *C*, both *A*s are at *P* and B_2 is at the initial endowment point *E*. In this situation B_1 has no incentive to change, but B_2 has a strong incentive to offer a better deal to one of the *A*s than the one offered by trader B_1. So long as B_2 offers one of the *A*s, say A_2, a trade on the contract curve which allows A_2 to reach a higher indifference curve than U'_A, the initial agreement with B_1 will be broken and recontracting will take place.

The implication is that the ability of the *A*s to turn to someone else, rather than deal with a single trader, means that the *B*s now compete against each other. However, trader B_1, who cannot prevent the recontracting, has an incentive to make yet a better offer. Hence, the recontracting process continues. The stylized process of recontracting with the two *B*s competing against each other will produce a final settlement at the point *C** in Fig. 2. This has the property that the indifference curve U'''_A passes through *C** and *P**, where *P** is halfway between *C** and *E*. This means that the two *A*s are indifferent between *C** and *P**, and since they cannot both reach any point between *C** and *P** along the line *C** *E,* they are unable to improve on *C**. Hence there is no need to leave one of the *B*s in isolation and the two *B*s will trade with the two *A*s at point *C**.

This argument has shown that at the final settlement all traders are at a common point on the contract curve and the limit has moved inwards along the old contract curve. The analysis can be repeated by starting with an alternative situation whereby the *A*s are initially assumed to be able to appropriate all the gains from trade. The point *C*′ would then no longer qualify as a point on the new contract curve. The introduction of the additional pair of traders means that the contract curve shrinks, and the range of indeterminacy involved in barter is correspondingly reduced.

The extent to which the contract curve shrinks when the additional pair of traders is introduced is influenced by the fact that the *A*s cannot get further than halfway along a ray from a point on the contract curve to the endowment position.

However, if there are three pairs of *As* and three pairs of *B*s, the repetition of the above analysis involves two of the *A*s dealing with two of the *B*s at a point on the contract curve. The two *A*s then share their resources equally with the remaining



Edgeworth, Francis Ysidro (1845–1926), Fig. 2 The new limit to the contract curve

A while the third *B* is isolated. The *A*s are able to consume together at a point which is two-thirds of the way along the ray from the initial endowment position to the point on the contract curve where the trade involving the two *A*s and two *B*s takes place.

With *N* pairs, the *A*s can reach a proportion $\frac{(N-1)}{N}$ of the way from the endowment point to the contract curve. Thus as *N* increases, the values of *k* approaches unity. This means that the *A*s can reach all the way from *E* to the contract curve, so that the final settlement must be such that the indifference curve is tangential to the ray from the origin. *A* final settlement with many traders is therefore shown in Fig. 3 as point *P* on the contract curve. The effect of working in from the point C' would lead to an equivalent result for an indifference curve of the *B*s, shown as U_B^*.

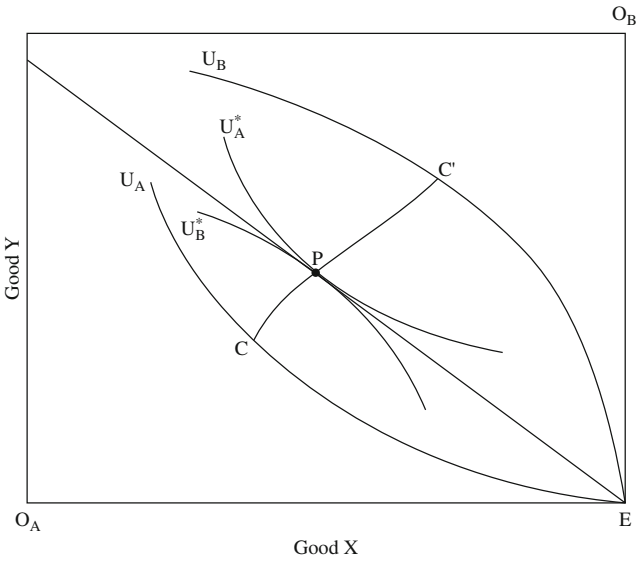
The result is that the final settlement looks just like a price-taking equilibrium. The figure illustrates the case where there is a single price-taking equilibrium. If there are multiple equilibria, the recontracting process causes the number of final settlements, with sufficiently large *N,* to shrink to the number of price-taking equilibria. (For discussion of utility functions involving multiple equilibria, and comparison of bargaining, competitive and utilitarian solutions, see Creedy 1994a.) This argument relating to the shrinking contract curve, first established by Edgeworth, is often referred to as the *limit theorem.*

After Edgeworth's terse discussion, he stated:

> If this reasoning does not seem satisfactory, it would be possible to give a more formal proof; bringing out the important result that the common tangent to both indifference curves . . . is the vector from the origin. (1881, p. 38)

The price-taking solution is necessarily on the contract curve. This gives rise to what is now referred to as the 'first fundamental theorem' of welfare economics -that a price-taking equilibrium is Pareto efficient. Furthermore, the use of price-taking provides a considerable reduction in the amount of information required by traders when compared with the recontracting process. Given an equilibrium set, individuals need to know only the prices of goods, whereas in the recontracting process they have to learn a considerable amount of information about other individuals' preferences and endowments. But Edgeworth placed more stress on the equivalence of the competitive price-taking solution with a recontracting barter process involving large numbers.

Given that coalitions among traders are allowed in the recontracting process, a price-taking equilibrium cannot be blocked by a coalition of traders. In this sense the competitive equilibrium is robust. The argument that a complex process of bargaining among a large number of individuals produces a result which replicates a price-taking equilibrium, allowing for the free flow of



Edgeworth, Francis Ysidro (1845–1926), Fig. 3 Final settlement with many traders

information using recontracting and enabling coalitions of traders to form and break up, is an important result that is far from intuitively obvious. The recontracting process can be said to represent a competitive process, and the contract curve shrinks essentially because of the competition between suppliers of the same good, although it is carried out in a barter framework in which explicit prices are not used (although rates of exchange are equivalent to price ratios).

The price-taking equilibrium, in contrast, does not actually involve a competitive process. Individuals simply believe that they must take market prices as given and outside their control. They respond to those prices without any reference to other individuals. But the result is that the price-taking equilibrium looks just like a situation in which all activity is perfectly coordinated.

Edgeworth suggested that similar results apply when some of the assumptions are relaxed. Thus, 'when we suppose plurality of natures as well as persons, we have to suppose a plurality of contract-curves . . . Then, by considerations analogous to those already employed, it may appear that the quantity of final settlements is diminished as the number of competitors is increased' (1881, p. 40). He then briefly considered different numbers of *A*s and *B*s, concluding that 'the theorem admits of being extended to the general case of unequal numbers and natures' (1881, p. 43). However, some of the results do not hold in the general case; for example, equality within the group of *A*s no longer holds when there are unequal numbers of *A*s and *B*s. A considerable number of articles have been written, since the late 1950s, examining various aspects of the Edgeworth recontract model under different assumptions.

Reciprocal Demand Curves

It has been mentioned that Edgeworth included in his diagram (1881, p. 28) the reciprocal demand curve, or offer curve, of each individual, although such curves were then called 'demand-and-supply curves'. Edgeworth mentioned them only briefly in the text (1881, p. 39), but the lack of emphasis is understandable since in imperfect competition they are not relevant. Edgeworth's contribution was to provide the basic 'analytics' of the offer curve in terms of indifference curves, whereby it is 'the locus of the point where lines from the origin touch curves of indifference' (1881, p. 113).

When there is a lack of competition, giving rise to indeterminacy, there is nothing to ensure that individuals will trade on their offer curves and, as Edgeworth argued, 'the conceptions of demand and supply at a price are no longer appropriate'

(1881, p. 31). It is this general preference, in favour of the analysis of barter in noncompetitive situations, to which Marshall objected and which led to the controversy discussed below.

The Utilitarian Calculus

Having shown how indeterminacy can be removed by increasing the number of traders, Edgeworth turned to consider the role of arbitration in resolving the conflict between traders, in a 'world weary of strife' (1881, p. 51). The principle of arbitration examined was, not surprisingly, the utilitarian principle, which Edgeworth had earlier used to examine the optimal distribution. However, the new context of indeterminacy led him to a deeper justification of utilitarianism as a principle of distributive justice. Having arrived at this new link between 'impure' (egoistic) and 'pure' utilitarianism, Edgeworth had only to reorientate his earlier analysis of optimal distribution, contained in his paper in *Mind* of 1879.

The need for arbitration with indeterminacy had been stated by Jevons as follows:

> The dispositions and force of character of the parties ... will influence the decision. These are motives more or less extraneous to a theory of economics, and yet they appear necessary considerations in this problem. It may be that indeterminate bargains of this kind are best arranged by an arbitrator or third party. (1871, pp. 124–5)

Edgeworth's statement of the same point was as usual rather less prosaic: 'The whole creation groans and yearns, desiderating a principle of arbitration, and end of strifes' (1881, p. 51). Edgeworth argument involved two steps. First, he showed that the principle of utility maximization places individuals on the contract curve, because the first-order conditions are equivalent to the tangency of indifference curves.

> It is a circumstance of momentous interest that one of the in general indefinitely numerous settlements between contractors is the utilitarian arrangement ... the contract tending to the greatest possible total utility of the contractors. (1881, p. 53)

Edgeworth recognized that this result was not sufficient to justify the use of utilitarianism as a principle of arbitration. It is only a necessary condition of a principle of arbitration that it should place the parties somewhere on the contract curve. Edgeworth's justification for utilitarianism as a principle of justice, comparing points along the contract curve, was as follows:

> Now these positions lie in a reverse order of desirability for each party; and it may seem to each that as he cannot have his own way, in the absence of any definite principle of selection, he has about as good a chance of one of the arrangements as another... both parties may agree to commute their chance of any of the arrangements for ... the utilitarian arrangement. (1881, p. 55)

The important point to stress about this statement is that Edgeworth clearly viewed distributive justice in terms of choice under uncertainty. He argued that the contractors, faced with uncertainty about their prospects, would choose to accept an arrangement along utilitarian lines. A crucial component of this argument, also clearly stated by Edgeworth in this quotation, is the use of equal a priori probabilities.

The importance to him of this new justification of utilitarianism cannot be exaggerated. Indeed the whole of *Mathematical Psychics* seems to be imbued with a feeling of excitement generated by his discovery of a justification based on a 'social contract'. This provided the crucial link between 'impure' and 'pure' utilitarianism in a more satisfactory way than his earlier appeal to evolutionary forces.

Edgeworth believed that he had provided an answer to an age-old question, stating 'by what mechanism the force of self-love can be applied so as to support the structure of utilitarian politics, neither Helvetius, nor Bentham, nor any deductive egoist has made clear' (1881, p. 128). Nevertheless this argument was neglected until restatements along similar lines were made by Harsanyi (1953, 1955) and Vickrey (1960). The maximization of expected utility, with each individual taking the a priori view that any outcome is equally likely, was shown to lead to the use of a social welfare function which maximizes the sum of individual utilities. This approach is now usually described as 'contractarian neo-utilitarianism'.

In discussing the utilitarian solution as a principle of arbitration in indeterminate contract, Edgeworth did not clearly indicate in 1881 that the utilitarian solution of maximum total utility could specify a position which makes one of the parties worse off than in the no-trade situation. This was nevertheless later made explicit when, after proposing arbitration along utilitarian lines, he added 'subject to the condition that neither should lose by the contract' (1925, ii, p. 102). This possibility of course depends largely on the initial endowments of the individuals.

Later Work in Economics

After the publication of *Mathematical Psychics*, Edgeworth concentrated increasingly on mathematical statistics, in particular on the problem of statistical inference, but, following his appointment to the Drummond Chair at Oxford, Edgeworth again made important contributions to economics, although this work mainly involved reactions to, and discussions arising from, the later work of other authors.

Demand and Exchange

In the *Principles of Economics* (1890, Appendix F) Marshall included a brief discussion of Edgeworth's analysis of barter, and produced a figure showing the contract curve. During the following year, in the course of a review written in Italian (translated in Edgeworth, 1925, ii, pp. 315–19), Edgeworth criticized Marshall for not having dealt sufficiently with the problem of indeterminacy. The basic problem was that Marshall, using a model in which a series of trades are allowed to take place at disequilibrium prices, believed he had shown that prices will eventually settle at the price-taking equilibrium. However, the argument was not transparent.

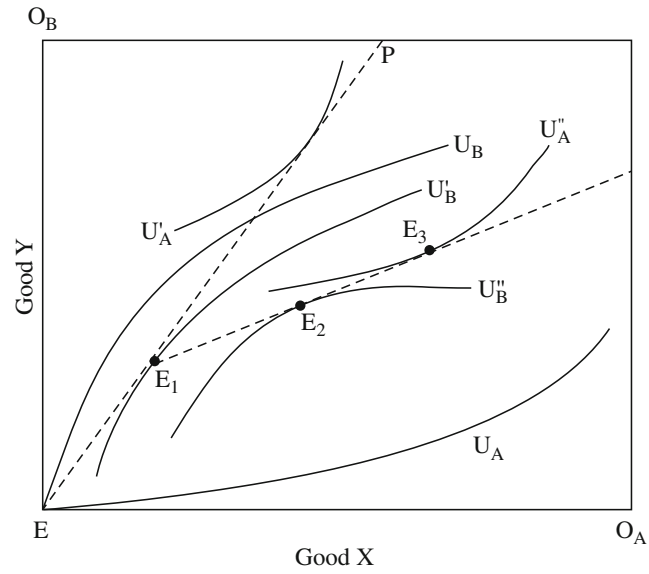
The adjustment process involves moving from the initial endowment point in a series of trades, where trading at 'false' prices is allowed at each step. The process must conclude with both individuals at a point on the contract curve. A feature of the process is the assumption that each stage or iteration of the sequence involves Pareto improvements: individuals trade only if it makes them better off. Furthermore, it involves trading at the 'short end' of the market, that is, the minimum of supply and demand. This arises from the impossibility of forcing any individual either to buy or sell more than desired at any price.

An example of two disequilibrium trades is shown in Fig. 4, where the endowment moves from E to E_1, and then to E_2. With a price line represented by EP, there is an excess supply of good X as person A tries to reach the indifference curve U'_A and person B wishes to reach U'_B. Trade takes place at E_1, the short end of the market. Point E_1 then becomes the new endowment point. At the second trading stage, the price of X must be lowered to induce person B to purchase more. At a price represented by the line E_1P_1 through the new endowment point, the excess supply is lower than formerly and trade takes place at E_2. Comparing U'_A and U'_B with U''_A and U''_B with UA and UB respectively, it can be seen that E_2 is a Pareto improvement relative to E_1. It is also clear that person A is better off the slower the fall is in the price of X relative to Y at each stage.

The combination of Pareto-efficient moves at each stage and an adjustment process such that an excess supply leads to a price reduction, and vice versa, produces a stable process that converges to an equilibrium somewhere on the contract curve. (This type of sequence of disequilibrium trades was later used by Launhardt; see Creedy 1994b.)

The basic problem was that Marshall believed that his assumption of an additive utility function, combined with the assumption that the marginal utility of one good is constant for both individuals, guaranteed a determinate price, if the good having constant marginal utility was money. Indeed, this case was mentioned by Edgeworth (see 1925, ii, p. 317 n.1). The contract curve is a straight line parallel to the y axis (where this good is the one with constant marginal utility), along which the rate of exchange is constant. So the equilibrium price does not depend on the sequence of trades. However, Edgeworth's point was that the total amount spent on good x remains indeterminate.

There was a later, though much milder, disagreement between Marshall and Edgeworth



Edgeworth, Francis Ysidro (1845–1926), Fig. 4 Disequilibrium trades

over the so-called Giffen good. In a book review, Edgeworth argued that, 'even the milder statement that the elasticity of demand for wheat may be positive, though I know it is countenanced by high authority, appears to me so contrary to a priori probability as to require very strong evidence (1909, p. 104). The 'authority' was of course Marshall (1890, p. 132), who replied directly to Edgeworth that, 'I don't want to argue ... But... the matter has not been taken quite at random' (Pigou 1925, p. 438). Marshall gave a numerical example involving a journey travelled by two methods, where the distance travelled by the cheaper and slower method must increase when its price increases. For further details, see Creedy (1990).

It has been mentioned that Edgeworth introduced the generalized utility function. An implication is that it allows for complementarity, although Edgeworth did not explicitly consider this in 1881. The first formal definition of complementarity is attributed to Auspitz and Lieben, and it was used by Edgeworth in his paper on the pure theory of monopoly, and also by Pareto: this amounts to what is now called 'gross' complementarity, defined in terms of cross-price elasticities. It is also sometimes referred to, using the initials of the four people mentioned above, as ALEP complementarity.

The first major criticism came from Johnson (1913), who pointed out that the criterion was not invariant with respect to monotonic transformations of the utility function. His treatment was extended by Hicks and Allen (1934), so that the modern definition involves 'net' complements in terms of compensated price changes. There is no symmetry between gross substitutes and complements as only the matrix of (compensated) substitution elasticities is assumed to be symmetric.

Monopoly and Oligopoly

In a paper first published in Italian in 1897, and not translated until the collected *Papers* (1925), Edgeworth examined several problems relating to monopoly. He began his discussion with Cournot's (1838) example of the 'source minérale' in which there are 'two monopolists' (that is, duopolists), each owning a spring of mineral water. It would be natural for Edgeworth to expect an indeterminate price in this 'small numbers' context. Cournot had arrived at a determinate solution for price and output, but Edgeworth showed that 'when two or more monopolists are dealing with competitive groups, economic equilibrium is indeterminate' (1925, p. 116). The daily output from each spring was assumed to be limited to identical fixed amounts, delivery costs were zero and all consumers had the same demand

curve (purchasing one unit only of output). Hence demand is $n(1 - p)$ where n is the number of customers and p is the price. Cournot's solution was that the price would be $p = 1/4$, but Edgeworth argued that one of the 'monopolists' had an incentive to raise the price back to $p = 1/2$, which is the revenue maximizing price, so that there is not a determinate price. He argued that:

> at every stage ... it is competent to each monopolist to deliberate whether it will pay him better to lower his price against his rival as already described, or rather to raise it to a higher . . . for that remainder of customers of which he cannot be deprived by his rival. . . . Long before the lowest point has been reached, that alternative will have become more advantageous than the course first described' (1925, p. 120)

Edgeworth went on to say 'the matter may be put in a clearer light', and he then defined what are now called the reaction curve and isoprofit lines (in that order) for variations in prices. However, it was not until Bowley's (1924) discussion that these matters began to be presented in a more transparent manner.

Edgeworth then considered the case of complementary demand within the context of 'bilateral monopoly', where the two goods are demanded in fixed proportions for use in the production of a further article. An interesting feature is that he wrote the equations of the reaction curves and explicitly dealt with what are now called conjectural variations, reflecting the extent to which one duopolist is expected to change price in response to changes made by the second duopolist. In discussing this problem Edgeworth also introduced the further important concept of the 'saddle point', which he called the 'hog's back', clearly indicating its importance for stability.

The No-Profit Entrepreneur

Walras (1874, p. 225) had introduced the concept of the entrepreneur who neither gains nor loses. This result applied only to the competitive equilibrium, where there are no incentives for entrepreneurs to enter any industry. This does not of course mean that there are no profits, in the accounting sense, since the returns to homogeneous units of inputs of organization and management services are subsumed in the costs of the firm.

Edgeworth's criticisms of this concept of the no-profit entrepreneur, reproduced in his *Papers* (1925), recognized that with Walras's assumptions there was nothing illogical about the argument. The theory simply means that nothing remains 'after the entrepreneur has paid a normal salary to himself' (1925, pp. 26, 30). Furthermore, 'if [the general expenses] are taken into account, the argument becomes a fortiori. For why should not a substantial remuneration for the entrepreneur be included in the general expenses of the business' (1925, ii, p. 469). Edgeworth's difference with Walras was to some extent 'only verbal', but he was also unhappy with the idea that entrepreneurship is homogeneous and divisible.

The Theory of Taxation

In the 1890s Edgeworth produced two surveys of considerable importance. These surveys, of the pure theory of taxation and of the pure theory of international values, were both published in the *Economic Journal* and subsequently reproduced (with alterations) in his *Papers* (1925, vol. ii). Each survey consisted of three separate parts, and displayed a staggering breadth of knowledge and command of the subject. They represent his most serious attempts to produce any kind of synthesis of a branch of economic literature. Edgeworth began his survey with the rather strong statement that 'the science of taxation comprises two subjects to which the character of pure theory may be ascribed; the laws of incidence, and the principle of equal sacrifice' (1925, p.64). He then considered a variety of special cases and contexts of tax incidence. The basic framework for incidence analysis was the simple partial equilibrium approach, still used in many basic textbooks, in which the incidence depends on the relative values of supply and demand elasticities.

The basic approach to incidence analysis actually stemmed from the important paper by Jenkin (1871). It suggests that in general the price of the taxed good will either remain constant (in the extreme case of inelastic supply) or will increase. However, this result ignores interrelationships

among commodities. Edgeworth showed that, when such interrelationships are explicitly allowed, there are some circumstances in which the price of the taxed good will actually fall. When discussing this 'paradox', Edgeworth reproduced his argument which had in fact been explored in more detail in his paper on monopoly, published in Italian in the same year (translated in Edgeworth, 1925, *i,* pp. 111–42). Edgeworth first stated his 'tax paradox' in the following terms:

> when the supply of two or more correlated commodities – such as the carriage of passengers by rail first class or third class – is in the hands of a single monopolist, a tax on one of the articles – e.g. a percentage of first class fares – may prove advantageous to the consumers as a whole. . . . The fares for all the classes might be reduced. (1925, p. 139)

Edgeworth regarded this result as an example of a situation where, 'the abstract reasoning serves as a corrective to what has been called the "metaphysical incumbus" of dogmatic laisser faire' (1925, *i,* p. 139; see also 1925, ii, pp. 93–4). Essentially the two commodities must be substitutes in consumption and production, and the result is partly brought about by the fact that the monopolist has an incentive to increase the supply of the untaxed commodity. Edgeworth also recognized that the result could occur in competitive markets (see 1925, p. 63). As with many of Edgeworth's original results, this tax paradox was not a subject of continuous development. Its main practical importance perhaps arises from the fact that in the early 1930s it attracted the attention of Hotelling (1932). For further discussion of the paradox, see Creedy (1988).

The section of the taxation survey which attracted most immediate attention was Edgeworth's discussion of the various 'sacrifice' theories of the distribution of the tax burden, and his qualified support for progressive taxation. Edgeworth's attitude to taxation was similar to that of the major classical economists in that he rejected a benefit approach, on the argument that taxation is not an economic bargain governed by competition. Thus in his view the problem was to determine 'the distribution of those taxes which are applied to common purposes, the benefits whereof cannot be allocated to particular classes of citizens' (1925, p. 103). A principle of justice is thus required. His approach can be seen as marking a crucial stage in the transition towards a 'welfare economics' view of public finance, rather than using a special set of 'tax maxims' such as the famous criteria laid down by Adam Smith.

Not surprisingly, Edgeworth (1925, p. 102) argued along neo-contractarian lines set down in *Mathematical Psychics* that the utilitarian arrangement would be accepted by individuals uncertain of their own prospects and taking an equal a priori view of the probabilities. He suggested that

> each party may reflect that, in the long run of various cases ... of all the principles of distribution which would afford him now a greater, now a smaller proportion of the sum-total utility obtainable . . . the principle that the collective utility should be on each occasion a maximum is most likely to afford the greatest utility in the long run to him individually

Having established the use of utilitarianism as a principle of distributive justice, Edgeworth then succinctly stated the main argument:

> The condition that the total net utility procured by taxation should be a maximum then reduces to the condition that the total disutility should be a minimum . . . it follows in general that the marginal disutility incurred by each taxpayer should be the same. (1925, p. 103)

The implication is that, if all individuals have the same cardinal utility function, after-tax incomes would be equalized. Edgeworth also clearly recognized that, if there is considerable dispersion of pre-tax incomes relative to the total amount of tax to be raised, where there is 'not enough tax to go around' (1925, ii, p. 103), the equimarginal condition cannot be fully satisfied unless there is a 'negative income tax' which raises the incomes of the poorest individuals to a common level. Thus, 'the acme of socialism is for a moment sighted' (1925, p. 104). But Edgeworth immediately considered the practical limitations to such high progressive taxation. The following quotation illustrates one of Edgeworth's favourite metaphors, his respect for Sidgwick, his attitude to authority, his views on utilitarianism and the

applicability of pure theory, and of course his unmistakable style:

> In this misty and precipitous region let us take Professor Sidgwick as our chief guide. He best has contemplated the crowning height of the utilitarian first principle, from which the steps of a sublime deduction lead to the high tableland of equality; but he also discerns the enormous interposing chasms which deter practical wisdom from moving directly towards that ideal. (1925, p. 104)

Among the various limitations, Edgeworth noted differences in individual utility functions, population effects, the disincentives to work, growth of culture and knowledge, savings, and of course the problem of evasion.

International Trade

Edgeworth's survey of the pure theory of international values was in some ways responsible for a change of emphasis in the approach to trade theory, despite the fact that it contained few original analytical contributions. Indeed, he said that, 'Mill's exposition of the general theory is still unsurpassed' (1925, p. 20), and acknowledged further that, 'what is written ... after a perusal of [Marshall's] privately circulated chapters . . . can make no claim to originality' (1925, p. 46). Edgeworth saw trade theory as an application of the general theory of exchange:

> The fundamental principle of international trade is that general theory ... the Theory of Exchange ... which ... constitutes the 'kernel' of most of the chief problems in economics. It is a corollary of the general theory that all the parties to a bargain look to gain by it . . . This is the generalised statement of the theory of comparative cost. (1925, p. 6)

Thus the gains from trade are analogous to the gains from exchange in simple barter and 'It is useful . . . to contemplate the theory of distribution as analogous to that of international trade proper' (1925, p. 19). Hence trade theory is to Edgeworth simply one more application of the general method of *Mathematical Psychics.* In directly applying the theory of exchange to that of trade, Edgeworth was quite content to use community indifference curves without clearly specifying how aggregation might be carried out. He said only that 'by combining properly the utility curves for all the individuals, we obtain what may be called a collective utility curve' (1925, p. 293).

One of Edgeworth's criticisms of Mill (1848) was that the latter took as his measure of the gain from trade the change in the ratio of exchange of exports against imports. Thus Mill in this case 'confounds "final" with integral utility' (1925, p. 22). The same point had in fact been made by Jevons (1871, pp. 154–6). However, Edgeworth, while preferring total utility, admitted that Mill was not otherwise led to serious error in using his own measure.

Edgeworth's survey was, as always, extremely wide-ranging, though for later developments the most interesting parts are concerned with his elucidation of Mill's 'recognition of the case in which an impediment may be beneficial – or an improvement prejudicial – to one of the countries' (1925, p. 9). These cases would now be discussed under the headings of the 'optimal tariff' and 'immiserizing growth'. In the case of an optimal tariff, a country acts as monopolist and imposes a price which enables that country to attain its highest indifference curve, subject to the other country's offer curve. However, this position is not on the contract curve. The detailed specification of the optimum tariff in terms of elasticities had to wait until Bickerdike (1906) and Pigou (1908) and the later revivals of interest in the 1940s. Edgeworth's judgement of Bickerdike was that he had 'accomplished a wonderful feat. He has said something new about protection' (1925, ii, p. 344).

Edgeworth could not of course be expected to support the use of such tariffs in practice. He acknowledged the possibility of retaliation, but also:

> For one nation to benefit itself at the expense of... others is contrary to the highest morality . . . But in an abstract study upon the motion of projectiles in vacuo, *I* do not think it necessary to enlarge upon the horrors of war. (1925, p. 17 n. 5)

The 'highest morality' was, of course, the principal of utilitarianism.

Conclusions

It has been seen that Edgeworth did not begin working and writing in economics until his

mid-30s, but in common with the majority of neoclassical economists he soon pursued an academic career as a professor of economics. Indeed, in a period which saw the rapid and widespread professionalization of the subject Edgeworth held an academic position in England that was regarded as second only to that of Alfred Marshall. In spite of his wide range of reading and sympathies, Edgeworth's work was characterized by the fact that it was virtually all addressed to his fellow professional economists. So uncompromising was he in his view that economics is a very difficult subject offering only remote and nearly always negative policy advice that it may fairly be said that his work was addressed to just a small number of 'fellow travellers' in the rarefied atmosphere of the 'higher regions' of pure theory. However, Edgeworth imposed no geographical limitations, and with his considerable linguistic skills and international sympathies was in contact with the majority of leading economists around the world.

The distinguishing feature of the neoclassical 'revolution' was its emphasis on exchange as the central economic problem. The success of this shift of focus from production and distribution to exchange was closely associated with the fact that it had as its foundation a model based on utility maximization. This allowed for a deeper treatment of the gains from exchange and the wider considerations of economic welfare. Schumpeter summarized the point by stating that utility analysis must be understood in terms of exchange as the central 'pivot' and 'the whole of the organism of pure economics thus finds itself unified in the light of a single principle' (1954, p. 913). This is indeed the context in which Edgeworth's work in economics must be seen. Schumpeter's remark is merely a more prosaic expression of Edgeworth's view quoted above that '"Mechanique Sociale" may one day take her place along with "Mechanique Celeste" [sic], throned each upon the double-sided height of one maximum principle'. The central theme of Edgeworth's work is also clear in his revealing statement, taken from his presidential address to Section *F* of the Royal Society, that:

> It may be said that in pure economics there is only one fundamental theorem, but that is a very difficult one: the theory of bargain in a wide sense. (1925, ii, p. 288)

This perspective helps the major thread which runs through all Edgeworth's work in economics to be seen. His earlier mathematical analysis of the implications of utilitarianism for the optimal distribution, written before he turned to economics, was not only highly original (and esoteric) but laid the foundation for his work in economics. Thus, the transition from *New and Old Methods of Ethics* to *Mathematical Psychics* was not a shift in major preoccupations but rather a change of emphasis. Distribution was then seen as an important concomitant of exchange, so that the analysis of contract became central for Edgeworth. Edgeworth's emphasis on the indeterminacy (the inability of utility maximization alone to determine the rate of exchange, only a range of efficient exchanges) which results from the existence of a small number of traders led him to his path-breaking analysis of the role of numbers in competition, along with the efficiency properties of competitive equilibria.

The analysis of the utilitarian objective as an arbitration rule led Edgeworth directly to his new 'social contract' argument in explaining the acceptance of utilitarianism as a principle of social justice. It was the realization of this new justification of utilitarianism, using his newly developed analytical tools, which generated the excitement that is clearly evident in his first work in economics. While *Mathematical Psychics* developed the techniques of indifference curves and the contract curve within the 'Edgeworth box' – tools which are now ubiquitous in economic analysis – Edgeworth himself was clearly driven mainly by his ability to link the analysis of private contracts in markets to that of a social contract in which utilitarianism is the 'sovereign principle'. The integration of his analysis of barter, and the effects of the introduction of additional traders into the market, with the demonstration that the utilitarian arrangement prescribes a point on the contract curve of efficient exchanges and is acceptable to risk-averse traders, was to Edgeworth nothing short of 'momentous'.

The results are of course highly abstract. In discussing their ultimate value suggested that:

> Considerations so abstract it would of course be ridiculous to fling upon the flood-tide of practical politics … it is at a height of abstraction in the rarefied atmosphere of speculation that the secret springs of action take their rise, and a direction is imparted to the pure foundation of youthful enthusiasm whose influence will ultimately affect the broad current of events. (1881, p. 128)

The intellectual pleasure derived from being able to draw together so many different subjects of analysis, and strands of his enormous range of learning, is clearly evident. However, it is precisely this wide field of vision, combined with the technical level and idiosyncratic style of writing, which made *Mathematical Psychics* so difficult for his contemporaries, and which continue to make the book seem so strange and yet so rewarding to the modern reader.

Edgeworth, Maria (1767–1849)

J. P. Croshaw

Born in England of an Irish land-owning family, Maria Edgeworth began her career as amanuensis and co-author to her father Richard Lovell Edgeworth, the educator and amateur inventor. Her first publications were a series of moral tales for children (*The Parents' Assistant*, 1796, and *Early Lessons*, 1802) which aimed to instil the virtues she saw as essential to a 'good' individual and so a 'good' society: honesty, frugality and hard work. These characteristics match rather precisely those of Adam Smith's 'prudent man' in the *Wealth of Nations.* Her tales teach the value of a work ethic, sharply contrasting the evils of sloth and idleness with the pleasures of diligence and achievement. Indeed, her attitude towards this aspect of labour did not exclude her own privileged class of landowners, who, as she witnessed in her own country, frequently abused the landlord-tenant contract.

In 1800 she published the work which is, perhaps, of most interest to economists, *Castle Rackrent.* Through the character of Thady Quirk, an ancient retainer of the Rackrent family, she recounts the history of three generations of absentee landlords, of their tenants and of the depths to which the Rackrent fortunes had fallen through successive generations of dissolute lifestyle. The book not only influenced prominent literary figures of the time (for example, Turgenev and Walter Scott) but also established a literary precedent for the development of fictional characters within the context of a realistic historical, social and economic setting - an approach which, in England, could be said to reach its peak with George Eliot's *Middlemarch.* In the 19th century the name Rackrent came to stand for the embodiment of the vices of the landed aristocracy and was freely used as such by writers like Carlyle and, later, her nephew F. Y. Edgeworth.

Maria Edgeworth continued her critical examination of the landlord-tenant relationship in novels like *The Absentee* (1812) and *Ennui* (1825) where she addressed issues such as leases, population and economic progress and the impact of manufacture on a traditional agricultural economy. Her letters to David Ricardo confirm her interest in the poverty and distress among the Irish agricultural peasantry. She initiated and engaged in a vigorous correspondence with Ricardo over the potato question and the effects of famines in the 1820s. On this subject she differed with both Ricardo and Malthus arguing that the essential cause of the difficulty lay in mismanagement. She rather amusingly suggested that instead of theorizing from afar, Ricardo should travel to Ireland and see for himself.

Education in Developing Countries

Paul Glewwe

Abstract

In many developing countries, children complete few years of schooling and learn little during their time in school. There are many estimation problems that confound attempts to understand the impact of education policies on years of schooling and learning while in school. Recent research has focused on implementing randomized trials to get around estimation problems based on retrospective data. While some useful results have been found, many additional studies are still under way. As these results accumulate it is likely that general conclusions can be drawn, but the evidence to date is too limited to draw general policy recommendations.

O1

Most economists who study economic growth agree that an educated citizenry is necessary for sustained economic growth, and virtually all international development organizations concur (UNDP 1990; World Bank 2001), and so those organizations provide substantial financial resources and policy advice to promote education in developing countries. Yet in many developing countries, especially the poorest, many children leave school at a young age and learn little during the time they spend in school. These problems have led many economists and other social scientists to turn their attention to education in developing countries.

This article summarizes recent research on the factors that affect the amount of time that children spend in school and the factors that determine how much they learn during their time in school. Thus, it focuses on the factors that shape education outcomes as opposed to the impact of education on income, economic growth and other phenomena (for a recent assessment of the impact of education on other socioeconomic outcomes, see Glewwe 2002). This article also omits, due to space constraints, a discussion of estimation issues (see Glewwe 2002, and Glewwe and Kremer 2006, for thorough discussions of estimation problems and possible solutions).

Factors that Determine Years of Schooling

In developing countries, parents usually decide how many years their children will attend school. Each year, parents consider the costs and expected benefits of an additional year of schooling and then enrol their children for another year if the expected benefits outweigh the estimated costs. The main costs are school fees and other payments required by schools, transportation and (occasionally) meals and housing, and the opportunity cost of the children's time. There may also be an additional, 'psychic' cost; some parents may dislike particular values that schools attempt to instil in students. For many parents, the largest of these costs is the value of their children's time; in developing countries, especially in rural areas, children's time is valuable because they can help in household farming activities.

The main benefits of schooling are the skills learned (which usually reap substantial monetary returns in the labour market), increased employment opportunities that come with educational credentials, and the direct satisfaction and social approval that parents receive from having educated children. While the decision rule to continue schooling when the benefits outweigh the costs

would seem to hold as a tautology, there are circumstances in which children are not enrolled in school even when the economic benefits outweigh the costs. This could occur because the costs are incurred today while the benefits accrue over many years in the future. In particular, parents who have low incomes and cannot obtain credit may not send their children to school even though the present discounted value at prevailing interest rates is positive.

Given this type of decision making by parents, policies to increase school enrolment must focus on reducing the costs of schooling, increasing the benefits of education, or providing access to credit. Reductions in fees are easy to implement, and in some countries (such as Mexico) parents with low incomes receive monthly payments if their children are enrolled in school. Of course, this entails potentially large budgetary costs, so some governments try to limit fee exemptions and outright subsidies to households or communities that are particularly needy. Evidence from many developing countries indicates that reducing fees or providing payments conditional on school enrolment can lead to large increases in enrolment; studies in Honduras, Kenya, Mexico and Nicaragua document these impacts (see Glewwe and Kremer 2006, for further details and references).

The main alternative policy for increasing school enrolment is to increase the expected returns. These returns will increase if the relative price of skilled labour increases, and if schools become more effective at providing academic skills. While some economists have shown that increased returns to education does raise school enrollment (Foster and Rosenzweig 1996), most policy research has focused on what makes schools more efficient at raising students' skills. This research is discussed in the next section.

Three additional points regarding policies to increase years of schooling deserve attention. First, improvements in the health and nutritional status of both very young and school-age children are another potentially important route to increase the time that children spend in school (see Glewwe and Miguel 2006, for a review of this literature). Second, many policy discussions presume that the main reason children are not in school is that no school is available, yet in most countries schools are available but parents opt not to enrol their children because they judge that the costs outweigh the benefits (see Glewwe and Zhao 2005). Third, the role of credit constraints in determining years in school is an under-researched topic, in terms of both the impact of credit constraints and policies that could loosen those constraints.

Factors that Determine Student Learning

In principle, student learning can be depicted as a production process in which student, household, teacher and school characteristics combine to produce students' academic skills. While the existence of an academic skills production function is true almost by definition, there are serious problems that confound attempts to estimate this process. The main problem is omitted variables bias: students, households, teachers and schools can vary in hundreds of ways, and no data-set contains all variables that are potentially important. Indeed, important factors such as student innate ability, teacher effort and parental encouragement are almost impossible to measure and likely to be correlated with the observed variables. This problem applies to virtually all studies based on retrospective (non-experimental) data; indeed, it is probably the main reason that different studies find very different results (the main alternative explanation is that educational production functions are very different in different countries). A second serious estimation problem is attenuation bias. Much of the data on students, households, teachers and schools has a substantial amount of measurement error. This typically leads to underestimation of the true impacts of variables, which may explain, at least in part, why many variables in estimates of the determinants of student learning are statistically insignificant.

In recent years economists and other social scientists have turned to natural experiments and randomized trials to estimate the impacts of

particular school characteristics, policies and programmes on student academic achievement. Natural experiments result from institutions and policies that cause random variation in school or student characteristics, which can be used to analyse the impact of those characteristics on student learning (and on time spent in school). Randomized trials are controlled experiments designed by researchers and school officials that generate random variation in a school characteristic or policy, which again allows one to estimate the impact of the characteristic or policy on learning. Natural experiments are relatively rare, but in recent years randomized trials have been implemented in many countries in Africa, Asia and Latin America.

One of the first randomized trials was conducted in Nicaragua in the late 1970s. The results indicated that workbooks and radio instruction had significant impacts on pupils' math scores. In the Philippines in the early 1980s, provision of textbooks raised students' performance on academic tests, but in Kenya in the late 1990s the only effect of textbooks was among the better students, perhaps because the textbooks provided were too difficult for most students. Other randomized trials conducted in Kenya suggest little impact on test scores from reductions in class size, provision of flip charts, and provision of deworming medicine. On a more positive note, school meals in Kenya raised test scores in schools that had well-trained teachers, but not in schools with poorly trained teachers. In public schools in an urban area of India, a remedial education programme increased test scores at a relatively low cost. Finally, a computer-assisted learning programme in India also appears to have increased test scores. The positive impacts of radio education in Nicaragua and computer instruction in India suggest that using modern technologies may be particularly helpful in schools with weak teachers. (For citations and more detailed discussion, see Glewwe and Kremer 2006.)

While natural experiments and especially randomized trials may seem to avoid the estimation problems that plague retrospective studies, more randomized studies are needed before general conclusions can be drawn that can guide policy in countries that have not yet had such studies. Moreover, randomized trials can also suffer from estimation problems. One problem is that parents of students in the control schools (or schools excluded from the evaluation) may try to enrol their children in the treatment schools. This may affect the results by increasing class size (if class size affects learning). This would not occur if the policy were implemented nationwide. In addition, children who transfer into treatment schools may not be a random sample of the general student population. A related problem is that marginal students in the treatment schools are less likely to drop out (if the intervention raises student achievement), which leads to underestimation of the impact of the policy on learning if comparisons are made based on all students currently enrolled in school. A final problem with randomized trials is that the evaluation itself may lead the treatment group to change its behaviour, or the control group to change its behaviour, because both groups know that their results are being used in an evaluation.

In summary, recent research on education in developing countries has provided fairly convincing evidence of the impact on time in school and on learning for particular policies in particular countries. Many additional studies are currently under way, and as these results accumulate it is likely that general conclusions can be drawn. This should lead to better education policies, which will contribute to higher economic growth and, ultimately, a higher quality of life in developing countries.

Education Production Functions

Eric A. Hanushek

Abstract

The accumulated economic analysis of education suggests that current provision of schooling is very inefficient. Commonly purchased inputs to schools – class size, teacher experience, and teacher education – bear little systematic relationship to student outcomes, implying that conventional input policies are unlikely to improve achievement. At the same time, differences in teacher quality have been shown to be very important. Unfortunately, teacher quality, defined in terms of effects on student performance, is not closely related to salaries or readily identified attributes of teachers.

A simple production model lies behind much of the analysis in the economics of education. The common inputs are things like school resources, teacher quality, and family attributes; and the outcome is student achievement. Knowledge of the production function for schools can be used to assess policy alternatives and to judge the effectiveness and efficiency of public provided services. This area is, however, distinguished from many because the results of analyses enter quite directly into the policy process.

Historically, the most frequently employed measure of schooling has been attainment, or simply years of schooling completed. The value of school attainment as a rough measure of individual skill has been verified by a wide variety of studies of labour market outcomes (for example, Mincer 1970; Psacharopoulos and Patrinos 2004). However, the difficulty with this common measure of outcomes is that it assumes a year of schooling produces the same amount of student achievement, or skills, over time and in every country. This measure simply counts the time spent in schools without judging what happens in schools – thus, it does not provide a complete or accurate picture of outcomes.

Recent direct investigations of cognitive achievement find significant labour market returns to individual differences in cognitive achievement (for example, Lazear 2003; Mulligan 1999; Murnane et al. 2000). Similarly, society appears to gain in terms of productivity; Hanushek and Kimko (2000) demonstrate that quality differences in schools have a dramatic impact on productivity and national growth rates. (A parallel line of research has employed school inputs to measure quality but has not been as successful. Specifically, school input measures have not proved to be good predictors of wages or growth.)

Because outcomes cannot be changed by fiat, much attention has been directed at inputs – particularly those perceived to be relevant for policy such as school resources or aspects of teachers.

Analysis of the role of school resources in determining achievement begins with the Coleman Report, the US government's monumental study on educational opportunity released

in 1966 (Coleman et al. 1966). That study's greatest contribution was directing attention to the distribution of student performance – the outputs as opposed to the inputs.

The underlying model that has evolved as a result of this research is very straightforward. The output of the educational process – the achievement of individual students – is directly related to inputs that both are directly controlled by policymakers (for example, the characteristics of schools, teachers, and curricula) and are not so controlled (such as families and friends and the innate endowments or learning capacities of the students). Further, while achievement may be measured at discrete points in time, the educational process is cumulative; inputs applied sometime in the past affect students' current levels of achievement.

Family background is usually characterized by such socio-demographic characteristics as parental education, income, and family size. Peer inputs, when included, are typically aggregates of student socio-demographic characteristics or achievement for a school or classroom. School inputs typically include teacher background (education level, experience, sex, race, and so forth), school organization (class sizes, facilities, administrative expenditures, and so forth), and district or community factors (for example, average expenditure levels). Except for the original Coleman Report, most empirical work has relied on data constructed for other purposes, such as a school's standard administrative records. Based upon this, statistical analysis (typically some form of regression analysis) is employed to infer what specifically determines achievement and what is the importance of the various inputs into student performance.

Measured School Inputs

The state of knowledge about the impacts of resources is best summarized by reviewing available empirical studies. Most analyses of education production functions have directed their attention at a relatively small set of resource measures, and this makes it easy to summarize the results (Hanushek 2003). The 90 individual publications that appeared before 1995 contain 377 separate production function estimates. For classroom resources, only nine per cent of estimates for teacher education and 14% for teacher–pupil ratios yielded a positive and statistically significant relationship between these factors and student performance. Moreover, these studies were offset by another set of studies that found a similarly negative correlation between those inputs and student achievement. Twenty-nine per cent of the studies found a positive correlation between teacher experience and student performance; however, 71% still provided no support for increasing teacher experience (being either negative or statistically insignificant). Studies on the effect of financial resources provide a similar picture. These indicate that there is very weak support for the notion that simply providing higher teacher salaries or greater overall spending will lead to improved student performance. Per pupil expenditure has received the most attention, but only 27% of studies showed a positive and significant effect. In fact, seven per cent even suggested that adding resources would harm student achievement. It is also important to note that studies involving pupil spending have tended to be the lowest-quality studies as defined below, and thus there is substantial reason to believe that even the 27% figure overstates the true effect of added expenditure.

These studies make a clear case that resource usage in schools is subject to considerable inefficiency, because schools systematically pay for inputs that are not consistently related to outputs.

Study Quality

The previous discussions do not distinguish among studies on the basis of any quality differences. The available estimates can be categorized by a few objective components of quality. First, while education is cumulative, frequently only current input measures are available, which results in analytical errors. Second, schools operate within a policy environment set almost always at higher levels of government. In the United

States, state governments establish curricula, provide sources of funding, govern labour laws, determine rules for the certification and hiring of teachers, and the like. In other parts of the world, similar policy setting, frequently at the national level, affects the operations of schools. If these attributes are important – as much policy debate would suggest – they must be incorporated into any analysis of performance. The adequacy of dealing with these problems is a simple index of study quality.

The details of these quality issues and approaches for dealing with them are discussed in detail elsewhere (Hanushek 2003) and only summarized here. The first problem is ameliorated if one uses the 'value added' versus 'level' form in estimation. That is, if the achievement relationship holds at different points in time, it is possible to concentrate on the growth in achievement and on exactly what happens educationally between those points when outcomes are measured. This approach ameliorates problems of omitting prior inputs of schools and families, because they will be incorporated in the initial achievement levels that are measured (Hanushek 1979). The latter problem of imprecise measurement of the policy environment can frequently be ameliorated by studying performance of schools operating within a consistent set of policies – for example, within individual states in the USA or similar decision-making spheres elsewhere. Because all schools within a state operate within the same basic policy environment, comparisons of their performance are not strongly affected by unmeasured policies (Hanushek et al. 1996).

If the available studies are classified by whether or not they deal with these major quality issues, the prior conclusions about research usage are unchanged (Hanushek 2003). The best quality studies indicate no consistent relationship between resources and student outcomes.

An additional issue, which is particularly important for policy purposes, concerns whether this analytical approach accurately assesses the causal relationship between resources and performance. If, for example, school decision-makers provide more resources to those they judge as most needy, higher resources could simply signal students known for having lower achievement. Ways of dealing with this include various regression discontinuity or panel data approaches. When done in the case of class sizes, the evidence has been mixed (Angrist and Lavy 1999; Rivkin et al. 2005).

An alternative involves the use of random assignment experimentation rather than statistical analysis to break the influence of sample selection and other possible omitted factors. With one major exception, this approach nonetheless has not been applied to understand the impact of schools on student performance. The exception is Project STAR, an experimental reduction in class sizes that was conducted in the US state of Tennessee in the mid-1980s (Word et al. 1990). To date, it has not had much impact on research or our state of knowledge. While Project STAR has entered into a number of policy debates, the interpretation of the results remains controversial (Krueger 1999; Hanushek 1999).

Magnitude of Effects

Throughout most consideration of the impact of school resources, attention has focused almost exclusively on whether a factor has an effect on outcomes that is statistically different from zero. Of course, any policy consideration would also consider the magnitude of the impacts and where policies are most effective. Here, even the most refined estimates of, say, class size impacts does not give very clear guidance. The experimental effects from Project STAR indicate that average achievement from a reduction of eight students in a classroom would increase by about 0.2 standard deviations, but only in the first grade of attendance in smaller classes (kindergarten or first grade) (see Word et al. 1990; Krueger 1999). Angrist and Lavy (1999), with their regression discontinuity estimation, find slightly smaller effects in grade five and approximately half the effect size in grade four. Rivkin et al. (2005), with their fixed effects estimation, find effects half of Project STAR in grade four and declining to insignificance by grade seven. Thus, from a policy perspective the alternative estimates are both small in economic

terms when contrasted with the costs of such large class size reductions and inconsistent across studies.

Do Teachers and Schools Matter?

Because of the Coleman Report and subsequent studies discussed above, many have argued that schools do not matter and that only families and peers affect performance. Unfortunately, these interpretations have confused measurability with true effects.

Extensive research since the Coleman Report has made it clear that teachers do indeed matter when assessed in terms of student performance instead of the more typical input measures based on characteristics of the teacher and school. When fixed effect estimators that compare student gains across teachers are used, dramatic differences in teacher quality are seen.

These results can also be reconciled with the prior ones. These differences among teachers are simply not closely correlated with commonly measured teacher characteristics (Hanushek 1992; Rivkin et al. 2005). Moreover, teacher credentials and teacher training do not make a consistent difference when assessed against student achievement gains (Boyd et al. 2006; Kane et al. 2006). Finally, teacher quality does not appear to be closely related to salaries or to market decisions. In particular, teachers exiting for other schools or for jobs outside of teaching do not appear to be of higher quality than those who stay (Hanushek et al. 2005).

Some Conclusions and Implications

The existing research suggests inefficiency in the provision of schooling. It does not indicate that schools do not matter. Nor does it indicate that money and resources never impact achievement. The accumulated research surrounding estimation of education production functions simply says there currently is no clear, systematic relationship between resources and student outcomes.

Educational Finance

William A. Fischel

Abstract

The American system of government-financed education is decentralized among 50 states and more than 15,000 local school districts. Local funds are derived from local property taxes, and this system tends to make local spending unequal. State- government efforts to equalize education spending involve manipulating the local 'tax price' with matching grants. School districts with low tax prices are not, however, necessarily populated by rich people, so the distribution of state funds may penalize many low-income districts with large amounts of non-residential property.

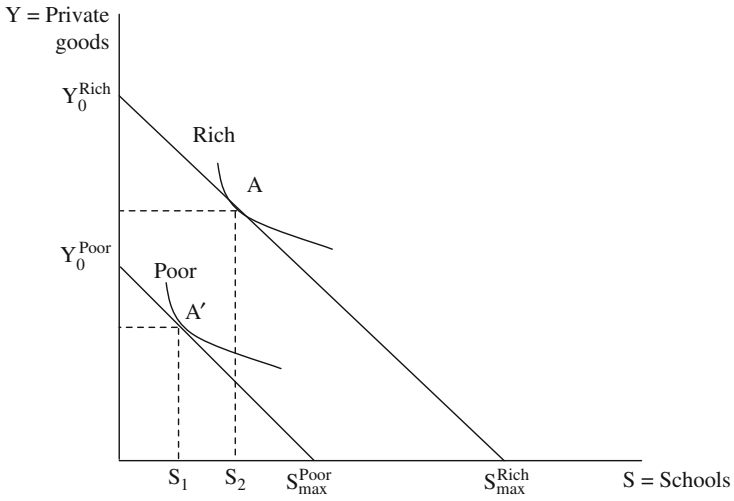
This article deals with the government-financed system of education in the United States, which is referred to as 'public' education. Educational finance in the United States is different from that of other nations, which typically fund education from national taxes. Within each American state, a substantial portion of education is financed by local governments, although the proportion financed locally has declined from 83.2% in 1920 to 43.2% in 2000.

The state–local system of finance stems from the history and geography of the United States and the federal nature of its government. The 50 states are, in the eyes of the national government, primarily responsible for education. In most states, implementation of this responsibility is delegated to local municipal corporations called 'school districts'. The school district is more than a local administrative agency of the state. It is a distinct political entity that usually has some correspondence with the geographic area of a municipality. The district, however, has a separate board of directors, which is locally elected. The board then selects a superintendent of schools to manage the district's education. Boards have the authority to levy taxes, which are almost always on property within their district, and spend the revenue they derive from them. The state government may prescribe curricular standards for public schools, but the method of achieving these standards is the responsibility of the local district.

School districts and school boards were once the most common form of local government in the United States, numbering about 200,000 in 1900. The number of school districts declined steadily throughout the twentieth century, which can largely be accounted for by the consolidation of rural one-room school districts into larger units. By 1970, one-room schools were essentially extinct, and since 1970 the total number of school districts has declined only slightly, numbering about 16,000 at the beginning of the twenty-first century.

Despite their numerical decline in rural areas, there are many school districts in most metropolitan areas. Urban households that are already on the move for job- related reasons have the luxury of choosing a home within one of several school



Educational Finance, Fig. 1 School spending in rich and poor districts

districts in most regions of the nation. Choosing among school districts and the resulting competition among districts to obtain residents is consistent with the model proposed by Tiebout (1956). Numerous tests of the Tiebout model indicate that the quality of schooling is important to most home buyers (Oates 1969; Bradbury et al. 2001). There is also evidence that spatial competition makes school districts more efficient in delivering education services (Hoxby 2000).

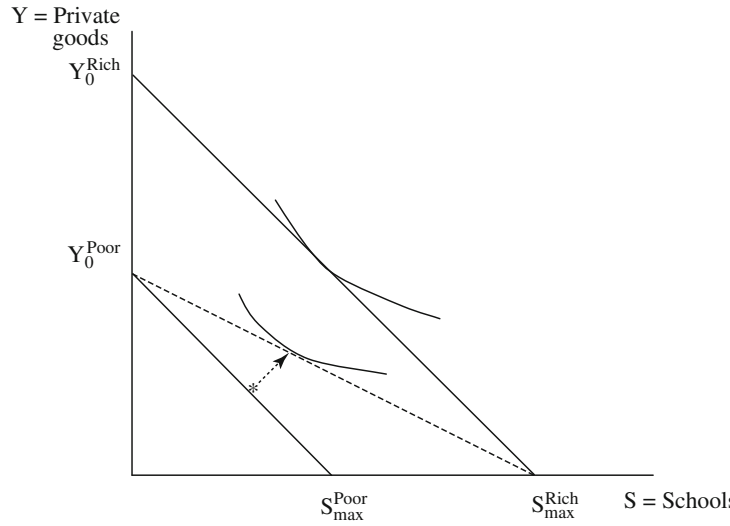
One-room schools of the nineteenth century were usually 'ungraded'. Students were instead divided into skill-specific recitation groups, formed without regard for chronological age. In this system, uniformity of education was not critical. New pupils could be placed according to what they knew in particular subjects rather than by age. But when almost all schools were age-graded, it paid for each district to offer an age-specific curriculum that allowed both teachers and pupils to be interchangeable among schools and districts (Fischel 2006a).

Standardization of age-graded curricula became widespread by about 1940 and was brought about by two forces, one local and the other statewide. Property-owning voters in a given district would find that potential homebuyers would shun them if they did not offer a standard, public-school education. Voters would thus support taxes necessary to fund standardized schools. However, differences in the economic make-up and tax-bases of local districts sometimes made this difficult to do.

Figure 1 illustrates the problem for attempts to fund schools from local sources. It depicts a trade-off between local school spending and other goods for the median voter (the voter with the median income, assumed always to be in the majority in local elections) in two separate communities, a rich district and a poor district. The decisive voter chooses the mix of school spending and private goods that achieves the highest indifference curve that his private–public budget line allows (Bergstrom and Goodman 1973). Because at the local level education is essentially a private good, the slope of the budget lines is the 'tax price' of school spending for the median voter in each community.

The tax price is not a tax rate. A school district composed exclusively of mansions will have, for a given level of spending, a much lower property tax *rate* than a district composed of modest-sized homes. But if the second moment of the distribution of wealth is the same in both communities, the *tax price* faced by the median voter in each will be the same. A 1000 dollar increase in per-pupil spending will cost the median voter the same amount of money in both cases, if one assumes that the number of public-school children per household is the same in both.

The other generalization that Fig. 1 illustrates is that average income of a district accounts for



Educational Finance, Fig. 2 Subsidies to poor districts

much of the differences in spending per pupil. Even though the tax prices are the same, the positive income elasticity of demand for education (estimated at somewhere between 0.5 and 1.0) causes the richer community to choose a higher level of school inputs (Bergstrom et al. 1982). While much of the criticism of these differences is based on equity concerns, there are efficiency reasons to promote a relatively uniform system of education (Benabou 1996).

The way most states have attempted to equalize education opportunities is to reduce the tax price of spending in poorer districts. State funds (from statewide taxes) are offered to the poorer community in proportion to the district's own tax effort. The poorer median voter thus perceives, as indicated by the dotted budget line in Fig. 2, that for every dollar raised locally, the state will send it another dollar. The tax price has been cut in half in the graphical example, so that the poorer community will choose to spend an amount closer to that of the richer district.

By manipulating the local tax price, state governments can in principle induce a substantial equality of school spending in nominally independent districts, though state officials still seem surprised that there is an income effect as well as a substitution effect from lowering the tax price. They seem to expect that the arrow in Fig. 2 should point horizontally to the right. Instead, local voters use the subsidy (the reduced tax price) to both increase local spending on schools, which is the desired substitution effect, and to reduce their own local taxes (nudging the arrow's direction upwards), which is the income effect.

Another factor can also account for differences in local tax prices. The poorer district may have a substantial amount of non-residential property to tax. Commercial and industrial uses do not come with children attached (at least in metropolitan areas, where workers can live in other communities), and so their tax revenues amount to a subsidy to their school district. The effect of this is the same as a matching-grant subsidy by the state. And the effect is not trivial. Nationally, almost one-half of all property taxes are paid by non-residential property owners, which puts them on the same order of magnitude as state funds for public education.

Although both state subsidies and a large non-residential tax base reduce the tax price, they have been treated differently in recent years. The school finance litigation movement began with *Serrano v. Priest* in California in 1971 (Brunner and Sonstelie 2006). Its objective was to use state constitutional directives (equal protection and school funding clauses) to improve schools in poor districts. For strategic reasons, the movement focused its remedial efforts on

differences in tax base per pupil rather than differences in spending per pupil or on educational outcomes. Many state courts thus ruled that unequal tax bases, not unequal spending, were constitutionally suspect and ordered legislatures to transfer funds from the 'property rich' to the 'property poor'.

What this remedy overlooked is that low-income communities are as likely to be 'property rich' (on the widely used 'tax base per-pupil' standard) as high-income communities. This is because many urban districts have a large non-residential property tax base that offsets the lower valued residential tax base. (The poor may have migrated there for jobs or rezoned land to attract industry, something most affluent suburbs are reluctant to do.) Besides this, poorer cities often have relatively few children in public schools because of an aged population or because low-quality public schools encourage the use of private schools. In any case, many of the court-induced 'equalization' remedies have actually caused state funds to be removed from low-income (but 'property rich') districts to higher-income districts that are 'property poor' because of their modest nonresidential tax base and large school-age population.

An alternative response to the difficulties of distributing state funds to school districts is simply to have the state government run the schools without the intermediation of local school boards and districts. Another is a voucher system, in which the state gives public funds to parents and allows them to select whatever school they want. Both are certainly viable means of school finance, and it is worth asking why they have not been embraced.

Full state funding forgoes the local monitoring of school performance by voters. Capitalization of school quality in local home values creates a feedback mechanism for local governance. The median voter in most jurisdictions is a homeowner, and voters therefore care about the consequences of school governance. School superintendents who waste local taxpayers' money will find that their tenure is short as voters become dissatisfied. Even if they keep their jobs, the declines in taxable property value due to inefficient policies will leave them with less revenue to spend in the future (Hoxby 1999). Neither of these desirable feedback effects is likely to occur under a state-managed system.

The drawback of school vouchers appears to be that voters are reluctant to embrace them as a general practice. American voters appear to perceive benefits from local public schools that go beyond educational qualities. One benefit I have advanced is that public schools create location-specific social capital among adults (Fischel 2006b). Adults with children are more likely to know the parents of their children's schoolmates. This creates a network of adult social capital that lowers the transaction costs of public participation in municipal affairs. A voucher system disperses children to various schools and thus does not create the same location- specific social capital that public schools do. In any case, America's continuing embrace of locally run and locally financed public education reflects the school's central role in facilitating local self-governance.

Effective Demand

J. A. Kregel

Abstract

By 'effective demand' Keynes meant the forces determining changes in the scale of output and employment as a whole. It was intended to replace Say's Law. For Keynes, since entrepreneurs maximized monetary returns, not employment or physical output, there was no reason why their investment decisions should lead to an equilibrium at full employment. Since this account permitted any level of employment to emerge as a stable equilibrium, including full employment, it is more general than the classical Say's Law position, in which the only stable equilibrium was the limit set by full employment as given in the labour market.

'Effective demand' is the term used by Keynes in his *General Theory* (1936a) to represent the forces determining changes in the scale of output and employment as a whole. Keynes attributed the first discussions of the determinants of the supply and demand for output as a whole to the classical economists, in particular the debate between Ricardo and Malthus concerning the possibility of 'general gluts' of commodities, or what has come to be known as Say's Law of Markets. Indeed, Keynes's theory was intended to replace Say's Law, although the emergence of effective demand from his *Treatise on Money* (1930) critique of the quantity theory of money, and his insistence on its application in what he originally called a 'monetary production economy', suggests that it should also be seen in antithesis to classical monetary theory. For Adam Smith (1776, p. 285), 'A man must be perfectly crazy who . . . does not employ all the stock which he commands, whether it be his own or other peoples' on consumption or investment. As long as there was what Smith called 'tolerable security', economic rationality implied that it was impossible for demand for output as a whole to diverge from aggregate supply. Although Smith (1776, p. 73) did call the demand 'sufficient to effectuate the bringing of the commodity to the market', the 'effectual demand' 'of those who are willing to pay the natural price' of the commodity, the idea referred to divergence of market from natural price of particular commodities and the process of gravitation of prices to their natural values. J.B. Say's discussion of the problem of the 'disposal of commodities' adopted Smith's position. Against those who held that 'products would

always be abundant, if there were but a ready demand, or market for them,' Say's 'law of markets' argued 'that it is production which opens a demand for products' (1855, pp. 132–3); if production determined ability to buy, then demand could not be deficient. While excesses in particular markets were admitted, they would always be offset by deficiencies in others. Ricardo used similar arguments against Malthus, who responded by suggesting that:

> from the want of a proper distribution of the actual produce, adequate motives are not furnished to continued production, . . . the grand question is whether it [actual produce] is distributed in such a manner between the different parties concerned as to occasion the most effective demand for future produce . . . (Malthus 1821)

Malthus argues that the composition of output affects its quantity by producing doubts in the minds of Smith's rational entrepreneurs concerning the 'security' of their future profit.

The final word in the classical debate was J.S. Mill's 'On the Influence of Consumption on Production', which sought exceptions to the proposition that 'All of which is produced is already consumed, either for the purpose of reproduction or enjoyment' so that 'There will never, therefore, be a greater quantity produced, of commodities in general, than there are customers for' (1874, pp. 48–9). Mill accused those who argued that demand limits output of a fallacy of composition, for the individual shopkeeper's failure to sell is due to a disproportion of demand which cancels out for the nation as a whole. Mill also notes that the argument that every purchaser must be a seller presumes barter, for money enables exchange ' to be divided into two separate acts' so one 'need not buy at the same moment when he sells' (p. 70). To avoid this problem 'money must itself be considered as a commodity', for 'there cannot be an excess of all other commodities, and an excess of money at the same time' (p. 71). Mill admits that if money were 'collected in masses', there might be an excess of all commodities, but this would mean only a temporary fall in the value of all commodities relative to money. Similarly to Smith's 'tolerable security', Mill explains an excess of commodities in general by 'a want of commercial confidence', which he denies may be caused by an overproduction of commodities (p. 74).

Mill's defence of Say's Law highlights the importance of the classical quantity theory, which was originally formulated to oppose the undue emphasis given to precious metals as components of national wealth by the mercantilists. Hume noted that labour, not gold, produced the commodities which composed national wealth; that gold was only as good as the labour it commanded to produce output. Thus the classical position that the velocity of circulation of money was independent of its quantity was built on the view that money would only be held to be spent. Money could at best cause temporary general gluts; in the long term, 'rational' men would not choose to hold money rather than spend it.

On the eve of the marginal revolution, classical theory thus admitted the temporary occurrence of general gluts explained by cyclical disproportions in demand for money and commodities due to crises of confidence. It is paradoxical that, while the marginal revolution was motivated by the failure of classical theory to give sufficient attention to the role of demand in value theory, it failed to extend its analysis of demand to output as a whole in either the long or the short period. Indeed, the emphasis on individual equilibrium produced by the subjective theory of value which replaced the classical theory, made separate discussion of aggregate supply and demand redundant. Thus Keynes's reference to 'the disappearance of the theory of demand and supply for output as a whole, that is the theory of employment *after* it has been for a quarter of a century the most discussed thing in economics' (Keynes 1936c).

But it was discussion, not Say's Law, which disappeared from neoclassical economics. Thus Keynes classed economists from Smith and Ricardo to Marshall and Pigou as 'Classical', for, despite antagonistic theories of value and distribution, they all held a similar theory of supply and demand for output as a whole.

Keynes suggests that this was due more to the failure of neoclassical economists to heed Mill's warning concerning the extension of the

conditions faced by the individual to the economy as a whole, than to positive analysis. If consumers (producers) maximize utility (profit) subject to an income (cost) constraint, reaching the maximum by substituting in consumption (production) goods (inputs) which were cheaper per unit of utility (output), then excess supply of any good (resource) is due to its price exceeding its marginal utility (productivity). Market competition would lead to relative price adjustments which eliminate excess supply. Since it was impossible for any single good (resource) to be unsold (unemployed), it was natural to extend this analysis to the aggregate level to deny the possibility of general gluts without further analysis.

Any divergence from this position was explained, not by reference to hoarding money due to crises of confidence, but by temporary impediments to the automatic adjustment of relative prices in competitive markets. Thus, despite their new marginal theory of value, Keynes's contemporaries reached a similar result that divergence of employment from its full employment level would be determined by temporary non-persistent causes eliminated in the long run.

From 1921 to 1939 the unemployment rate in the United Kingdom never fell below ten per cent, peaking in 1932 at 22.5 per cent (over 2.7 million). This exceeded the limits that most economists attributed to short-period frictions. The self-adjusting nature of the neoclassical version of Say's Law that Keynes chose to criticize was thus contradicted by reference to economic events as well as by Keynes's conception of effective demand.

Keynes was not concerned with impediments to the equality of the supply and demand, but with the

> problem of the equilibrium of supply and demand for output as a whole, in short, of effective demand . . . When one is trying to discover the volume of output and employment, it must be this point of equilibrium for which one is searching.

While the Classics solved the problem by assuming the identity of savings and expenditure on investment goods, neoclassical theory presumed Say's Law 'without giving the matter the slightest discussion' (1936b, p. 215).

Keynes's theory of effective demand thus had to replace Say's Law. To do this Keynes departed from the Classical position on two points. The first was to assume that wages exceed subsistence so that expenditure on consumption goods does not exhaust factor incomes. As expressed in Keynes's psychological law of consumption, this implied that as output increased, the gap between aggregate expenditure and factor costs increased, so that unless investment expenditure expanded to fill the gap, entrepreneurs would experience losses.

The second departure was from the assumption that rationality dictated that entrepreneurs' savings represented productive investment expenditure. If investment could produce losses, or changes in interest rates change capital values, then greater future enjoyment might be assured by not investing; holding money might be 'rational' in such conditions. Further, in a monetary economy, nothing guarantees that maximization of returns in money will maximize either productive capacity or the demand for labour.

In Keynes's theory the propensity to consume and the multiplier produce the proposition that it is the level of output which adjusts saving to investment, rather than the rate of interest, while the explanation of the decisions over the level of investment in a monetary economy requires an explanation of rates of interest in money terms. The two factors are closely related.

In a 1934 letter to Kahn, Keynes gives a 'precise definition of what is meant by effective demand' (1934a, p. 422). If O is the level of output, W the marginal prime cost of production for that output, and P the expected selling price, 'Then OP is effective demand'. The classical theory that 'supply creates its own demand' assumes that OP equals OW, irrespective of the value of O, 'so that effective demand is incapable of setting a limit to employment which consequently depends on the relation between marginal product in wage-goods industries and marginal disutility of employment'. Thus, what Keynes later called (1936a, ch. 2) the two 'classical' postulates limit O at full employment. In contrast,

> On my theory OW $\neq$ OP for *all* values of O, and entrepreneurs have to choose a value of O for which it is equal – otherwise the equality of price and

> marginal prime cost is infringed. This is the real starting point of everything.

The key point was thus the impact of different levels of O on the difference between costs and prices, that is on entrepreneurs' profits. Keynes took up this question, in an undated exchange with Sraffa of about the same time (1934b, pp. 157ff). Keynes notes that a non-unitary marginal propensity to consume implies OP $\neq$ OW for any O, and generates.

> the general principle that *any* expansion of output gluts the market unless there is a *pari passu* increase of investment appropriate to the community's marginal propensity to consume; and any contraction leads to windfall profits to producers unless there is an appropriate *pari passu* contraction of investment.

The level of O at which OP = OW will be determined by the level of investment and the propensity to consume. Changes in the rate of investment, based on entrepreneurs' expectations of their future profits, will determine O.

In an early draft of the *General Theory* Keynes (1973a, p. 439) put it this way:

> Effective demand is made up of the sum of two factors based respectively on the expectation of what is going to be consumed and on the expectation of what is going to be invested.

Thus the theory of effective demand required, in addition to explanation of consumption based on the propensity to consume, an explanation of variations in the level of investment. Since neoclassical theory resolved this problem by presuming that investment was brought into balance with full employment saving by means of the rate of interest, Keynes located the 'flaw being largely due to the failure of the Classical doctrine to develop a satisfactory theory of the rate of interest' (1934c, p. 489).

Keynes concentrated his efforts to produce a theory of interest compatible within this theory of effective demand within what he called a monetary production economy. The *Treatise on Money* (1930) had explained changes in prices in terms of households' consumption decisions relative to entrepreneurs' production decisions. If these decisions were incompatible, investment diverged from saving and prices of consumption goods adjusted producing windfall profits or losses. The prices of investment goods were determined separately from this process, by means of the interaction of the bearishness of the public reflecting their decisions to hold bank deposits or securities on the one hand, and the monetary policy of the banking system on the other.

Investment goods are held because their present costs or supply prices are lower than the present value of their anticipated future earnings or demand prices; the larger this difference, the higher the expected rate of return. Since any change in the price of a durable capital asset will influence its rate of return, a theory that explains the price of capital assets also explains rates of return (which Keynes called marginal efficiency). With the demand price of an asset based on the value of expected future earnings discounted by the rate of interest, it is clear why a satisfactory theory of interest is crucial to the explanation of effective demand.

But money was a durable asset like any other, and as such it has a spot or demand price and a supply price or forward price, which determine the money rate of interest. Keynes thus transformed his concept of bearishness into liquidity preference which, together with banking policy, would determine the rate of interest. For Keynes, 'the money rate of interest . . . is nothing more than the percentage excess of a sum of money contracted for forward delivery . . . over what we may call the "spot" or cash price of the sum thus contracted for forward delivery' (1936a, p. 222), it is:

> the premium obtainable on current cash over deferred cash . . . No one would pay this premium unless the possession of cash served some purpose, that is had some efficiency. Thus we may conveniently say that interest on money measures the marginal efficiency of money measured in terms of itself as a unit. (1937a, p. 101)

Since both money and capital assets had marginal efficiencies representing their rates of return, profit-maximizing individuals in a monetary economy would demand money and capital assets in proportions which equated their respective returns. The equilibrium level of output chosen by entrepreneurs would then be represented by

equality of the marginal efficiency of capital and the rate of interest (the marginal efficiency of money). The question of the effect of an increase in output on profit raised by a propensity to consume less than unity can now be seen as the effect of an increase in investment on the marginal efficiency of money relative to the marginal efficiencies of capital assets. Since these marginal efficiencies reflect pairs of spot and forward asset prices, the question can also be put as the effect of an increase in investment on relative money prices. Thus Keynes's independent variables, the propensity to consume, the efficiency of capital and liquidity preference, given expectations and monetary policy, interact to determine effective demand.

Since this equilibrium could be described by S = I, or equality between the rate of interest and the marginal efficiency of capital, the level of output which equates aggregate demand and supply also equates marginal efficiency with the rate of interest. To complete his theory of effective demand, Keynes faced the question first raised by Wicksell of the causal relation between the natural and the money rate of interest. Just as Keynes rejected the determination of the level of O at which OP = OW by the equality of the marginal productivity and disutility of labour, he rejected marginal productivity as the determinant of marginal efficiency and the real rate of interest determining the money rate because it was based on 'circular reasoning' (1937b, p. 212).

Keynes argues instead that it is the marginal efficiency of capital assets which adapts to the money rate of interest rather than vice versa. These two points of departure are discussed in Chapters 16 and 17 of the *General Theory,* where Keynes points out that the money rate of return to be expected from a capital asset depends on the relation of anticipated money receipts relative to expected money costs, and that there is no reason to believe that these will be related in any predictable way to the asset's physical productivity. Wicksell's natural rate, derived from physical relations of production and exchange, has no application in a monetary economy; Keynes thus substitutes the concept of marginal efficiency.

Keynes also notes that increased investment in particular capital assets increases supply prices and reduces demand prices, causing a decline in marginal efficiencies; an increase in output thus leads to investment in assets with lower rates of return. At some point the marginal efficiency of money will make investment in money as profitable as the purchase of capital assets. At this point the rate of interest equals the marginal efficiency of capital, and any further increase in output would confirm Keynes's 'general principle' that any further expansion in output gluts the market, for increased income is not spent but held in the form of money which becomes a 'generalised sink for purchasing power'.

The question that distinguishes Keynes's theory is thus why money's liquidity premium does not fall as output expands, for this is what prevents investment from rising by just the amount to fill the gap created by the propensity to consume being less than one. To describe these 'essential properties of interest and money', Keynes departs from Mill's position that money is just another commodity. When money is the debt of the banking system its price and quantity behaviour will differ from physical commodities, for it has no real costs of production nor real substitutes. Thus an asset which has a negligible elasticity of production and substitution with respect to a change in effective demand, will have a rate of return which responds less rapidly to an expansion in demand. As long as the rate of interest falls less rapidly than the marginal efficiencies of capital assets, its rate will be the one which sets the point at which further expansion creates losses.

Thus the propensity to consume shows that investment will have to increase by the amount of the gap between incomes and expenditures as incomes rise if entrepreneurs are not to make losses, while the marginal efficiency of capital and liquidity preference in a monetary production economy explain why the behaviour of the rate of interest relative to the marginal efficiency of capital makes it unlikely that the rate of investment should adjust by just that amount. Since entrepreneurs maximize monetary returns, not employment or physical output, there is no reason why their investment decisions should lead to an equilibrium at full employment. Keynes's explanation

of the limit to the level of employment permits any level as a stable equilibrium, including full employment; it is thus more general than the classical Say's Law position, in which the only stable equilibrium was the limit set by full employment as given in the labour market.

Effective Protection

W. M. Corden

The effective rate of protection is the rate of protection provided to the value added in the production of a product. Let the effective price be defined as the domestic price of a unit of value added. Then the effective rate of protection (henceforth, ERP) is the proportional increase in the effective price made possible by tariffs and other measures. It is to be contrasted with the nominal tariff and (more generally) nominal rate of protection, which refers to the proportional increase in the nominal price. If the only policy instruments are tariffs, the ERP depends not only on the nominal tariff on the commodity concerned but also on the tariffs on the inputs and on the input coefficients.

Consider the simple case of an importable product, j, which has only a single input, also an importable, i. There are no taxes and subsidies affecting j and i other than the import tariffs. The formula for the ERP for the activity producing j is then

$$g_j = \frac{t_j - a_{ij}t_i}{1 - a_{ij}}$$

where gj is the ERP, tj is the tariff on j, ti is the tariff on i, and aij is the share of i in the cost of j in the absence of tariffs.

This shows that if tj = ti, then gj = tj. It is common for input tariffs to be low relative to final goods tariffs, that is, tj > ti, and in that case gj > tj, an important result, since it shows that effective rates tend to be higher than nominal rates. A rise in the input tariff clearly reduces effective protection for the using industry, even though it raises protection for the input-producing activity.

Actual measurements involve using a'_{ij}, which is the input share that results after the tariffs have raised both the domestic final good price and the domestic input price. The connection between the input share before tariffs are imposed (aij) and after (a'_{ij}) is as follows:

$$a'_{ij} = a_{ij}\frac{1+t_i}{1+t_j}$$

and from this, and the formula for the ERP given above, one can obtain the formula which is commonly used in empirical studies, namely:

$$g_j = \frac{1-a_{ij}}{\frac{1}{1+t_j} - \frac{a'_{ij}}{1+t_i}} - 1.$$

The effective protection concept can be extended to allow for all taxes and subsidies affecting tradeable goods, i.e. all importables and exportables. An export subsidy raises the domestic price of an exportable; if the input is an exportable, then ti represents the rate of subsidy, and if the activity for which the ERP is being calculated is an exportable, then tj can represent the subsidy. Similarly, export taxes, production taxes, consumption taxes, and production and consumption subsidies can be allowed for. A production tax or subsidy for the final product will affect tj, while a consumption tax or subsidy for the input will affect ti. Thus the ERP measure allows a single figure to sum up the net result of various trade and non-trade taxes and subsidies affecting any particular activity.

The ERP measurements revealed at an early stage the high protection that developed countries provided for final processing of primary products even in cases where nominal tariffs were low, the reason being the duty-free entry of the basic materials. The measurements also bring out the negative effective protection provided for exports in many countries: the exports receive no subsidies or other assistance, i.e. tj = 0 for most exports, but import tariffs on their inputs make their tis positive. It was also noted that tariff reductions are not always what they seem: an offer of tariff cuts at an international negotiation may actually raise the ERP for some domestic industries.

Much attention has been given in the literature to the discovery of negative value added, a discovery which was a by-product of effective protection calculations. There are cases where the free trade price of the final product is less than the free trade price of its inputs, so that under free trade the effective price would be negative. One possible reason for this phenomenon is that transport costs on inputs may be much higher than those on the final product. There would then be no production of the final good under free trade. But a sufficiently high tariff on the final good relative to the tariff on the input could make the effective price domestically positive, so that domestic production begins. The rate of protection is then infinite, and algebraically the calculation of the ERP will yield a negative figure. Clearly domestic production of a product where the cost of imported inputs exceeds the free trade price of the final product is an extreme form of waste.

General Equilibrium

The next step is to put ERPs into a general equilibrium framework. One can imagine a scale of effective rates, which will include ERPs for all traded activities, including both exportables and importables. The scale will give some indication of the direction in which resources have been pulled by the protective structure. Of course, actual resource movements will also depend on production substitution elasticities, that is, on the whole general equilibrium system, so that the scale is only indicative of resources movement effects. The crucial point is that, in general equilibrium, relative ERPs matter, not absolute rates. This is simplest to see in a model with only two activities where both may be obtaining positive ERPs (if one is an export, this implies it is getting an export subsidy), and resources will then tend to move into the activity with the relatively higher ERP.

There are complications, and it has been shown in the literature that one can produce paradoxes. For example, in a three-activity model, with A and B complementary in a general equilibrium sense, protection of A may expand B even though B may get a lower ERP than C. It must also be remembered that relative nominal rates will determine the direction in which consumption is pulled or distorted.

The idea of the scale of ERPs was first presented in Corden (1966), where it was said that

Assuming normal non-zero substitution elasticities in production, [the scale of effective rates] tells us the direction in which this structure causes resources to be pulled as between activities producing traded goods. Domestic production will shift from low to high effective-protective-rate activities.

This was too strong. It is true in a rather special model, later set out formally in Jones (1975), but more generally, there are various 'paradoxical' circumstances where it need not be true. Several articles have explored such possibilities, and examples are expounded in Corden (1971).

At the general equilibrium level the important and somewhat complex issue also arises of whether particular traded goods activities are protected relative to non-tradeables, and what the role of the exchange rate is. The basic point is that the imposition of a protective structure which is generally positive will tend to draw resources out of non-tradeables, and if the nominal rates are also mainly positive, divert consumption towards non-tradeables. Assuming balance initially, protection then results in excess demand for non-tradeables. Balance would be restored by a rise in the price of non-tradeables, relative to the free trade prices of tradeables, this being a real appreciation. It could be brought about with a fixed nominal exchange rate combined with an absolute rise in the price of non-tradeables, or by a nominal appreciation when the price of non-tradeables is constant, possibly because the nominal wage is given.

The usual expositions assumed the average price-level of non-tradeables constant, and stressed the exchange rate adjustment that then needs to be associated with a change in protection levels. When this adjustment is taken into account one can obtain a net protective rate which shows whether a particular activity is protected relative to non-tradeables. For example, a particular activity may obtain an ERP of 10 per cent but, if the protection for it and all other activities were removed, there might have to be a devaluation which is equivalent to a uniform tariff and export subsidy of, say, 15 per cent. In that case this activity would have obtained a higher effective price under free trade, so that the system of protection has provided it with negative net effective protection. Relative to non-tradeables, it has been anti-protected. If its resources were primarily mobile into and out of non-tradeables, it would expand as a result of a movement towards free trade.

Key Assumptions

The theory of effective protection, at least in its more formal version, makes a number of assumptions. The first is the small country assumption, namely the assumption that the country concerned faces given prices of its exports and imports (the terms of trade being exogenous). The second assumption is that for all tradeable goods some trade remains, so that domestic prices are determined by the given world prices as modified by tariffs, export subsidies and other interventions. Thirdly, imports are assumed to be perfect substitutes for the import-competing goods for which the ERPs are calculated. Finally, it is assumed that there are fixed coefficients between final outputs and traded inputs, even though substitution between the domestic factors that contribute to value added can be allowed.

Much theoretical work has gone into exploring the implications of removing the last assumption, though all the others are also important. It does not follow that calculations of ERPs are meaningless when these assumptions do not hold, but figures must be interpreted with care, as discussed in Corden (1971).

Normative Implications

Do ERPs have normative significance? The formal theory of effective protection and tariff structure was developed with the focus on a question of positive economics: namely, how does a protective structure affect the allocation of resources? But the great interest in the theory and the widespread activity in making calculations has been motivated by a concern with normative issues. It must be stressed again that only relative effective rates matter. Knowing a single effective rate on its own sheds no light on either positive or normative

implications. The frequent assumption, often only implicit, has been that free trade with appropriate exchange rate adjustment would be the optimal situation, and that non-uniform effective rates therefore impose a production cost of protection – that is, a welfare loss through a distortion in resource use. Large divergences are then an indication of a high cost of protection. Furthermore, the structure of effective protection gives then a guide to the welfare (or efficiency) effects of tariff changes: a change that reduces a divergence between effective rates is likely to reduce the cost of protection.

A practical implication is that if there is to be gradual tariff reduction without extra costs being imposed during the process, any increase of such divergences should be avoided. This will be so, for example, if high effective rates are always reduced first. In a three-product model, with industry A getting 0 per cent, industry B 20 per cent and industry C 50 per cent, a reduction in B's effective rate first would increase the divergences between the ERPs on B and C, so that the ERP of C should be reduced first. This is the concertina method of tariff reduction, but may have quite complicated implications in terms of nominal tariffs. Radial (uniform across-the-board) reductions would also avoid divergences being increased. Finally, it must be remembered that nominal tariffs affect the pattern of consumption whether by final users, or in use of inputs, so that divergences in nominal tariffs determine the consumption cost of protection.

If there are other (non-trade) distortions in the economy, a tariff distortion may actually be offsetting. Thus, if an industry is established on the basis of a very high tariff (relative to other industries), so that a positive cost of protection might be expected, there may be a gain if (for example) the industry uses labour for which it has to pay a wage that exceeds its opportunity cost owing to distortions in the labour market. When such non-trade distortions are prevalent one cannot use effective rates on their own as indicators of which activities should expand and which decline if resource allocation is to improve. The broader concept of domestic resource cost has been developed to take all distortions into account.

Practical Problems

The calculation of ERPs and their use as a guide to policy has become very widespread, especially in developing countries. But all sorts of practical problems arise in the calculations, essentially because the assumptions of the formal theory do not hold, and many ways have been devised to deal with these problems. The problems can only be listed here, but they are important for practitioners. For more details, see Corden (1975) and Balassa et al. (1982).

When quotas are the principal method of protection, comparisons between domestic and world market prices must be made in order to obtain the implicit nominal rates of protection which must be the starting point for any calculations. When tariffs alone are relevant there may be tariff redundancy, so that, again, price comparisons must be made; a difficulty here is that the quality of the local product and the import may differ. Available input-output coefficients in most countries are rarely sufficiently disaggregated for the ERP calculations. There is a need for tariff averaging, and this has built-in biases.

A decision has to be made as to how to treat non-traded inputs into the tradeable products for which ERPs are calculated. This last issue has given rise to much theoretical discussion (on which see Corden 1971, 1975). The correct method appears to be very complicated: lump the non-traded and primary-factor content of non-traded inputs with value added, but group the traded-input content of non-traded inputs with traded inputs. Tariffs on traded inputs into non-traded inputs then reduce the ERP for the final product.

The Substitution Problem

By far the most sophisticated theoretical work has gone into the 'substitution problem'. This involves removing the assumption of fixed coefficients between the final output and the produced traded inputs. Thus substitution between traded inputs and the primary factor content of value added is allowed for. Two distinct issues then arise.

First, suppose that the production functions are separable, so that substitution between traded inputs and the various primary factors, for example, labour and capital, is 'unbiased'. In that case, the concept of value added retains a clear meaning. One can think of a 'value added product' which is combined with traded inputs in varying proportions (depending on the input tariff and the final good tariff, among other things), to make a final product. Since the ERP is the proportional increase in the effective price, which is the price of this 'value added product'. ERP also then has a clear meaning. But the problem remains that measurements based on the coefficients after tariffs have been imposed (which is what the data yield) will have a bias, reflecting the substitution effects. It can be shown that the tendency will always be to overstate the 'true' ERPs. The problem is then one of inevitable measurement error. Since one is interested in the relative position in the scale of effective rates and in the divergences between ERPs, it is relevant that the measurement error will differ between ERPs, depending on production functions and relationships between final goods and input tariffs. Fortunately, there is some possibility that this complication may not be important in practice.

The second issue is more fundamental. If production functions are not separable, so that substitution is 'biased', the whole concept of the 'value added product' and hence of ERP is thrown into doubt. The question is whether 'value added' has a meaning. One really needs to assume that, on a probability basis, the bias is generally zero.

Are General Equilibrium Models Preferable?

Another basic criticism of the ERP concept and of all the resources that have gone into calculations of ERPs can be made. It has been pointed out that a scale of ERPs is an imperfect and possibly misleading indicator of resource allocation movements. Actual resource pulls also depend on supply elasticities, on production functions, and on a whole lot of complex interactions which have been analysed in the literature, but which deprive the scale of effective rates of any simple significance. Various paradoxes have been shown to be possible – for example, that resources will be drawn into a low ERP activity out of a high ERP one under particular factor-intensity and relative tariff conditions. The conclusion of some critics has been either that no measurements are any use or that one might as well use only nominal rates. Another view is that the best approach is to use computable general equilibrium models, and these make ERPs redundant.

The answer must be that if the data and estimates for complete general equilibrium models are available – and sufficiently disaggregated with respect to activities or industries to be policy-relevant – there is indeed no need to calculate ERPs. The latter contain some information, taking into account input tariffs, and so on, but pause half-way to the complete answer. The case for ERPs calculations and their use for policy must be that the data and estimated functional relationships required for complete and detailed general equilibrium models do not usually exist, and certainly not in sufficiently disaggregated form, so that ERPs, which are feasible to calculate, give some indication of possible resource pulls and costs of protection. The extensive theoretical work is designed to indicate the direction of various probable biases and to bring out the stringent assumptions required for firm conclusions to be reached from the data.

The Literature

Until the mid–1960s the vertical relationships between tariff rates derived from the input-output relationships between products were completely neglected in the literature of trade theory. In fact tariff theory was either narrowly partial equilibrium, focusing on just one vertically integrated product, or consisted of two-sector general equilibrium models. A major feature of the theory of tariff structure was not just to bring out the relevance of input tariffs but also to focus on the horizontal general equilibrium relationships when there are more than two products.

With regard to the ERP concept itself, while there were early precursors, the first extended exposition was in Barber (1955), the first systematic theoretical papers were a 1965 paper of Johnson's, reprinted in Johnson (1971), and Corden (1966). The latter paper opened up various general equilibrium issues, the significance of the scale of effective rates, the problem of non-traded inputs, the substitution problem, and so on, and later a systematic and more complete exposition was presented in Corden (1971), which also contains a history of the ERP concept and references to various precursors. Pioneering empirical work was done in Balassa (1965) and Basevi (1966). Later Balassa became a sponsor of major multi-country empirical studies (Balassa et al. 1971, 1982), and these volumes also contain extensive reviews by Balassa of theoretical and measurement issues.

The central theoretical issues of the meaning of ERPs have been discussed in numerous papers subsequent to the early work. Particularly to be noted are Jones (1975) and Ethier (1977). In addition, there have been several articles on the 'substitution problem', beginning with Jones (1971), a paper reprinted in Corden (1971), and Ethier (1972), followed by papers by Bruno, by Khang and by Bhagwati and Srinivasan, all in the Journal of International Economics of 1973.

'Effectual Demand' in Adam Smith

Carlo Panico

Smith's notion of 'effectual demand' is still the subject of several discussions dealing with the role of demand in classical and neoclassical theories of price and distribution and with the influence of demand on 'division of labour' and economic progress. Smith defined 'effectual demand' as the 'demand of those who are willing to pay the natural price of the commodity, or the whole value of rent, labour and profit, which must be paid in order to bring it thither' (Smith 1776,

vol. 1, p. 58). According to him, when the quantity of any commodity brought to market falls short of the effectual demand, those who demand it.

Cannot be supplied with the quantity they want. Rather than want it altogether, some of them will be willing to give more. A competition will immediately begin among them, and the market price will rise more or less above the natural price (ibid.).

On the other hand, 'when the quantity brought to market exceeds the effectual demand,... the market price will sink more or less below the natural price' (p. 59), whereas 'when the quantity brought to market is just sufficient to supply the effectual demand and no more, the market price naturally comes to be ... the same with the natural price' (ibid.).

'Effectual demand' is thus defined as the demand for any *individual* commodity, corresponding to the natural price for it. It was a *long-period* concept, since it was associated with those prices which allow the payment of wages, rents and profits at their natural levels, and which hold when in all industries productive capacity is fully adjusted and a uniform rate of profits is earned (see Smith 1776, vol. 1, pp. 59–65).

The definition of 'effectual demand' was introduced in dealing with the adjustment process between demand and supply. This process was conceived to occur on a *single* market assuming as known the natural prices of that and all other commodities. The process of adjustment implies, therefore, a *prior* determination of distributive variables and of all natural prices, *associated with given levels of effectual demand in each industry.* Smith's notion of 'effectual demand' thus refers as much to a specific industry as to the whole economy: it can be seen as a 'micro' and a 'macroeconomic' concept.

The study of effectual demand involves a description of how the working of competition enforces natural prices but does not constitute a theory of what determines them. Smith never derived demand-functions for any commodity. 'Effectual demand' represented a point, and no attempt was made to determine the magnitude of the rise (fall) in demand when the price falls below (rises above) its natural level. He thus used a different notion from that implied by demand-curves in neoclassical theory, which requires a specific ordering between *each* price-quantity point. ... The theory does not regard these points as results of accidental and temporary deviations of the quantity supplied from the 'normal' level, but rather as determinate points likely to emerge from a repetition of events (Garegnani 1983, p. 310).

Smith's notion of effectual demand has been recalled by those who, following Sraffa's rehabilitation of the surplus approach of the classical political economists (Sraffa 1960), have proposed to separate the analysis of price and distribution from that of the levels of output and demand. Within this approach, *given the level and the composition of output* and one distributive variable, it is possible to determine the 'socially necessary' technique, the other distributive variables and natural prices. The levels of output and demand in each industry, taken as given, represent long-period values, since they are associated with fully adjusted productive capacity and uniform rates of profit in all industries.

The analysis of the classical tradition is characterized by integration between historical, institutional and economic factors. This approach is applied to the analysis of the level and composition of demand. The analysis of the aggregate level is related to Say's law, whose acceptance is an open option in classical political economy. Among the elements affecting the composition of demand, two groups of factors appear to emerge in Smith's writings. First of all, *objective* factors, like the degree of development of the economy and the distribution of income among different classes of society. Secondly, *subjective* factors, which are influenced by customs, social rules and fashion. The limited attention paid to substitution within the bundle of commodities demanded by different income groups suggests a minor role attributed to this factor, without denying the possibility of its further analysis, carried out case by case.

Marx analysed the factors influencing demand in a similar way. His stress was on objective factors, that is on the ratio of total surplus-value to wages and the proportions in which the surplus-

value is split up among profits, interests, ground rents, taxes, etc. (see Marx 1894, pp. 181–2). Given the historically achieved degree of development of the economy (whose analysis is not based on the acceptance of Say's law) and the distribution of income, it is possible to determine the average level of demand for different commodities from each class or social group. The total consumption expenditure of each class is an increasing function of the income earned (Marx 1894, pp. 188–9), while the composition of its consumption is influenced by habits and rules which, over a certain historical period, are dominant within that class. Limited possibilities of substitution within the bundle of commodities demanded by each class are recognized, and again appear left to be studied case by case.

The working class must find at least the same quantity of necessities on hand if it is to continue living in its accustomed average way, although they may be more or less differently distributed among the different kinds of commodities . . . The same, with more or less modification, applies to other classes (Marx 1972a, pp. 188).

Besides, Marx pointed out that the analysis of demand has to recognize the distinction between the part coming from consumers and that coming from entrepreneurs requiring means of production in order to meet what he called the need for commodities in the market, depending on the 'actual social needs of the different classes and on the income available to them' (Marx 1894, pp. 188–9).

Some remarkable similarities can be found between this approach and that followed by Keynes in the *General Theory*. In chapters 8 and 9 of this work, the factors affecting aggregate consumption are examined in an analysis which is separate from that determining prices and distribution, and which pays hardly any attention to substitution within the bundle of commodities demanded for consumption, a factor to which a secondary role appears to be attributed. According to Keynes (see 1936, pp. 90–95), total consumption depends partly on total income, partly on other objective circumstances, like the interest rate, and partly on subjective factors, which 'include those psychological characteristics of human nature and those social practices and institutions' (p. 91), which are unlikely to change over limited periods of time except in abnormal or revolutionary circumstances, and which it is necessary to consider 'in an historical inquiry or in comparing one social system with another of a different type' (ibid.). Talking of the interest rate, Keynes concluded that its influence on consumption is open to a great deal of doubt. . . .[Its influence] is complex and uncertain, being dependent on conflicting tendencies . . . Substantial changes in the rate of interest tend to modify social habits considerably, thus affecting the subjective propensity to spend – though in which direction it would be hard to say, except in the light of actual experience (p. 93).

Thus, as in classical tradition, the actual influence of the factors considered is evaluated by Keynes according to the historical circumstances considered, taking into account that their influence may be uncertain in its intensity and direction. The integration between economic and institutional and social factors also emerges in the analysis of the influence of subjective factors (pp. 107–112), whose relative strength will vary enormously according to the institutions and organisation of the economic society which we presume, according to habits formed by race, education, convention, religion and current moral, according to present hopes and past experience, according to the scale and technique of capital equipment, and according to the prevailing distribution of wealth and the established standards of life (p. 109).

However, the principle of substitution and that of diminishing marginal returns play a primary role in Keynes's analysis of investment in the *General Theory*. In this respect, Keynes said, 'I am simply accepting the usual theory of the subject' (Keynes 1973, p. 615), 'meaning exactly the same as Marshall . . . means' (p. 630). Yet, alongside this neoclassical element, Keynes referred to other factors influencing investment, like the present and expected level of effective demand (see Keynes 1936, p. 147), which may come from the private or the public sector and may affect what he

called 'the state of long-term expectation'. The analysis of investment of the *General Theory* may thus suggest some elements to develop a theory of demand within classical tradition.

One element is that 'the state of long-term expectation is often steady' (Keynes 1936, p. 162), since factors like the institutional environment and government policies do not only influence it, but also 'exert their compensating effects' on its fluctuations, together with factors related to the maintenance of the efficiency of capital goods. Within this line, government policies, and industrial policy in particular, relations between industry and finance, industrial relations and the history of competitiveness and technological changes are to be seen as relevant factors affecting the prevailing state of long-term expectation (see Eatwell 1983, p. 283).

Another element is that there may be 'short-period changes in the state of long-term expectation' (Keynes 1936, p. 164) due, among other things, to reactions of investors during the transition process from one state of long-term expectation, 'which has its definite corresponding level of long-period employment' (ibid., p. 48) with fully adjusted capacity, to another to which a new long-period position corresponds. This process was described by Keynes in chapter 5 of the *General Theory* (1936, pp. 46–50), where he concluded that 'a mere change in expectation is capable of producing an oscillation of the same kind of a shape as a cyclical movement, in the course of working itself out' (p. 49). This chapter points out the possibility of presenting a long-period analysis of demand and output, which is integrated with an analysis of the cyclical movements of the economy.

Smith's notion of 'effectual demand' thus appears a fruitful concept linking the classical theory of prices and distribution and that of output and demand. The historical elements present in the latter theory underline an outstanding feature of Smith's and of classical political economists' work, i.e. that the analysis of output and demand is part of the analysis of concrete 'historical processes' of accumulation which, as said above, can show cyclical fluctuations around the main trend.

Efficiency Bounds

Han Hong

Abstract

In large sample analysis, the performances of estimators can be approximated by the asymptotic variances. In parametric models, maximum likelihood estimators often achieve the efficient Cramer–Rao lower bound, while efficient GMM estimation can be achieved by choosing the weighting matrix and the instruments optimally. Semiparametric efficiency bound is defined by the supremum of the Cramer–Rao bounds for all parametric models that satisfy the semiparametric restrictions. The efficiency bounds for asymptotically linear semiparametric estimators are given by the variances of the efficient influence functions, which are the projections of the linear influence functions onto the tangent spaces of the semiparametric models.

Oftentimes we want to compare estimators. For a given parameter in which we are interested, there are typically many estimators that can estimate it consistently. We need to choose the best estimator, or the estimator that is the closest to the true parameter value. The mean square error (MSE), $E\left(\hat{\theta}-\theta\right)^2$, is frequently used as a measure of closeness. However, there can be many other various measures of closeness, and often they do not agree with each other. See, for example, Amemiya (1994, pp. 116–24).

Even with a given measurement of closeness, such as the MSE, it is typically not possible to rank two estimators. For two estimators X and Y of θ, X is better than Y only if $E(X-\theta)^2 \leq E(Y-\theta)^2$ for all $\theta \in \Theta$. An estimator that is not dominated by another estimator in the above sense is called admissible.

A uniformly 'most' efficient estimator does not exist. To find an efficient estimator, one needs to confine the analysis to a limited class of estimators, such as unbiased estimators or equivariant estimators. Alternatively, one can rely on a subjective strategy such as average risk optimality which requires a prior distribution over the parameter space, or use a pessimistic and risk-averse approach such as minimax optimality.

In large sample analysis, the performance measures of estimators can often be approximated by their asymptotic distribution. Under suitable regularity conditions, many estimators are consistent and converge to the true parameter values at $\sqrt{n}$ rate. These estimators can be compared based on their asymptotic variance. The notation of efficiency bound usually refers to the largest lower bound for the variances that can be achieved by $\sqrt{n}$ consistent and asymptotically normal estimators under suitable regularity conditions.

Asymptotic Efficiency in Parametric Models

In parametric models, the variance of an unbiased estimator has to be larger than the Cramer–Rao lower bound, which is defined as the inverse of the information matrix:

$$V\left(\hat{\theta}\right) \geq -\left(E\frac{\partial^2 \log L}{\partial \theta^2}\right)^{-1},$$

where L is the likelihood function. Proofs of this result can be found, for example, in Amemiya (1994, pp. 138–39; 1985, pp. 14–17). A consistent estimator is said to be asymptotically efficient if its asymptotic variance achieves the Cramer–Lao lower bound. Under suitable regularity assumptions such as those given in Theorem 4.1.3 in Amemiya (1985), the maximum likelihood estimator is asymptotically efficient.

There exist super-efficient estimators whose asymptotic variances are smaller than the Cramer–Rao lower bound on a set of parameter θ with Lebesgue measure zero, such as Hodges's estimator defined as

$$w_T = \begin{cases} 0 & \text{if} \quad \left|\hat{\theta}\right| < T^{1/4} \\ \hat{\theta} & \text{if} \quad \left|\hat{\theta}\right| \geq T^{-1/4} \end{cases}$$

where $\sqrt{T}\left(\hat{\theta}-\theta\right) \xrightarrow{d} N(0, v(\theta))$. One can show that $\sqrt{T}(w_T-\theta) \xrightarrow{d} N(0, v(\theta))$ if $\theta \neq 0$ and $\sqrt{T}(w_T) \xrightarrow{d} 0$ if $\theta = 0$. However, the better behaviour of w_T at $\theta = 0$ comes at the expense of erratic

behaviour when θ is close to 0. See for example, van der Vaart (1999, p. 110).

A common alternative to maximum likelihood is generalized method of moment estimators (GMM). Its asymptotic efficiency is extensively discussed in Newey and McFadden (1994). While GMM estimators are less efficient than maximum likelihood (see, for example, the proof in Newey and McFadden (1994, p. 2163), oftentimes they are easy to compute, especially when maximum likelihood is computationally infeasible. For a given set of unconditional moment conditions, a proper choice of the weighting matrix or the linear combination matrix minimizes the asymptotic variance. For a given set of conditional moment conditions, a proper choice of instruments can also minimize the asymptotic variance.

A GMM estimator can be formed from the over-identified moment conditions $Em(z;\theta) \equiv 0$ by minimizing a quadratic form based on a weighting matrix W:

$$\frac{1}{T}\sum_{t=1}^{T} m\left(z_t;\hat{\theta}\right) W \frac{1}{T}\sum_{t=1}^{T} m\left(z_t;\hat{\theta}\right).$$

The resulting estimator has asymptotic variance $(G\prime WG)^{-1}(G'W\Omega WG)(G\prime WG)^{-1}$, where $G = E\frac{\partial}{\partial\theta}m(z;\theta)$ and $\Omega = Var(m(z;\theta))$ Hansen (1982) showed that the optimal choice of $W = \Omega^{-1}$, which equates $G'WG = G'W\Omega WG$. In this case the asymptotic variance is reduced to $(G'\Omega^{-1}G)^{-1}$.

Alternatively, a set of over-identified moment conditions $Em(z;\theta) \equiv 0$ can be translated into a set of exactly identified moment conditions by a linear combination matrix $AEm(z;\theta) \equiv 0$. Given A, the resulting method of moment estimator that equates $A\sum_{t=1}^{T} m\left(z_t;\hat{\theta}\right)$ to zero has asymptotic variance $(AG)^{-1}(A\Omega A')(G'A')^{-1}$. As a rule of thumb, the optimal choice of A should simplify this asymptotic variance, by equating $AG = A\Omega A' = G'A'$. The resulting optimal $A = G'\Omega^{-1}$ gives rise to the same asymptotic distribution as the above optimally weighted GMM estimator of Hansen (1982), which minimizes

$$\frac{1}{T}\sum_{t=1}^{T} m\left(z_t;\hat{\theta}\right) \Omega^{-1} \frac{1}{T}\sum_{t=1}^{T} m\left(z_t;\hat{\theta}\right).$$

Many economic models, such as those based on Euler equations, are stated in terms of conditional moment conditions of the form $E(m(z;\beta)|\, x) = 0$ for almost all x. These conditional moment conditions can be translated into exactly identified unconditional moment conditions using an instrument matrix $A(x) : EA(x)m(z;\beta) = 0$. The question arises as to what is the optimal instrument matrix $A(x)$. For a given choice of $A(x)$, the resulting method of moment estimator that equates $\frac{1}{T}\sum_{t=1}^{T}(x_t)m(z_t;\beta) = 0$ has asymptotic variance $(EA(x)G(x))^{-1}EA(x)\Omega(x)A(x)'\ (EG(x)'\ A(x)')^{-1}$, where $G(x) = E\left(\frac{\partial}{\partial\theta}m(z;\theta)|\, x\right)$ and $\Omega(x) = Var(m(z;\beta)|\, x)$. We can then equate

$$EA(x)G(x) = EA(x)\Omega(x)A(x)'$$

to obtain the optimal instrument matrix $A(x) = G(x)'\Omega(x)^{-1}$. The resulting efficient asymptotic variance is therefore $(EG(x)'\Omega(x)^{-1}G(x))^{-1}$.

Formal proofs of these derivations can be found in, for example, Newey and McFadden (1994). Estimators that achieve these efficiency bounds typically involve two-step or multi-step procedures and possibly nonparametric methods, such as Newey and Powell (1990).

Asymptotic Efficiency in Semiparametric Models

Semiparametric models are extensions of parametric models where some components are specified nonparametrically with unknown functional forms. Generalized method of moment models are semiparametric models if the data-generating process is not fully specified. A partial linear model is another example. Other popular semiparametric models are surveyed in Powell (1994).

Intuitively, the variance of an estimator for a semiparametric model should be larger than the Cramer–Rao lower bound for any parametric sub-model that satisfies the semiparametric restrictions. The semiparametric efficiency bound is

therefore defined to be the supremum of the Cramer–Rao bounds for all parametric models that satisfy the semiparametric restrictions. Extensive results for semiparametric efficiency bounds are developed in, among others, Bickel et al. (1993) and Newey (1990). In this section we give a brief summary of some of the results presented in Newey (1990). The next section will apply these results to a particular estimation problem.

Because of pathological cases such as the super-efficient estimator, the semiparametric efficiency bound is used to provide a lower bound only for *regular* estimators. Consider a parameter of interest that is a smooth function of the underlying parametric path: $\beta(\theta)$. A regular estimator $\hat{\beta}$ is one where for each θ_0 the limiting distribution of $\sqrt{T}\left(\hat{\beta} - \beta(\theta_T)\right)$ does not depend on θ_T as long as $\sqrt{T}(\theta_T - \theta_0)$ is bounded. The super-efficient estimator is not regular.

Most estimators in econometrics are asymptotically linear, in the sense that they have an influence function representation as

$$\sqrt{T}\left(\hat{\beta} - \beta_0\right) = \frac{1}{\sqrt{T}} \sum_{t=1}^{T} \psi(z_t) + o_p(1).$$

In particular, almost all econometric estimators asymptotically solve some moment conditions $\frac{1}{\sqrt{T}} \sum_{t=1}^{T} m\left(z_t; \hat{\beta}\right) = o_p(1)$, in which case the linear influence function is given by $\psi(z_t) = -G^{-1}m(z_t; \beta)$ for $G = E\frac{\partial}{\partial \beta} m(z_t; \beta)$.

Asymptotically linear estimators are regular if and only if for all parametric sub-models $\frac{\partial}{\partial \theta}\beta(\theta) = E\psi S_\theta'$. When $\psi(z_t) = -G^{-1}m(z_t; \beta)$, this follows from differentiating $E_\theta m(z; \beta(\theta)) = 0$ with respect to θ. The asymptotic variance of an asymptotically linear estimator is $E\psi\psi'$, which is apparently larger than that of the maximum likelihood estimator $\beta\left(\hat{\theta}\right)$ of any parametric sub-model, which is given through information matrix and the delta method as

$$\left(\frac{\partial}{\partial \theta}\beta(\theta)\right)\left(E\left(S_\theta S_\theta'\right)\right)^{-1}\left(\frac{\partial}{\partial \theta}\beta(\theta)\right)' = E\left[\psi S_\theta'\right]\left(ES_\theta S_\theta'\right)^{-1}E[S_\theta \psi'].$$

A starting point for calculating the semiparametric efficiency bound is to restrict attention to differentiable parameters $\beta(\theta)$ which satisfies $\frac{\partial \beta(\theta)}{\partial \theta} = E\left(dS_\theta'\right)$ for some d and all parametric sub-models. Such d are not unique. Adding a random vector that is orthogonal to S_θ preserves the validity of d. In fact, any linear influence function ψ can serve as a d. For differentiable parameters, if we use the invariance principle and the delta method, the Cramer–Rao lower bound for estimating $\beta(\theta)$ is

$$\left(\frac{\partial}{\partial \theta}\beta(\theta)\right)\left(E\left(S_\theta S_\theta'\right)\right)^{-1}\left(\frac{\partial}{\partial \theta}\beta(\theta)\right)' = E\left[dS_\theta'\right]\left(ES_\theta S_\theta'\right)^{-1}E[S_\theta d']$$

Obviously, this is the variance of $d_\theta = E[dS_\theta](E[S_\theta S_\theta])^{-1}S_\theta$, which is the projection of d onto the linear space spanned by the score functions S_θ.

As the class of parametric sub-models expands, the linear space it spans also increases and the variance of d_θ also increases. The semiparametric efficiency bound should be the limit of this progress of increments. Formally, the tangent space is defined to be the mean square closure of all linear combinations of scores S_θ for smooth parametric sub-models, and the efficiency bound is given by the variance of the projection of d onto the tangent space T. In other words, the efficiency bound is given by $V = E[\delta\delta']$ where $\delta \in T$ and $E[d - \delta)'\iota] = 0$ for all $\iota \in T$.

Application

In this section we illustrate the computation of semiparametric efficiency bound using a model of non-classical measurement errors, studied in Chen et al. (2005) and Chen et al. (2004), where information from a primary data-set and from an auxiliary data-set need to be efficiently combined. Their models extend the results in the treatment effect literature on the mean parameter (see Hahn 1998, Hirano et al. 2003 and Imbens et al. 2005), to measurement error models where parameters

are generically defined through nonlinear moment conditions.

Consider the following model. The researcher is interested in a parameter β defined by the moment condition $Em(Y; \beta) = 0$ if and only if $\beta = \beta_0$. The researcher has access to a primary data-set which is a random sample from the population of interest. However, the true variable Y is not always observed in the primary data-set. Instead, a proxy variable X is observed throughout the primary data. For a subset of the primary data-set, which we will call the auxiliary data-set, X is validated so that both Y and X are observed. We will use the random variable $D = 0$ to denote observations in the auxiliary data-set where both X and Y are observed, and will use $D = 1$ to denote the rest of the primary data-set where only X is observed. Chen et al. (2004) call this the 'verify-in-sample' case. They make the following conditional independence assumption:

Assumption 4.1 $Y \perp D|X$.

Under this assumption, we follow the framework of Newey (1990) to show that the efficiency bound for estimating β is given by $\left(J_\beta \Omega_\beta^{-1} J_\beta\right)^{-1}$, where for

$$\mathcal{J}_\beta = \frac{\partial}{\partial \beta} E[m(Y;\beta)] \text{ and } \Omega_\beta = E\left[\frac{1}{1-p(X)} V[m(Y;\beta)|X] + \mathrm{E}(X;\beta)\mathrm{E}(X;\beta)'\right].$$

To demonstrate this result, we follow the steps in the efficiency framework of Newey (1990). First we characterize the properties of the tangent space under Assumption 4.1. Next we write the parameter of interest in its differential form and therefore find a linear influence function d. Finally, we conjecture and verify the projection of d onto the tangent space and the variance of this projection gives rise to the efficiency bound. We first go through these three steps under the assumption that the moment conditions exactly identify β. Finally, the results are extended to over-identified moment conditions by considering their optimal linear combinations.

First we assume that the moment conditions exactly identify β.

Step 1 Consider a parametric path θ of the joint distribution of Y, X and D. Define $p_\theta(x) = P_\theta(D = 1|\, x)$. Under assumption 1, the joint density function for Y, D and X can be factorized into

$$f_\theta(y,x,d) = f_\theta(x) p_\theta(x)^d [1 - p_\theta(x)]^{1-d} f_\theta(y|x)^{1-d}. \tag{1}$$

The resulting score function is then given by

$$S_\theta(d,y,x) = (1-d) s_\theta(y|x) + \frac{d - p_\theta(x)}{p_\theta(x)(1-p_\theta(x))} \dot{p}_\theta(x) + t_\theta(x),$$

where

$$s_\theta(y|x) = \frac{\partial}{\partial \theta} \log f_\theta(y|x), \dot{p}_\theta(x) = \frac{\partial}{\partial \theta} p_\theta(x), t_\theta(x) = \frac{\partial}{\partial \theta} \log f_\theta(x).$$

The tangent space of this model is therefore given by:

$$\mathcal{T} = \{(1-d) s_\theta(y|x) + a(x)(d - p_\theta(x)) + t_\theta(x)\} \tag{2}$$

where $\int s_\theta(y|x) f_\theta(y|x) dy = 0, \int t_\theta(x) f_\theta(x) dx = 0$, and $a(x)$ is any square integrable function.

Step 2 As in the method of moment model in Newey (1990), the differential form of the parameter β can be written as

$$\begin{aligned} \frac{\partial \beta(\theta)}{\partial \theta} &= -\left(\mathcal{J}_\beta\right)^{-1} E\left[m(Y;\beta) \frac{\partial \log f_\theta(Y,X)}{\partial \theta'}\right] \\ &= -\left(\mathcal{J}_\beta\right)^{-1} \{E[m(Y;\beta)(s_\theta(Y|X)' + t_\theta(X)')]\} \\ &= -\left(\mathcal{J}_\beta\right)^{-1} \{E[m(Y;\beta) s_\theta(Y|X)'] + E[\mathcal{E}(X) t_\theta(X)']\} \end{aligned} \tag{3}$$

Therefore $d = \mathcal{J}_\beta^{-1} m(Y;\beta)$. Since $\mathcal{J}_\beta$ is only a constant matrix of nonsingular transformation. The projection of d onto the tangent space will be $\mathcal{J}_\beta$

multiplied by the projection of $m(Y;\beta)$ onto the tangent space. Therefore we only need to consider the projection of $m(Y;\beta)$ onto the tangent space.

Step 3 We conjecture that this projection takes the form of

$$\tau(Y,X,D) = \frac{1-D}{1-p(X)}[m(Y;\beta) - \mathcal{E}(X)] + \mathcal{E}(X)$$

To verify that this is the efficient influence function we need to check that $\tau(Y, X,D)$ lies in the tangent space and that

$$E[(m(Y;\beta) - \tau(Y,X,D))s_\theta(Y,X)] = 0.$$

or that

$$E[m(Y;\beta)s_\theta(Y,X)] = E[\tau(Y,X,D)s_\theta(Y,X)]. \quad (4)$$

To see that $\tau(Y, X, D)$ lies in the tangent space, note that the first term in $\tau(Y, X, D)$ has mean zero conditional on X, and corresponds to the first term of $(1 - d)s_\theta(y|x)$ in the tangent space. The second term in $\tau(Y, X, D)$,$\mathsf{E}(x)$, has unconditional mean zero and obviously corresponds to the $t_\theta(x)$ in the tangent space.

To verify (4), one can make use of the representation of $E[m(Y;\beta)s_\theta(Y, X)]$ in (3), by verifying the two terms in $\tau(Y, X, D)$ separately. The second term is obvious and tautological. The first part,

$$E\left[\frac{1-D}{1-p(X)}[m(Y;\beta) - E(X)]s_\theta(Y,X)\right] = E[m(Y;\beta)s_\theta(Y,X)],$$

follows from the conditional independence Assumption 4.1 and the score function property $E[s\theta(Y, X)|\, X] = 0$. Therefore we have verified that $\tau(Y, X, D)$ is the efficient projection and that the efficiency bound is given by

$$V = \left(\mathcal{J}_\beta\right)^{-1} E\left[\tau(Y,X,D)\tau\left(Y,X,D\right)'\right]\left(J_\beta\right)^{\prime-1} = \left(\mathcal{J}_\beta\right)^{-1} E\left[\frac{1}{1-p(X)} Var\left(m(Y;\beta)\middle|X\right) + \mathcal{E}(X)\mathcal{E}(X)'\right]\left(\mathcal{J}_\beta\right)^{\prime-1}$$

Finally, consider the extensions of these results to the over-identified case. When $dm > d_\beta$, the moment condition is equivalent to the requirement that for any matrix A of dimension $d_\beta \times d_m$ the following exactly identified system of moment conditions holds

$$\mathsf{A}E(m(Y;\beta)] = 0.$$

Differentiating under the integral again, we have

$$\frac{\partial\beta(\theta)}{\partial\theta} = -\left(\mathsf{A}E\left[\frac{\partial m(Y;\beta)}{\partial\beta}\right]\right)^{-1} \times E\left[\mathsf{A}m(Y;\beta)\frac{\partial \log f_\theta\left(Y,X\middle|D=1\right)}{\partial\theta'}\right].$$

Therefore, any regular estimator for β will be asymptotically linear with influence function of the form

$$-\left(\mathsf{A}E\left[\frac{\partial m(Y;\beta)}{\partial\beta}\right]\right)^{-1}\mathsf{A}m(Y;\beta).$$

For a given matrix A, the projection of the above influence function onto the tangent set follows from the previous calculations, and is given by

$$-\left[\mathsf{A}J_\beta\right]^{-1}\mathsf{A}\tau(y,x,d).$$

The asymptotic variance corresponding to this efficient influence function for fixed A is therefore

$$\left[\mathsf{A}J_\beta\right]^{-1}\mathsf{A}\Omega\mathsf{A}'\left[J_\beta\mathsf{A}'\right]^{-1} \quad (5)$$

where

$$\Omega = E[\tau(Y,X,D)\tau(Y,X,D)']$$

as calculated above. Therefore, the efficient influence function is obtained when A is chosen to minimize this efficient variance. It is easy to show that the optimal choice of A is equal to $J'_\beta\Omega^{-1}$, so that the asymptotic variance becomes

$$V = \left(\mathcal{J}'_\beta\Omega^{-1}\mathcal{J}_\beta\right)^{-1}.$$

Different estimation methods can be used to achieve this semiparametric efficiency bound. In particular, Chen et al. (2004) showed that both a semiparametric conditional expectation projection estimator and a semiparametric propensity score estimator based on a sieve nonparametric first-stage regression achieve this efficiency bound.

Conclusion

As discussed in Newey (1990), while the calculation of the tangent space and the efficient projection is easy in several important examples, including the one above, it can be difficult in general. A variety of techniques are available to characterize the tangent space and the efficient projection. Some of these are discussed in details in Newey (1990) and Bickel et al. (1993).

Even in parametric models, the notion of asymptotic efficiency is more complex when one compares estimators that do not converge $\sqrt{n}$ rate or are not asymptotically distributed. Comparing these estimators requires the choice of a loss function, and different loss functions can lead to different efficiency rankings (see Ibragimov and Has'minskii 1981). In econometrics, these estimators sometimes arise in structural models in labour economics and in industrial organization. The efficiency properties of these estimators are analysed in Hirano and Porter (2003) and Chernozhukov and Hong (2004).

Efficiency Wages

Andrew Weiss

Abstract

Efficiency wages capture the effect of compensation on the behaviour of workers, as well as on the quality of workers attracted and retained

by the firm. This effect has greater significance in some areas than others, and can be used to explain wage differentials among firms and industries, as well as to explain why firms respond to demand shocks by reducing their labour force rather than cutting wages, and may ration jobs even in normal times. At the macroeconomic level efficiency wages can explain persistent long-term unemployment as an equilibrium outcome in a competitive labour market.

'Efficiency wages' is a term used to express the idea that labour costs can be described in terms of efficiency units of labour rather than in terms of hours worked, and that wages affect the performance of workers. In this respect, labour differs from most other inputs (with the notable exception of credit), in which inputs are well defined independently of prices. Models of efficiency wages explore the implications of the interconnections between compensation and productivity. On the macroeconomic level, efficiency wages can explain persistent unemployment without relying on either structural imperfections such as search costs or fixed-length contracts or irrational behaviour such as money illusion, which would cause real wages to fail to adjust to market conditions. (For some of the earliest such models, see Futia 1977; Salop 1979; Solow 1979; Shapiro and Stiglitz 1984; Weiss 1981.) At the level of the firm, efficiency wages can result in job queues (excess supply of labour) and can explain why seemingly identical workers may receive different wages at different firms, and why these observed wage differentials are positively correlated with firm characteristics such as profitability, high capital–labour ratios, and establishment size (Brown and Medoff 1989). These market imperfections arise because employers cannot costlessly observe the ability and productivity of workers or because of capital market imperfections that prevent workers from 'buying' the high-wage jobs.

Efficiency wage models have one or more of the following characteristics:

1. Compensation levels and rules affect the types of workers who are attracted to, and retained by, the firm – this is normally referred to as the sorting effect of wages.
2. Compensation rules create incentives for workers to behave in ways that increase firm profits.
3. Wages affect the nutrition and health of workers and thus higher wages directly increase productivity (these 'nutrition' models are most applicable in poor countries).

Consequences of the use of efficiency wages are:

1. Compensation levels within a firm may not be proportionate to relative productivity.
2. Compensation could be a function of characteristics of the establishment employing the worker.
3. Wages could rise more steeply with tenure than does productivity.
4. Some firms could have an excess supply of workers.
5. A frictionless economy could be in a long-run equilibrium with unemployment.

The sorting effects of wages enable a firm to benefit from private information that the employee knows about himself and that is either not available to the firm or would be costly for the firm to acquire. High compensation enables the firm to draw from a larger and better pool of workers. Firms that test job applicants will also find that, by offering a higher wage, the expected

quality of the worker hired, conditional on the applicants test score, will also be higher.

The test could be in the form of a low-wage probation period for new hires. Using a low-wage probation period, followed by a significant wage increase, followed by high wages for workers who perform well during the probation period, the firm can attract job applicants with positive private information about their ability. If the test is imperfect, the use of a low-wage probation period will also discourage applications from risk-averse applicants as well as applicants with a higher cost of capital. Wages that increase steeply with tenure will attract workers who have low quit propensities (aside from their incentive effect of deterring quits). Groshen and Loh (1993) have found that much of the return to tenure takes place at the end of low-wage probationary periods.

Sorting effects of efficiency wages may also explain why firms do not cut wages in response to a fall in demand. If a firm were to cut the wages, it may find that its better workers are most likely to quit. Thus, a profit maximizing firm could find that its best response to a fall in demand for its product would be to fire workers rather than to cut wages.

Most of the efficiency wage models have focused on the ways in which compensation affects the behaviour of workers.

The incentive effects of wages stem from the effect of the level of compensation on the cost to the worker of being fired. Thus, wages above the market clearing level will increase effort, decrease employee theft, decrease absenteeism, and decrease quits. See, for example, Salop and Salop (1976), Klein et al. (1991), and Weiss (1984) on quits; Shapiro and Stiglitz (1984) on effort; Lazear and Rosen (1981), Weiss (1985) on absenteeism.

Levels of compensation also affect the attitude of the employee towards the firm. Thus, paying wages above the market clearing level may have multiple beneficial effects for the firm including: reducing employee theft, increasing unobserved effort, and inducing higher levels of care, which will decrease costs incurred from damage to the firm's property. Greater loyalty to the firm will also encourage workers to acquire firm-specific human capital, to report theft of firm property, and to allocate the worker's effort in ways that benefit the firm. See Akerlof (1984) on gift exchange.

Higher levels of compensation will also reduce the time needed to fill vacancies (Lang 1991). In this case the behaviour being affected is the application process.

Wages directly affect the productivity of workers through their effect on the nutrition of workers as well as their access to clean water and medical care and other goods and services that directly improve their productivity. These 'nutrition' effects are strongest in poor countries and could also possibly explain poverty traps for particularly poor workers who do not have access to firms that are offering efficiency wages.

The importance of these effects will vary across firms. For instance, we would expect that capital-intensive firms will derive the greatest benefit from reductions in absenteeism and quits, and from increased productivity of their employees. Capital-intensive firms will also tend to be most vulnerable to careless behaviour by workers that would damage the valuable property. Larger firms have more difficulty monitoring individual effort and directing the effort in ways that fit the needs of the firm. Consequently, the efficiency wage models would predict that compensation would be correlated with firm size. The direct effects of wages through better nutrition and health take some time to affect productivity, so we would expect that firms with lower costs of capital will offer higher wages – in poor countries these tend to be foreign firms. (In poor countries, in which the nutrition effects are strongest, we might see that wages would be correlated with a firm's cost of capital as well as with the ability of the firm to retain workers after their productivity has been enhanced by the higher wages. The nutrition effects of wages may take some time to affect productivity.) Finally, if high wages are used to attract better workers, then we would expect that when workers are laid off from firms in high-wage industries they will tend to get jobs in other high-wage industries (see Gibbons and Katz 1992).

All of these implications of the efficiency wage model have been confirmed by empirical studies

of the relationship between firm characteristics and wages. (In cases in which wages directly affects productivity we would expect that firms that are likely to be able to retain their workers will also pay higher wages. However, since wages directly affects turnover, and prices vary according to the presence of competitive firms, this implication of the nutrition version of the efficiency wage model is more difficult to verify.) Of course, many if not all of these empirical findings can be explained by other models. For example, the relationship between prior and posterior industry wages for laid-off workers can be explained by competitive models in which workers are being selected based on attributes, such as pulchritude, that are directly observed by the firm but not by the researchers.

Thus, efficiency wages can explain why empirical studies of the relationship between wage and characteristics of establishments find that large, capital-intensive establishments are most likely to pay wages that are above market clearing levels – and in the case of poor countries why foreign firms tend to pay higher wages. The efficiency wage models also can explain why firms fire workers rather than cutting wages, offer wages that attract an excess supply of workers, and pay some of their workers to take early retirement or seek to impose mandatory retirement. See, for instance, Brown and Medoff (1989). Finally, efficiency wage theory can explain the persistence of involuntary unemployment in a free market economy.

Efficient Allocation

Stanley Reiter

JEL Classifications
D5

Analysis of efficiency in the context of resource allocation has been a central concern of economic theory from ancient times, and is an essential element of modern microeconomic theory. The ends of economic action are seen to be the satisfaction of human wants through the provision of goods and services. These are supplied by

production and exchange and limited by scarcity of resources and technology. In this context efficiency means going as far as possible in the satisfaction of wants within resource and technological constraints. This is expressed by the concept of Pareto optimality, which can be stated informally as follows: a state of affairs is Pareto optimal if it is within the given constraints and it is not the case that everyone can be made better off in his own view by changing to another state of affairs that satisfies the applicable constraints.

Because knowledge about wants, resources and technology is dispersed, efficient outcomes can be achieved only by coordination of economic activity. Hayek (1945) pointed out the role of knowledge or information, particularly in the context of prices and markets, in coordinating economic activity. Acquiring, processing and transmitting information are costly activities themselves subject to constraints imposed by technological and resource limitations. Hayek pointed out that the institutions of markets and prices function to communicate information dispersed among economic agents so as to bring about coordinated economic action. He also drew attention to motivational properties of those institutions, or incentives. In this context, the concept of efficiency takes account of the organizational constraints on information processing and transmission in addition to those on production of ordinary goods and services. The magnitude of resources devoted to business or governmental bureaucracies, and to some of the functions performed by industrial salesmen, attests to the importance of these constraints. Economic analysis of efficient allocation has formally imposed only the constraints on production and exchange, and until recently recognized organizational constraints only in an informal way. But it is these constraints that motivate the pervasive and enduring interest in decentralized modes of economic organization, particularly the competitive mechanism.

It is necessary to limit the scope of this essay so that it is not coextensive with microeconomic theory. The main limitation imposed here is to confine attention to models in which either the role of information is ignored, or in which agents do not behave strategically on the basis of private information. In so doing, a large and important class of models involving problems of efficient allocation in the presence of incentive constraints is excluded.

The main ideas of efficient resource allocation are present in their simplest form in the linear activity analysis model of production. We begin with that model.

E

Efficiency of Production: Linear Activity Analysis

The analysis of production can to some extent be separated from that of other economic activity. The concept of efficiency appropriate to this analysis descends from that of Pareto optimality, which refers to both productive and allocative efficiency in the full economy in which production is embedded. It is useful to begin with a model in which technological possibilities afford constant returns to scale, that is, with the (linear) activity analysis model of production pioneered by Koopmans (1951a, b, 1957), and closely related to the development of linear programming associated with Dantzig (1951a, b) and independently with the Russian mathematician Kantorovitch (1939, 1942) and Kantorovitch and Gavurin (1949).

The two primitive concepts of the model are *commodity* and *activity*. A list of n commodities is postulated; a commodity *bundle* is given by specifying a sequence of n numbers $a_1, a_2, \ldots, a_n$. Technological possibilities are thought of as knowledge of how to transform commodities. Such knowledge may be described in terms of collections of activities called *processes*, much as knowledge of how to prepare food is described by recipes. A recipe commonly has two parts, a list of ingredients or inputs and of the output(s) of the recipe, and a description of how the ingredients are to be combined to produce the output(s). In the activity analysis model the description of productive activity is suppressed. Only the specification of inputs and outputs is retained; this defines the production process.

Commodities are classified into 'desired', 'primary' and 'intermediate' commodities. Desired commodities are those whose consumption or availability is the recognized goal of production; they satisfy wants. Primary commodities are those available from nature. (A primary commodity that is also desired is listed separately among the desired commodities and must be transformed by an act of production into its desired form). Intermediate commodities are those that merely pass from one stage of production to another. Each commodity can exist in any non-negative amount (*divisibility*). Addition and subtraction of the numbers measuring the amount of a commodity represent joining and separating corresponding amounts of the commodity.

An activity is characterized by a *net output number* for each commodity, which is positive if the commodity is a net output, negative if it is a net input and zero if it is neither. The term *input-output vector* is also used for this ordered array of numbers. Activity analysis postulates a finite number of basic activities from which all technologically possible activities can be generated by suitable combination. Allowable combinations are as follows. If two activities are known to be possible, then the activity given by their algebraic sum is also possible, i.e. if $a = (a_1, a_2, \ldots, a_n)$ and $b = (b_1, b_2, \ldots, b_n)$, then $a + b = (a_1 + b_1, a_2 + b_2, \ldots, a_n + b_n)$ is also possible. Thus, additivity embodies an assumption of non-interaction between productive activities, at least at the level of knowledge. Furthermore, if an activity is possible, then so is every non-negative multiple of it (*proportionality*), i.e. if $a = (a_1, a_2, \ldots, a_n)$ is possible, then so is $\mu a = (\mu a_1, \mu a_2, \ldots, \mu a_n)$ for any non-negative real number μ. This expresses the assumption of constant returns to scale. The family of activities consisting of all non-negative multiples of a given one forms a process. Since there is a finite number of basic activities, there is also a finite number of basic processes, each intended to describe a basic method of production capable of being carried out at different levels, or intensities.

The assumptions of additivity and proportionality determine a linear model of technology that can be given the following form. Let A be an n by k matrix whose jth column is the input-output vector representing the basic activity that defines the jth basic process, and let $x = (x_1, x_2, \ldots, x_n)$ be the vector whose jth component x_j is the scale (level or intensity) of the jth basic process. Let $y = (y_1, y_2, \ldots, y_n)$ be the vector of commodities. Technology is represented by a linear transformation mapping the space of activity levels into the commodity space, i.e.

$$y = Ax \quad x \geq 0.$$

With the properties assumed, a process can be represented geometrically in the commodity space by a halfline from the origin including all non-negative multiples of some activity in that process. The finite number of halflines representing basic processes generate a convex polyhedral cone consisting of all activities that can be expressed as sums of activities in the basic processes, or equivalently, as non-negative linear combinations of the basic activities, sometimes called a *bundle of basic activities*. This cone is called the *production set*, or set of *possible productions*.

Two other assumptions are made about the production set itself, rather than just the individual activities. First, there is no activity, whether basic or derived, in the production set with a positive net output of some commodity and non-negative net outputs of all commodities. This excludes the possibility of producing something from nothing, whether directly or indirectly. Second, it is assumed that the production set contains at least one activity with a positive net output of some commodity.

If the availability of primary commodities is subject to a bound, the technologically possible productions described by the production set are subject to another restriction; only those possible productions that do not require primary inputs in amounts exceeding the given bounds can be produced. Furthermore, because intermediate commodities are not desired in themselves, their net output is required to be zero. (Strictly speaking, the technological constraint on intermediate commodities is that their net output be non-negative. The requirement that they be zero can be viewed as one of elementary efficiency, excluding

accumulation or necessity to dispose of unwanted goods.) With these restrictions the model can be written

$$y = Ax, \quad x \geq 0, \quad y_i = 0$$

if i is an intermediate commodity, and

$$y_i \geq r_i$$

if i is a primary commodity, where r_i is the (non-positive) limit on the availability of primary commodity i. This leads to the concept of an *attainable* activity.

A bundle of basic activities is *attainable* if the resulting net outputs are non-negative for all desired commodities, zero for intermediate commodities and non-positive for primary commodities, and if the total inputs of primary commodities do not exceed (in absolute amount) the prescribed bounds of availability of those commodities. The set of activities satisfying these conditions is a truncated convex polyhedral cone in the commodity space called the *set of attainable productions*.

The concept of productive efficiency in this model is as follows. An activity (a bundle of basic activities) is *efficient* if it is attainable and if every activity that provides more of some desired commodity and no less of any other is not attainable.

This concept can be seen to be a specialization of Pareto optimality. If for each desired commodity there is at least one consumer who is not satiated in that commodity, at least in the range of production attainable within the given resource limitations, then increasing the amount of any desired commodity without decreasing any other can improve the state of some non-satiated consumer without worsening that of any other.

Characterizing Efficient Production in Terms of Prices

Efficient production can be characterized in terms of *implicit prices*, also called *shadow prices*, or in the context of linear programming, *dual variables*. Efficient activities are precisely those that maximize profit for suitably chosen prices. The profit returned by a process carried out at the level x is

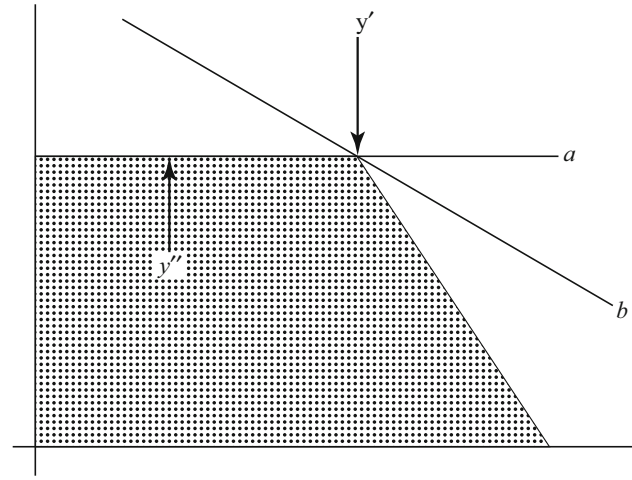
$$x \sum_i p_i a_i,$$

where the prices are $p = (p_1, \ldots, p_n)$, and $a = (a_1, \ldots, a_n)$ is the basic activity defining theprocess; the profit on the bundle of activities Ax at prices p is given by the inner product $py = pAx$.

This characterization is the economic expression of an important mathematical fact about convex sets in $n - 1$ dimensional Euclidean space, namely that through every point of the space not interior to the convex set in question there passes a hyperplane that contains the set in one of its two halfspaces (Fenchel 1950; Nikaido 1969, 1970). (A hyperplane in n dimensional space is a level set of a linear function of n variables, and thus is a translate of an $n - 1$ dimensional linear subspace. A hyperplane is given by an equation of the form $c_1x_1 + c_2x_2 + \cdots + c_nx_n = k$, where the x's are variables, the c's are coefficients defining the linear function and k is a constant identifying the level set. A hyperplane divides the space into two halfspaces corresponding to the two inequalities $c_1x_1 + c_2x_2 + \cdots + c_nx_n \gtreqless k$ respectively.) It can also be seen that a point of a convex set is a boundary point if and only if it maximizes a linear function on the (closure of the) set. These facts can be used to characterize efficient production because the attainable production set is convex and efficient activities are boundary points of it. Because the efficient points are those, roughly speaking, on the 'north-east' frontier of the set, the linear functions associated with them have non-negative coefficients, interpreted as prices. On the other hand, if a point of the attainable set maximizes a linear function with strictly positive coefficients (prices), then it is on the 'north-east' frontier of the set.

In Fig. 1 the set enclosed by the broken line and the axes is the projection of the attainable set on the output coordinates; inputs are not shown. The point y' in the figure is efficient; the point y' is not; both y' and y'' maximize a linear function with

Efficient Allocation, Fig. 1



non-negative coefficients (the level set containing y' is labelled a and also contains y''). However, y' maximizes a linear function with positive coefficients (one such, whose level set through y' is labelled b, is shown), while y'' does not.

These implicit, or efficiency prices arise from the logic of efficiency or maximization when the relevant sets are convex, not from any institutions such as markets or exchange. An important reason for interest in them is the possibility of achieving efficient performance by decentralized methods. As described above, under the assumptions of additivity and constant returns to scale the production set can be seen to be generated by a finite number of basic processes, each of which consists of the activities that are non-negative multiples of a basic activity, the multiple being the scale (level, or intensity) at which the process is operated. Following the presentation of Koopmans (1957), each basic process is controlled by a manager, who decides on its level. The manager of a process is assumed to know only the input-output coefficients of his process. Each primary resource is in the charge of a resource holder, who knows the limit of its availability. Efficiency prices are used to guide the choices of managers and resource holders. (Under constant returns to scale, if an activity yields positive profit at a given system of prices, then increasing the scale of the process containing that activity increases the profit. Since the scale can be increased without bound, if the profitability of a process is not zero or negative, then, in the eyes of its manager, who does not know the aggregate resource constraints, it can be made infinite. Therefore, the systems of prices that can be considered for the role of efficiency prices must be restricted to those *compatible with the given technology*, namely prices such that no process is profitable and at least one process breaks even). Two propositions characterize efficient production by prices and provide the basis for an interpretation in terms of decentralized control of production.

> In a given linear activity analysis model, if there is a given system of prices compatible with the technology, in which the prices of all desired commodities are positive, then any attainable bundle of basic activities selected only from processes that break even and which utilizes all positively priced primary commodities to the limit of their availability and does not use negatively priced primary commodities at all, is an efficient bundle of activities.
>
> In a given linear activity analysis model, each efficient bundle of activities has associated with it at least one system of prices compatible with the technology such that every activity in that bundle breaks even and such that prices of desired commodities are positive, and the price of a primary commodity is non-negative, zero or non-positive, according as its available supply is full, partly, or not used at all (Koopmans 1957).

These propositions are stated in a static form. There is no reference to managers raising or lowering the levels of the processes they control, or to

resource holders adjusting prices. A dynamic counterpart of these propositions would be of interest, but because of the linearity of the model such dynamic adjustments are unstable (Samuelson 1949).

It should also be noted that the concept of decentralization is not explicitly defined in this literature; the interpretation is by analogy with the competitive mechanism. Nevertheless, the interest in characterizing efficiency by prices and their interpretation in terms of decentralization is an important theme in the study of efficient resource allocation.

The linear activity analysis model has been generalized in several directions. These include dropping the assumption of proportionality, dropping the restriction to a finite number of basic activities, dropping the restriction to a finite number of commodities and dropping the restriction to a finite number of agents. Perhaps the most directly related generalization is to the nonlinear activity analysis, or nonlinear programming, model.

Efficiency of Production: Nonlinear Programming

In the nonlinear programming model there is, as in the linear model, a finite number of basic processes. Their levels are represented by a vector $x = (x_1, x_2, \ldots, x_k)$, where k is the number of basic processes. Technology is represented by a nonlinear transformation from the space of process levels to the commodity space (still assumed to be finite dimensional), written

$$y = F(x), \quad x \geq 0.$$

The production set in this model is the image in the commodity space of the non-negative orthant of the space of process levels. Under the assumptions usually made about F, the production set is convex, though, of course, not a polyhedral cone.

In this model as in the linear activity analysis model a central result is the characterization of efficient production in terms of prices. The simplest case to begin with is that of one desired commodity, say, one output, with perhaps several inputs. In this case the (vector-valued) function F can be written

$$F(x) = [f(x), g_1(x), g_2(x), \ldots, g_m(x)],$$

where the value of f is the output, and $g_1, \ldots, g_m$ correspond to the various inputs. Resource constraints are expressed by the conditions

$$g_j(x) \geq 0, \quad for\ j = 1, 2, \ldots, m,$$

and non-negativity of process levels by the condition, $x \geq 0$. (Here the resource constraints $r_j \leq h_j(x) \leq 0$ are written more compactly as $h_j(x) - r_j = g_j(x) \geq 0$.)

In this model the definition of efficient production given in the linear model amounts to maximizing the value of f subject to the resource and non-negativity constraints just mentioned.

Problems of constrained maximization are intimately related to saddle-point problems. Let L be a real valued function defined on the set $X \times Y$ in R^n. A point (x^*, y^*) in $X \times Y$ is a *saddle point* of L if

$$L(x, y^*) \leq L(x^*, y^*) \leq L(x^*, y),$$

for all x in X and all y in Y. The concept of a concave function is also needed. A real valued function f defined on a convex set X in R^n is a *concave function* if for all x and y in X and all real numbers $0 \leq a \leq 1$

$$f(ax + (1 - a)y) \geq af(x) + (1 - a)f(y).$$

The following mathematical theorem is fundamental.

Theorem (Kuhn and Tucker 1951; Uzawa 1958): Let f and $g_1, g_2, \ldots, g_m$ be real valued concave functions defined on a convex set X in R^n. If f achieves a maximum on X subject to $g_j(x) \geq 0$, $j = 1, 2, \ldots, m$ at the point x^* in X, then there exist non-negative numbers $p_0^*, p_0^*, \ldots, p_m^*$, not all zero, such that $p_0^* f(x) + p^* g(x) \leq p_0^* f(x^*)$ for all x in X, and furthermore, $p^* g(x)^* = 0$. (Here the vectors $p^* = (p_1^*, p_2^*, \ldots, p_m^*)$, and $g(x) = [g_1(x), g_2(x), \ldots, g_m(x)]$). The vector p^* may be chosen so that

$$\sum_{0}^{m} p_j^* = 1.$$

An additional condition (Slater 1950) is important. (It ensures that the coefficient p_0 of f is not zero.)

Slater's Condition There is a point x' in X at which $g_j(x') > 0$ for all $j = 1, 2, \ldots, m$.

If attention is restricted to concave functions, as in the Kuhn-Tucker-Uzawa Theorem, the relation between constrained maxima and saddle points can be summarized in the following theorem.

Theorem If f and $g_j, j = 1, 2, \ldots, m$ are concave functions defined on a convex subset X in R^n, and if Slater's Condition is satisfied, then x^* in X maximizes f subject to $g_j(x) \geq 0, j = 1, 2, \ldots, m$, if and only if there exists $\lambda^* = (\lambda_1^*, \lambda_2^*, \ldots, \lambda_m^*)$, $\lambda_j^* \geq 0$ for $j = 1, 2, \ldots, m$, such that (x^*, λ^*) is a saddle point of $L(x, \lambda) = f(x) + \lambda g(x)$ on $X \times R_+^n$.

This theorem is easily seen to cover the case where some constraints are equalities, as in the case of intermediate commodities. The sufficiency half of this theorem holds for functions that are not concave.

The auxiliary variables $\lambda_1, \lambda_2, \ldots, \lambda_m$, called *Lagrange multipliers*, play the role of efficiency prices, or shadow prices; they evaluate the resources constrained by the condition $g(x) \geq 0$. The maximum characterized by the theorem is a global one, as in the case of linear activity analysis.

If the functions involved are differentiable, a saddle point of the Lagrangean can be studied in terms of first-order conditions. The first-order conditions are necessary conditions for a saddle point of L. If the functions f and the g's are concave on a convex set X, then the first-order conditions at a point (x^*, λ^*) are also sufficient; that is, they imply that (x^*, λ^*) is a saddle point of L. Thus,

Theorem If $f, g_1, g_2, \ldots, g_m$ are concave and differentiable on an open convex set X in R^n, and if Slater's Condition is satisfied, then x^* maximizes f subject to $g_j(x) \geq 0$ for $j = 1, 2, \ldots, m$ if and only if there exists numbers $\lambda_1^*, \lambda_2^*, \ldots, \lambda_m^*$ such that the first-order conditions for a saddle point of $L(x, \lambda) = f(x) + \lambda g(x)$ are satisfied at (x^*, λ^*).

If there are non-negativity conditions on the x's,

$$g_j(x) \geq 0, \quad x \geq 0, \quad x \text{ in } R^n$$

and the first-order conditions can be written

$$\begin{gathered} f_x^* + \lambda^* g_x^* \leq 0, \left(f_x^* + \lambda^* g_x^*\right) x^* = 0, \\ \lambda^* g(x^*) = 0, \quad g(x^*) \geq 0, g(x^*) \geq 0, \\ \lambda^* \geq 0 \quad \text{and } \lambda^* g(x^*) = 0, \end{gathered}$$

where f_x^* denotes the derivative of f evaluated at x^*. In more explicit notation, the conditions $f_x^* + \lambda^* g_x^* = 0$ can be written as

$$\partial f / \partial x_i + \sum_{j=1}^{m} \lambda_j^* \partial g_j / \partial x_i = 0, \quad i = 1, 2, \ldots, n$$

When the assumption of concavity is dropped, it is no longer possible to ensure that the local maximum is also a global one. However, it is still possible to analyse local constrained maxima in terms of local saddle-point conditions. In this case a condition is needed to ensure that the first-order conditions for a saddle point are indeed necessary conditions. The Kuhn-Tucker Constraint Qualification is such a condition. Arrow et al. (1961) have found a number of conditions, more useful in application to economic models, that imply the Constraint Qualification.

The case of more than one desired commodity leads to what is called the *vector maximum problem*, Kuhn and Tucker (1951). This may be defined as follows. Let $f_1, f_2, \ldots, f_k$ and $g_1, g_2, \ldots, g_m$ be real valued functions defined on a set X in R^n. We say x^* in X achieves a (global) *vector maximum* of $f = (f_1, f_2, \ldots, f_k)$ subject to $g_j(x) \geq 0, j = 1, 2, \ldots, m$ if,

(I) $g_j(x^*) \geq 0, j = 1, 2, \ldots, m$,

(II) there does not exist x' in X satisfying $f_i(x') \geq f_i(x^*)$ for $i = 1, 2, \ldots, k$ with $f_i(x') \geq f_i(x^*)$ for some value of i, and $g_j(x') \geq 0$ for $j = 1, 2, \ldots, m$.

This is just the concept of an efficient point expressed in the present notation.

A vector maximum has a saddle-point characterization similar to that for a scalar valued function.

Theorem Let $f_1, f_2, \ldots, f_k$ and $g_1, g_2, \ldots, g_m$ be real valued concave functions defined on a convex X set in R^n. Suppose there is x^0 in X such that $g_j(x^0) \geq 0, j = 1, 2, \ldots, m$, (Slater's Condition). If x^* achieves a vector maximum of f subject to $g(x) \geq 0$ then there exist $a = (a_1, a_2, \ldots, a_k)$ and $\lambda^* = (\lambda_1^*, \lambda_2^*, \ldots, \lambda_m^*)$ with $a_j \geq 0$ for all j, $a \neq 0$ and $\lambda \geq 0$ such that (x^*, λ^*) is a saddle point of the Lagrangean $L(x, \lambda) = af(x) + \lambda g(x)$.

Several different 'converses', to this theorem are known. One states that if x^* maximizes $L(x, \lambda^*)$ for some strictly positive vector a and non-negative λ^*, and if $\lambda^* g(x^*) = 0$ and $g(x^*) \geq 0$, then x^* gives a vector maximum of f subject to $g(x) \geq 0$, and x in X. Another, parallel to the result for the case of one desired commodity, is the following.

Theorem Let f and g be functions as in the theorem above. If there are positive real numbers $a_1, a_2, \ldots, a_k$ and if (z^*, λ^*) is a saddle point of the Lagrangean L (defined as above) then (I) x^* achieves a maximum of f subject to $g(x) \geq 0$ on X, and (II) $\lambda^* g(x^*) = 0$.

The positive numbers $a_1, \ldots, a_k$ are interpreted as prices of desired commodities, and the non-negative numbers λ_j^* are prices of the remaining commodities. The condition $\lambda^* g(x^*) = 0$ which arises in these theorems states that the value of unused resources at the efficiency prices λ^* is zero; that is, resources not fully utilized at a vector maximum have a zero price.

The connection between vector maxima and Pareto optima is as follows. Because a vector maximum is an efficient point (for the vectorial ordering of the commodity space), it is a Pareto optimum for appropriately specified (non-satiated) utility functions, as was already pointed out in the case of the linear activity analysis model. Furthermore, if the functions $f_1, \ldots, f_k$ are themselves utility functions, and the variable x denotes allocations, with the constraints g defining feasibility, then a vector maximum of f subject to the constraints $g(x) \geq 0$ and x in X is a Pareto optimum, and vice versa. Hence the saddle-point theorems give a characterization of Pareto optima by prices. The interpretation of prices in terms of decentralized resource allocation described in the linear activity analysis model also applies in this nonlinear model. The proofs of these theorems reveal an important logical role played by the principle of marginal cost pricing.

The basic theorems of nonlinear programming, especially the Kuhn-Tucker-Uzawa Theorem in the setting of the vector maximum problem, have been extended to the case of infinitely many commodities. (Hurwicz 1958, first obtained the basic results in this field.) Technicalities aside, the theorems carry over to certain infinite dimensional spaces, namely linear topological spaces, or in the case of first-order conditions, Banach spaces.

Dropping the restriction to a finite number of basic processes leads to classical production or transformation function models of production, whose properties depend on the detailed specifications made.

Samuelson (1947) used Lagrangean methods to analyse interior maxima subject to equality constraints in the context of production function models, as well as that of optimization by consumers. He also gave the interpretation of Lagrange multipliers as shadow prices.

Efficient Allocation in an Economy with Consumers and Producers

In an economy with both consumption and production decisions, efficiency is concerned with distribution as well as production. Data about restrictions on consumption and the wants of consumers must be specified in addition to the data about production. The elements of the models are as follows.

The commodity space is denoted X; it might be l-dimensional Euclidean space, or a more abstract space such as an additive group in which, for example, some coordinates are restricted to have integer values. There is a (finite) list of consumers, 1, 2,. . ., n, and a similar list of producers, 1, 2,. . ., m. A *state* of the economy is an array consisting of a commodity bundle for

each agent in the economy, consumer or producer. This may be written $(\langle x^i\rangle, \langle y^j\rangle)$, where $\langle x^i\rangle = (x^1, x^2, \ldots, x^n)$ and $\langle y^j\rangle = (y^1, y^2, \ldots, y^m)$ and x^i and y^j are commodity bundles. Absolute constraints on consumption are expressed by requiring that the allocation $\langle x^i\rangle$ belong to a specified subset X of the space X^n of allocations.

Examples of such constraints are:

1. The requirement that the quantity of a certain commodity be non-negative.
2. The requirement that a consumer requires certain minimum quantities of commodities in order to survive.

Each consumer i has a preference relation, denoted $\succsim_i$, defined on X. This formulation admits externalities in consumption, including physical externalities and externalities in preferences; for example, preferences that depend on the consumption of other agents, termed non-selfish preferences. The consumption set of the ith consumer is the projection X^i of X onto the space of commodity bundles whose coordinates refer to the holdings of the ith consumer.

Technology is specified by a production set Y, a subset of X^m, consisting of those arrays $\langle y^j\rangle$ of input-output vectors that are jointly feasible for all producers. The production set of the jth producer, denoted Y^j, is the projection of Y onto the subspace of X^m whose coordinates refer to the jth producer.

The (aggregate) initial endowment of the economy is denoted by w, a commodity bundle in X.

These specifications define an *environment*, a term introduced by Hurwicz (1960) in this usage and according to him suggested by Jacob Marschak. This term refers to the primitive or given data from which analysis begins. Each environment determines a set of *feasible* states. These are the states $(\langle x^i\rangle, \langle y^j\rangle)$ such that $\langle x^i\rangle$ is in X, $\langle y^j\rangle$ is in Y and

$$\sum x^i - \sum y^j \leq w.$$

An environment determines the set of states that are Pareto optimal for that environment. Explicitly, they are the states $(\langle x^{*i}\rangle, \langle y^{*j}\rangle)$ that are feasible in the given environment, and such that if any other state $(\langle x^i\rangle, \langle y^j\rangle)$ has the property that $\langle x^i\rangle \succsim_i \langle x^{*i}\rangle$ for all i with $\langle x^i\rangle \succ_i \langle x^{*i}\rangle$ for some i', then $(\langle x^i\rangle, \langle y^j\rangle)$ is not feasible in the given environment.

It is important to note that the set of feasible states and the set of Pareto optimal states are completely determined by the environment; specification of economic organization is not involved.

At this level of generality, where externalities in consumption and production are admitted as possibilities, and where commodities may be indivisible, no general characterization of Pareto optima in terms of prices is possible. (Indeed, Pareto optima may not exist. Conditions that make the set of feasible allocations non-empty and compact and preferences continuous suffice to ensure the existence of Pareto optima.) In environments with externalities, or other non-neoclassical features, Pareto optima are generally not attainable by decentralized processes.

If the class of environments under consideration is restricted to the neoclassical environments, the fundamental theorems of welfare economics provide a characterization of Pareto optimal states via efficiency prices. That characterization has a natural interpretation in terms of a decentralized mechanism for allocation of resources.

The framework for these results is obtained by restricting the class of environments specified above as follows. The commodity space is to be Euclidean space of l dimensions, i.e. $X = R^l$. The consumption set for the economy is to be the product of its projections, i.e. $X = X^1 \times X^2 \times \cdots \times X^n$. This expresses the fact that if each agent's consumption is feasible for him, the total array is jointly feasible. Furthermore, each agent is restricted to having selfish preferences; that is, agent i's preference relation depends only on the coordinates of the allocation that refer to his holdings. In that case the preference relation $\succsim_i$ may be defined only on X^i, for each i. Similarly, externalities are ruled out in production, i.e. $Y = Y^1 \times Y^2 \times \cdots \times Y^m$.

The concept of an *equilibrium relative to a price system* (Debreu 1959) serves to characterize Pareto optima by prices. A price system, denoted p, is an

element of R^l; the environment $e = [(X^i), (\succsim_i), (Y^j), w]$ is of the restricted type specified above (free of externalities and indivisibilities).

A state $[(x^{*i}), (y^{*j})]$ of e is an *equilibrium relative to price system p* if:

1. For every consumer i, x^{*i} maximizes preference $\succsim_i$ on the set of consumption bundles whose value at the prices p does not exceed the value of x^{*i} at those prices, i.e., if x^i is in $\{x^i \text{ in } x^i : px^i \leq px^{*i}\}$ then $x^i \preccurlyeq ix^{*i}$.
2. For every producer j , y^{*j} maximizes profit py^j on Y^j.
3. Aggregate supply and demand balance, i.e.

$$\sum_i x^{*i} - \sum_i y^{*j} = w.$$

An equilibrium relative to a price system differs from a competitive equilibrium (see below) in that the former does not involve the budget constraints applying to consumers in the latter concept. In an equilibrium relative to a price system the distribution of initial endowment and of the profits of firms among consumers need not be specified.

The first theorem of neoclassical welfare economics states, subject only to the exclusion of externalities and a mild condition that excludes preferences with thick indifference sets, that a state of an environment e that is an equilibrium relative to a price system p is a Pareto optimum of e (Koopmans 1957).

The second welfare theorem is deeper and holds only on a smaller class of environments, sometimes referred to in the literature as the *classical environments* (called neoclassical above). One version of this theorem is as follows. Let $e = [(X^i), (\succsim_i), (Y^j), w]$ be an environment such that for each i

1. X^i is convex.
2. The preference relation $\succsim_i$ is continuous.
3. The preference relation $\succsim_i$ is convex.
4. The set $\Sigma_j Y_j$ is convex.

Let $[(x^{*i}), (y^{*j})]$ be a Pareto optimum of e such that there is at least one consumer who is not satiated at x^{*i}. Then there is a price system p, with not all components equal to 0, such that – except for Arrow's (1951) 'exceptional case', where p is such that for some i the expenditure px^{*i} is a minimum on the consumption set X^i – the state $[(x^{*i}), (y^{*j})]$ is an equilibrium relative to p.

(The condition that preferences are convex and not satiated is sufficient to exclude 'thick' indifference sets. A preference relation on X^i is convex if whenever x' and x'' are points of X^i with x' strictly preferred to x'' then the line segment connecting them (not including the point x'') is strictly preferred to x'. The consumption set X^i must be convex for this property to make sense. A preference relation is not satiated if there is no consumption preferred to all others.)

Hurwicz (1960) has given an alternative formalization of the competitive mechanism in which Arrow's exceptional case presents no difficulties.

If the exceptional case is not excluded, then it can still be said that:

1. x^{*i} minimizes expenditure at prices p on the upper contour set of x^{*i}, for every i, and
2. y^{*j} maximizes 'profit' py^j on the production set Y^j, for every j.

The state (x^*, y^*) together with the prices p, constitute a *valuation equilibrium* (Debreu 1954).

As in the case of efficiency prices in pure production models, these prices have in themselves no institutional significance. They are, however, in the same way as other efficiency prices, suggestive of an interpretation in terms of decentralization.

If, in addition to the restriction to classical environments, the economic organization is specified to be that of a system of markets in a private ownership economy, and if agents are assumed to take prices as given, then the welfare theorems can translate into the assertion that the set of Pareto optima of an environment e and the set of competitive equilibria for e (subject to the possible redistribution of initial endowment and ownership shares) are identical. More precisely, the specification of the environment given above is augmented by giving each consumer a bundle of commodities, his initial endowment, denoted w^i.

The total endowment is $w = \Sigma_i w^i$. Furthermore, each consumer has a claim to a share of the profits of each firm; the claims for the profit of each firm are assumed to add up to the entire profit. When prices and the production decisions of the firms are given, the profits of the firms are determined and so is the value of each consumer's initial endowment. Therefore, the income of each consumer is determined. Hence, the set of commodity bundles a consumer can afford to buy at the given prices, called his *budget set*, is determined; this consists of all bundles in his consumption set whose value at the given prices does not exceed his income at the given prices. Competitive behaviour of consumers means that each consumer treats the prices as given constants and chooses a bundle in his budget set that maximizes his preference: that is, a bundle x^i that is in X^i and such that if any other bundle x'^i is preferred to it, then x'^i is not in his budget set.

Competitive behaviour of firms is to maximize profits computed at the given prices p, regarded by the firms as constants; that is, a firm chooses a production vector y^j in its production set with the property that any other vector affording higher profits than py^j is not in the production set of firm j.

A *competitive equilibrium* is a specification of a commodity bundle for each consumer, a production vector for each firm, and a price system, together denoted $[(x^{*i}), (y^{*j}), p^*]$, where p^* has no negative components, satisfying the following conditions:

1. For each consumer i the bundle x^{*i} maximizes preference on the budget set of i.
2. For each firm j the production vector y^{*j} maximizes profit p^*y^j on the production set Y^j.
3. For each commodity, the total consumption does not exceed the net total output of all firms plus the total initial endowment, i.e. $\Sigma_i x^{*i} - \Sigma_j y^{*j} \leq w = \Sigma_i w^i$;
4. For those commodities k for which the inequality in 3 is strict; that is, the total consumption is less than initial endowment plus net output, the price p_k^* is zero.

The welfare theorems stated in terms of equilibrium relative to a price system translate directly into theorems stated in terms of competitive equilibrium. Briefly, every competitive equilibrium allocation in a given classical environment is Pareto optimal in that environment, and every Pareto optimal allocation in a given classical environment can be made a competitive equilibrium allocation of an environment that differs from the given one only in the distribution of the initial endowment. (Arrow (1951), Koopmans (1957), Debreu (1959) and Arrow and Hahn (1971) give modern and definitive treatment of the classical welfare theorems.)

It should be noted that the equilibria involved must exist for these theorems to have content. Sufficient conditions for existence of competitive equilibrium, which, since a competitive equilibrium is automatically an equilibrium relative to a price system, are also sufficient for existence of an equilibrium relative to a price system, include convexity and continuity of consumption sets and preferences and of production sets, as well as some assumptions which apply to the environment as a whole, restricting the ways in which individual agents may fit together to form an environment (Arrow and Debreu 1954; Debreu 1959; McKenzie 1959).

The second welfare theorem involves redistribution of initial endowment. This is essential because the set of competitive equilibria from a given initial endowment is small (essentially finite) (Debreu 1970), while the set of Pareto optima is generally a continuum. The set of Pareto optima cannot in general be generated as competitive allocations without varying the initial point. If redistribution is done by an economic mechanism, then it should be a decentralized one to support the interpretation given of the second welfare theorem. No such mechanism has been put forward as yet. Redistribution of initial endowment by lump-sum taxes and transfers has been discussed. A customary interpretation views these as brought about by a process outside economics, perhaps by a political process; no claim is made that such processes are decentralized. Some economists consider dependence on redistribution unsatisfactory because information about initial endowment is private; only the individual agent knows his own endowment. Consequently the

expression of that information through political or other action can be expected to be strategic. The theory of second-best allocations has been proposed in this context. Redistribution of endowment is excluded, and the mechanism is restricted to be a price mechanism, but the price system faced by consumers is allowed to be different from that faced by producers; all agents behave according to the rules of the (static) competitive mechanism. The allocations that satisfy these conditions, when the price systems are variable, are maximal allocations in the sense that they are Pareto optimal within the restricted class just defined. These are so-called *second-best* allocations. This analysis was pioneered by Lipsey and Lancaster (1956) and Diamond and Mirrlees (1971).

Efficient Allocation in Non(Neo)Classical Environments

The term *nonclassical* refers to those environments that fail to have the properties of classical ones; there may be indivisible commodities, nonconvexities in consumption sets, preferences or production sets, or externalities in production or consumption. An example of nonconvex preference would arise if a consumer preferred living in either Los Angeles or New York to living half the time in each city, or living halfway between them, depending on the way the commodity involved is specified. A production set representing a process that affords increasing returns to scale is an example of nonconvexity in production. A large investment project such as a road system is an example of a significant indivisibility. Phenomena of air or water pollution provide many examples of externalities in consumption and production.

The characterization of optimal allocation in terms of prices provided by the classical welfare theorems does not extend to nonclassical environments. If there are indivisibilities, equilibrium prices may fail to exist. Lerner (1934, 1947) has proposed a way of optimally allocating resources in the presence of indivisibilities. It would typically require adding up consumers' and producers' surplus.

Increasing returns to scale in production generally results in non-existence of competitive equilibrium, because of unbounded profit when prices are treated as given. Nash equilibrium, a concept from the theory of games, can exist even in cases of increasing returns. The difficulty is that such equilibria need not be optimal. Similar difficulties occur in cases of externalities.

Failure of the competitive price mechanism to extend the properties summarized in the classical welfare theorems to nonclassical environments has led economists to look for alternative ways of achieving optimal allocation in such cases. Such attempts have for the most part sought institutional arrangements that can be shown to result in optimal allocation. Ledyard (1968, 1971) analysed a mechanism for achieving Pareto optimal performance in environments with externalities. The use of taxes and subsidies advocated by Pigou (1932) to achieve Pareto optimal outcomes in cases of externalities is such an example. In a similar spirit Davis and Whinston (1962) distinguish externalities in production that leave marginal costs unaffected from those that do change marginal costs. In the former case they propose a pricing scheme, but one that involves lump-sum transfers. Marginal cost pricing, including lump-sum transfers to compensate for losses, which was extensively discussed as a device to achieve optimal allocation in the presence of increasing returns (Lerner 1944; Hotelling 1938; and many others) is another example of a scheme to realize optimal outcomes in nonclassical environments in a way that seeks to capture the benefits associated with decentralized resource allocation. In the case of production under conditions of increasing returns, the use of nonlinear prices has been suggested in an effort to achieve optimality with at least some of the benefits of decentralization. (See Arrow and Hurwicz 1960; Heal 1971; Brown and Heal 1982; Brown et al. 1986; Jennergren 1971; Guesnerie 1975.)

In the case of indivisibilities, and in the context of productive efficiency, integer programming algorithms exist for finding optima in specific problems, but a general characterization in terms of prices such as exists for the classical environments is not available. A decentralized process,

involving the use of randomization, whose equilibria coincide with the set of Pareto optima has been put forward by Hurwicz et al. (1975). This process has the property that the counterparts of the classical welfare theorems hold for environments in which all commodities are indivisible, and the set of feasible allocations is finite, or in which there are no indivisible commodities, or externalities, but there may be nonconvexities in production or consumption sets, or in preferences. This, of course, includes the possibility of increasing returns to scale in production.

The schemes and processes that have been proposed, including many not described here, are quite different from one another. If attention is confined to pricing schemes without additional elements, such as lump-sum transfers, it may be satisfactory to proceed on the basis of an informal intuitive notion of decentralization. This amounts in effect to identifying decentralization with the competitive mechanism, or more generally with price or market mechanisms. If a broader class of processes is to be considered, including some already mentioned in this discussion, then a formal concept of decentralized resource allocation process is needed.

Efficient Allocation Through Informationally Decentralized Processes

A formal definition of a concept of *allocation process* was first given by Hurwicz (1960). He also gave a definition of *informational decentralization* applying to a broad class of allocation mechanisms, based in part on a discussion by Hayek (1945) of the advantages of the competitive market mechanism for communicating knowledge initially dispersed among economic agents so that it can be brought to bear on the decisions that determine the allocation of resources. Hurwicz's formulation is as follows.

There is an initial dispersion of information about the environment; each agent is assumed to observe directly his own characteristic, e^i, but to know nothing directly about the characteristics of any other agent. In the absence of externalities, specifying the array of individual characteristics specifies the environment, i.e. $e = (e^1, \ldots, e^n)$. When there are externalities, an array of individual characteristics, each component of which corresponds to a possible environment, may not together constitute a possible environment. In more technical language, when there are externalities the set of environments is not the Cartesian product of its projections onto the sets of individual characteristics.

The goal of economic activity, whether efficiency, Pareto optimality or some other desideratum such as fairness, can be represented by a relation between the set of environments and the set of allocations, or outcomes. This relation assigns to each environment the set of allocations that meet the criterion of desirability. In the case of the Pareto criterion, the set of allocations that are Pareto optimal in a given environment is assigned to that environment. Formally, this relation is a correspondence (a set-valued function) from the set of environments to the set of allocations.

An allocation process, or mechanism, is modelled as an explicitly dynamic process of communication, leading to the determination of an outcome. In formal organizations standardized forms are frequently used for communication; in organized markets like the Stock Exchange, these include such things as order forms; in a business, forms on which weekly sales are reported; in the case of the Internal Revenue Service, income tax forms. A form consists of entries or blanks to be filled in a specified way. Thus, a form can be regarded as an ordered array of variables whose values come from specified sets. In the Hurwicz model, each agent is assumed to have a *language*, denoted M^i for the ith agent, from which his (possibly multi-dimensional) *message*, m^i, is chosen. The *joint message* of all the agents, $m = (m^1, \ldots, m^n)$ is in the *message space* $M = M^1 \times \ldots \times M^n$. Communication takes place in time, which is discrete; the message $m_t = \left(m_t^1, \ldots, m_t^n\right)$ denotes the message at time t. The message an agent emits at time t can depend on anything he knows at that time. This consists of what the agent knows about the environment by direct observation, by assumption, (*privacy*) his own characteristics, e^i for agent i, and what he has learned from others via the messages received from them. The agents' behaviour

is represented by *response functions*, which show how the current message depends on the information at hand. Agent i's message at time t is

$$m_i^i = f^i\left(m_{t-1}, m_{t-2}, \ldots, e^i\right), i = 1, \ldots, n, \quad t = 0, \ 1, \ 2, \ldots$$

If it is assumed that memory is finite, and bounded, it is possible without loss of generality to take the number of past periods remembered to be one. (If memory is unbounded, taking the number of periods remembered to be one excludes the possibility of a finite dimensional message space.) In that case the response equations become a system of first order temporally homogeneous difference equations in the messages. Thus:

$$m_i^i = \ f_i\left(m_{t-1}; e^i\right) \ \ i = 1, \ldots, n, t = 0, \ldots,$$

which can be written more compactly as

$$(^*) m_t = f(m_{t-1}; e).$$

(This formulation can accommodate the case of directed communication, in which some agents do not receive some messages; if agent i is not to receive the message of j, then f^i is independent of m^j, although m^j appears formally as an argument.) Analysis of informational properties of mechanisms is to begin with separated from that of incentives. When the focus is on communication and complexity qsts, the response functions are not regarded as chosen by the agent, but rather by the designer of the mechanism.

The iterative interchange of messages modelled by the difference equation system (*) eventually comes to an end, by converging to a stationary message. (It is also possible to have some stopping rule, such as to stop after a specified number of iterations.) The stationary message, which will be referred to as an *equilibrium message*, is then translated into an outcome, by means of the *outcome function*:

$$h : M \to Z,$$

where Z is the space of outcomes, usually allocations or trades. An allocation mechanism so modelled is called an *adjustment process*; it consists of the triple (M, f, h). Since no production or consumption takes place until all communication is completed, these processes are *tâtonnement* processes.

A more compact and general formulation was given by Mount and Reiter (1974) by looking only at message equilibria when attention is restricted to static properties. A correspondence is defined, called the *equilibrium message correspondence*. It associates to each environment the set of equilibrium messages for that environment. In order to satisfy the requirement of privacy, namely that each gent's message depend on the environment only through the agent's characteristic, the equilibrium message correspondence must be the intersection of individual message correspondences, each associating a set of message acceptable to the individual agent as equilibria in the light of his own characteristic. Thus the equilibrium message correspondence

$$\mu : E \to M,$$

is given by

$$\mu(e) = \bigcap_i \mu^i(e^t),$$

where $\mu^i : E^i \to M$, is the individual message correspondence of agent i. Note that here the message space M need not be the Cartesian product of individual languages. In the case of an adjustment process, the equilibrium message correspondence is defined by the conditions

$$\mu^i\left(e^i\right) = \left\{m \ \ in \ \ M | f^i\left(m; e^i\right) = m^i\right\}, \quad i = 1, \ldots, n$$

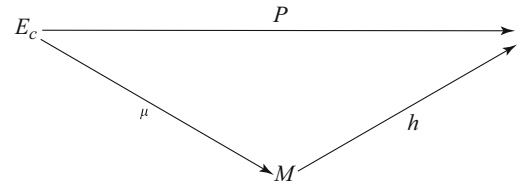
together with the condition that μ is the intersection of the μ^i. Specification of the outcome function $h : M \to Z$ completes the model, (M, μ, h).

The performance of a mechanism of this kind can be characterized by the mapping defined by the composition of the equilibrium message correspondence μ and the outcome function h. The mapping $h\mu; E \to Z$, possibly a correspondence, specifies the outcomes that the mechanism (M, μ, h) generates in each environment in E. A mechanism, whether in

the form of an adjustment process, or in the equilibrium form, is called *Pareto-satisfactory* (Hurwicz 1960) if for each environment in the class under consideration, the set of outcomes generated by the mechanism coincides with the set of Pareto optimal outcomes for that environment. Allowance must be made for redistribution of initial endowment, as in the case of the second welfare theorem. (A formulation in the framework of mechanisms is given in Mount and Reiter 1977.)

The competitive mechanism formalized as a static mechanism is as follows. (Hurwicz 1960, has given a different formulation, and Sonnenschein 1974, has given an axiomatic characterization of the competitive mechanism from a somewhat different point of view.) The message space M is the space of prices and quantities of commodities going to each agent (it has dimension $n(l-1)$ when there are n agents and l commodities, taking account of budget constraints and Walras' Law), the individual message correspondence μ^i maps agent i's characteristic e^i to the graph of his excess demand function. The equilibrium message is the intersection of the individual ones, and is therefore the price-quantity combinations that solve the system of excess demand equations. The outcome function h is the projection of the equilibrium message onto the quantity components of M. Thus $h\mu(e)$ is a competitive equilibrium allocation (or trade) when the environment is e. The classical welfare theorems state that for each e in E_c, $h[\mu(e)] = p(e)$, where E_c denotes the set of classical environments and P is the Pareto correspondence. (Allowance must be made for redistribution of initial endowment in connection with the second welfare theorem. Explicit treatment of this is omitted to avoid notational complexity. The decentralized redistribution of initial endowment is, as in the case of the second welfare theorem, not addressed.) The welfare theorems can be summarized in the Mount-Reiter diagram (Fig. 2) (Reiter 1977).

The welfare theorems state that this diagram *commutes* in the sense that starting from any environment e in E_c one reaches the same allocations via the mechanism, that is, via $h\mu$, as via the Pareto correspondence P.



Efficient Allocation, Fig. 2

With welfare theorems as a guide, the class of environments E_c can be replaced by some other class E, and the Pareto correspondence can be replaced by a correspondence, P, embodying another criterion of optimality, and one can ask whether there is a mechanism, (M, μ, h) that makes the diagram commute, or, in other words, *realizes* P? Without further restrictions on the mechanism, this is a triviality, because one agent can act as a central agent to whom all others communicate their environmental characteristics; the central agent then has the information required to evaluate P.

The concept of an *informationally decentralized mechanism* defined by Hurwicz (1960) makes explicit intuitive notions underlying the view that the price mechanism is decentralized.

Informationally decentralized processes are a subclass of so-called *concrete processes*, introduced by Hurwicz (1960). These are processes that use a language and response rules that allow production and distribution plans to be specified explicitly. The informationally decentralized processes are those whose response rules permit agents to transmit information only about their own actions, and which in effect require each agent to treat the rest of the economy either as one aggregate, or in a symmetrical way that, like the aggregate, gives anonymity to the other agents.

In the case of static mechanisms, the requirements for informational decentralization boil down to the condition that the message space have no more than a certain finite dimension, and in some cases only that it be of finite dimension. In the case of classical environments this can be seen to include the competitive mechanism, and to exclude the obviously centralized one mentioned above.

Without going deeply into the matter, an objective of this line of research is to analyse explicitly

the consequences of constraints on economic organization that come from limitations on the capacity of economic agents to observe, communicate and process information. One important result in this field is that there is no mechanism (M, μ, h) where μ preserves privacy, that uses messages smaller (in dimension) than those of the competitive mechanism (Hurwicz 1972b; Mount and Reiter 1974; Walker 1977; Osana 1978). Similar results have been obtained for environments with public goods, showing that the Lindahl mechanism uses the minimal message space (Sato 1981). Another objective is to analyse effects on incentives arising from private motivations in the presence of private information; that is, information held by one agent that is not observable by others, except perhaps at a cost. (There is a large literature on this subject under the rubric 'incentive compatibility', or 'strategic implementation' (Dasgupta et al. 1979; Hurwicz 1971, 1972a). The informational requirements of achieving a specified performance taking some aspects of incentive compatibility into account have been studied by Hurwicz (1976), Reichelstein (1984a, 1984b) and by Reichelstein and Reiter (1985).

Some important results for non-neoclassical environments can be mentioned. Hurwicz (1960, 1972a) has shown that there can be no informationally decentralized mechanism that realizes Pareto optimal performance on a class of environments that includes those with externalities. Calsamiglia (1977, 1982) has shown in a model of production that if the set of environments includes a sufficiently rich class of those with increasing returns to scale in production, then the dimension of the message space of any mechanism that realizes efficient production cannot be bounded.

Efficient Allocation with Infinitely Many Commodities

An infinite dimensional commodity space is needed when it is necessary to make infinitely many distinctions among goods and services. This is the case when commodities are distinguished according to time of availability and the time horizon in the model is not bounded or when time is continuous, or according to location when there is more than a finite number of possible locations; differentiated commodities provide other examples, and so does the case of uncertainty with infinitely many states. The bulk of the literature deals with the infinite horizon model of allocation over time, though recently more attention is given to models of product differentiation. Ramsey (1928) studied the problem of saving in a continuous time infinite horizon model with one consumption good and an infinitely lived consumer. He used as the criterion of optimality the infinite sum (integral) of undiscounted utility. Ramsey's contribution was largely ignored, and rediscovered when attention returned to problems of economic growth. A model of maximal sustainable growth based on a linear technology with no unproduced inputs was formulated by von Neumann (1937 in German; English translation, 1945–6). This contribution was unknown among English-speaking economists until after World War II. Study of intertemporal allocation by Anglo-American economists effectively began with the contributions of Harrod (1939) and Domar (1946). These models were concerned with stationary growth at a constant sustainable rate (stationary growth paths) rather than full intertemporal efficiency. Malinvaud (1953) first addressed this problem in a pioneering model of intertemporal allocation with an infinite horizon.

Efficient allocation over (discrete) time would be covered by the finite dimensional models described above if the time horizon were finite. It might be thought that a model with a sufficiently large but still finite horizon would for all practical purposes be equivalent to one with an infinite horizon, while avoiding the difficulties of infinity, but this is not the case, because of the dependence of efficient or optimal allocations on the value given to final stocks, a value that must depend on their uses beyond the horizon.

Malinvaud (1953) formulated an important infinite horizon model, which is the infinite dimensional counterpart of the linear activity analysis model of Koopmans. In Malinvaud's model time is discrete. The time horizon consists of an infinite sequence of time periods. At each

date there are finitely many commodities. All commodities are desired in each time period, and no distinction is made between desired, intermediate and primary commodities. As in the activity analysis model, there is no explicit reference to preferences of consumers. Productive efficiency over time is analysed in terms of the output available for consumption, rather than the resulting utility levels.

Technology is represented by a production set X^t for each time period $t = 1, 2, \ldots$, an element of X^t being an ordered pair (a^t, b^{t+1}) of commodity bundles where a^t represents inputs to a production process in period t, and b^{t+1} represents the outputs of that process available at the beginning of period $t+1$. Here both a^t and b^{t+1} are non-negative. The set X^t is the aggregate production set for the economy during period t. The net outputs available for consumption are given by

$$y^t = b^t - a^t, \text{for} \quad t \geq 1,$$

where b^1 is the initial endowment of resources available at the beginning of period 1. A *programme* is an infinite sequence $\langle (a^t, b^{t+1}) \rangle$; it is a *feasible programme* if (a^t, b^{t+1}); is in X^t, and $b^t - a^t \geq 0$ for each $t \geq 1$, given b^1. The sequence $y = \langle y^t \rangle$ is called the *net output programme* associated with the given programme; it is a *feasible net output programme* if it is the net output programme of a feasible programme. A programme is *efficient* if it is (1) feasible and (2) there is no other programme that is feasible, from the same initial resources b^1, and provides at least as much net output in every period and a larger net output in some period. This is the concept of efficient production, already seen in the linear activity analysis model, now extended to an infinite horizon model. The main aim of this research is to extend to the infinite horizon model the characterization of efficient production by prices seen in the finite model. This goal is not quite reached, as is seen in what follows.

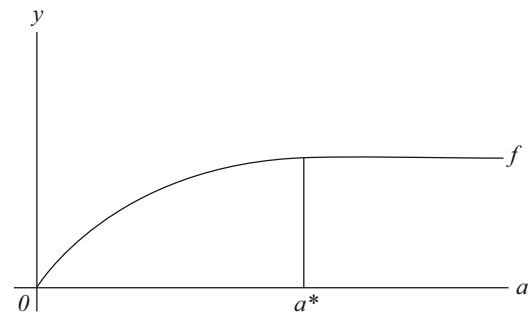
The main difficulties presented by the infinite horizon are already present in a special case of the Malinvaud model with one good and no consumers. Let Y be the set of all non-negative sequences $y = (y_t)$ that satisfy $0 \leq y_t = f(a_{t-1}) - a_t$ for $t \geq 1$, and $0 \leq y^0 = b^1 - a^0$, $b^1 > 0$, where f is a real-valued continuous concave function on the non-negative real numbers (the production function), $f(0) = 0$, and b^1 is the given initial stock. The set Y is the set of all feasible programmes. A programme $y' - y > 0$. A price system is an infinite sequence $p = (p^t)$ of non-negative numbers. Denote by P the set of all price systems.

Malinvalud recognized the possibility that an efficient net output programme (y^t) need not have an associated system of non-zero prices (p^t) relative to which the production programme generating y satisfies the condition of intertemporal profit maximization, namely that

$$P^{t+1} f(a^t) - p^t a^t \geq p^{t+1} f(a) - p^t a$$

for all t and every $a \geq 0$. (Here (a^t) is the sequence of inputs producing y.) A condition introduced by Malinvaud, called *nontightness*, is sufficient for the existence of such non-zero prices. Alternative proofs of Malinvaud's existence theorem were given by Radner (1967) and Peleg and Yaari (1970). (An example showing the possibility of non-existence given by Peleg and Yaari (1970) is as follows. Suppose f is as shown in Fig. 3.

At an interior efficient, and therefore value maximizing, programme the first-order necessary conditions for a maximum imply $p^{t+1} \dot{f}(a^t) = p^t$. If there is a time at which $a^t = a^*$, in an efficient programme, then, since $\dot{f}(a^*) = 0$ it follows that prices at all prior and future times are 0. (Non-tightness rules out such examples.)



Efficient Allocation, Fig. 3

On the side of sufficiency, Malinvaud showed that intertemporal profit maximization relative to a strictly positive price system p is not enough to ensure that a feasible programme is efficient. An additional (transversality) condition is needed. In the present model the following to such a condition;

$$\lim_{t\to\infty} p^t y^t = 0.$$

Cass (1972) has given a criterion that completely characterizes the set of efficient programmes in a one-good model with strictly concave and smooth production technology that satisfies endpoint conditions $0 \leq f'(\infty) < 1 < f'(x) < \infty$ for some $x > 0$. Cass's criterion, states that a programme is *inefficient* if and only if the associated competitive prices – that is, satisfying $p^{t+1} f'(a^t) = p^t$ – also satisfy $\Sigma_{t=1}^{\infty}(1/p^t) < \infty$. This criterion may be interpreted as requiring the terms of trade between present and future to deteriorate sufficiently fast. Other similar conditions have been presented (Benveniste and Gale 1975; Benveniste 1976; Majumdar 1974; Mitra 1979). It is hard to see how any transversality condition can be interpreted in terms of decentralized resource allocation.

An alternate approach to characterizing efficient programmes was taken by Radner (1967), based on value functions as introduced in connection with valuation equilibrium by Debreu (1954). (Valuation equilibrium was discussed in connection with Arrow's exceptional case, above.) The value function approach was followed up by Majumdar (1970, 1972) and by Peleg and Yaari (1970). A price system defines a continuous linear functional, (a real-valued linear function) on the commodity space. This function assigns to a programme its present value. The present value may not be well-defined, because the infinite sequence that gives it diverges. This creates certain technical problems passed over here. A more important difficulty is that linear functionals exist that are not defined by price systems. Radner's approach was to characterize efficient programmes in terms of maximization of present value relative to a linear functional on the commodity space. Radner showed, technical matters aside, that:

1. If a feasible programme maximizes the value of net output (consumption) relative to a strictly positive continuous linear functional, then it is efficient.
2. If a given programme is efficient, then there is a nonzero non-negative continuous linear functional such that the given programme maximizes the value of net output relative to that functional on the set of feasible programmes.

These propositions seem to be the precise counterparts of the ones characterizing efficiency in the finite horizon model. Unfortunately, a linear functional may not have a representation in the form of the inner product of a price sequence with a net output sequence. (The production function $f(a) = a^{\beta}$, with $0 < \beta < 1$ provides an example. It is known that the programme with constant input sequence $x_t = (1/\beta)^{\beta/\beta - 1}$ and output sequence $y_t = (1/\beta)^{\beta/\beta - 1} - (1/\beta)^{1/\beta - 1} t = 1, 2, \ldots,$ is efficient, and therefore there is a continuous linear functional relative to which it is value maximizing. But there is no price sequence (p^t) that represents that linear functional.) This presents a serious problem, because in the absence of such a representation it is unclear whether this characterization has an interpretation in terms of decentralized allocation processes; profit in any one period can depend on 'prices at infinity'.

This approach has the advantage that it is applicable not only to infinite horizon models, but to a broader class in which the commodity space is infinite dimensional. Bewley (1972), Mas-Colell (1977) and Jones (1984) among others discuss Pareto optimality and competitive equilibrium in economies with infinitely many commodities. Hurwicz (1958) and others analysed optimal allocation in terms of nonlinear programming in infinite dimensional spaces. Theorems of programming in infinite dimensional spaces are also used in some of the models mentioned in this discussion.

The basic difficulties encountered in the one-good model, apart from the numerous technical problems that tend to make the literature large and

diverse as different technical structures are investigated, are on the one hand the fact that transversality conditions are indispensable, and on the other the possibility that linear functionals, even when they exist, may not be representable in terms of price sequences. These problems raise strong doubt about the possibility of achieving efficient intertemporal resource allocation by decentralized means, though they leave open the possibility that some other decentralized mechanism, not using prices, might work. Analysis of this possibility has just begun, and is discussed below.

The difficulties seen in the one-good production model persist in more elaborate ones, including multisectoral models with efficiency as the criterion, and models with consumers in which Pareto optimality is the criterion. McFadden et al. (1980) studied a model in which there are firms, and overlapping generations of consumers, as in the model first investigated by Samuelson (1958). Each consumer lives for a finite time and has a consumption set and preferences like the consumers in a finite horizon model. A model with overlapping generations of consumers presents the fundamental difficulty that consumers cannot trade with future consumers as yet unborn. This difficulty can appear even in a finite horizon model if there are too few markets. The economy is closed in the sense that there are no non-produced resources; the von Neumann growth model is an example of such a model. Building on the results of an earlier investigation (Majumdar et al. 1976), these authors introduced several notions of price systems, of competitive equilibrium, efficiency and optimality, and sought to establish counterparts of the classical welfare theorems. To summarize, in the 1976 paper they strengthen an earlier result of Bose (1974) to the effect that the problem of proper distribution of goods in essentially a short-run problem, and that the only long-run problem, one created by the infinite horizon, is that of inefficiency through overaccumulation of capital. In the 1980 paper the focus is on the relationships among various notions of equilibrium and Pareto optimality. The force of their results is, as might be expected, that the difficulties already seen in one-good model without consumers persist in this model. A transversality condition is made part of the definition of competitive equilibrium in order to obtain the result that an equilibrium is optimal. A partial converse requires some additional assumptions on the technology (reachability) and on the way the economy fits together (nondecomposability). These results certainly illuminate the infinite horizon model with overlapping generations of consumers and producers, but the possibility of efficient or optimal resource allocation by decentralized means is not different from that in the one-good Malinvaud model.

Hurwicz and Majumdar in an unpublished manuscript dated 1983, and later Hurwicz and Weinberger (1984), have addressed this issue directly, building on the approach of mechanism theory.

Hurwicz and Majumdar have studied the problem of efficiency in a model with an infinite number of periods. In each period there are finitely many commodities, one producer who is alive for just one period, and no consumers' choices. The criterion is the maximization of the discounted value of the programme (well-defined in this model). The producer alive in any period knows only the technology in that period. The question is whether there is a (static) privacy preserving mechanism using a finite dimensional message space whose equilibria coincide with the set of efficient programmes. The question can be put as follows. In each period a message is posted. The producer alive in that period responds 'Yes' or 'No'. If every producer over the entire infinite horizon answers 'Yes', the programme is an outcome corresponding to the equilibrium consisting of the infinite succession of posted messages. Since each producer knows only the technology prevailing in the period when he is alive, the process preserves privacy. If in addition the message posted in each period is finite dimensional, the process is informationally decentralized. Period-by-period profit maximization using period-by-period prices is a mechanism of this type; the message posted in each period consists of the vector of prices for that period, and the production plan for that period, both finite dimensional. The object is to characterize all efficient programmes as equilibria of such a mechanism.

This would be an analogue of the classical welfare theorems, but without the restriction to mechanisms that use prices in their messages.

The main result is in the nature of an impossibility theorem. If the technology is constant over time, and that fact is common knowledge at the beginning, the problem is trivial since knowledge of the technology in the first period automatically means knowledge of it in every period. On the other hand, if there is some period whose technology is not known in the first period, then there is no finite dimensional message that can characterize efficient programmes, and in that sense, production cannot be satisfactorily decentralized over time.

Hurwicz and Weinberger (1984) have studied a model with both producers and consumers. As with producers, there is a consumer in each period, who lives for one period. The consumer in each period has a one-period utility function, which is not known by the producer; similarly the consumer does not know the production function. The criterion of optimality is the maximization of the sum of discounted utilities over the infinite horizon. Hurwicz and Weinberger show that there is no privacy preserving mechanism of the type just described whose equilibria correspond to the set of optimal programmes. It should be noted that their mechanism requires that the first-period actions (production, consumption and investment decisions) be made in the first period, and not be subject to revision after the infinite process of verification is completed. (On the other hand, under tâtonnement assumptions it may be possible to decentralize. In this model t*â*tonnement entails reconsideration 'at infinity'.)

If attention is widened to efficient programmes, and if technology is constant over time, there is an efficient programme with a fixed ratio of consumption to investment. This programme can be obtained as the equilibrium outcome of a mechanism of the specified type. However, this corresponds to only one side of the classical welfare theorems. It says that the outcome of such a mechanism is efficient; but it does not ensure that every efficient programme can be realized as the outcome of such a mechanism. The latter property fails in this model.

Efficient Markets Hypothesis

Andrew W. Lo

Abstract

The efficient markets hypothesis (EMH) maintains that market prices fully reflect all available information. Developed independently by Paul A. Samuelson and Eugene F. Fama in the 1960s, this idea has been applied extensively to theoretical models and empirical studies of financial securities prices, generating considerable controversy as well as fundamental insights into the price-discovery process. The

most enduring critique comes from psychologists and behavioural economists who argue that the EMH is based on counterfactual assumptions regarding human behaviour, that is, rationality. Recent advances in evolutionary psychology and the cognitive neurosciences may be able to reconcile the EMH with behavioural anomalies.

There is an old joke, widely told among economists, about an economist strolling down the street with a companion. They come upon a $100 bill lying on the ground, and as the companion reaches down to pick it up, the economist says, 'Don't bother – if it were a genuine $100 bill, someone would have already picked it up'. This humorous example of economic logic gone awry is a fairly accurate rendition of the efficient markets hypothesis (EMH), one of the most hotly contested propositions in all the social sciences. It is disarmingly simple to state, has far-reaching consequences for academic theories and business practice, and yet is surprisingly resilient to empirical proof or refutation. Even after several decades of research and literally thousands of published studies, economists have not yet reached a consensus about whether markets – particularly financial markets – are, in fact, efficient.

The origins of the EMH can be traced back to the work of two individuals in the 1960s: Eugene F. Fama and Paul A. Samuelson. Remarkably, they independently developed the same basic notion of market efficiency from two rather different research agendas. These differences would propel the them along two distinct trajectories leading to several other breakthroughs and milestones, all originating from their point of intersection, the EMH.

Like so many ideas of modern economics, the EMH was first given form by Paul Samuelson (1965), whose contribution is neatly summarized by the title of his article: 'Proof that Properly Anticipated Prices Fluctuate Randomly'. In an informationally efficient market, price changes must be unforecastable if they are properly anticipated, that is, if they fully incorporate the information and expectations of all market participants. Having developed a series of linear-programming solutions to spatial pricing models with no uncertainty, Samuelson came upon the idea of efficient markets through his interest in temporal pricing models of storable commodities that are harvested and subject to decay. Samuelson's abiding interest in the mechanics and kinematics of prices, with and without uncertainty, led him and his students to several fruitful research agendas including solutions for the dynamic asset-allocation and consumption-

savings problem, the fallacy of time diversification and log-optimal investment policies, warrant and option-pricing analysis and, ultimately, the Black and Scholes (1973) and Merton (1973) option-pricing models.

In contrast to Samuelson's path to the EMH, Fama's (1963, 1965a, b, 1970) seminal papers were based on his interest in measuring the statistical properties of stock prices, and in resolving the debate between technical analysis (the use of geometric patterns in price and volume charts to forecast future price movements of a security) and fundamental analysis (the use of accounting and economic data to determine a security's fair value). Among the first to employ modern digital computers to conduct empirical research in finance, and the first to use the term 'efficient markets' (Fama 1965b), Fama operationalized the EMH hypothesis – summarized compactly in the epigram 'prices fully reflect all available information' – by placing structure on various information sets available to market participants. Fama's fascination with empirical analysis led him and his students down a very different path from Samuelson's, yielding significant methodological and empirical contributions such as the event study, numerous econometric tests of single-and multi-factor linear asset-pricing models, and a host of empirical regularities and anomalies in stock, bond, currency and commodity markets.

The EMH's concept of informational efficiency has a Zen-like, counter-intuitive flavour to it: the more efficient the market, the more random the sequence of price changes generated by such a market, and the most efficient market of all is one in which price changes are completely random and unpredictable. This is not an accident of nature, but is in fact the direct result of many active market participants attempting to profit from their information. Driven by profit opportunities, an army of investors pounce on even the smallest informational advantages at their disposal, and in doing so they incorporate their information into market prices and quickly eliminate the profit opportunities that first motivated their trades. If this occurs instantaneously, which it must in an idealized world of 'frictionless' markets and costless trading, then prices must always fully reflect all available information. Therefore, no profits can be garnered from information-based trading because such profits must have already been captured (recall the $100 bill on the ground). In mathematical terms, prices follow martingales.

Such compelling motivation for randomness is unique among the social sciences and is reminiscent of the role that uncertainty plays in quantum mechanics. Just as Heisenberg's uncertainty principle places a limit on what we can know about an electron's position and momentum if quantum mechanics holds, this version of the EMH places a limit on what we can know about future price changes if the forces of economic self-interest hold.

A decade after Samuelson's (1965) and Fama's (1965a, b, 1970) landmark papers, many others extended their framework to allow for risk-averse investors, yielding a 'neoclassical' version of the EMH where price changes, properly weighted by aggregate marginal utilities, must be unforecastable (see, for example, Leroy 1973; Rubinstein 1976; Lucas 1978). In markets where, according to Lucas (1978), all investors have 'rational expectations', prices do fully reflect all available information and marginal-utility-weighted prices follow martingales. The EMH has been extended in many other directions, including the incorporation of non-traded assets such as human capital, state-dependent preferences, heterogeneous investors, asymmetric information, and transactions costs. But the general thrust is the same: individual investors form expectations rationally, markets aggregate information efficiently, and equilibrium prices incorporate all available information instantaneously.

The Random Walk Hypothesis

The importance of the EMH stems primarily from its sharp empirical implications many of which have been tested over the years. Much of the EMH literature before LeRoy (1973) and Lucas (1978) revolved around the random walk hypothesis (RWH) and the martingale model, two statistical descriptions of unforecastable price changes that were initially taken to be implications of the

EMH. One of the first tests of the RWH was developed by Cowles and Jones (1937), who compared the frequency of *sequences* and *reversals* in historical stock returns, where the former are pairs of consecutive returns with the same sign, and the latter are pairs of consecutive returns with opposite signs. Cootner (1962, 1964), Fama (1963, 1965a), Fama and Blume (1966), and Osborne (1959) perform related tests of the RWH and, with the exception of Cowles and Jones (who subsequently acknowledged an error in their analysis – Cowles 1960), all of these articles indicate support for the RWH using historical stock price data.

More recently, Lo and MacKinlay (1988) exploit the fact that return variances scale linearly under the RWH – the variance of a two-week return is twice the variance of a one-week return if the RWH holds – and construct a variance ratio test which rejects the RWH for weekly US stock returns indexes from 1962 to 1985. In particular, they find that variances grow faster than linearly as the holding period increases, implying positive serial correlation in weekly returns. Oddly enough, Lo and MacKinlay also show that individual stocks generally do satisfy the RWH, a fact that we shall return to below.

French and Roll (1986) document a related phenomenon: stock return variances over weekends and exchange holidays are considerably lower than return variances over the same number of days when markets are open. This difference suggests that the very act of trading creates volatility, which may well be a symptom of Black's (1986) noise traders.

For holding periods much longer than one week – for example, three to five years – Fama and French (1988) and Poterba and Summers (1988) find negative serial correlation in US stock returns indexes using data from 1926 to 1986. Although their estimates of serial correlation coefficients seem large in magnitude, there is insufficient data to reject the RWH at the usual levels of significance. Moreover, a number of statistical artifacts documented by Kim et al. (1991) and Richardson (1993) cast serious doubt on the reliability of these longer-horizon inferences.

Finally, Lo (1991) considers another aspect of stock market prices long thought to have been a departure from the RWH: long-term memory. Time series with longterm memory exhibit an unusually high degree of persistence, so that observations in the remote past are non-trivially correlated with observations in the distant future, even as the time span between the two observations increases. Nature's predilection towards long-term memory has been well-documented in the natural sciences such as hydrology, meteorology, and geophysics, and some have argued that economic time series must therefore also have this property.

However, using recently developed statistical techniques, Lo (1991) constructs a test for long-term memory that is robust to short-term correlations of the sort uncovered by Lo and MacKinlay (1988), and concludes that, despite earlier evidence to the contrary, there is little support for long-term memory in stock market prices. Departures from the RWH can be fully explained by conventional models of short-term dependence.

Variance Bounds Tests

Another set of empirical tests of the EMH starts with the observation that in a world without uncertainty the market price of a share of common stock must equal the present value of all future dividends, discounted at the appropriate cost of capital. In an uncertain world, one can generalize this *dividend-discount model* or *present-value relation* in the natural way: the market price equals the conditional expectation of the present value of all future dividends, discounted at the appropriate risk-adjusted cost of capital, and conditional on all available information. This generalization is explicitly developed by Grossman and Shiller (1981).

LeRoy and Porter (1981) and Shiller (1981) take this as their starting point in comparing the variance of stock market prices to the variance of *ex post* present values of future dividends. If the market price is the conditional expectation of present values, then the difference between the two, that is, the forecast error, must be uncorrelated with the conditional expectation by construction.

But this implies that the variance of the *ex post* present value is the sum of the variance of the market price (the conditional expectation) and the variance of the forecast error. Since volatilities are always non-negative, this variance decomposition implies that the variance of stock prices cannot exceed the variance of *ex post* present values. Using annual US stock market data from various sample periods, LeRoy and Porter (1981) and Shiller (1981) find that the variance bound is violated dramatically. Although LeRoy and Porter are more circumspect about the implications of such violations, Shiller concludes that stock market prices are too volatile and the EMH must be false.

These two papers ignited a flurry of responses which challenged Shiller's controversial conclusion on a number of fronts. For example, Flavin (1983), Kleidon (1986), and Marsh and Merton (1986) show that statistical inference is rather delicate for these variance bounds, and that, even if they hold in theory, for the kind of sample sizes Shiller uses and under plausible data-generating processes the sample variance bound is often violated purely due to sampling variation. These issues are well summarized in Gilles and LeRoy (1991) and Merton (1987).

More importantly, on purely theoretical grounds Marsh and Merton (1986) and Michener (1982) provide two explanations for violations of variance bounds that are perfectly consistent with the EMH. Marsh and Merton (1986) show that if managers smooth dividends – a well-known empirical phenomenon documented in several studies of dividend policy – and if earnings follow a geometric random walk, then the variance bound is violated in theory, in which case the empirical violations may be interpreted as *support* for this version of the EMH.

Alternatively, Michener constructs a simple dynamic equilibrium model along the lines of Lucas (1978) in which prices do fully reflect all available information at all times but where individuals are risk averse, and this risk aversion is enough to cause the variance bound to be violated in theory as well.

These findings highlight an important aspect of the EMH that had not been emphasized in earlier studies: tests of the EMH are always tests of joint hypotheses. In particular, the phrase 'prices fully reflect all available information' is a statement about two distinct aspects of prices: the information content and the price formation mechanism. Therefore, any test of this proposition must concern the *kind* of information reflected in prices, and *how* this information comes to be reflected in prices.

Apart from issues regarding statistical inference, the empirical violation of variance bounds may be interpreted in many ways. It may be a violation of EMH, or a sign that investors are risk averse, or a symptom of dividend smoothing. To choose among these alternatives, more evidence is required.

Overreaction and Underreaction

A common explanation for departures from the EMH is that investors do not always react in proper proportion to new information. For example, in some cases investors may overreact to performance, selling stocks that have experienced recent losses or buying stocks that have enjoyed recent gains. Such overreaction tends to push prices beyond their 'fair' or 'rational' market value, only to have rational investors take the other side of the trades and bring prices back in line eventually. An implication of this phenomenon is price reversals: what goes up must come down, and vice versa. Another implication is that *contrarian* investment strategies – strategies in which 'losers' are purchased and 'winners' are sold – will earn superior returns.

Both of these implications were tested and confirmed using recent US stock market data. For example, using monthly returns of New York Stock Exchange (NYSE) stocks from 1926 to 1982, DeBondt and Thaler (1985) document the fact that the winners and losers in one 36-month period tend to reverse their performance over the next 36-month period. Curiously, many of these reversals occur in January (see the discussion below on the 'January effect'). Chopra et al. (1992) reconfirm these findings after correcting for market risk and the size effect.

And Lehmann (1990) shows that a zero-net-investment strategy in which long positions in losers are financed by short positions in winners almost always yields positive returns for monthly NYSE/AMEX stock returns data from 1962 to 1985.

However, Chan (1988) argues that the profitability of contrarian investment strategies cannot be taken as conclusive evidence against the EMH because there is typically no accounting for risk in these profitability calculations (although Chopra et al. 1992 do provide risk adjustments, their focus was not on specific trading strategies). By risk-adjusting the returns of a contrarian trading strategy according to the capital asset pricing model, Chan (1988) shows that the expected returns are consistent with the EMH.

Moreover, Lo and MacKinlay (1990c) show that at least half of the profits reported by Lehmann (1990) are not due to overreaction but rather the result of positive cross-autocorrelations between stocks. For example, suppose the returns of two stocks A and *B* are both serially uncorrelated but are positively cross-autocorrelated. The lack of serial correlation implies no overreaction (which is characterized by negative serial correlation), but positive cross-autocorrelations yields positive expected returns to contrarian trading strategies. The existence of several economic rationales for positive cross-autocorrelation that are consistent with EMH suggests that the profitability of contrarian trading strategies is not sufficient evidence to conclude that investors overreact.

The reaction of market participants to information contained in earnings announcements also has implications for the EMH. In one of the earliest studies of the information content of earnings, Ball and Brown (1968) show that up to 80 per cent of the information contained in the earnings 'surprises' is anticipated by market prices.

However, the more recent article by Bernard and Thomas (1990) argues that investors sometimes underreact to information about future earnings contained in current earnings. This is related to the 'post-earnings announcement drift' puzzle first documented by Ball and Brown (1968), in which the information contained in earnings announcement takes several days to become fully impounded into market prices. Although such effects are indeed troubling for the EMH, their economic significance is often questionable – while they may violate the EMH in frictionless markets, very often even the smallest frictions – for example, positive trading costs, taxes – can eliminate the profits from trading strategies designed to exploit them.

Anomalies

Perhaps the most common challenge to the EMH is the anomaly, a regular pattern in an asset's returns which is reliable, widely known, and inexplicable. The fact that the pattern is regular and reliable implies a degree of predictability, and the fact that the regularity is widely known implies that many investors can take advantage of it.

For example, one of the most enduring anomalies is the 'size effect', the apparent excess expected returns that accrue to stocks of small-capitalization companies – in excess of their risks – which was first discovered by Banz (1981). Keim (1983), Roll (1983), and Rozeff and Kinney (1976) document a related anomaly: small capitalization stocks tend to outperform large capitalization stocks by a wide margin over the turn of the calendar year. This so-called 'January effect' seems robust to sample period, and is difficult to reconcile with the EMH because of its regularity and publicity. Other well-known anomalies include the Value Line enigma (Copeland and Mayers 1982), the profitability of short-term return-reversal strategies in US equities (Rosenberg et al. 1985; Chan 1988; Lehmann 1990; and Lo and MacKinlay 1990c), the profitability of medium-term momentum strategies in US equities (Jegadeesh 1990; Chan et al. 1996; and Jegadeesh and Titman 2001), the relation between price/earnings ratios and expected returns (Basu 1977), the volatility of orange juice futures prices (Roll 1984), and calendar effects such as holiday, weekend, and turn-of-the-month seasonalities (Lakonishok and Smidt 1988).

What are we to make of these anomalies? On the one hand, their persistence in the face of public scrutiny seems to be a clear violation of the EMH.

After all, most of these anomalies can be exploited by relatively simple trading strategies, and, while the resulting profits may not be riskless, they seem unusually profitable relative to their risks (see, especially, Lehmann 1990).

On the other hand, EMH supporters might argue that such persistence is in fact evidence in favour of EMH or, more to the point, that these anomalies cannot be exploited to any significant degree because of factors such as risk or transactions costs. Moreover, although some anomalies are currently inexplicable, this may be due to a lack of imagination on the part of academics, not necessarily a violation of the EMH. For example, recent evidence suggests that the January effect is largely due to 'bid–ask bounce', that is, closing prices for the last trading day of December tend to be at the bid price and closing prices for the first trading day of January tend to be at the ask price. Since small-capitalization stocks are also often low-price stocks, the effects of bid–ask bounce in percentage terms are much more pronounced for these stocks – a movement from bid to ask for a $5.00 stock on the NYSE (where the minimum bid-ask spread was $0.125 prior to decimalization in 2000) represents a 2.5 per cent return.

Whether or not one can profit from anomalies is a question unlikely to be settled in an academic setting. While calculations of 'paper' profits of various trading strategies come easily to academics, it is virtually impossible to incorporate in a realistic manner important features of the trading process such as transactions costs (including price impact), liquidity, rare events, institutional rigidities and non-stationarities. The economic value of anomalies must be decided in the laboratory of actual markets by investment professionals, over long periods of time, and even in these cases superior performance and simple luck are easily confused.

In fact, luck can play another role in the interpretation of anomalies: it can account for anomalies that are not anomalous. Regular patterns in historical data can be found even if no regularities exist, purely by chance. Although the likelihood of finding such spurious regularities is usually small (especially if the regularity is a very complex pattern), it increases dramatically with the number of 'searches' conducted on the same set of data. Such *data-snooping* biases are illustrated in Brown et al. (1992) and Lo and MacKinlay (1990b) – even the smallest biases can translate into substantial anomalies such as superior investment returns or the size effect.

Behavioural Critiques

The most enduring critiques of the EMH revolve around the preferences and behaviour of market participants. The standard approach to modelling preferences is to assert that investors optimize additive time-separable expected utility functions from certain parametric families – for example, constant relative risk aversion. However, psychologists and experimental economists have documented a number of departures from this paradigm, in the form of specific behavioural biases that are ubiquitous to human decision-making under uncertainty, several of which lead to undesirable outcomes for an individual's economic welfare – for example, overconfidence (Fischoff and Slovic 1980; Barber and Odean 2001; Gervais and Odean 2001), overreaction (DeBondt and Thaler 1985), loss aversion (Kahneman and Tversky 1979; Shefrin and Statman 1985; Odean 1998), herding (Huberman and Regev 2001), psychological accounting (Tversky and Kahneman 1981), miscalibration of probabilities (Lichtenstein et al. 1982), hyperbolic discounting (Laibson 1997), and regret (Bell 1982). These critics of the EMH argue that investors are often – if not always – irrational, exhibiting predictable and financially ruinous behaviour.

To see just how pervasive such behavioural biases can be, consider the following example which is a slightly modified version of an experiment conducted by two psychologists, Kahneman and Tversky (1979). Suppose you are offered two investment opportunities, A and B: A yields a sure profit of $240,000, and B is a lottery ticket yielding $1 million with a 25 per cent probability and $0 with 75 per cent probability. If you had to choose between A and *B,* which would you prefer? Investment *B* has an expected

value of $250,000, which is higher than A's payoff, but this may not be all that meaningful to you because you will receive either $1 million or zero. Clearly, there is no right or wrong choice here; it is simply a matter of personal preferences. Faced with this choice, most subjects prefer A, the sure profit, to B, despite the fact that B offers a significant probability of winning considerably more. This behaviour is often characterized as 'risk aversion' for obvious reasons. Now suppose you are faced with another two choices, C and D: C yields a sure loss of $750,000, and *D* is a lottery ticket yielding $0 with 25 per cent probability and a loss of $1 million with 75 per cent probability. Which would you prefer? This situation is not as absurd as it might seem at first glance; many financial decisions involve choosing between the lesser of two evils. In this case, most subjects choose D, despite the fact that D is more risky than C. When faced with two choices that both involve losses, individuals seem to be 'risk seeking', not risk averse as in the case of A versus B.

The fact that individuals tend to be risk averse in the face of gains and risk seeking in the face of losses can lead to some very poor financial decisions. To see why, observe that the combination of choices A and D is equivalent to a single lottery ticket yielding $240,000 with 25 per cent probability and − $760,000 with 75 per cent probability, whereas the combination of choices B and C is equivalent to a single lottery ticket yielding $250,000 with 25 per cent probability and − $750,000 with 75 per cent probability. The B and C combination has the same probabilities of gains and losses, but the gain is $10,000 higher and the loss is $10,000 lower. In other words, B and C is formally equivalent to A and D plus a sure profit of $10,000. In light of this analysis, would you still prefer A and D?

A common response to this example is that it is contrived because the two pairs of investment opportunities were presented sequentially, not simultaneously. However, in a typical global financial institution the London office may be faced with choices A and B and the Tokyo office may be faced with choices C and D. Locally, it may seem as if there is no right or wrong answer – the choice between A and B or C and D seems to be simply a matter of personal risk preferences – but the globally consolidated financial statement for the entire institution will tell a very different story. From that perspective, there *is* a right and wrong answer, and the empirical and experimental evidence suggests that most individuals tend to select the wrong answer. Therefore, according to the behaviouralists, quantitative models of efficient markets – all of which are predicated on rational choice – are likely to be wrong as well.

Impossibility of Efficient Markets

Grossman and Stiglitz (1980) go even farther – they argue that perfectly informationally efficient markets are an *impossibility* for, if markets are perfectly efficient, there is no profit to gathering information, in which case there would be little reason to trade and markets would eventually collapse. Alternatively, the degree of market *inefficiency* determines the effort investors are willing to expend to gather and trade on information, hence a non-degenerate market equilibrium will arise only when there are sufficient profit opportunities, that is, inefficiencies, to compensate investors for the costs of trading and information gathering. The profits earned by these attentive investors may be viewed as 'economic rents' that accrue to those willing to engage in such activities. Who are the providers of these rents? Black (1986) gave us a provocative answer: 'noise traders', individuals who trade on what they consider to be information but which is, in fact, merely noise.

The supporters of the EMH have responded to these challenges by arguing that, while behavioural biases and corresponding inefficiencies do exist from time to time, there is a limit to their prevalence and impact because of opposing forces dedicated to exploiting such opportunities. A simple example of such a limit is the so-called 'Dutch book', in which irrational probability beliefs give rise to guaranteed profits for the savvy investor. Consider, for example, an event *E,* defined as 'the S&P 500 index drops by five per cent or more next Monday', and suppose an individual has the following irrational beliefs: there is

a 50 per cent probability that E will occur, and a 75 per cent probability that E will *not* occur. This is clearly a violation of one of the basic axioms of probability theory – the probabilities of two mutually exclusive and exhaustive events must sum to 1 – but many experimental studies have documented such violations among an overwhelming majority of human subjects.

These inconsistent subjective probability beliefs imply that the individual would be willing to take both of the following bets B_1 and B_2:

$$B_1 = \begin{cases} \$1 \text{ if } E \\ -\$1 \text{ otherwise} \end{cases}, B_2 = \begin{cases} \$1 \text{ if } E^c \\ -\$1 \text{ otherwise} \end{cases}$$

where E^c denotes the event 'not E'. Now suppose we take the opposite side of both bets, placing \$50 on B_1 and \$25 on B_2. If E occurs, we lose \$50 on B_1 but gain \$75 on B_2, yielding a profit of \$25. If E^c occurs, we gain \$50 on B_1 and lose \$25 on B_2, also yielding a profit of \$25. Regardless of the outcome, we have secured a profit of \$25, an 'arbitrage' that comes at the expense of the individual with inconsistent probability beliefs. Such beliefs are not sustainable, and market forces – namely, arbitrageurs such as hedge funds and proprietary trading groups – will take advantage of these opportunities until they no longer exist, that is, until the odds are in line with the axioms of probability theory. (Only when these axioms are satisfied is arbitrage ruled out. This was conjectured by Ramsey 1926, and proved rigorously by de Finetti 1937, and Savage 1954.) Therefore, proponents of the classical EMH argue that there are limits to the degree and persistence of behavioural biases such as inconsistent probability beliefs, and substantial incentives for those who can identify and exploit such occurrences. While all of us are subject to certain behavioural biases from time to time, according to EMH supporters market forces will always act to bring prices back to rational levels, implying that the impact of irrational behaviour on financial markets is generally negligible and, therefore, irrelevant.

But this last conclusion relies on the assumption that market forces are sufficiently powerful to overcome any type of behavioural bias, or equivalently that irrational beliefs are not so pervasive as to overwhelm the capacity of arbitrage capital dedicated to taking advantage of such irrationalities. This is an empirical issue that cannot be settled theoretically, but must be tested through careful measurement and statistical analysis. The classic reference by Kindleberger (1989) – where a number of speculative bubbles, financial panics, manias, and market crashes are described in detail – suggests that the forces of irrationality can overwhelm the forces of arbitrage capital for months and, in several well-known cases, years.

So what does this imply for the EMH?

The Current State of the EMH

Given all of the theoretical and empirical evidence for and against the EMH, what can we conclude? Amazingly, there is still no consensus among economists. Despite the many advances in the statistical analysis, databases, and theoretical models surrounding the EMH, the main result of all of these studies is to harden the resolve of the proponents of each side of the debate.

One of the reasons for this state of affairs is the fact that the EMH, by itself, is not a well-defined and empirically refutable hypothesis. To make it operational, one must specify additional structure, for example, investors' preferences or information structure. But then a test of the EMH becomes a test of several auxiliary hypotheses as well, and a rejection of such a joint hypothesis tells us little about which aspect of the joint hypothesis is inconsistent with the data. Are stock prices too volatile because markets are inefficient, or due to risk aversion, or dividend smoothing? All three inferences are consistent with the data. Moreover, new statistical tests designed to distinguish among them will no doubt require auxiliary hypotheses of their own which, in turn, may be questioned.

More importantly, tests of the EMH may not be the most informative means of gauging the efficiency of a given market. What is often of more consequence is the efficiency of a particular market *relative* to other markets – for example, futures vs. spot markets, auction vs. dealer markets. The advantages of the concept of relative efficiency, as

opposed to the all-or-nothing notion of absolute efficiency, are easy to spot by way of an analogy. Physical systems are often given an efficiency rating based on the relative proportion of energy or fuel converted to useful work. Therefore, a piston engine may be rated at 60 per cent efficiency, meaning that on average 60 per cent of the energy contained in the engine's fuel is used to turn the crankshaft, with the remaining 40 per cent lost to other forms of work, such as heat, light or noise.

Few engineers would ever consider performing a statistical test to determine whether or not a given engine is perfectly efficient – such an engine exists only in the idealized frictionless world of the imagination. But measuring relative efficiency – relative, that is, to the frictionless ideal – is commonplace. Indeed, we have come to expect such measurements for many household products: air conditioners, hot water heaters, refrigerators, and so on. Therefore, from a practical point of view, and in light of Grossman and Stiglitz (1980), the EMH is an idealization that is economically unrealizable, but which serves as a useful benchmark for measuring relative efficiency.

The desire to build financial theories based on more realistic assumptions has led to several new strands of literature, including psychological approaches to risktaking behaviour (Kahneman and Tversky 1979; Thaler 1993; Lo 1999), evolutionary game theory (Friedman 1991), agent-based modelling of financial markets (Arthur et al. 1997; Chan et al. 1998), and direct applications of the principles of evolutionary psychology to economics and finance (Lo 1999, 2002, 2004, 2005; Lo and Repin 2002). Although substantially different in methods and style, these emerging sub-fields are all directed at new interpretations of the EMH. In particular, psychological models of financial markets focus on the manner in which human psychology influences the economic decision-making process as an explanation of apparent departures from rationality. Evolutionary game theory studies the evolution and steady-state equilibria of populations of competing strategies in highly idealized settings. Agent-based models are meant to capture complex learning behaviour and dynamics in financial markets using more realistic markets, strategies, and information structures. And applications of evolutionary psychology provide a reconciliation of rational expectations with the behavioural findings that often seem inconsistent with rationality.

For example, in one agent-based model of financial markets (Farmer 2002), the market is modelled using a non-equilibrium market mechanism, whose simplicity makes it possible to obtain analytic results while maintaining a plausible degree of realism. Market participants are treated as computational entities that employ strategies based on limited information. Through their (sometimes suboptimal) actions they make profits or losses. Profitable strategies accumulate capital with the passage of time, and unprofitable strategies lose money and may eventually disappear. A financial market can thus be viewed as a co-evolving ecology of trading strategies. The strategy is analogous to a biological species, and the total capital deployed by agents following a given strategy is analogous to the population of that species. The creation of new strategies may alter the profitability of pre-existing strategies, in some cases replacing them or driving them extinct.

Although agent-based models are still in their infancy, the simulations and related theory have already demonstrated an ability to understand many aspects of financial markets. Several studies indicate that, as the population of strategies evolves, the market tends to become more efficient, but this is far from the perfect efficiency of the classical EMH. Prices fluctuate in time with internal dynamics caused by the interaction of diverse trading strategies. Prices do not necessarily reflect 'true values'; if we view the market as a machine whose job is to set prices properly, the inefficiency of this machine can be substantial. Patterns in the price tend to disappear as agents evolve profitable strategies to exploit them, but this occurs only over an extended period of time, during which substantial profits may be accumulated and new patterns may appear.

The Adaptive Markets Hypothesis

The methodological differences between mainstream and behavioural economics suggest that an alternative to the traditional deductive approach of neoclassical economics may be necessary to reconcile the EMH with its behavioural critics. One particularly promising direction is to view financial markets from a biological perspective and, specifically, within an evolutionary framework in which markets, instruments, institutions and investors interact and evolve dynamically according to the 'law' of economic selection. Under this view, financial agents compete and adapt, but they do not necessarily do so in an optimal fashion (see Farmer and Lo 1999; Farmer 2002; Lo 2002, 2004, 2005).

This evolutionary approach is heavily influenced by recent advances in the emerging discipline of 'evolutionary psychology', which builds on the seminal research of E.O. Wilson (1975) in applying the principles of competition, reproduction, and natural selection to social interactions, yielding surprisingly compelling explanations for certain kinds of human behaviour, such as altruism, fairness, kin selection, language, mate selection, religion, morality, ethics and abstract thought (see, for example, Barkow et al. 1992; Gigerenzer 2000). 'Sociobiology' is the rubric that Wilson (1975) gave to these powerful ideas, which generated a considerable degree of controversy in their own right, and the same principles can be applied to economic and financial contexts. In doing so, we can fully reconcile the EMH with all of its behavioural alternatives, leading to a new synthesis: the adaptive markets hypothesis (AMH).

Students of the history of economic thought will no doubt recall that Thomas Malthus used biological arguments – the fact that populations increase at geometric rates whereas natural resources increase at only arithmetic rates – to arrive at rather dire economic consequences, and that both Darwin and Wallace were influenced by these arguments (see Hirshleifer 1977, for further details). Also, Joseph Schumpeter's view of business cycles, entrepreneurs and capitalism have an unmistakeable evolutionary flavour to them; in fact, his notions of 'creative destruction' and 'bursts' of entrepreneurial activity are similar in spirit to natural selection and Eldredge and Gould's (1972) notion of 'punctuated equilibrium'. More recently, economists and biologists have begun to explore these connections in several veins: direct extensions of sociobiology to economics (Becker 1976; Hirshleifer 1977); evolutionary game theory (Maynard Smith 1982); evolutionary economics (Nelson and Winter 1982); and economics as a complex system (Anderson et al. 1988). And publications like the *Journal of Evolutionary Economics* and the *Electronic Journal of Evolutionary Modeling and Economic Dynamics* now provide a home for research at the intersection of economics and biology.

Evolutionary concepts have also appeared in a number of financial contexts. For example, Luo (1995) explores the implications of natural selection for futures markets, and Hirshleifer and Luo (2001) consider the long-run prospects of overconfident traders in a competitive securities market. The literature on agent-based modelling pioneered by Arthur et al. (1997), in which interactions among software agents programmed with simple heuristics are simulated, relies heavily on evolutionary dynamics. And at least two prominent practitioners have proposed Darwinian alternatives to the EMH. In a chapter titled 'The Ecology of Markets', Niederhoffer (1997, ch. 15) likens financial markets to an ecosystem with dealers as 'herbivores', speculators as 'carnivores', and floor traders and distressed investors as 'decomposers'. And Bernstein (1998) makes a compelling case for active management by pointing out that the notion of equilibrium, which is central to the EMH, is rarely realized in practice and that market dynamics are better explained by evolutionary processes.

Clearly the time is now ripe for an evolutionary alternative to market efficiency. To that end, in the current context of the EMH we begin, as Samuelson (1947) did, with the theory of the individual consumer. Contrary to the neoclassical postulate that individuals maximize expected utility and have rational expectations, an evolutionary perspective makes considerably more modest claims, viewing individuals as organisms that

have been honed, through generations of natural selection, to maximize the survival of their genetic material (see, for example, Dawkins 1976). While such a reductionist approach can quickly degenerate into useless generalities – for example, the molecular biology of economic behaviour – nevertheless, there are valuable insights to be gained from the broader biological perspective. Specifically, this perspective implies that behaviour is not necessarily intrinsic and exogenous, but evolves by natural selection and depends on the particular environment through which selection occurs. That is, natural selection operates not only upon genetic material but also upon social and cultural norms in *Homo sapiens*; hence Wilson's term 'sociobiology'.

To operationalize this perspective within an economic context, consider the idea of 'bounded rationality' first espoused by Nobel-prize-winning economist Herbert Simon. Simon (1955) suggested that individuals are hardly capable of the kind of optimization that neoclassical economics calls for in the standard theory of consumer choice. Instead, he argued that, because optimization is costly and humans are naturally limited in their computational abilities, they engage in something he called 'satisficing', an alternative to optimization in which individuals make choices that are merely satisfactory, not necessarily optimal. In other words, individuals are bounded in their degree of rationality, which is in sharp contrast to the current orthodoxy – rational expectations – where individuals have unbounded rationality (the term 'hyperrational expectations' might be more descriptive). Unfortunately, although this idea garnered a Nobel Prize for Simon, it had relatively little impact on the economics profession. (However, his work is now receiving greater attention, thanks in part to the growing behavioural literature in economics and finance. See, for example, Simon 1982; Sargent 1993; Rubinstein 1998; Gigerenzer and Selten 2001.) Apart from the sociological factors discussed above, Simon's framework was commonly dismissed because of one specific criticism: what determines the point at which an individual stops optimizing and reaches a satisfactory solution? If such a point is determined by the usual cost–benefit calculation underlying much of microeconomics (that is, optimize until the marginal benefits of the optimum equals the marginal cost of getting there), this assumes the optimal solution is known, which would eliminate the need for satisficing. As a result, the idea of bounded rationality fell by the wayside, and rational expectations has become the de facto standard for modelling economic behaviour under uncertainty.

An evolutionary perspective provides the missing ingredient in Simon's framework. The proper response to the question of how individuals determine the point at which their optimizing behaviour is satisfactory is this: such points are determined not analytically but through trial and error and, of course, natural selection. Individuals make choices based on past experience and their 'best guess' as to what might be optimal, and they learn by receiving positive or negative reinforcement from the outcomes. If they receive no such reinforcement, they do not learn. In this fashion, individuals develop heuristics to solve various economic challenges, and, as long as those challenges remain stable, the heuristics will eventually adapt to yield approximately optimal solutions to them.

If, on the other hand, the environment changes, then it should come as no surprise that the heuristics of the old environment are not necessarily suited to the new. In such cases, we observe 'behavioural biases' – actions that are apparently ill–advised in the context in which we observe them. But rather than labelling such behaviour 'irrational', it should be recognized that suboptimal behaviour is not unlikely when we take heuristics out of their evolutionary context. A more accurate term for such behaviour might be 'maladaptive'. The flopping of a fish on dry land may seem strange and unproductive, but under water the same motions are capable of propelling the fish away from its predators.

By coupling Simon's notion of bounded rationality and satisficing with evolutionary dynamics, many other aspects of economic behaviour can also be derived. Competition, cooperation, market-making behaviour, general equilibrium, and disequilibrium dynamics are all adaptations designed to address certain environmental challenges for the human species, and by viewing them through the lens of evolutionary biology

we can better understand the apparent contradictions between the EMH and the presence and persistence of behavioural biases.

Specifically, the adaptive markets hypothesis can be viewed as a new version of the EMH, derived from evolutionary principles. Prices reflect as much information as dictated by the combination of environmental conditions and the number and nature of 'species' in the economy or, to use the appropriate biological term, the *ecology*. By 'species' I mean distinct groups of market participants, each behaving in a common manner. For example, pension funds may be considered one species; retail investors, another; market-makers, a third; and hedge-fund managers, a fourth. If multiple species (or the members of a single highly populous species) are competing for rather scarce resources within a single market, that market is likely to be highly efficient – for example, the market for 10-Year US Treasury Notes reflects most relevant information very quickly indeed. If, on the other hand, a small number of species are competing for rather abundant resources in a given market, that market will be less efficient – for example, the market for oil paintings from the Italian Renaissance. Market efficiency cannot be evaluated in a vacuum, but is highly context-dependent and dynamic, just as insect populations advance and decline as a function of the seasons, the number of predators and prey they face, and their abilities to adapt to an ever-changing environment.

The profit opportunities in any given market are akin to the amount of food and water in a particular local ecology – the more resources present, the less fierce the competition. As competition increases, either because of dwindling food supplies or an increase in the animal population, resources are depleted which, in turn, causes a population decline eventually, decreasing the level of competition and starting the cycle again. In some cases cycles converge to corner solutions, that is, certain species become extinct, food sources are permanently exhausted, or environmental conditions shift dramatically. By viewing economic profits as the ultimate food source on which market participants depend for their survival, the dynamics of market interactions and financial innovation can be readily derived.

Under the AMH, behavioural biases abound. The origins of such biases are heuristics that are adapted to non-financial contexts, and their impact is determined by the size of the population with such biases versus the size of competing populations with more effective heuristics. During the autumn of 1998, the desire for liquidity and safety by a certain population of investors overwhelmed the population of hedge funds attempting to arbitrage such preferences, causing those arbitrage relations to break down. However, in the years prior to August 1998 fixed-income relative-value traders profited handsomely from these activities, presumably at the expense of individuals with seemingly 'irrational' preferences (in fact, such preferences were shaped by a certain set of evolutionary forces, and might be quite rational in other contexts). Therefore, under the AMH, investment strategies undergo cycles of profitability and loss in response to changing business conditions, the number of competitors entering and exiting the industry, and the type and magnitude of profit opportunities available. As opportunities shift, so too will the affected populations. For example, after 1998 the number of fixed-income relative-value hedge funds declined dramatically – because of outright failures, investor redemptions, and fewer start-ups in this sector – but many have reappeared in recent years as performance for this type of investment strategy has improved.

Even fear and greed – the two most common culprits in the downfall of rational thinking according to most behaviouralists – are the product of evolutionary forces, adaptive traits that enhance the probability of survival. Recent research in the cognitive neurosciences and economics, now coalescing into the discipline known as 'neuroeconomics', suggests an important link between rationality in decision-making and emotion (Grossberg and Gutowski 1987; Damasio 1994; Elster 1998; Lo and Repin 2002; and Loewenstein 2000), implying that the two are not antithetical but in fact complementary. For example, contrary to the common belief that emotions have no place in rational financial decision-making processes, Lo and Repin (2002) present preliminary evidence that physiological variables associated with the autonomic nervous system are

highly correlated with market events even for highly experienced professional securities traders. They argue that emotional responses are a significant factor in the real-time processing of financial risks, and that an important component of a professional trader's skills lies in his or her ability to channel emotion, consciously or unconsciously, in specific ways during certain market conditions.

This argument often surprises economists because of the link between emotion and behavioural biases, but a more sophisticated view of the role of emotions in human cognition shows that they are central to rationality (see, for example, Damasio 1994; Rolls 1999). In particular, emotions are the basis for a reward-and-punishment system that facilitates the selection of advantageous behaviour, providing a numeraire for animals to engage in a 'cost–benefit analysis' of the various actions open to them (Rolls 1999, ch. 10.3). From an evolutionary perspective, emotion is a powerful adaptation that dramatically improves the efficiency with which animals learn from their environment and their past (see Damasio 1994). These evolutionary underpinnings are more than simple speculation in the context of financial market participants. The extraordinary degree of competitiveness of global financial markets and the outsize rewards that accrue to the 'fittest' traders suggest that Darwinian selection – 'survival of the richest', to be precise – is at work in determining the typical profile of the successful trader. After all, unsuccessful traders are eventually eliminated from the population after suffering a certain level of losses.

The new paradigm of the AMH is still under development, and certainly requires a great deal more research to render it 'operationally meaningful' in Samuelson's sense. However, even at this early stage it is clear that an evolutionary framework is able to reconcile many of the apparent contradictions between efficient markets and behavioural exceptions. The former may be viewed as the steady-state limit of a population with constant environmental conditions, and the latter involves specific adaptations of certain groups that may or may not persist, depending on the particular evolutionary paths that the economy experiences. More specific implications may be derived through a combination of deductive and inductive inference –for example, theoretical analysis of evolutionary dynamics, empirical analysis of evolutionary forces in financial markets, and experimental analysis of decision-making at the individual and group level.

For example, one implication is that, to the extent that a relation between risk and reward exists, it is unlikely to be stable over time. Such a relation is determined by the relative sizes and preferences of various populations in the market ecology, as well as institutional aspects such as the regulatory environment and tax laws. As these factors shift over time, any risk–reward relation is likely to be affected. A corollary of this implication is that the equity risk premium is also time-varying and path-dependent. This is not so revolutionary an idea as it might first appear – even in the context of a rational expectations equilibrium model, if risk preferences change over time, then the equity risk premium must vary too. The incremental insight of the AMH is that aggregate risk preferences are not immutable constants, but are shaped by the forces of natural selection. For example, until recently US markets were populated by a significant group of investors who had never experienced a genuine bear market – this fact has undoubtedly shaped the aggregate risk preferences of the US economy, just as the experience since the bursting of the technology bubble in the early 2000s has affected the risk preferences of the current population of investors. In this context, natural selection determines who participates in market interactions; those investors who experienced substantial losses in the technology bubble are more likely to have exited the market, leaving a markedly different population of investors. Through the forces of natural selection, history matters. Irrespective of whether prices fully reflect all available information, the particular path that market prices have taken over the past few years influences current aggregate risk preferences. Among the three fundamental components of any market equilibrium – prices, probabilities, and preferences – preferences is clearly the most fundamental and least understood. Several large bodies of research have developed around these issues – in economics

and finance, psychology, operations research (also called 'decision sciences') and, more recently, brain and cognitive sciences – and many new insights are likely to flow from synthesizing these different strands of research into a more complete understanding of how individuals make decisions (see Starmer 2000, for an excellent review of this literature). Simon's (1982) seminal contributions to this literature are still remarkably timely and their implications have yet to be fully explored.

Conclusions

Many other practical insights and potential breakthroughs can be derived from shifting our mode of thinking in financial economics from the physical to the biological sciences. Although evolutionary ideas are not yet part of the financial mainstream, the hope is that they will become more commonplace as they demonstrate their worth – ideas are also subject to 'survival of the fittest'. No one has illustrated this principal so well as Harry Markowitz, the father of modern portfolio theory and a Nobel laureate in economics in 1990. In describing his experience as a Ph.D. student on the eve of his graduation, he wrote in his Nobel address (Markowitz 1991, p. 476):

> . . . [W]hen I defended my dissertation as a student in the Economics Department of the University of Chicago, Professor Milton Friedman argued that portfolio theory was not Economics, and that they could not award me a Ph.D. degree in Economics for a dissertation which was not Economics. I assume that he was only half serious, since they did award me the degree without long debate. As to the merits of his arguments, at this point I am quite willing to concede: at the time I defended my dissertation, portfolio theory was not part of Economics. But now it is.

In light of the sociology of the EMH controversy (see, for example, Lo 2004), the debate is likely to continue. However, despite the lack of consensus in academia and industry, the ongoing dialogue has given us many new insights into the economic structure of financial markets. If, as Paul Samuelson has suggested, financial economics is the crown jewel of the social sciences, then the EMH must account for half the facets.

Egalitarianism

Harry Brighouse and Adam Swift

Abstract

This article surveys a variety of egalitarian theories. We look at a series of different answers to the question of what the metric of justice should be. Then we survey different interpretations of the egalitarian distributive rule, including 'equality', 'prioritizing benefit to the least advantaged' and 'sufficiency'. Theories also differ by whether they see equality as properly holding within social institutions or being a principle that applies more cosmically. Finally, we observe that egalitarian theories differ as to the weight they grant to egalitarian values relative to other values.

All modern political theories assume that persons are in some relevant sense moral equals, entitled to equal concern, respect or treatment, and that a theory of justice must interpret and reflect that moral equality. This commitment is sometimes dubbed the 'egalitarian plateau', and it has been a common foundational moral assumption since Locke. Contemporary theories differ in how they *interpret* the egalitarian plateau. Two kinds of theory of justice are usually counted as egalitarian. Theories of distributive equality concern themselves with the relative standing of individuals in the distribution of benefits and burdens; theories of relational equality concern themselves with the relative standing of individuals when they face each other in the public sphere.

The Metric

One key question concerns the metric of equality: what, precisely, is it that egalitarians should seek to equalize? The literature falls into three main camps. Resourcists argue that people should be equal in the space of resources, meaning that they should have equal opportunity for achieving holdings of alienable goods. How are holdings priced? Ronald Dworkin imagines a hypothetical auction in which persons with equal holdings of some

currency bid for available goods until markets clear (Dworkin 2000). The distribution after the auction is equal if no one prefers anyone else's bundle of goods to her own; the distribution is then said to pass the 'envy test'. The intuitive idea is that the price of some good is set by the opportunity cost to others of that good. We have to tailor our preferences to our resources; equality is achieved when all face the same budget constraint, not when all achieve equal satisfaction.

Equality of resources has difficulty with the intuition that those with less socially valued talent, and in particular those with serious impairments, should receive compensation. Two strategies are available. One is to adopt a view that talent is socially constructed, so that much of the disadvantage faced by the less talented and the impaired is a consequence not of their lack of talent but of the fact that social institutions are maladapted to their natural endowments (Pogge 2003). This view allows resourcists to call for the reform of social institutions in the name of equality, without demanding compensation for impairments. The problem with this strategy is that some mental and physical impairments *intrinsically* cause disadvantage; there is no feasible set of social arrangements that would not make it more difficult for people with the impairments to derive satisfaction from resources. So an alternative strategy is to make the cut between persons and resources in a different place, regarding talents as resources and disabilities as resource-deficits. Dworkin's own version of this strategy proposes compensating the less talented with additional income, the amount calculated by looking at the insurance that talented individuals would have bought against a lack of talents if they had no knowledge of their probability of having the talents.

An alternative metric is welfare; egalitarians of welfare would seek to equalize levels of welfare (understood sometimes as idealized preference satisfaction, sometimes in terms of internal states such as happiness). This view handles talent-inequality in a straightforward manner; the less talented and the disabled should be compensated up to the level where they enjoy as much welfare as anyone else. But it faces the problem that there is no reason for people to moderate their preferences; since welfare is a direct target, those with expensive tastes receive more resources than those with inexpensive tastes, which is widely regarded as intuitively unfair. An alternative view – equality of opportunity for welfare – deals with this problem by seeking equality of welfare except when inequalities are the result of voluntary well-informed choices rather than bad luck or circumstances outside the agent's control (Arneson 1989). Again, the less talented are straightforwardly compensated for the way in which they find it harder than others to derive satisfaction, but those who cultivate expensive tastes are not. However, those with non-cultivated expensive preferences are also compensated, even if they could easily be overcome; this view does not see lack of talent, and disability in particular, as morally more urgent than expensive preferences. (See Roemer 1986, for an argument that equality of resources implies equality of welfare.)

All of the views deploying an 'opportunity' metric, including Dworkin's resourcist view, presume the desirability of holding people accountable for their voluntary choices, but compensating them for deficits that are beyond their control. Views of this kind are sometimes referred to as varieties of 'luck egalitarianism'. Inequalities resulting from voluntary choice are acceptable because they reflect a deeper sense in which we are equal as moral agents; choice legitimizes inequality, brute luck does not. (For an elegant attempt both to conceptualize and operationalize equality of opportunity *tout court*, see Roemer 1998.)

The main rival account – namely, the capabilities approach developed by Amartya Sen and Martha Nussbaum – focuses on the *preconditions* of agency (Sen 1999; Nussbaum 2000). Equality of capabilities demands that people be equal in the space of the functionings or livings that they are substantively able to achieve. Walking is a functioning, so are eating, reading, mountain climbing, and chatting. 'The concept of functionings… reflects the various things a person may value doing or being – varying from the basic (being adequately nourished) to the very

complex (being able to take part in the life of the community)' (Sen 1999, p. 75). But when we make interpersonal comparisons of well-being we should find a measure that incorporates references to functionings but also reflects the intuition that what matters is not merely achieving the functioning but being free to achieve it. So we should look at 'the freedom to achieve actual livings that one can have a reason to value' (Sen 1999, p. 73) or, to put it another way, 'substantive freedoms – the capabilities – to choose a life one has reason to value'. The idea is that people should be equal in this space.

The capabilities approach avoids the problems of the standard welfarist approaches by focusing on *choice* (thus treating inequalities arising from voluntary choices differently from those arising from circumstances). It avoids the difficulty resourcist accounts have with unequal talent by focusing on *functionings*; talent deficits are compensated for by looking not at what others would pay to avoid them but at the valuable activities the deficits deprive people of access to. Some theorists place the capabilities account in the welfarist camp (Williams 2002) but it is not implausible to think of it as a variant of resourcism, distinguished by its approach to the valuation of talents.

A major recent development in the debates about egalitarianism has involved criticisms of luck egalitarianism. Each of the luck egalitarian principles, taken alone, imposes heavy costs on those who endure misfortunes for which they can be held responsible, even if those costs place the agent below the threshold for full participation in social affairs. An alternative has developed which is best described as 'relational egalitarianism'. Relational egalitarianism is not directly concerned with equality in terms of the distribution of any particular currency, but endorses the idea that individuals should have equal standing in the public sphere. This vague idea has several instantiations. Elizabeth Anderson (1999, p. 304) talks of seeking 'a social order in which persons stand in relations of equality'; Nancy Fraser (1998, p. 30) says that 'Justice requires social arrangements that permit all (adult) members of society to interact with one another as peers'. Both fill out their theories with more details. According to Fraser (1998, p. 24), 'It is unjust that some individuals and groups are denied the status of full partners in social interaction, simply as a consequence of institutionalized patterns of interpretation and evaluation in whose construction they have not equally participated and that disparage their distinctive characteristics or the distinctive characteristics assigned to them'. A third variant of relational egalitarianism spells it out specifically in terms of political equality, the idea being that it is particularly important that people enjoy equal availability of or opportunity for political power or influence (Christiano 1995). This variant is typically less hostile than other variants to luck egalitarianism.

Each of the views reviewed in this section allows inequality along some dimensions. Relational egalitarianisms allow such inequalities of income, wealth, welfare or capabilities as are compatible with equal political influence, or interaction as peers, or 'equal opportunity for participation as a peer'. These permitted inequalities may be great or very small, and how great or small may vary by social context. Principles demanding equality of opportunity are consistent with great inequalities in outcome, and consistent also with some being very badly off in absolute terms. While equality of opportunity conceptions place no limit on how badly off someone may be as a result of her own imprudent choices, equality of social standing demands that no one fall below the threshold needed for equal participation, even if she makes numerous imprudent choices.

The Distributive Rules

Do egalitarians even care about *equality*? Principles demanding equality of X seem vulnerable to an obvious objection. In some dynamic situations it is possible to produce more of X by distributing X unequally, and to ensure that even those with least have more than under an equal distribution. For example, we can sometimes produce more wealth by judiciously attaching higher income to more productive positions in the economy, and to

longer work hours; the higher income acts both as a signal and as an incentive to produce more. That greater production can be turned to the benefit of those with least. But, the objection goes, it would be perverse to prefer an equal situation in which everyone has less to one in which everyone has more, even if we have to sacrifice equality for the sake of that additional product.

This is known as the 'levelling down' objection to equality. Egalitarians make two distinct responses. The first is to concede the argument, abandoning 'equality' and replacing it with 'giving priority to the interests of the least advantaged'. John Rawls's difference principle, which states that 'social and economic inequalities are to be arranged to the maximum benefit of the least advantaged', embodies one variant of this response, a variant that gives *absolute* priority to the prospects of the least advantaged (Rawls 1971, 2001). A weaker variant in this family of views, usually known as 'prioritarianism', simply says that it is more urgent to provide benefits to those with less advantage than to those with more (Parfit 2000).

An alternative response is to assert value pluralism. This response acknowledges that priority to the least advantaged is an important value and perhaps more important than equality, so that when it comes to policy or action prioritarian principles should govern. But it says that equality nevertheless matters some; there is one way in which an unequal distribution is worse than an equal distribution, even if, all things considered, it is better; the way in which it is worse is that it is unequal and for that reason unfair (Temkin 2002). This response is bolstered by the observation that there is nothing eccentric about endorsing a principle that values distributions that benefit nobody; the retributive principle of proportionality between punishment and crime, for example, calls for harming the criminal even when there is no gain to anyone else in harming him.

Some reject principles of equality and priority on the grounds that all that matters for the purposes of justice is that all have enough. Sufficientarian theories are not usually counted as within the egalitarian family, because they eschew any fundamental concern with relativities. Relativities may matter in determining what is enough for people to live a decent life in any given social environment, but ultimately what matters is not where someone ranks in the distribution of resources (or anything else) but whether she has enough. However, as suggested above, sufficientarian principles also have a place in some variants of egalitarianism. While relational egalitarianism places no principled limits on the level of material or welfare inequality, and gives no general priority to the least advantaged, it does set a floor – all must have sufficient resources to be full participants in social interaction. Equality of political influence demands that all have sufficient resources, personal and financial, to play an equal role in political life, but, as long as it is possible to insulate politics from residual inequalities of wealth, it is not concerned with equalizing or prioritizing benefit to the least advantaged.

Many theories of justice that do not fit the above characterizations of egalitarianism nevertheless incorporate some elements of egalitarian thinking. John Rawls's theory of justice, for example, prioritizes the principle that certain basic liberties (not including strong property rights) be equally distributed, then demands that within that constraint fair equality of opportunity should be implemented, and then that social and economic inequalities be arranged to the greatest benefit of the least advantaged in so far as that is possible without jeopardizing the equal liberty and fair equality of opportunity principle (Rawls 1971, 2001). Michael Walzer's (1983) theory of 'complex equality' takes seriously widely shared intuitions that different goods are subject to different distributive rules. For example, while income should be distributed according to productive contribution, as will tend to result from market interactions, the inequalities this norm generates should be prevented from translating into unequal access to certain key goods like health care and educational opportunities, the distribution of which should be governed by need and the requirements of equal opportunity respectively. It is unclear in what sense Walzer's 'complex equality' is genuinely an egalitarian position, since it is in principle consistent with unequal

and coinciding distributions of all goods that are not themselves governed by egalitarian norms.

Priority and equality coincide in practice for one class of goods: positional goods. These have the property that the contribution an individual's share of the good makes to her absolute position is determined by how much of the good she has relative to others. The credentialing aspect of education is a paradigm case; how useful a degree is in landing a job (as opposed to the learning one achieved in the process of getting the degree) depends entirely on the credentials of one's competitors for that job. (Other cases are detailed in Hirsch 1976.) Those who give priority to the worst-off will countenance inequalities in positional goods only in so far as they are required by or result in the least advantaged benefiting overall (Brighouse and Swift 2006).

The Scope of Equality

Whatever the right distribuendum, and whatever the appropriate distributive principle, it is a further question who should be equal to whom. Some limit the application of their egalitarianism to members of the same society or system of cooperation, or to those subject to the same coercive structure (Nagel 2005), or hold that it is states that owe their citizens a particular duty to treat them with equal concern and respect (Dworkin 2000). Others believe that egalitarian principles should apply to all human beings, irrespective of the relations that obtain between them. If we restrict the application of egalitarian principles to schemes of cooperation, that does not exclude the possibility of a global egalitarianism, since most now accept that in the modern world social cooperation extends well beyond national boundaries (Julius 2006). But consider this version of Derek Parfit's divided world case. All the people in A are half as well off as all the people in B, but A and B have no knowledge of or contact with each other (Parfit 2000). Is there anything regrettable from the perspective of injustice about this inequality? If so, then the scope of justice is cosmic, not simply social. In the stated version of the divided world case this difference is motivationally inert, since the people in B do not have the relevant knowledge. But, if they did, cosmic egalitarianism would give them a reason to try to find a way to contact and interact with the people on A, while intra-societal egalitarianism would provide them with no such reason.

The divided world case brings out another difference in orientation. Where members of A and B have no interaction, or even knowledge of each other, equality can be valued only intrinsically rather than because of its effects on members of A or Often, however, inequality with respect to some goods is devalued, and equality valued, instrumentally, because of its absolute effects on those subject to the unequal distribution – usually its effects on the relatively disadvantaged. Thus, for example, economic inequalities are thought to undermine the fairness of legal or political processes, or occupational or other status hierarchies are claimed to harm the health of those on the lower rungs. Those who value equality intrinsically would hold that there is a reason to level down for the sake of equality or fairness, whereas instrumental egalitarians might seek the more equal distribution of some goods, not for egalitarian reasons *stricto sensu*, but to eliminate the bad effects of certain kinds of inequality.

The Subject of Justice

A further dividing line between egalitarians concerns the subject of justice. Rawls stipulates that the subject is the 'basic structure of society', which consists of some of the central, interaction-shaping institutions of a society: for example, the constitution, the legally recognized forms of property, the structure of the economy, the design of the legislature, and the judiciary. The idea is that these institutions govern the division of the advantages that accrue from social cooperation, and they assign the basic rights and responsibilities to citizens. So a society is just when those institutions are arranged according to the correct principles.

Rawls officially exempts individual actions and motives from evaluation from the perspective of egalitarian justice, as long as individuals obey the rules set by a just basic structure. But this has

the consequence that a society in which talented individuals take advantage of the prerogatives not to serve the least advantaged that are built into the principles that he thinks justice requires of coercive institutions is no less just than one in which they are much more strongly motivated by the desire to benefit the least advantaged through their choices regarding work. A society with an egalitarian governing ethos, on this view, is no more just than one without, even when the least advantaged are much better off. But the motivations and actions of talented individuals affect the prospects and status of others in ways that have 'profound and pervasive influence on persons' (Rawls 2001, p. 55), which is Rawls's central reason for focusing on the basic structure. So some egalitarians regard justice as commenting not only on the broad coercive outline of society, but also on less officially coercive institutions such as a society's ethos (Cohen 1997). For a powerful defence of an account intermediate between Cohen's and Rawls's, see Julius 2003).

Other Values

Most egalitarian theorists are value pluralists; they believe that equality (or priority) of their preferred metric matters, but so do other principles. Observing that equality or priority is sometimes in conflict with liberty or privacy or efficiency does not require us to reject one of the conflicting values. It requires us, instead, to evaluate reasons for considering one of the values more morally important than the others, and, in the light of that evaluation, to establish which should give way in different conflicts. Unless the relationship between values is one of lexical priority (in which case the prior value always trumps subordinate values, which can be pursued only when there is no conflict), different trade-offs between values will be mandated in different conflicts. But lexical priority is unlikely to hold between genuine values. If a value matters *at all*, it is hard to believe it could never be the case that a very large amount of it was greater than a very small amount of a conflicting value *however great that conflicting value is*.

Overview

Egypt, one of the most economically diversified countries in the Middle East, has been embroiled in economic turmoil since the overthrow of Hosni Mubarak in 2011.

The 1980s was a decade of macroeconomic disorder in Egypt before an IMF-backed reform programme in the 1990s helped it achieve economic stability. However, the late 1990s saw a downturn and privatization efforts stalled in the early 2000s. In 2004 an economically liberal cabinet was appointed and the reform agenda was revived, with President Mubarak investing political capital in structural reforms to generate jobs and promote foreign investment.

Growth in Egypt averaged 6.4% per year between 2005 and 2008, underpinned by record levels of foreign direct investment and a favourable external environment. The economy held up relatively well during the global financial crisis, with a decline in remittances and external demand partially offset by resilient domestic demand and strong performances in the construction, communications and trade sectors.

In 2009 agriculture accounted for 13.7% of GDP, industry 37.3% and services 49.0%.

GDP fell by 9% in the first quarter of 2011 following the revolution in January of that year. Revenues from tourism collapsed, triggering a slide in foreign reserves. Unemployment climbed to 13% and gross public debt rose to nearly 100% of GDP by late June 2013. Long-term stability is likely to remain elusive as the country struggles through its political transition.

Currency

The monetary unit is the *Egyptian pound* (EGP) of 100 *piastres*. Inflation rates (based on IMF statistics) for fiscal years:

Faced with slowing economic activity, the country devalued the Egyptian pound four times in 2001. In January 2003 the Egyptian pound was allowed to float against the dollar after years of a government-controlled foreign exchange regime. In June 2009 foreign exchange reserves were US$29,278 m., gold reserves totalled 2.43 m. troy oz and total money supply was £E182,991 m.

Budget

The financial year runs from 1 July. Budgetary central government revenues in 2008–09 (provisional) were £E282,505 m. and expenditures £E308,070 m. Taxes on income, profits and capital gains accounted for 28.4% of revenue and taxes on goods and services 22.2%. Main items of expenditure were subsidies (30.5%) and compensation of employees (24.7%).

Performance

Real GDP growth rates (based on IMF statistics):

Total GDP in 2012 was US$262.8 bn.

2002	*2003*	*2004*	*2005*	*2006*	*2007*	*2008*	*2009*	*2010*	*2011*
2.4%	3.2%	8.1%	8.8%	4.2%	11.0%	11.7%	16.2%	11.7%	11.1%

2002	*2003*	*2004*	*2005*	*2006*	*2007*	*2008*	*2009*	*2010*	*2011*
3.2%	3.2%	4.1%	4.5%	6.8%	7.1%	7.2%	4.7%	5.1%	1.8%

Banking and Finance

The Central Bank of Egypt (founded 1960) is the central bank and bank of issue. The *Governor* is Hisham Ramez.

In 2003, four major public-sector commercial banks accounted for some 77% of all banking assets: the National Bank of Egypt (the largest bank, with assets of £E299 bn. in June 2010), the Banque Misr, the Bank of Alexandria and the Banque du Caïre. There were 40 banks in total in 2008. Foreign banks have only been allowed to operate since 1996.

Foreign direct investment inflows, which were just US$237 m. in 2003, rose to US$11.6 bn. in 2007, but declined to US$6.4 bn. in 2010.

In 2010 external debt totalled US$34,844 m., representing 16.2% of GNI.

There are stock exchanges in Cairo and Alexandria.

E

Einaudi, Luigi (1874–1961)

F. Caffé

Keywords
Economic liberalism; Einaudi, L.; Mill, J. S.; Public finance; Tax incentives for saving; Taxable income

JEL Classifications
B31

An outstanding Italian economist and influential figure on the broader political and cultural scene, Einaudi was born in Carru (Piedmont) on 24 March 1874 and died in Rome on 30 October 1961. He graduated in law from Turin in 1895 and then, while continuing with this studies, embarked on a career in journalism. The success he achieved in both fields underlined his rare talent and his endless capacity for work. In fact, his academic progress was so rapid that in 1907 he was appointed as professor of public finance at the University of Turin. Meanwhile, he wrote articles for the most influential Italian daily newspaper of the period, the *Corriere delle Serra*, which not only brought him national recognition but also earned him the reputation of 'educator' of the entire country. He became a member of the Senate in 1919, but retired from all political and public activity with the advent of fascism. Towards the end of the First World War he went into exile in Switzerland. On his return, he was appointed Governor of the Bank of Italy (1945), Vice-

President of the Cabinet and Minister in charge of the Budget (1947), and was finally elected President of the Republic of Italy (1948–1955). At the end of his seven-year presidential term of office, he was made a life member of the Senate.

The most important aspect of Einaudi's achievements is the use he made of his academic and journalistic ability, as foundations for his activity as a statesman and politician. In addition, close study of his strictly scientific works reveals the extent to which he drew on the wealth of knowledge and experience which he had gained also in other fields. The 3,800 recorded items of Einaudi's works cover such a wide range of interests that it is necessary here to concentrate on his contributions to the study of public finance and his ideas on economic policy. Einaudi's main contributions to the study of public finance were investigations, based on the classical ideas of John Stuart Mill, which gave a solid logical basis to the principle of the exclusion of savings from taxable income; his research into the theory of capitalization of taxation; his critical and constructive contributions on the effects of certainty and stability of fiscal principles; his important analysis of the concept of taxable income which he identified with normal income, or, in other words, with the average income potentiality of the person subject to taxation.

Einaudi's position vis-à-vis public intervention in the economy was not hostile in principle, though he undoubtedly took a limited view of state interference in economic life. Since, for Einaudi, 'All liberties were jointly liable', autonomous sources of income were a necessity to prevent people from being subjected to a single centralizing order of the state. He asserted this during the 20 years of fascism, when he continued to teach with the same independence of mind and without compromising his fidelity to economic liberalism. Even though Einaudi had been stressing the usefulness of productive public expenditure since 1919, he showed a singular lack of comprehension of the Keynesian contribution, in the belief that it would be an inevitable cause of inflation.

Selected Works

On Luigi Einaudi himself there is a Bibliografia degli scritti edited by Luigi Firpo under the auspices of the Bank of Italy, Turin, 1971. It is useful to divide his work into the three main areas which he outlined: theory, politics and history. Representative works of the three sections are as follows:

1912. *Intorno al concetto di reddito imponibile e di un sistema di imposte sul reddito consumato*. Turin: V. Bona.

1919. *Osservazioni critiche intorno alla teoria dell'ammortamento dell'imposta e teoria delle variazioni nei redditi e nei valori capitali sussequenti all'imposta*. Turin: Fratelli Bocca.

1929. *Contributo all ricerca della 'ottima imposta'*. Milan: Bocconi.

1938. *Miti e paradossi delli giustizia tributaria*. Turin: Luigi Einaudi.

The following handbooks are available:

1914. *Corso di scienza delle finanze*. Turin: Tip. e Bono.

1932–66. *Principi di scienza delle finanze*. Turin: La Riforma Sociale.

1932. *Il sistema tributario italiano*. Turin: La Riforma Sociale.

With reference to the history of finance and the history of ideas see:

1908. *La finanza sabauda all'aprirsi del secolo XVIII e durante la guerra di successione spagnola*. Turin: Società Tip. Editrice Nazionale.

1927. *La guerra e il sistema tributario italiano*. Bari: Laterza.

1953. *Saggi bibliografici e storici intorno alle dottrine economiche*. Rome: Ediz. Storia e Litteratura.

Einaudi's journalistic work has been largely collected in eight volumes comprising the *Cronache economiche e politiche di un trentennio* (1893–1925), Turin: Ed. Einaudi, 1959–65, and in *Lo scrittoio del Presidente 1948–1955*, Turin: Ed. Einaudi, 1956. For many years Einaudi was Italian correspondent for the *Economist*.

Einzig, Paul (1897–1973)

Brendan Brown

Einzig was born in Brasov, Transylvania (Austria-Hungary). He was both a prolific, widely read author on international monetary topics and a renowned journalist. Educated in Hungary and France, he received his PhD from the University of Paris. In 1919, Einzig settled in the UK. Soon he became the Paris correspondent of the *Financial News* and was appointed its political editor in 1929. When the *Financial News* was bought by the *Financial Times,* Einzig became the political editor of the latter newspaper. Also he wrote the daily 'Lombard Street Column' during the mid- and late 1930s and many feature articles on currency questions. One of his top 'scoops' as a journalist was the revelation in 1943 of how the Swiss National Bank was buying looted gold from the Reichsbank on a huge scale. Already in 1939, Einzig's book *The Bloodless Invasion* had provided an original account of how Nazi Germany in its exchange rate policies exploited South-East Europe.

Einzig wrote more than 50 books on financial topics. Perhaps *A Dynamic Theory of Forward Exchange* (1961) is the best example of his powerful combination of economic, practical and historical knowledge. The book has a section describing the methods of intervention by central banks in forward exchange markets in the interwar period – and also by the Austrian and Russian central banks in the late 19th century. Einzig takes issue with the 'static theory of forward exchange' in which forward rates are shown as determined by given international interest rate differentials. He stresses that these themselves are influenced by speculation in the forward market. Einzig showed that except in the case of perfect arbitrage, forward markets have to be considered explicitly in an analysis of international short-term capital movements.

In *Primitive Money, in its Ethnological, Historical and Economic Aspects*, Einzig looks at how different commodities came to be used as money in primitive and ancient society. He refutes the hypothesis that money developed primarily through the progress of division of labour and the resulting complexity of trade, which made barter increasingly cumbersome. Much more important was the designation of a commodity for use in non-commercial payments (religious sacrifices, blood money, bride prices etc.).

Eisner, Robert (1922–1998)

James K. Galbraith

Abstract

Robert Eisner, a leading American macroeconomist and theorist of the investment function, was an architect of the Keynesian ascendancy in post-war America. He developed the accounting foundations of Keynesian macroeconomics, finally producing a Total Income System of Accounts. His ideas found

application in his later, policy-oriented writings on the budget deficit, the current account, and the Social Security system. His embrace of capital budgeting underpinned a strong advocacy of liberal expenditure on infrastructure, education, and research and development. He was throughout motivated by a commitment to larger social goals, especially full employment, peace, and justice.

Robert Eisner, a leading American macroeconomist and theorist of the investment function, graduated in history from College of the City of New York in 1940, took an MA in sociology from Columbia University in 1942 and, following service in the army and the Office of Price Administration, a Ph.D. in economics under Fritz Machlup at Johns Hopkins University in 1951. He joined the faculty of Northwestern University in 1952, rising to hold the William R. Kenan Professorship of Economics from 1974 until his retirement in 1994. He served as President of the American Economic Association in 1988.

Eisner was an architect of the Keynesian ascendancy in post-war America. Much of his work was devoted to technical developments in that tradition; his singular distinction lay in taking the accounting foundations of Keynesian macroeconomics seriously and in developing their implications with utmost rigour. This thread runs through his writing from his earliest papers on the 'Invariant Multiplier', the permanent income hypothesis, liquidity preference and the liquidity trap. It reaches its apogee in his work on a Total Income System of Accounts (TISA). It suffuses his later, policy-oriented writings on the meaning and implications of deficits in the budget, current account, and Social Security system.

No shrinking violet, Eisner liked to call his shots. Thus, H. S.Houthaker 'has not performed [a] test correctly'; 'Bronfenbrenner and Mayer. . . confound. . . issues of elasticity with those of slope'; 'Re-estimation with Pifer's data and application of appropriate statistical tests contradict Pifer's conclusions' (1998a, pp. 8, 27, 48). The tone is ever tactful, the intent always the pursuit of truth, the subtext a certain delight in finding the exact, fatal weakness of an opposing view. Late in his life, this author heard Eisner speak to a room of senior officials in China on the error and futility of the one-child policy, a delicate issue which he raised in the same spirit and with deeply impressive effect.

Underpinning his technical precision lay an unflagging commitment to larger social goals, especially full employment, peace, and justice. Eisner actively advocated all three throughout his career, but especially in the later years when he appeared frequently on the opinion pages of the *Wall Street Journal,* as a leading director of Economists Allied for Arms Reduction, and in causes devoted to the advancement of women in the economics profession.

For instance, in a 1952 paper in the *American Economic Review* (1998a, 106–17) Eisner analysed the relationship of replacement costs to depreciation allowances in a growing economy. In doing so he called attention to the fact that growth in the latter usually exceeded that in the former, resulting in reported profits that were understated for purposes of both taxation and collective bargaining. Pointedly, he suggested the work ought to interest both revenue officers and trade unionists.

Yet Eisner's views were often unfashionable and politically inconvenient. In important papers in the 1980s, at a time when Democrats had taken the veil of fiscal virtue, he undertook with Paul

Pieper to show that (among numerous other difficulties with budget accounting) inflation had rendered the deficit meaningless, introducing vast inconsistencies between the nominal budget deficit and the change in the real public debt. Thus, the Reagan deficits were far smaller than normally supposed, while those of Carter were surpluses in real terms – likely to produce fiscal drag and so to bear partial responsibility for the stagnation of those years. Correctly accounting for inflation, Eisner argued, might have forestalled the new classical critique that led many in those years to abandon Keynesian principles.

A closely related cause was the misunderstanding of 'national saving' and the fallacious popular argument that to reduce deficits would lead to increased capital formation. In 1995, Eisner argued that to take the accounting relation between public and private saving

> as evidence that reducing the federal deficit must raise national saving should be recognized, on even the slightest reflection, as patently absurd. It is startlingly akin to the assumption, more than half a century ago, that saving and investment would be increased if we all undertook to save more by consuming less. Perhaps! But that is exactly the proposition to be proved, or supported by empirical evidence, not assumed. (1998a, p. 322)

Second only to correct reasoning, evidence mattered. In the 1990s Eisner took up arms against the 'governing myth' of economic policy, the natural rate of unemployment introduced by Friedman and Phelps in 1968. From this strangely selfdamaging justification for perpetually high unemployment, Eisner hoped for a 'NAIRU escape'. His method was largely econometric, and in what may have been his final paper, published in 1998 (1998a, pp. 454–87), he argued that a separate analysis of low-unemployment cases showed no relationship between full employment and rising inflation. This position was to be vindicated dramatically in the two years following his death.

Eisner embraced capital budgeting, so that the liabilities acquired by the government might be properly offset against corresponding assets. This position helped underpin a strong advocacy of liberal expenditure on infrastructure, education, and research and development. It also provides one bridge between the Keynesian Eisner and his counterpart, the theorist of investment, public finance, and peace economics and stalwart defender of Social Security, all of which he was.

Eisner's investigations of investment involved pioneering use of corporate records. They permitted cross-section analysis of firm decisions, showing that the concepts of macro models, such as the accelerator, operated differently on firms from different industries or with differing recent growth histories. In numerous studies, Eisner criticized neoclassical investment theories. Rejecting the notions of a desired capital stock and unit relative price elasticity, he adhered to a Keynesian relation of investment to expected profitability and of expected profits to the rate of growth. An important theme in this work concerns the appropriate level of aggregation at which to take measurements. Eisner found that firms appropriately assess the growth of their own industry to be the most relevant to profit prospects, not the inherently variable growth of individual firms or the potentially irrelevant growth of generalized aggregate demand.

Eisner's Total Income System of Accounts marked the peak of his campaign to rationalize economic measurement and theory. The importance of changing household relations appears vividly in his initial motivation for this work: 'What happens to income, output, and productivity when clotheswashing moves from the washtub and the professional laundry to the laundromat and to the automatic washer and dryer. . .?' (1998b, p. 188). Particularly noteworthy is capital accumulation by households in a country where transportation is provided mainly and increasingly by private car. The challenge of TISA remains to be taken up by most economists and national income statisticians.

Finally, midway through the Vietnam War Eisner deflated the view that President Johnson might have forestalled inflation by raising taxes; the only sure way to that end, he showed, would have been to avoid the war. This insight led to papers on the 'staggering cost' of the Vietnam war, much in the spirit of total accounts, and on post-cold war disarmament. Equally, to the end of his life Robert Eisner defended Social Security from all those who would cut it. Spurious and persistent allegations of financial 'crisis' notwithstanding, he

believed that a rich and civilized society can, and should, provide decent incomes and care for its old.

Elasticities Approach to the Balance of Payments

Murray C. Kemp

Keywords
Elasticities approach to the balance of payments; Excess demand

JEL Classifications
F32

The substance of a theory is independent of the manner in which it is dressed. In particular, it is a matter of style only whether or not formulae are expressed in terms of elasticities of demand and supply, or in terms of ordinary derivatives. To speak of an 'elasticities approach' to the balance of payments is therefore to speak no sense at all.

However, behind the nonsensical label there hides a coherent and distinctive theory of what determines the response of a country's balance of payments to parametric changes in its rate of exchange, that is, to changes in the terms on which its currency exchanges for other currencies. The theory goes back to a paper published by Charles Bickerdike (1920).

Consider a simplified world containing just two countries (the 'home' country and the 'foreign') and producing and trading just two commodities. Let R be the price of foreign currency in terms of home currency, let p_i be the home price of the ith commodity in terms of home currency (so that, in arbitrage equilibrium, $p_i^* = p_i/R$ is the foreign price of the commodity in terms of foreign currency), and let B be the home balance of trade in terms of foreign currency. Then, writing $z_i(p_i)$ and $z_i^*(p_i^*)$ as the home and foreign excess demands for the ith commodity, Bickerdike's model of the balance of payments reduces to the system of three equations

$$\begin{aligned} z_i(p_i) + z_i^*(p_i/R) &= 0 \ (i = 1, 2) \\ B &= -(1/R)[p_1 z_1(p_1) + p_2 z_2(p_2)] \end{aligned} \tag{1}$$

In this system the rate of exchange R is treated as a parameter and p_1, p_2 and B as variables to be determined. Differentiating (1) with respect to R, solving for $\mathrm{d}B$ and the $\mathrm{d}p_i$, and converting to elasticities, we obtain

$$\mathrm{d}B = \left\{ -p_2^* z_2^* \left[\frac{\eta_1^*(1+\eta_1)}{\eta_1^* - \eta_1} - \frac{\eta_2^*(1+\eta_2)}{\eta_2^* - \eta_2} \right] - B \right\} \frac{\mathrm{d}R}{R} \tag{2}$$

and

$$\frac{\mathrm{d}p_i}{p_i} = \frac{\eta_i^*}{\eta_i^* - \eta_i} \frac{\mathrm{d}R}{R}, \ i = 1, 2 \tag{3}$$

where $\eta_i \equiv (dz_i/dp_i)(p_i/z_i)$ and $\eta_i^* \equiv (dz_i^*/dp_i^*)(p_i^*/z_i^*)$. In the special case in which B is initially zero, (2) takes the simpler form

$$dB = -p_2^* z_2^* \left[\frac{\eta_1^*(1+\eta_1)}{\eta_1^* - \eta_1} - \frac{\eta_2^*(1+\eta_2)}{\eta_2^* - \eta_2}\right]\frac{dR}{R} \quad (4)$$

Equation (2) is often referred to as the Bickerdike–Robinson–Metzler formula: however, the role of Robinson (1947) and of Metzler (1949) was that of expositor only.

Suppose for concreteness that the home country exports the first commodity and imports the second, so that η_1 and η_2^* are export-supply elasticities and η_2 and η_1^* import-demand elasticities. Suppose further that all marginal propensities to buy are positive, so that η_1 and η_2^* are positive, η_2 and η_1^* negative. Then for the balance of payments to improve in response to devaluation it suffices that the sum of the two import demand elasticities exceed 1 in magnitude, that is, that the Marshall-Lerner condition be satisfied. Thus Eq. (4) can be rewritten as

$$dB = -p_2^* z_2^* \left[\frac{\eta_1\eta_2^*(1+\eta_1^*+\eta_2) - \eta_1^*\eta_2(1+\eta_1+\eta_2^*)}{(\eta_1 - \eta_1^*)(\eta_2 - \eta_2^*)}\right] \times \frac{dR}{R}$$

with all terms of known sign except $(1 + \eta_2^* + \eta_2)$. For a positive response of the balance of payments to devaluation it suffices also that the terms of trade improve, or at least that they not worsen. For changes in the terms of trade are indicated by changes in p_1/p_2 and, from Eq. (3),

$$\frac{d(p_1/p_2)}{p_1/p_2} = \frac{dp_1}{p_1} - \frac{dp_2}{p_2} = \left(\frac{\eta_1^*}{\eta_1^* - \eta_1} - \frac{\eta_2^*}{\eta_2^* - \eta_2}\right)\frac{dR}{R}$$

If this expression is non-negative then, from (4), dB must be positive.

Bickerdike's theory is very special in that the excess demand for each commodity depends on the money price of that commodity only. Implicitly, all 'cross' price elasticities are set equal to zero. For more general theories and, in particular, more general versions of (4), the reader is referred to Negishi (1968), Kemp (1970), Dornbusch (1975) and Kyle (1978).

Elasticity

Peter Newman

Abstract

Formally invented by Marshall, the concept of elasticity of demand goes beyond the notion, which can be found in classical economics, that demand varies less or more than price. The crucial property that alone makes elasticity so important in pure and applied economics is that the elasticity measure is *invariant* to changes in units of measurement of quantities and prices.

One day in the winter of 1881–2 Alfred Marshall came down from the sunny rooftop of his hotel in Palermo 'highly delighted', for he had just invented elasticity of demand (Keynes 1925, pp. 39 n. 3, 45 n. 2). So delighted was he that within a mere four years he had introduced the word *elasticity* into the technical literature of economics (Marshall 1885), which by his own standards was rushing pell-mell into print. But if the speed of its introduction was uncharacteristic the manner of it was not, tucked away as it was at the end of a lecture dull even for its time, and giving no hint that elasticity was new and exciting (1885, p. 187).

The notion that demand varies less or more than price can of course be found rather often in classical economics, especially in John Stuart Mill (Edgeworth 1894, p. 691). But to turn that trite idea into something useful requires a firm grip on the prior idea of quantity demanded *at a price*. So it is not surprising that the only ancient who came close to Marshall's idea was Cournot himself, the inventor of (among much else) the demand function.

In fact Cournot came so close that it is hard to understand, first, why he did not go all the way, and second, why Marshall gave him no credit for showing that way. Such lack of generosity is the more puzzling since we know that between the time when (according to Mrs Marshall) he invented elasticity, and the late spring of 1882 when he first drafted the chapter on Elasticity for the *Principles*, Marshall reread Cournot (Whitaker 1975, vol. 1, p. 85).

Starting with the demand function $D = F(p)$, Cournot pointed out that $pF(p)$ is total revenue, so that for maximum revenue the price p must be such that $F(p) + pF'(p) = 0$ (1838, p. 56). Thus total revenue will increase or decrease with increa se in price according as $\Delta D/\Delta p$ is larger or smaller than D/p, where ΔD is the absolute value of the change in quantity demanded.

> Commercial statistics should therefore be required to separate articles of high economic importance into two categories, according as their current prices are above or below the value which makes a maximum of $pF(p)$. We shall see that many economic problems have different solutions, according as the article in question belongs to one or other of these two categories. (Bacon's translation 1897, p. 54)

Let f be a real-valued nonzero differentiable function whose domain is some open interval I of the real line. In conformity with Marshall's Mathematical Appendix (1890, Note IV, pp. 738–40), the *elasticity of f at the point x,* denoted by $\eta_f(x)$, is defined here to be the *number* $xf'(x)/f(x)$. *The function* $\eta_f(x)$,defined by this formula is called the *elasticity of f.* To define the elasticity of *demand,* some authors prefer to follow the convention $f(x) = -xf'(x)/f(x)$, which is not used here. Unfortunately there is no standard notation for elasticity, since the obvious candidates are already taken, e for e and E for the expectations operator.

Cournot's critical value of p, his criterion for sorting out commodities, is simply that p^* for which $\eta_f(p^*) = -1$; he was close indeed. However, unlike Marshall (who is crystal clear on the point) there is no trace in Cournot of the crucial property that the elasticity measure is *invariant* to changes in units of measurement of quantities and prices, and it is this property alone that makes it so important in pure and applied economics.

A little calculus will prove such invariance, but is more enlightening to apply the dimensional analysis of Jevons and Wicksteed. Let the dimension of x be X and that of $f(x) = y$ be Y, so that $f'(x)$ has dimension YX^{-1}. The dimension of $\eta_f(x)$ is then $X \cdot YX^{-1} \cdot Y^{-1}$ and everything cancels. The elasticity of f at x is a pure number, unaffected by change in the units of either x or y. (This application is so obvious that the most plausible explanation of why it was not included in Wicksteed 1894, is that his entry was actually written before Marshall's *Principles* appeared.) Although invariance to transformation of units is the key property of elasticities, partly as a consequence the measure has a number of other agreeable properties. For example, it is easily seen that $\eta_f(x) = d \log f(x)/d \log x$, which paves the way for a whole calculus of elasticities in terms of logarithmic derivatives (Champernowne 1935; Allen 1938, pp. 251–4). One simple application of this calculus is the formula $\eta_{fg}(x) = \eta_f(x) + \eta_g(x)$, where fg is the product of f and g (with a corresponding formula for the quotient function f/g), while another is the characterization of constant elasticity functions as those which are linear in logarithms, that is, of Wicksell–Cobb–Douglas type. Incidentally,

Douglas's paper of 1927 was apparently intended to introduce elasticity of supply, which is odd since it had already appeared 20 years before (and rather late at that) in the fifth edition of the *Principles* (see Marshall 1961, vol. 2, p. 521).

The extension of elasticity to functions of more than one variable is easy – one simply uses the partial derivatives f_i rather than the derivative f' – and is staple fare in textbooks (see for example Allen 1938, pp. 310–12). However, many of those textbooks underplay another useful property of elasticities of strictly monotonic functions (such as the usual demand and supply curves) which follows from the inverse function theorem. Considering just functions of one variable, if we write $\Phi = f^{-1}$then from that theorem $\Phi' = f^{-1}$, so from this and the definition of elasticity,

$$\eta_\Phi(y) = y\Phi'(y)/\Phi(y) = f(x)/xf'(x) = \left(\eta_f(x)^{-1}\right),$$

that is, the elasticity of the inverse function is the inverse of the elasticity. Two obvious applications of this to the elementary theory of the firm are:

(i) Since the revenue function is $R(q) = pq = q\Phi(q)$,

$$\begin{aligned}\text{marginal revenue } (mr) &= \Phi(q) + q\Phi'(q)\\ &= \Phi(q)[1 + ?(q\Phi'(q)/\Phi(q)] = \Phi(q)\\ &\quad \times (1 + \eta_\Phi(q)),\end{aligned}$$

from which one can derive the more usual but less intuitive formula $mr = p[1 + (1/\eta_f(p))]$; and (ii) since at the firm's profit maximizing output marginal cost $mc = mr$, the Lerner (1934) measure of monopoly power (p –mc)/p may be written $[\Phi(q) - mr]/\Phi(q) = 1 - [\Phi(q)(1 + \eta_\Phi(q)]/\Phi(q) = -\eta_\Phi(q)$.

Arc elasticity, which is really ordinary elasticity with the index number problem thrown in, was introduced quite early by Dalton (1920, pp. 192–7). But the heyday of elasticities of all kinds came later, in the 1930s, so much so that it is small wonder that in the immediate post-war period Samuelson (1947, pp. 4–5) used elasticity statements to exemplify what he meant both by 'meaningful theorems' and by non-meaningful theorems in economics. A peculiar aspect of some of the elasticity measures introduced then was their definition not in terms of the properties of a given *function f* (as here), but rather as the ratio of proportionate change in one variable to proportionate change in another, allegedly causative, variable, without any explicit functional relationship intervening. Thus with Hicks's 'elasticity of expectations' (1939, p. 205) there *is* no 'expectation function' of which it is an elasticity, as that term is defined above. Similarly, although the elasticity of substitution (σ) invented by Hicks (1932) and Robinson (1933) immediately provoked many articles in response (for example, Lerner 1933), at no time was a 'substitution function' introduced whose elasticity it was. The lack of a generating function for σ might help to explain why its use often occasions technical difficulty.

It is of some interest to apply duality theory to the problem of deriving simple formulas for entities like σ (cf. Woodland 1982, p. 31). Consider the elasticity of substitution σbetween two consumer's goods x and y, with no restriction being placed on preferences apart from the smoothness conditions implicit at this level of analysis. First, take advantage of homogeneity in both the ordinary and compensated demand functions to write the former function as $f(p, m)$ and the latter as $h(p, t)$, where p is the price of x in terms of y, m is the consumer's income in terms of y, and t is the *maximized* level of utility for the price-income situation (p, m). Put $x^* = f(p, m)$. Finally, observe that σ is wholly determined by the price slope corresponding to p together with the indifference curve corresponding to t, so that we may write $\sigma = \sigma(p, t)$.

From a modern version of the fundamental equation of value theory (Hicks 1939, p. 309),

$$f_p(p, m) = h_p(p, t) - x^* f_m(p, m) \qquad (1)$$

where f_p, h_p and f_m are, in sequence, the partial derivatives of f and h with respect to p, and of f with respect to m. Multiplying (1) by $p/f(p, m)$ and writing $\eta_{fp}, \eta_{fm}$for the two partial elasticities of f, we obtain

$$\eta_{fp}(p,m) = ph_p(p,t)/x^* - px^* mf_m(p,m)/(mf(p,m)) = ph_p(p,t)/x^* - k\eta_{fm}(p,m) \quad (2)$$

where $k = px^*m$, that is, the fraction of m spent on x. Now since t is the maximized level of utility, given local non-satiation $x^* = h(p, t)$. Hence, the first term on the right-hand side of (2) is $\eta_{hp}(p, t)$, the partial elasticity of h with respect to p, and (2) becomes

$$\eta_{fp}(p,m) = \eta_{hp}(p,t) - k\eta_{fm}(p,m). \quad (3)$$

A standard result of Hicks and Allen (1934, see Hicks 1981, p. 20) for the two-good case can be written in the present notation as

$$-\eta_{fp}(p,m) = k\eta_{fh}(p,m) + (1-k)\sigma(p,t) \quad (4)$$

so from (3) and (4),

$$(k-1)\sigma(p,t) = \eta_{hp}. \quad (5)$$

Let the cost (expenditure) function for this problem be $c(p, t)$, and denote its partial derivative with respect to p by c_p. Then, writing η_{cpp} for the partial elasticity of c_p with respect to p, since Shephard's Lemma implies $c_p = h$ we have

$$\eta_{hp}(p,t) = \eta_{cpp}(p,t). \quad (6)$$

Now $k = px^*/m = ph(p, m)/m = pc_p(p, t)/m$. Because t is the maximized level of utility $m = c(p, t)$, so $k = pc_p(p, t)/c(p, t) = \eta_{cp}(p, t)$, where η_{cp} is the partial elasticity of c with respect to p. Substituting from this and (6) into (5),

$$\sigma(p,t) = \eta_{cpp}(p,t)/\big(\eta_{cp}(p,t) - 1\big). \quad (7)$$

Thus the elasticity of substitution in this two-good case can be expressed entirely in terms of the cost function.

Elasticity of Intertemporal Substitution

Christopher Bliss

Abstract

The elasticity of intertemporal substitution (EIS) measures the willingness on the part of the consumer to substitute future consumption for present consumption. It plays a key role in the theory of consumption and saving, in particular in the life-cycle version of that theory.

The EIS and Consumption Theory

The elasticity of intertemporal substitution (EIS) is an important number in macroeconomic theory. It measures the willingness on the part of the consumer to substitute future consumption for present consumption. This parameter plays a key role in the theory of consumption and saving, in particular in the life-cycle version of that theory. For a start we examine the role of the EIS in a basic life-cycle model. In that model there is complete certainty concerning prices, future income, and preferences present and future. The consumer can lend and borrow at will at a single invariant rate of interest, subject only to a lifetime budget constraint. Preferences are additively separable. The consumer chooses present and future consumption to maximize:

$$\sum_{t=1}^{T} \delta^{t-1} U[c_t] \tag{1}$$

where c_t is consumption in period t, and $0 < \delta < 1$, and where δ is the rate at which utility is discounted. Lifetime utility (1) is maximized subject to the lifetime budget constraint:

$$\sum_{t=1}^{T} c_t \left(\frac{1}{1+r}\right)^{t-1} \leq \sum_{t=1}^{T} y_t \left(\frac{1}{1+r}\right)^{t-1} \tag{2}$$

where the y values are incomes in the various periods, and r is the real rate of interest. Assuming positive consumptions in all periods, the maximization of (1) requires:

$$\frac{dU[c_t]}{dc_t}\delta^{t-1} - \lambda\left(\frac{1}{1+r}\right)^{t-1} = 0 \tag{3}$$

where λ is the Lagrange multiplier. From (3), taking logs:

$$\ln\frac{dU[c_{t+1}]}{dc_{t+1}} - \ln\frac{dU[c_t]}{dc_t} = \ln\left(\frac{1}{1+r}\right) - \ln\ \delta \tag{4}$$

Differentiating (4) with respect to r and holding c_t constant gives:

$$\frac{\dfrac{d^2U[c_{t+1}]}{dc^2{}_{t+1}}}{\dfrac{dU[c_{t+1}]}{dc_{t+1}}}\frac{dc_{t+1}}{dr} = -\frac{1}{(1+r)} \tag{5}$$

A useful way of writing (5) is:

$$\frac{1}{c_{t+1}}\frac{dc_{t+1}}{dr} = -\frac{1}{(1+r)}\frac{\dfrac{dU[c_{t+1}]}{dc_{t+1}}}{\dfrac{d^2U[c_{t+1}]}{dc_{t+1}}} \tag{6}$$

Or equivalently:

$$\frac{1}{c_{t+1}}\frac{dc_{t+1}}{dr} = \frac{\sigma(c_{t+1})}{1+r} \tag{7}$$

where σ is the EIS, defined as:

$$\sigma(c) = -\frac{\dfrac{dU[c]}{dc}}{c\dfrac{d^2U[c]}{dc^2}} \tag{8}$$

Equation (7) indicates that the size of the EIS will be a crucial determinant of how far consumption levels will respond to changes in the interest rate.

The effect of a small change in r analysed above is a standard partial equilibrium result, in which enough is held constant to obtain a definite result. The calculation shows how two solution paths compare with regard to c_{t+1}, as r is varied slightly, when for each of these paths c_t takes the same optimal value. For that special case, (7) says that c_{t+1} increases with r, which is to say that c_{t+1} increases relative to c_t. In that particular sense a small increase in r encourages saving. Even for the two-period model popular for classroom exposition, it cannot be shown that a rise in r encourages saving. However in the two-period model it is true for any separable lifetime utility function, as (1), that c_1 declines as r increases, provided that $c_2 > y_2$, the usual case. When r increases the substitution effect always favours lower early consumption. When $y_2 > c_2$, however, the income effect opposes the substitution effect, and the outcome is uncertain.

Equation (8) shows that the second derivative of the utility function, how curvy it is if one likes, is crucial in giving a specific value to the EIS. If:

$$U(c) = c^{\frac{\sigma-1}{\sigma}} \tag{9}$$

then the EIS is constant, independent of c, and equal to σ.

Consumption Smoothing and Risk Aversion

The EIS as defined in (8) is the same as the Arrow–Pratt measure of relative risk aversion. It is no accident that consumption substitution through time, with no uncertainty whatsoever, and risk aversion, where uncertainty is necessarily involved, should involve the same parameter. Absolute risk aversion is related to the willingness of a consumer to accept a lottery ticket in preference to a sum of money available for certain, the certain sum being lower than the expected value of the lottery. One can think of the extra expected value in the better-than-fair lottery as a premium needed to entice the agent to accept the risk. The higher is relative risk aversion, the larger must be the expected-value premium in the lottery. Arrow (1971, ch. 3) provides a detailed discussion, and references the parallel and independent work of Pratt.

Now consider the life-cycle maximization of (1) subject to (2). To make the explanation as simple as possible let δ and r both be zero. The consumer maximizes:

$$\sum_{t=1}^{T} U[c_t] \tag{10}$$

subject to the lifetime budget constraint:

$$\sum_{t=1}^{T} c_t \le \sum_{t=1}^{T} y_t \tag{11}$$

With U [ ] a concave function, it is evident that the consumer will consume at the same level in each period:

$$c_t = \frac{\sum_{t=1}^{T} y_t}{T} \tag{12}$$

In the particular sense defined by this special case, the consumer is averse to consumption variability over time. It is the same as the risk-averse consumer disliking variations in wealth when different states of the world are realized. That each period of time will certainly arrive, whereas only one state of the world will be realized, is irrelevant in the *ex ante* view of the consumer facing uncertainty. A risk-averse agent can be induced to accept a gamble if the odds are sufficiently favourable, that is, if the expected-value premium

is sufficiently large. Similarly, a life-cycle planner will opt for a non-constant consumption plan if it provides a larger total consumption sufficient to compensate for the unattractive variability. A positive rate of interest plays the same role as an expected-value premium. It is the sweetener that persuades the consumer to accept variability. For this reason it is no surprise to find that the extent to which the consumer will respond to the sweetener, in either case, is governed by precisely how much the consumer dislikes variability. And the EIS, or the coefficient of relative risk aversion, as the case may be, measures that dislike of variability.

The argument just completed ignores the part played by δ, the utility discount rate. The presence of a positive δ means that, were r zero, the consumer would choose a plan with consumption falling through time. Then a positive r, and especially an r greater than δ, persuades the consumer to select a consumption plan with consumption falling less rapidly or rising through time. How far an optimal plan responds to a given change in r is governed again by the EIS.

A Constant or a Variable Coefficient?

The EIS has been compared above to the coefficient of relative risk aversion. In the theory of risk aversion the emphasis is on the variability of the coefficient. On this turns the issue of whether the wealthy will be more or less willing to undertake risk than the poor. With the EIS the most common assumption is that it is a constant. A popular special case of (1) is:

$$U[c_1, c_2, \ldots, c_n] = c_1^{\frac{\sigma-1}{\sigma}} + \delta c_1^{\frac{\sigma-1}{\sigma}} + \ldots + \delta^{n-1} c_n^{\frac{\sigma-1}{\sigma}} \qquad (13)$$

This is the love-of-variety utility function of Dixit and Stiglitz (1977), with discounting added. The EIS measured at any of the consumptions above is σ.

The elegance and convenience of forms such as (13) has made them appealing. Thus Barro and Sala-i-Martin (1995), in their influential study of economic growth, assume that different countries or regions solve independent Ramsey optimal model problems. This leads to the condition:

$$\frac{1}{c}\frac{dc}{dt} = \sigma[AF_1\{k, 1\} - \delta] \qquad (14)$$

where F_1 is the marginal product of capital, c is consumption, k is capital, δ is the utility discount rate, A measures total factor productivity as it is affected by policy, culture, corruption, and so on, and σ is the EIS. The lower is k the larger is F_1. If this effect is not offset by poor countries having lower total factor productivities, and if all countries share the same values of δ and σ, then conditional β- convergence follows from (14), meaning that poor countries grow faster.

The poor will be reluctant to save if their value of σ is low. And this is a most plausible specification. When all the meals that one eats are small, it is rationally more difficult to postpone eating now for a larger meal later. This point has been recognized in the literature. For example, King and Rebelo (1993) allow for a utility function of the Stone–Geary form, where the consumer gives priority to a fixed basket of essentials until that basket has reaches a critical scale. With those preferences, the poorest consumers will not save at all, and there is the possibility of a poverty trap. The Stone–Geary utility function implies a zero value for the EIS at low consumptions, and positive values for higher consumptions.

The EIS in Consumption Studies

Many applied economists used to take the view that the value of σ is close to zero (see Hall 1988; Mankiw et al. 1985). This reflects the failure of consumption studies to find a significant effect of the rate of interest on saving. Such estimates are seriously biased if the consumer is constrained from borrowing freely (a feature ignored in the computations above) or if, as in Deaton (1992), most consumers save only to replenish

precautionary balances following negative shocks. Then the optimizing substitution-based theory does not apply. Blundell et al. (1994) and Attanasio and Browning (1995) show that representative consumer models give seriously misleading results when applied to aggregate consumption data. They use UK household expenditure data to model consumption at the individual level and obtain a greatly improved fit when they allow the rich to have a higher EIS than the poor. Does that mean that as economies grow richer over time, the average EIS will increase? This remains an unanswered question.

VEIS Functions

Let the utility function be chosen from a class of which the simplest case is:

$$U[c] = \int_0^c \exp\left\{\frac{1}{\beta x}\right\} dx \tag{15}$$

where β is a positive constant and c is the level of consumption. This is a VEIS utility function, where VEIS stands for *variable elasticity of intertemporal substitution*. Then:

$$\frac{dU[c]}{dc} = \exp\left\{\frac{1}{\beta x}\right\} > 0 \tag{16}$$

and:

$$\frac{d^2U[c]}{dc^2} = -\exp\left\{\frac{1}{\beta c}\right\}\frac{1}{\beta c^2} > 0 \tag{17}$$

U [•] is an increasing concave function. Now the EIS may be computed as:

$$-\frac{\dfrac{dU[c]}{dc}}{c\dfrac{d^2U[c]}{dc^2}} = \beta c \tag{18}$$

This increases linearly with consumption at rate β. The poor have a lower EIS and β- convergence will not necessarily prevail.

A Variable EIS in the Diamond Capital Model

In their deep study of the Diamond overlapping generations model with capital, De La Croix and Michel (2002) more or less dismiss the importance of multiple stable equilibria. To summarize, it is possible to obtain multiple stable steady-state solutions with simple functional forms, but these cases are unsatisfactory at best. If the production function is Cobb–Douglas and with a simple separable utility function, there are no cases of multiple stable steady states. With a logarithmic utility function and the constant elasticity of substitution in production $\rho > 0$, there can be two positive steady-states, but it may be that only the corner degenerate outcome is stable.

Rather than using given simple functional forms and looking for a few steady-state solutions, try for a continuum of solutions as follows. Assume:

$$-\frac{\dfrac{dU[c]}{dc}}{c\dfrac{d^2U[c]}{dc^2}} = \sigma(c) \tag{19}$$

where $\sigma(c)$ is an arbitrary positive increasing function of c. Then:

$$\frac{\dfrac{d^2U[c]}{dc^2}}{\dfrac{dU[c]}{dc}} = -\frac{1}{\sigma(c)c} \tag{20}$$

Integrating (20) gives:

$$\ln\frac{dU[c]}{dc} = -\int_a^c \frac{1}{\sigma(x)x}dx + \ln\ D \tag{21}$$

where a is a positive constant, and D is a constant of integration.

In a steady state solution to the Diamond model we must have:

$$\ln\frac{dU[c_1]}{dc} - \ln\frac{dU[c_2]}{dc} = \ln\ \delta - \ln\ R \tag{22}$$

where c_1 and c_2 are consumption in respectively the first and second period of a life, R is the gross

rate of return to saving, and δ is the discount factor. From (21) and (22):

$$\int_{c_1}^{c_2} \frac{1}{\sigma(x)x} dx = \ln\ \delta - \ln\ R \tag{23}$$

Now in steady state c_1, c_2 and R all depend upon capital per head k. If over some range of values of k every value gives a steady state, then (23) will be an identity in k. Let the per capita production function be Cobb–Douglas with coefficient α. Then (23) takes the form:

$$\int_{(1-\alpha)k^{\alpha}-k}^{k+\alpha k^{\alpha}} \frac{1}{\sigma(x)x} dx = \ln\ \delta - \ln\ \left(1 + \alpha k^{\alpha-1}\right) \tag{24}$$

When (24) is an identity in k, over an interval at least, then differentiating both sides of (24) gives:

$$\begin{aligned} &\frac{1}{\sigma(k+\alpha k^{\alpha})} \frac{1}{k+\alpha k^{\alpha}} \frac{1}{\sigma((1-\alpha)k^{\alpha}-k)} \\ &\quad \times \frac{1}{(1-\alpha)k^{\alpha}-k} \\ &\quad = \frac{\alpha(1-\alpha)k^{\alpha-2}}{1+\alpha k^{\alpha-1}} \end{aligned} \tag{25}$$

Take a given a value of k, and let $\sigma\ (c_1)$ values be known for the c_1 value implied by that k all the way up to the c_2 defined by the same k. Then $\sigma\ (c_2)$ values are determined by (25), which rolls out a solution for σ such that all values of k on a connected interval are steady-state equilibrium levels. The contrast to the case advanced by De La Croix and Michel is striking.

Concluding Remarks

The EIS is an important value, just as is its cousin, the coefficient of relative risk aversion. The use of a simple functional form has too often frozen the EIS as a constant. When it is allowed to vary, the β-convergence of growth theory is no longer secure; cross-section consumption studies perform better; and multiple equilibrium in the Diamond capital model is seen to be far more probable than previous studies indicate.

The concept of the elasticity of substitution, developed by Joan Robinson and John Hicks separately in the 1930s, represented an important addition to the marginal theory of the 1870s, in the tradition of Marshall, Edgeworth and Pareto. It brought together two concepts which were already well established in the literature – the ideas of elasticities (which derive from Mill) and those of substitution (which go back to Smith). The relationship defined by the concept is a mathematical one relating to utility and production functions, with considerable economic implications. It has two applications: to the theory of production, and in particular the isoquant relationship between factor inputs, and to consumer behaviour and the indifference curve. Let us look at each in turn.

The two inventors of the concept – Joan Robinson, in her *Economics of Imperfect Competition* (1933), and John Hicks in his *Theory of Wages* (1932) – each developed Marshall's formula for the elasticity of derived demand. Each defined the concept somewhat differently. For Hicks, the definition was the percentage change in the relative amount of the factors employed resulting from a given percentage change in the relative marginal products or relative prices, that is (following Samuelson 1968):

$$\sigma = \sigma_{12} = (F_1F_2/FF_{12})\sigma_{21},$$

where $F(V_1, V_2)$ is a standard neoclassical production function, and the subscripts are the partial derivatives. This is sometimes called the direct elasticity of substitution.For Joan Robinson, on the other hand, concerned with relative shares and hence distributional issues, the elasticity of substitution was defined as 'the proportionate change in the ratio of the amounts of the factors employed divided by the proportionate change in the ratio of their prices' (1933, p. 256):

$$\sigma = -\frac{\partial(V_1/V_2)/(V_1/V_2)}{\partial(W_1/W_2)/(W_1/W_2)}$$

where W_1 is the price of the V_1 factor.

These two definitions of the concept gave rise to a considerable debate in the early issues of the *Review of Economic Studies*, with in particular a notable contribution from Kahn (1933) concerned to identify how these concepts related to each other. It turns out that these two original definitions are identical when the production function is confined to two factors of production, where the partial derivatives of the production function are the marginal productivities of the factor inputs and yield the relevant factor prices. In addition, the contributors to the debate attempted to identify the implications of these somewhat abstract concepts. Amongst these were the joint determination by the elasticity of substitution and the factor supplies of the relative shares of the factor reward (wages and profits), and implications for the definition of imperfect competition with increasing returns to scale.

It is not surprising that it is with the cases where the restrictive neoclassical assumptions for the production function are not met that most interest arises. Two important developments are where production function involves three or more factors and in extending from Cobb–Douglas to constant elasticity of substitution (CES) production functions. But although considerable emphasis has been placed on the elasticity of substitution in production, it remains a technical concept concerning factor substitutability. It has no direct allocation consequence. Diminishing elasticity of substitution does not imply diminishing returns to scale, since for returns we must have prices. Thus it is restricted to describing the technical conditions of production. But, being a technical concept, it can be generalized to all forms of transformation.

Thus, as we noted above, along with a number of other concepts, these tools developed for production were taken over to consumer theory. Because of the implications the concept had for the development of consumer behaviour, and because of the insight which the resulting difficulties threw up concerning the concept more generally, this application is of special interest.

It was Hicks (and Allen) who made that step. While Joan Robinson's development of the concept was closely related to her extension of

Marshall's theory of the industry, Hicks was familiar with a very different approach to value theory, that of Edgeworth, Pareto and Walras. While Joan Robinson had focused on production substitutions, and hence isoquants, Hicks took the idea developed in that domain, and translated it across to consumer theory, and to the indifference curves which he had got from Edgeworth. In the two goods case, price elasticity could be represented in terms of his fundamental formula, according to which:

$$\text{Price elasticity} = k(\text{income elasticity}) + (1-k)(\text{e.s.})$$

where k is the total expenditure that is spent on the commodity. Thus, with income elasticity, consumer theory led into a representation of the effect of a price change in terms of the income and substitution effects, with elasticity being thus of prime importance in classifying goods by their demand characteristics.

But whereas the elasticity concept in production theory naturally led on to the possibility of measurement, that step in consumer theory was more contentious. For although this technical concept represented one important step in the development of the marginalist approach to the theory of value, the theory of demand behaviour requires a behavioural theory of choice. The elasticity of substitution with respect to the indifference curve is one technical component. But, as with production theory, prices, and in this case the budget line, are also required.

Technical concepts thus aided the formulation of modern consumer theory as outlined in Hicks and Allen's 'A Reconsideration of the Theory of Value' (1934) and the opening chapters of *Value and Capital* (1939), a path from which it has scarcely deviated. But, despite the mathematical elegance of this construction, it may be argued that it disguised many of the important underlying questions. The increased power of the indifference curve analysis begged the question of whether consumer preferences could in reality be represented in this abstract way. Ultimately, whether consumer behaviour is well described by concepts like the elasticity of substitution, depends upon whether preferences can be represented by complete, transitive, utility functions. Much recent evidence from psychologists and decision theorists suggests otherwise. Likewise for production theory, the concepts of capital and labour may be themselves ambiguous.

In many parts of the world buyers and sellers now trade electrical energy in liberalized markets. These markets have partially replaced cost-based regulation and government ownership.

Since the 1980s, governments in many countries have privatized and restructured their electricity industries. Liberalized electricity markets now operate in much of Europe, North and South America, New Zealand and Australia. These changes were primarily motivated by the perception that the previous regimes of either state ownership or cost-of-service regulation yielded inefficient operations and poor investment decisions. Liberalization of the electricity industry also reflected the progression of a deregulation movement that had already transformed infrastructure industries, including water, communications and transportation, in many countries. Although electricity shares many characteristics with other deregulated industries, the differences have proven to be more important than the similarities. Electricity has been one of the most challenging industries to liberalize and in most places new layers of regulations have replaced the old.

Historically, electricity was viewed as a natural monopoly. Typically, a single utility company generated, transmitted and distributed all electricity in its service territory. In much of the world, the monopoly was a state-owned utility. Within the United States, private investor-owned companies supplied the majority of customers, although federally and municipally owned companies played an important minority role. These companies operated under multiple layers of local, state and federal regulation.

Restructured electricity markets share a common basic organization. The three segments – generation, transmission, and distribution – have been unbundled. Wholesale generation, no longer viewed as a natural monopoly, is priced through a market process. Transmission and distribution remain regulated, although in many cases some form of incentive regulation has replaced cost-of-service regulation or state ownership.

Most wholesale electricity is traded through long-term (a week or longer) forward contracts. Many markets also feature day-ahead auction-based exchanges. Because supply and demand must be continually balanced to preserve transmission stability, transmission system operators run real-time balancing markets. Prices in these high-frequency markets can be highly volatile since electricity is non-storable and real-time demand fluctuates dramatically. To meet unforeseen contingencies, transmission system operators also contract for and occasionally use standby or reserve generation services. Many markets reflect price differences across geographical locations when parts of the transmission grid are congested (Schweppe et al. 1988; Chao and Peck 1992). Game theorists and experimental economists are involved in the ongoing process of designing electricity markets (Wilson 2002), while empirical researchers have used detailed auction data to estimate how well predictions from theoretical models describe firm behaviour (Wolak 2000; Hortascu and Puller 2004).

At the retail level, the vision of liberalization was to provide customers a choice among competing retailers who would operate as either resellers or integrated providers with access to customers through a regulated common-carriage distribution network. In most restructured US markets, retail competition for residential customers is very weak (Joskow 2005). Retail competition is more advanced in the United Kingdom, although evidence suggests that customers have been slow to take advantage of the ability to switch to a lower-priced retailer (Waddams 2004). Several authors have noted the economic benefits of allowing retail prices to vary to reflect real-time changes in the wholesale prices, although this sort of real-time retail pricing has been slow to take hold in practice (Borenstein and Holland 2005; Joskow and Tirole 2004).

Oligopoly simulation analysis indicates the potential for serious market power problems because suppliers face extremely inelastic demand and entry requires long lead times (Green and Newbery 1992). Empirical work has indicated that market power has indeed been present, although to varying degrees in different

markets. Wolfram (1999) found that prices in England and Wales were lower than static oligopoly models would suggest. By contrast, extreme levels of market power in California contributed to record high prices in 2000–1 (Borenstein et al. 2002). The explanations for these differences have focused on variations in the threat of future regulation and in the extent of long-term fixed price contracts (Bushnell et al. 2005).

Although the main motivation for market liberalization was to improve economic efficiency, there have been few attempts to measure efficiency changes. Newbery and Pollitt (1997) and Fabrizio et al. (2004) find modest positive effects of market liberalization on, respectively, industry efficiency in the United Kingdom and plant-level efficiency in the United States.

As electricity industry restructuring moves forward, the major unresolved question is the degree to which public policy will influence investment decisions. Electric generating plants are long-lived, so while operating efficiency gains appear to be real, the potential gains from improved investment stand to be larger. Also, policies to limit the environmental impact of electricity generation could affect the types of technologies in which we invest.

Electronic Commerce

Avi Goldfarb

Abstract

Electronic commerce is the exchange, distribution, or marketing of goods or services over the Internet. This article first reviews electronic commerce adoption across US industries.

While the Internet is used in most industries, it has had a profound impact only on a small number. Businesses that rely heavily on electronic commerce can be divided into four groups: retail, media, business-to-business and other intermediaries. Each of these is discussed. The article concludes with a discussion of some features of electronic commerce that are of special interest to economists: lower economic frictions, lower communication costs, lower marginal costs and rich data.

In this article, electronic commerce is defined as the exchange, distribution, or marketing of goods or services over the Internet.

There is, unfortunately, no standard definition used in the academic literature or the popular press. A broader definition would include all business facilitated by telephones, fax machines, televisions, and other technologies that are 'electronic'. This broad definition, however, becomes so large that it encompasses a substantial fraction of all economic activity since the 1950s. A narrower definition would focus only on items sold over the World Wide Web, the browser-enabled portion of the Internet. This definition omits much of the important business-to-business segment of electronic commerce and the numerous advertising-supported websites.

The definition used here encompasses a variety of ways in which businesses have used the Internet. The Internet is a worldwide network of computers that connect to each other using the communication protocols defined by TCP/IP. Electronic commerce includes businesses that have used the Internet to reach other businesses and to reach consumers directly. It includes businesses that sell products directly to their customers and businesses that function as intermediaries. This definition also includes businesses that operate only online, the online business of those that operate online and offline, and businesses that use the Internet but not as their primary business function.

Adoption of Electronic Commerce by Industry

While most attention has focused on those few businesses where the Internet is a fundamental part of their strategy, electronic commerce is just one aspect of business processes for most businesses. As of 2000, nearly 90 per cent of large US establishments used the Internet (Forman et al. 2002). Nearly all industries and cities had adoption rates well over 70 per cent. For the vast majority of these establishments, the Internet was used to send and receive email, to help automate some basic processes like inventory management, and/or for web browsing. This basic level of use was particularly important to establishments in rural areas (Forman et al. 2005). Overall, the impact on most industries, from nursing homes to construction to furniture manufacturing to petrol stations, has been limited. The Internet is used in day-to-day business activities, but it is a small piece in a much larger puzzle. Even in retail, the US Census reported that Internet sales (totalling $26.3 billion) were just 2.7 per cent of total US retail sales in the second quarter of 2006 (U.S. Census Bureau 2006b).

Still, a small portion of businesses have used the Internet to enhance business processes at a deep level. While little research has examined why some industries adopted quickly and others did not, it is the businesses that adopted quickly that get the majority of the attention. The Internet has had a profound effect on publishing, securities trading, some wholesaling, and some retailing (for example, books and computers). In particular, businesses that rely heavily on electronic commerce can be divided into four (not necessarily mutually exclusive) groups: retail, media, business-to-business (B2B), and other intermediaries.

Retail

Electronic commerce represents the introduction of a new sales channel. While the size of the online channel is still small relative to the entire retail sector, electronic commerce has had a large effect on some retail markets. According to the U.S.

Census, Internet sales made up over ten per cent of 2004 retail sales in two broad categories if online-only stores are included: electronics and appliance stores (that is, NAICS 443) and sporting goods, hobby, book, and music stores (that is, NAICS 451) (U.S. Census Bureau 2006a). Much of the literature on electronic commerce has focused on these categories, as well as motor vehicles and travel.

A new channel has the potential to create channel conflict. There is considerable evidence that consumers compare prices and options across channels (Prince 2006; Ellison and Ellison 2006). Forman et al. (2006) show that use of the online channel depends on local offline retail options. Also, Hendershott and Jie Zhang (2006) argue that manufacturers may face resistance from their retailers to setting up a direct online channel. They show that the benefits of selling directly to consumers (rather than though a retailer) depend on the relative online–offline search costs. The benefits of the online channel are largest for goods that are not widely available in retail stores (that is, high offline search costs) and for goods that do not need to be touched to assess quality (that is, low online search costs).

Media Websites

In addition to a new retail channel, the Internet has provided a new media outlet. This outlet has developed a market structure similar to the magazine industry (Goldfarb 2004). Media websites provide information to visitors and earn money (mostly) through advertising. In particular, entry is easy but distribution is difficult to achieve; concentration is largely determined by market size and distribution costs; large media conglomerates coexist with small niche players; and there is a high mortality rate. Online media appear to be particularly important to overcome local isolation (Sinai and Waldfogel 2004). The two-sided nature of the media market and the digital nature of the product mean that competition between media websites is different in nature from competition between online retailers.

Intermediaries

According to Alexa.com, six of the top seven most popular websites in October 2006 had roles as intermediaries: Yahoo, MSN, Google, MySpace, YouTube, and eBay. While these intermediaries may share features of media websites (Google) or retailers (eBay), their primary business is to facilitate online interactions. Without physical storefronts or displays, intermediaries help individuals (and firms) find each other online. Intermediaries allow people with heterogeneous tastes to find better matches in terms of media, products, and people (Scott Morton 2006).

Business to Business

Business-to-business (B2B) electronic commerce is a relatively under-researched area, perhaps because of the difficulties in obtaining data. Still, B2B transactions are many times the size of business-to-consumer transactions. Lucking-Reiley and Spulber (2001) summarize many of the key questions and opportunities in B2B electronic commerce including B2B exchanges, automatic ordering, and outsourcing. Some aspects of the Internet, such as asynchronous communication, may be particularly important for international B2B interactions. Many B2B applications can also be done on electronic data interchange (EDI) rather than the Internet.

Key Features of Electronic Commerce for General Economic Research

In addition to its widespread usage across industries and its profound impact on a small set of them, electronic commerce has a number of features that make it a particularly interesting area of study for economists.

Fewer Economic Frictions

The Internet reduces a number of economic frictions that are often cited as key contributors to

observed imperfections in markets. To the consumer, search and switching costs are reduced substantially. To the firm, menu and distribution costs may fall.

For consumers, the Internet makes it relatively easy to search through several retail options. Instead of having to walk from store to store, consumers can simply click from one company to another without leaving their desks. Furthermore, a number of intermediaries exist that reduce search costs even further. These 'shopbots' allows consumers to compare prices and features from several websites during a single keyword search. In addition to lower search costs, switching costs are also lower online than offline. It is not difficult to switch from one competitor to another. Much of the earliest research examining electronic commerce focused on why price dispersion persisted in this environment. Broadly speaking, this literature concluded that, all else equal, search and switching costs are lower online; however, firms created search and switching costs to overcome this challenge (Ellison and Ellison 2004). Consequently, there is still substantial price dispersion online. Still, low search costs do not mean zero search costs. Visibility matters to the long-term prospects of any business-to-consumer company. Many early Internet companies struggled because they misinterpreted low search costs as zero search costs, mistakenly assuming customers would arrive once they set up the website.

Firms also benefit from fewer frictions online. In particular, the menu costs of changing prices and updating product offerings are much lower online than offline. In addition to the reduction in menu costs, some firms benefit from lower distribution costs: for digital goods (namely, music, news and images) online distribution costs are near zero. Low menu costs combined with the digital nature of many online products allow for mass customization of products (Murthi and Sarkar 2003) and creative bundling, licensing, versioning and pricing strategies. Shapiro and Varian (1999) and Bakos and Brynjolfsson (1999) provide examples of a number of situations in which online firms are better able to match customers needs and therefore are better able to price discriminate.

Lower Communication Costs

The Internet reduces communication costs considerably. It provides an additional means of communication that creates new potential to interact with customers, suppliers and with other branches of the same firm. Internet communication differs from telephone communication in two primary ways. First, the marginal cost of communication is effectively zero, even over long distances. While establishing a connection is costly, each additional e-mail, web page viewed, and instant messaging interaction has no monetary cost to the communicator. Second, Internet communication is often asynchronous. Unlike telephone communications, the people communicating do not necessarily have to be available at the same time. This has many important applications. For example, it facilitates communication across time zones. Together, these features of Internet communication mean that geography may be less important online. Given access, people can communicate with any other person who has access, irrespective of location. Still, despite the substantial fall in long-distance communications costs, most online communication is local because social networks are local (Wellman 2001).

Lower Marginal Costs

Many goods sold over the Internet are digital in nature (for example, newspaper content, music, information). The marginal cost of replication for digital goods is near zero. Depending on the particular good, fixed costs may be high (software) or low (blogs). Shapiro and Varian (1999) discuss in detail the economics of goods with high fixed and low marginal costs. If fixed costs are high enough, this cost structure allows monopolists with broad flexibility in pricing, versioning and bundling policies. It also leads to substantial economies of scale and incentives to sell a broad scope of products. In markets with more than one player, this cost structure can lead to fierce competition and little profit. If fixed costs are low and entry is easy then prices should approach zero.

One misunderstood aspect of electronic commerce is that many Internet business models have not benefited from low marginal costs, and therefore have no cost advantage over offline competition. Low marginal costs apply only to digital goods

and services. In the late 1990s, many companies failed because their business models shipped heavy items to consumers. For example, taking orders for pet food and shipping it to customers involves very high marginal costs per item sold.

Rich Data

By definition, all online activity is digital. This means that it is relatively easy to record and store information on the behaviour of consumers and firms online. In contrast, it is extremely expensive to track all a shopper's activity in a typical offline store. Online, however, every item browsed and the time spent looking is easily recorded. This presents an opportunity for both firms and researchers. Firms can use this data to better understand their customers, which leads to more effective customization. Researchers can use this data to answer many questions that previously could not be answered due to data constraints. Online data has greatly enhanced of our understanding of a number of economic concepts including auctions (for example, Bajari and Hortacsu 2003), the economics of information (for example, Jin and Kato 2005), and social interactions (for example, Mayzlin and Chevalier 2006).

In summary, this article has identified some important features of electronic commerce and the some of the main areas of related economic research. Useful surveys of electronic commerce and related subjects include Scott Morton (2006), Hendershott (2007), and Ellison and Ellison (2005).

Elites and Economic Outcomes

Elise S. Brezis and Peter Temin

Abstract

Elites are a necessary part of economic activity. It therefore matters how elites are recruited and how they act. History is full of examples of elites that have acted well and also badly. Modern research has examined the training of elites, recruitment schemes and incentives for elites to discover how they can be used to promote, rather than impede, economic growth. The literature has also emphasized the effect of elite interconnection and elite recruitment on social mobility; it has shown that the standardization of elite education over the years may lead to uniformity and the creation of a transnational oligarchy.

A ruling elite (from the Latin *eligere*, 'to elect') is a small, dominant group that enjoys the power of decision in the various sectors of the economic and social organization of a state. It includes the bureaucrats and civil servants who rule the macro-environment; the political elite that governs and operates the executive, legislative and judicial structures; and the business elite. Non-ruling elites include the members of the media, academia and the intelligentsia.

Even in a democratic regime in which the power is meant to reside in the *demos* ('the people'), power is really concentrated in the hands of a few. All political organizations, even democracies, tend towards domination by an oligarchy, which Mills (1956) called the *power elite*. This is the *iron law of oligarchy* as stated by Michels (1915). This stratification of society based on the accumulation of decisionmaking power therefore differs from the familiar stratification based on income and economic means, or on ownership of the factors of production as emphasized by Marx.

The effects of elite actions on the economy operate through several channels: economic growth and development; social mobility; inequality; and the political system, which in turn affects the economy. The characteristics that affect these economic realms are (*a*) the extent of the intertwining and inter-connections of elites; and (*b*) the stability and recruitment of the elite.

Elites' Interconnections

The ruling elite can display unity and collusion, acting as a monolithic group, or it can be fragmented and characterized by dissociation and diversification of power, a 'polyarchy' that permits competition among its members.

The elite in non-democratic polities displays unity, has unlimited political and economic power, and typically acts on behalf of its own interests. But democracy should a priori impose some control on the power of the ruling elite. Indeed, Schumpeter (1954) claimed that the democratic process permits 'free competition among would-be leaders for the vote of the electorate' and that the masses can choose between various elites. In contrast, classical elite theorists such as Mosca (1939); Pareto (1935), Michels and Mills emphasized that there can be collusion even in

democracies. Numerous elites may not be mutually competitive and may not control and balance each other; instead, they may be intertwined as a unanimous, cohesive power elite.

Economic Consequences of the Extent of Interconnection

Inequality

The elite's plurality and competition ensures its responsiveness to the demands of the public, while a consensual elite might use its power for its own interests. Etzioni-Halevy (1997) claims that a unified elite does not use its power to reduce inequality and promote the development of a more egalitarian society, due to common recruitment and common interests. It is the plurality and differentiation of the members of the elite that enables them to countervail each others' power and to increase their responsiveness to the will of public. In consequence, elite homogeneity might actually increase the gap between the elite and the masses.

When the political elite controls wealth and the main factors of production, then elite and class stratifications coincide, and consequently power and wealth are in the hands of the same happy few. Engerman and Sokoloff (1997) showed that members of the elite who have power and wealth establish institutions that serve their own interests and exclude the masses from benefits. In consequence, inequality persists through institutional development in the elite's own favour. Justman and Gradstein (1999) added that elite unity leads to greater inequality through regressive redistribution policy. A power elite that controls wealth may refrain from investment in human capital of the majority because education would increase the latter's political voice and weaken the elite's hold on power (Easterly 2001); yet in some cases, the elite deliberately decides to forfeit power by investing in human capital as a consequence of a cost–benefit analysis (Bourguignon and Verdier 2000).

The extent of elite unity can be endogenously determined (Sokoloff and Engerman 2000), and elite unity can also be affected by revolutions, wars and economic growth. Justman and Gradstein (1999) argue that economic growth dilutes the power of the elite by broadening political participation and reducing inequality.

Economic Growth

A strong interconnection among elites has the consequence that all sectors of the economy are ruled by a group that thinks in a monolithic way. Two lines of thoughts have related a monolithic group to economic growth. The first one underlines that a monolithic group leads to the stagnation of ideas and attitudes, which in turn may prevent the adoption of major technological breakthroughs (Bourdieu 1977). The lack of competition in a monolithic powerful group also generates corruption, with harmful consequences for growth.

The second line of thought argues that wealthy elites with enough political power to block changes will not accept adopting institutions that would enhance growth, since they might hurt them. Acemoglu et al. (2001) developed this line of thought in relation to colonial impacts, showing that, wherever colonial governments were composed of few elite members, economic progress was reduced.

Following the same line of reasoning, Acemoglu and Robinson (2000) and Gradstein (2007) stressed that elite plurality, in which the political and economic elites are separate, explains the adoption of political franchise and industrialization in western Europe; while 19th-century eastern Europe, where elite unity was strong, did not adopt growth-enhancing institutions, since its elites held on to their wealth and power.

Paradoxically, in countries in which the elite was united and consensual, with common aims, the transition to capitalist production in the 1990s took place without violence, as in Poland and the Czech Republic. In contrast, wherever the elite was divided and fragmented, there were conflicts, especially on the ethno-nationalist level, as in Yugoslavia and Romania (Pakulski 1999).

Recruitment and Training of Elites

Plato claimed that government should be in the hands of the most able members of society, that is,

the *aristocracy* (Greek for 'rule by the best'), a term that became pejorative and was later changed to *meritocracy* (coined by Young 1958). Pareto argued that a stable economic system needs a *circulation of elites*, so that the most capable and talented are in the governing class. He stressed that the quality of the ruling class can be maintained only if social mobility is allowed, so that the non-elite has the possibility of entering the elite: 'History is a cemetery of aristocracies' (Pareto 1935). His theory may be viewed as a sort of social Darwinism in which mobility is needed, just as evolution relied upon competition and selection.

For millennia, recruitment of the Western elite was based on social inheritance and was carried out via heredity, nepotism and violence. Hereditary monarchy was considered the most legitimate means of recruitment for rulers, and the upper elite was made up of wealthy large landowners, an *état de fait* considered normal in agrarian societies. Nevertheless, there were some channels of entrance into the elite, such as military prowess and exploits or involvement in government finance (Brezis and Crouzet 2004).

In democracies, the political elite came to be recruited mainly by election. Yet for a long time, the franchise was not for all. Big landowners and members of the upper middle class were the overwhelming majority in parliaments and cabinets, even though some prominent business people entered the political elite. Only in the late 19th century did members of the lower middle class and working class enter the political elite.

From the 19th century onwards, the circulation of the business elite took two differing yet concurrent paths. The first was that economic growth led to spurts of new firms and the decline of others, allowing a new business elite to emerge (Schumpeter 1961). The second path was the rise of the professions, with competitive and meritocratic exams that led to circulation of elites (Perkin 1978). After the Second World War, the elite was mainly recruited through education into elite universities to which admission started to be conferred following success at meritocratic exams.

Economic Consequences of the Recruitment of Elites

Social Mobility in the Economy

Prior to recruitment through meritocracy, social mobility, and in particular the potential for non-elite members to enter the elite, was low. Temin (1999a, b) showed that today, as in the 1900s, and despite meritocracy, the American economic elite is composed almost entirely of white Protestant males who have been educated for the most part in Ivy League colleges. Although in 1900 the political elite was quite similar to the business elite, today the former is more diversified; the political elite has changed in its recruitment, while the economic elite has not. In other words, minorities have not penetrated the economic elite in the United States (see also Friedman and Tedlow 2003, which summarizes studies on US elite mobility, and Foreman-Peck and Smith 2004 on British elites).

Recruitment to a university through meritocratic entrance exams, does not, indeed, lead to enrolment from all classes of society according to distribution or ability, nor does it necessarily lead to the admission of the most talented. Recruitment by entrance exam still encompasses a bias in favour of elite candidates because this type of exam requires a pattern of aptitude and thinking that favours candidates from an elite background. All elite positions may be open to all applicants with the right qualifications, but they are more accessible to those with specific social, cultural and symbolic capital (Arrow et al. 2000). Thus the power elite maintains its status and power by a *strategy of distinction*, or a cultural bias that is necessary for accessing it (Bourdieu 1977). A small difference in culture and education leads to narrow recruitment, and in turn to class-based stratification in the recruitment of the elite, despite meritocratic selection for universities (Brezis and Crouzet 2006).

The relationship between mobility and the political system, as emphasized by Pareto, has been analysed by sociologists. For instance, Lengyel (1999) showed that circulation in the elite occurs at times of political upheavals and revolutions: the existing elite is eliminated and

replaced by a new one. The first-generation members of the elite following a political change have neither specific training and education nor specific origin; they are the trailblazers, the entrepreneurs who seized power on the strength of their competence. In the next generation, the elite becomes narrowly recruited from the best educated, and members are selected mostly by training and education. The elite returns to an occupational specialization, similar to the meritocratic profession criterion of earlier industrialization (Perkin 1978).

Economic Growth

A crucial element of economic growth is that the recruited elite be of the highest quality. Countries in which elites are recruited in a non-meritocratic way face the problem of the quality of their elites. However, the prevalence of meritocratic recruitment does not necessarily lead to the selection of the best ruling elites. Brezis and Crouzet (2006) argue that, when a country faces only mild technological and structural changes, the narrow recruitment, due to meritocracy, optimally fulfils its purpose, since the cultural bias of the elites is an advantage in the given type of technology. However, at times of major changes in technology, elites recruited this way are not the best for adopting new technologies.

Moreover, the homogeneity of the recruitment of elites through similar curricula leads to convergence of views; this, in turn, leads to a monolithic elite, which, as we have claimed above, may have negative consequences for economic growth.

Conclusion

In this short article, we have summarized the modern research that has examined recruitment schemes and incentives for elites to discover how they can be used to promote, rather than impede, economic growth. There is also an entire economic history literature that has enriched us with a wealth of knowledge on the business elite. The main works in this literature are by Cassis (1997); Crouzet (1999) and Lachmann (2000).

The literature cited herein seems to show that the structure of this small group called the elite has numerous effects on the world economy. In the opposite direction, globalization will also affect the elite, as we are now facing a globalization of education of the elite.

In its first wave, globalization of education will probably create a new collection of elites and elicit some changes, yet the unity and uniformity of the elite will be even greater, not only at the national level but also at the global level. National elites will be replaced by a worldwide elite, along with uniformity in culture and education. We will face an international technocratic elite with its own norms, ethos, and identity, as well as its private clubs like the Davos World Economic Forum – a transnational oligarchy.

American engineer and economic theorist, Ellet was born on 1 January 1810 at Penn's Manor, Pennsylvania, and died on 21 June 1862, a victim of the Civil War. Ellet grew up on a family farm but showed little inclination for agriculture: at age 17 he joined a surveying crew. With no formal education or training, he soon became an assistant engineer to Benjamin Wright, chief engineer of the Chesapeake and Ohio Canal. With ability and hard work Ellet taught himself mathematics and French, earning the respect of influential engineers. Letters of introduction to Lafayette and the American ambassador helped secure Ellet a place at the Ecole des Ponts et Chaussées, Dupuit's alma mater, in 1830. On his return to America in 1832 Ellet became the premier suspension bridge designer in America, building in 1849 the (then) longest suspension bridge in the world across the Ohio River at Wheeling. Colonel Ellet designed, constructed and commanded the ram fleet of the Union forces at the naval battle at Memphis, Tennessee. He

died as a result of a wound received in the heat of that battle.

Ellet spent most of his professional life as an engineer, but, in one major work and in a number of contributions to the *Journal of the Franklin Institute* between 1840 and 1844, he significantly advanced the economic theory of monopoly, input selection, spatial economics, benefit–cost theory and econometric estimation. All Ellet's contributions were facilitated by the use of the differential calculus, which permitted him to express the simple theory of the firm, and some of its extensions, in mathematical terms. In his *Essay on the Laws of Trade* (1839) Ellet established the demand curve for a monopoly railroad with distance as a variable. Utilizing firstorder conditions and solving for the gross toll on passenger traffic, Ellet demonstrated that the profit-maximizing toll would be equal to one-half the costs of transportation added to a constant quantity, a well-known result.

Ellet considered not one monopoly model but a multiplicity of them, including those dealing with freight transport, duopoly conditions and the principles of monopoly price discrimination. Further, Ellet's particular insights into simple and discriminatory pricing systems led him to provide, with distance as a variable, an amazingly complete mathematical and graphical analysis of the impact of changes in the pricing system upon the market area served by a profit-maximizing railroad (1840a). In this important contribution to market area analysis Ellet argued that a set of (constrained) discriminatory tolls inverse to distance, in contrast to tolls proportional to distance, could be devised whereby all interested parties (management, shippers, the state) could be made better off. In a series of papers (1842–4) Ellet extended his theoretical analysis of inputs and input selection (1839) to one of the earliest attempts to develop, empirically specify and test a theoretical cost function. Utilizing a 'law' of costs which included his selected determinants of annual total railway costs, Ellet estimated the empirical dimensions from data collected from the mid-1830s. He then reaffirmed the power of his initial equation with new and supplementary data.

In all, the calibre and completeness of Ellet's theoretical and empirical inventions would not compare unfavourably with those of von Thünen, Cournot, Dupuit or Lardner. Ellet, who was primarily an engineer, was America's best representative among the pioneer contributors to scientifically oriented economics in the 19th century.

American Economic Association; Commons, J.R.; Ely, R.T.; German Historical School; Institutionalism; Knies, K.G.A.

JEL Classifications
B31

Ely was born in Ripley, New York, on 13 April 1854 and died at Old Lyme, Connecticut, on 4 October 1943.

Ely's long and vigorous career epitomizes the general proposition that an economist can exert a major constructive influence on his subject and profession even though his original contribution to economic theory is negligible. A highly effective teacher and maker of careers for his former students; prolific author of popular articles, scholarly volumes, and publications series; organizer and fund-raiser for major research projects; founder of various academic institutes and associations; leader or participant in numerous reform societies; and centre of innumerable controversies, Ely was the most widely known, even notorious, economist in the USA around the turn of the 20th century.

After a brief spell as a country schoolteacher and a preliminary year at Dartmouth College, Ely graduated from Columbia College in 1876 and was awarded a three-year fellowship to study philosophy in Germany. He soon switched to political economy, came under the influence of Karl Knies at Heidelberg, where he obtained a Ph.D., summa cum laude, in 1878, and later attended Adolph Wagner's lectures in Berlin. Returning to the USA he was unemployed for more than a year before his appointment, initially on a half-time basis, at Johns Hopkins, where he taught from 1881 to 1892. He then moved to Wisconsin, founding an outstanding school of Economics, Political Science and History including such luminaries as F.J. Turner, E.A. Ross, and J.R. Commons. A unique collaboration developed between the social scientists and the state legislators, especially under the La Follette governorship, which pioneered major social and economic reform legislation. In 1925 Ely took his Institute for Research in Land Economics and Public Utilities, founded in 1920, from Madison to Northwestern University, and remained there until 1932, when he launched a new, but impoverished Institute for Economic Research in New York City. Eventually hit by the depression, Ely was forced to depend on the support of friends and former students as he completed his autobiography and failed to complete a massive history of American economic thought initiated 50 years earlier.

An ardent Christian Socialist and outspoken critic of laissez-faire individualism and 'old school' English classical economics, Ely delighted social reformers and outraged conservatives by his writings on such controversial current topics as socialism and the American labour movement. Prone to emotional overstatement and careless in exposition, his public pronouncements and reputation frequently embarrassed the aspiring young professional economists with whom he founded the American Economic Association, in 1885, and for a time discouraged some moderate and conservative economists from joining. Although Ely's original draft prospectus had been rejected, and the association's original constitution was toned down, and then dropped, the organization hovered uneasily between missionary evangelism and scholarly objectivity until he was obliged to relinquish his secretaryship in 1892.

Two years later, at Wisconsin, Ely's fellow professionals rallied around him when he was denounced for preaching socialism and encouraging strikes, and, although he was completely exonerated in a 'trial' that attracted national attention, Ely gradually became more conservative. Ironically, in the 1920s his institute was attacked, no doubt unfairly, as a tool of the public utilities, and was referred to disparagingly in a report on professional ethics by a committee of the American Association of University Professors, in 1930.

During his long lifetime Ely wrote extensively on an extraordinarily wide variety of topics, often in a popular and journalistic fashion. Nevertheless, he repeatedly opened up new research topics that were developed by his colleagues and former students – for example, in labour history, state taxation, land economics, and natural resources – and his various textbooks, especially the multi-edition *Outlines of Economics* which sold 350,000 copies, were both widely used and highly regarded.

At Wisconsin he helped to launch the American Association for Labor Legislation, of which he became President, and raised private resources to finance John R. Commons's massive *Documentary History of American Society* (11 vols, 1910–11). He served as President of the American Economic Association in 1900–1901.

Ely was a stimulating teacher whose ideas formed a direct link between the doctrines of the German Historical School and American institutionalism, a link most clearly evident in his neglected two-volume study of *Property and Contract in their Relations to the Distribution of Wealth* (1914). Many of his students went on to distinguished careers in academic and/or public life. He was undoubtedly an outstanding academic entrepreneur, and his contribution to the American Economic Association is recognized in its annual invited Richard T. Ely lecture, which was inaugurated in 1963.

Emergence

Yannis M. Ioannides

Abstract

With its philosophical pedigree and its use especially among life scientists and science writers since the early 1990s, the term 'emergence' in economics is more evocative than precise, reflects influence from physics and biology, and is now associated with phenomena where economic structures evolve into qualitatively different forms. These exhibit properties that are *emergent* in that they apply at an aggregate level but lack individual

analogues and therefore are not describable at the individual level. This article emphasizes applications that possess firm economic foundations, from the evolution of patterns in international trade to the establishment of a common currency.

Having acquired widespread use among life scientists and science writers since the early 1990s, the term 'emergence' in economics is more evocative than precise, reflects influence from physics and biology, and has come to be associated with phenomena involving evolution of economic structures into qualitatively different forms. These phenomena exhibit properties that are emergent in the sense that they are novel and apply at an aggregate more 'complex' level but lack individual analogues and therefore are not describable at, or reducible to, the individual level. A good case in point is the statement that consciousness is an emergent property of the brain. The notion of emergence originates in the philosophy of science, with John Stuart Mill being an important precursor (see Stanford Encyclopedia of Philosophy 2002).

This article reviews, albeit selectively, the recent usage of the term by emphasizing applications with predominantly economic phenomena where emergence of macroscopic properties may be elucidated by means of economic arguments. These range from neighbourhood tipping and evolution of patterns in international trade to emergence of urban structure and the establishment of norms and institutions and of a common currency, among many others.

More generally, emergent properties or behaviours have been studied in a variety of circumstances in nature, such as emergence of differentiated behaviour in colonies of animals, of herding behaviour in organizations and markets, of specialization of individuals into occupations and of cities and of regions and countries in specific products, of groups of biological cells in multicellular biological organisms and even of groups of processors in computer simulations involving cellular automata (see Holland 1998). The World Wide Web is an example of a decentralized engineering system that is continuously being modified by human initiatives in the form of actions by individuals and firms. The web has not been deliberately designed and no central organization administers how different sites are linked to others. Some of the properties of the graph topology of the web may be termed as *emergent*, such as that the number of links pointing to each page follows approximately a power law, with a few pages being pointed to by many others and most others seldom, and the fact that any pair of pages can be connected to each other through a relatively short chain of links in the average.

The presence of 'emergence' within the vocabulary of economists does suggest some interplay with multidisciplinary research by scientists who have been associated with the Santa Fe Institute (http://www.santafe.edu). To quote from Kauffman (1995, p. 24), an alternative definition of emergence is that '[t]he whole is greater than the sum of its parts'. And 'life itself is an emergent phenomenon . . . arising as the molecular diversity of a prebiotic chemical system increases beyond a threshold of complexity. If true, then life is not located in the property of any single molecule – in the details – but is a collective property of systems of interacting molecules.' The entirety of complex

molecules together is able to reproduce and evolve, a 'stunning property'.

Blume and Durlauf (2001) argue that emergence plays an important role even within the body of neoclassical economics proper. For example, the extent to which macroeconomics is a distinct discipline from microeconomics would be explained by emergent properties as alluded to by the statement 'aggregation is not summation' (see Kirman 1992). Consider, within microeconomics and general equilibrium theory, the metaphor of the invisible hand of the market (which goes back to Adam Smith), whereby individuals' pursuit of their own selfish aims leads to social outcomes that obey important social properties. Under certain conditions, after markets have brought about an equilibrium, it is impossible to make anyone better off without making someone worse off. Thus, the first fundamental theorem of welfare economics is an emergent property of social outcomes. However, the more modern work on emergence in economics has emphasized emergence of patterns. Similarly, Hayek's concept of spontaneous order may be considered an instance of emergence.

There are numerous other contexts where emergence has been alleged to occur. This article explores a number of examples of emergence that are limited to social and economic settings. They underscore the scope of the concept of emergence in such settings. As discussed earlier, there are many other contexts in socioeconomic settings and beyond, ranging from computation to the life sciences.

Emergent Social Interconnections

Suppose that a society consists of I individuals, where I is large, where any two individuals may be linked in a way that allows for communication, social relations, or social interactions. Let pk denote the probability that each individual is connected with exactly k other individuals. A literature going back to Erdös and Renyi (1960) and continuing at the time of writing up to Newman et al. (2001) has studied the topological properties of the (random) graph formed by the agents as nodes and connections between agents as edges when each agent's connections with other follows a given distribution p_k and the number of agents is large. According to Newman et al. (2001), depending upon whether the quantity $E[k^2] - 2E[k]$ is greater than or equal to 0, or falls below 0, there emerges, as I tends to infinity, a *proportion* of all individuals being interconnected, or, alternatively, the economy consists of different groups of finite sizes. In other words, the social structure undergoes a *phase transition* when this quantity exceeds 0: a giant interconnected component emerges. Intuitively, starting from a connected component of the graph, consider adding a new edge that connects with a previously isolated node of degree k. Doing so will change the number of nodes on the boundary of the connected component by $-1 + (k - 1) = k - 2$. The likelihood that a node is on the boundary of the connected component is proportional to k. The expected change in the number of nodes on the boundary when an additional node is connected is given by $\sum_i k_i (k_i - 2)/\sum_i k_i$. If this quantity is negative, then the number of nodes on the boundary decreases and therefore the connected component will stop growing. If it is positive, on the other hand, then the number of boundary nodes will grow and the connected component will grow, limited only by the size of the network.

In the simple case of the Erdös and Renyi random graph, where the number of connections is proportional to the number of individuals, the phase transition occurs when the factor of proportionality is equal to 1/2 and the corresponding average number of connections per person is equal to 1. Below this value, there are too few edges and the components of the random graph are small; above that value, a proportion of the entire graph belongs to a single, *giant* component. In this case, emergence of a qualitatively different social structure depends on the value of a single parameter (Kirman 1983; Ioannides 1990; Durlauf 1997). Individual behaviour that leads to a law for the number of individuals' connections does not necessarily imply the same macroscopic outcome in all circumstances. Similarly, social outcomes are not described by means of mere summation of individual actions; aggregation is

not summation (Kirman 1992). Kauffman (1995, p. 57) invokes this in the context of autocatalytic reactions and goes as far as seeing this 'as a toy version of phase transition that I believe led to the origin of life'.

Patterns of Residential Segregation

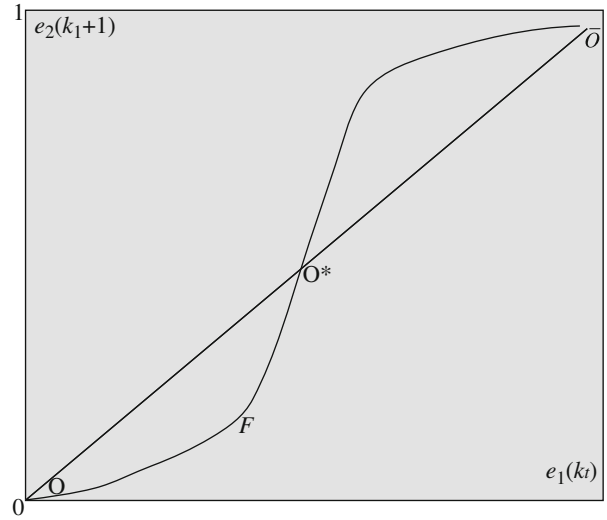
Now we turn to a description of neighbourhood tipping, which is originally due to Thomas C. Schelling (1978) and has been adapted here from recent works. Suppose that individual i is white and would live in a neighbourhood provided that the percentage of whites among her neighbours, $\omega \in [0, 1]$, is at leastw_i , $\omega \geq w_i$. She moves out otherwise. Individuals differ in terms of preference characteristic w_i, which is assumed to be distributed in a typical neighbourhood according to $F(\omega)$, when the analysis starts. For any neighbourhood with a share of white residents equal to u, the percentage of white individuals who would find living there acceptable are those with $w < \omega$. Their share is given by the value of the cumulative distribution function at ω, $F = F(\omega)$.

In Fig. 1, let the horizontal axis e_1 denote u and w_i, the vertical axis e_2 the cumulative distribution F, and $(O, \bar{O})$ the 45-degree line. As long as $\omega > F(\omega)$, whites have an incentive to exit the neighbourhood, causing a reduction of ω, and this process continues until there are no whites left; $\omega = 0$. If, on the other hand, $\omega \leq F(\omega)$, additional whites have an incentive to enter, and this process continues until $\omega = 1$. Thus, the process has three equilibria, $(O, O^*, \bar{O})$, of which the two extreme ones, either only blacks or no blacks in the neighbourhood, are stable, and the mixed one, with ω^* whites in the neighbourhood, where $\omega^* = F(\omega^*)$, unstable. The mixed equilibrium defines the *tipping point*. Individuals' preferences differ widely, but only extreme outcomes *emerge* at the social equilibrium. Schelling (1978) underscores how outcomes that persist may not be what individuals had intended.

Could such a stark outcome be due to the fact that the respective populations of individuals are not being replenished? It turns out that, if one goes deeper and allows for turnover and stochastic shocks, persistence of stable states may be rigorously characterized by means of the tools of stochastic stability theory (Blume and Durlauf 2003; Young 1998). Multiplicity of equilibria allows, of course, for accidents of history to become reinforced over time.

Emergence of Urbanization

The concentrated economic activity that we associate with the emergence of cities punctuates the



Emergence, Fig. 1 Neighbourhood tipping, poverty traps

physical and economic landscape throughout the world. How did it emerge? While small-scale agriculture and home production could be reasonably accurately referred to as spatially uniform distribution of economic activity, the world population is increasingly concentrated in cities. Also, urbanization has been closely associated with economic development.

Let us consider a simple setting where utility U depends on individual productivity, itself an increasing function $f(n_l)$, of the total number of others in the same location, n_l, and on the share of a fixed resource, R. Even when utility is assumed to be increasing and concave in both arguments, it is initially increasing, as a function of n_l, may reach a peak at n^*, and then may start decreasing. In other words, a larger population initially means more innovation and mutually beneficial interaction until congestion offsets them. Consider then two alternative locations, $l = 1, 2$, that do not interact spatially, and a total of N individuals who wish to locate so as to maximize utility. At a locational equilibrium, individuals must be indifferent as to where they locate. If $N < 2n^*$, the symmetric equilibrium, where $n_1 = n_2 = \frac{1}{2}N$, is unstable and agglomeration – that is, either site occupied by the entire population – is stable. Therefore, the trade-off between the value of agglomeration and the cost of congestion moves the economy away from the symmetric outcome (Anas 1992).

Consider next a setting where interactions do explicitly depend on distance to others, as with accessibility to others being valued and congestion disliked. If individuals are allowed to relocate, with probabilities that depend on expected utilities in each site relative to all other sites, then a dynamic model may be formulated that describes locational outcomes for an entire population. The economy may attain steady states that are either uniform (populations are equal across all sites) or uneven (with some sites having large and others small populations). Such a stylized reduced-form model of spatial patterns of human settlements (see Papageorgiou and Smith 1983) yields spatially uniform outcomes that are either stable or unstable. Agglomeration is determined by the interplay between the value of agglomeration and the cost of congestion. If the former dominates, spatially uniform steady states are unstable. Fujita et al. (1999), Chaps. 6 and 17) develop a model with ingredients from economic geography that incorporates trading costs and also allows for uniform distributions of economic activity to exhibit different stability properties. Again, conditions under which agglomerations prevail possess intuitive economic appeal.

E

Emergence of Poverty Traps

In a standard neoclassical growth model that extends over discrete time, with a demographic structure consisting of two overlapping generations and individuals living for two periods, working only in the first and retiring in the second, individual savings would be proportional to the wage rate under Cobb–Douglas preferences. Let the aggregate production function expressing output Y_t as a function of capital, labour and total factor productivity, K_t, L_t, A, respectively, be of the constant elasticity of substitution form,

$$Y_t = A\left(\delta K_t^{1-\frac{1}{\delta}} + (1-\delta)L_t^{1-\frac{1}{\delta}}\right)^{\frac{\sigma}{\sigma-1}}.$$

If the elasticity of substitution is sufficiently small – that is, complementarity between capital and labour is high – and total factor productivity sufficiently large, the time map of the economy – that is, the amount of capital per person next period (axis e_2) as a function of the amount of capital per person in the present period (axis e_1) – may be loosely graphed, as in Fig. 1. Therefore, depending upon the economy's starting point, it may end up at a steady state either with high or with low capital per person at a steady state. The mid-range ('symmetric') steady state is unstable. Therefore, conditions of productive complementarities, (even small) initial differences in capital per person, and possibly historical accidents as well across countries in terms of characteristics and endowments when growth starts, mitigate in favour of an explanation for

inequalities in incomes per person across different countries. The same mechanism worldwide produces sharply different outcomes (see Azariadis and Stachurski 2006, for an in-depth treatment).

Similar arguments may be developed in order to understand persistence in the inequality of the distribution of wealth within an economy. Matsuyama (2006) presents a model of emergent class structure, in which a society inhabited by inherently identical households may, depending upon parameter values, be endogenously split into the rich bourgeoisie and the poor proletariat. For some parameter values, the model has no steady state where all households remain equally wealthy. The model predicts emergent class structure or the rise of class societies. Even if every household starts with the same amount of wealth, the society will experience 'symmetry breaking' and will be polarized into two classes in steady state, where the rich maintain a high level of wealth partly due to the presence of the poor, who have no choice but to work for the rich at a wage rate strictly lower than the 'fair' value of labour.

It is worth noting that similar modelling tools may be used to express Adam Smith's famous dictum that 'the division of labour is limited by the extent of the market' and thus endogenize specialization (Weitzman 1994). The division of labour emerges as individuals in an economy acquire specialized roles.

Emergent Structures in International Economics: Autarky, Specialization, and International Currencies

Krugman (1995) and Matsuyama (1995) discuss how a world economy where all countries are initially identical and live in autarky (a 'symmetric' outcome) leads to a world that is separated into rich and poor regions, once countries engage in international trade. International trade *causes* specialization and agglomeration of different economic activities in different regions of the world to emerge, with some countries being rich and others poor. In several similarly motivated papers, Matsuyama (in particular, Matsuyama 2004, 2006) shows the effects of financial market globalization on the cross-country pattern of development in the world economy. In the absence of the international financial market, the world economy converges to the symmetric steady state, and the cross-country difference disappears in the long run. Financial market globalization causes the instability of the symmetric steady state and generates stable asymmetric steady states, in which the world economy is polarized into the rich and the poor. The world output is smaller, the rich are richer and the poor are poorer in these asymmetric steady states than in the (unstable) symmetric steady state. The model thus demonstrates the possibility that financial market globalization may cause, or at least magnify, inequality among nations, and that the international financial market is a mechanism through which some countries become rich at the expense of others. Furthermore, the poor countries cannot jointly escape from the poverty trap by merely cutting their links to the rich. Nor would foreign aid from the rich to the poor eliminate inequality; as in a game of musical chairs, some countries must be excluded from being rich.

Especially at times of political and economic upheavals, many different national currencies may circulate simultaneously within and across countries. From a modelling viewpoint, such circumstances fit neatly multiplicity of equilibria. Emergence of a particular currency as an international currency, which in turn depends on the degree of economic and financial integration, may be more of a decentralized phenomenon then the emergence and establishment of a national currency (Matsuyama et al. 1993). To start with, a national currency is typically fiat money, whose use is decreed although not necessarily ensured. World monetary history suggests that a bewildering variety of commodities have served as medium of exchange, unit of account and store of value, and may have coexisted at times of financial uncertainties. It has been known at least since Menger (1892) that fiat money comes to dominate other options, thus leading to establishment of monetary equilibria, because individuals accept fiat money in trade when it is convenient and they trust that others will do the same. Such an outcome may be fragile,

when trust in the currency is weakened, especially in time of war and other upheavals. Howitt and Clower (2000) employ 'rules' concerning transactor behaviour (instead of relying on a priori principles of equilibrium and rationality) to show computationally commodity 'money' as a possible emergent property of interactions between gain-seeking transactors who are unaware of any system-wide consequences of their own actions. Similar is the emergence of standards in new industries described by many writers.

Concluding Remarks

The scientific literature, along with popular science literature, on emergence has sought to explain the emergence of persistent patterns as outcomes of dynamic interactions between individuals, groups of individuals and other entities. Such emergence is typically intrinsic to specific nonlinear dynamic processes and represents international currency. Not all possible outcomes may be sustained at equilibrium, and economic and political structures emerge as a result of self-organization. Future research needs to go beyond evolutionary thinking and also deal with emergence in the context of purposeful action by forward-looking agents, as opposed to social outcomes of decentralized interactions of many agents.

Emerging Markets

Joshua Aizenman

Abstract

The club of high-performing emerging markets is fairly concentrated in East Asia. Their TFP growth may not be extraordinary, though their growth rate is unprecedented. Factors argued to promote growth include trade, investment, external financing, and good governance. The importance of external financing is overrated – higher growth induces higher saving rate, allowing investment to be self-financed. Institutional changes as the key for take-off remains debatable – India and China took off without any prior major institutional overhaul. Allowing newcomers to challenge incumbents and the capacity to adjust policies to shocks may be the keys for sustainable growth.

'Emerging markets' are countries or markets that are not well established economically and financially, but are making progress in that direction.

The growing focus on emerging markets follows exciting developments during the second half of the 20th century – the emergence of a growing class of (formerly) poor countries that took off, and managed to close half of their income gap with the OECD countries within a generation or two. Remarkably, from 1960 to 1989 seven high-performing Asian economies (HPAEs) experienced unprecedented growth rates of the real GDP per capita in the range of four to seven per cent. This phenomenon has been the focus of a notable research report by the World Bank (1992), whose title *The East Asian Miracle* suggests a possible, though controversial, interpretation. The big story of recent years has been that the two most populous countries, China and India, joined the HPAE club. With few exceptions (such as Chile and Botswana), the club of high-performing emerging markets is fairly concentrated in East Asia. The HPAEs' remarkable growth rates during recent decades imply a sizable drop in global poverty rates, also entailing greater concentration of the incidence of extreme poverty, mostly in Africa (see Fischer 2003). Yet the emerging markets phenomenon goes well beyond Asia, encompassing a growing share of developing countries that are closing, though at a lower rate than the HPAEs, their income gap with the OECD countries.

These developments were in sharp contrast to the pessimistic predictions made in the 1950–60s by several influential economic growth models (for a review, see Easterly 1999). The HPAE experience dispelled most of these fears. The superior performance of the HPAEs illustrated that the fast growth option is viable, raising pertinent questions, and stirring a lively debate. While the World Bank (1992) dubbed the experience of the HPAEs a 'miracle', Young (1995) questioned this 'miraculous' interpretation, arguing that it is in line with Solow's growth model. Specifically, he reasoned that most of the growth has been the outcome of very high rates of investment in tangible and human capital, and a sizable increase in labour market participation. Controlling for these factors, Young found that the HPAEs' total factor productivity growth is in line with the historical experience of other countries. The debate about

the role of accumulation in accounting for the HPAE experience is not over, yet the large drop of the growth rate of Japan in the 1990s, and the East Asian financial crisis of 1997, somehow deflated the 'East Asian miracle' hypothesis, suggesting the onset of Solow's growth convergence. Even if Young's thesis is correct, the speed and relative smoothness of the convergence of the HPAEs to the OECD's development level are without precedent. It raises questions about the obstacles preventing other countries from accomplishing this task, and about the ways to facilitate the take-off process in other regions.

The HPAE take-offs have been associated with fast growth of exports climbing, over time, the technology ladder of trade. This led to a lively debate about the importance of exports as the engine of growth: is the dominant causal association from exports to growth or vice versa? Earlier studies inferred that trade liberalization enhances growth (Ben-David 1993; Edwards 1998), a point disputed by Rodríguez and Rodrik (2001). Several authors revisited this issue, applying better controls, inferring strong growth effects of trade openness. Frankel and Romer (1999) applied measures of the geographic component of countries' trade to obtain instrumental variables estimates of the effect of trade on income. They inferred that ordinary least square (OLS) estimates understate the effects of trade, and that trade has a significant large positive effect on income. The contrast between the economic performance of the Soviet Union and that of China in the second part of the 20th century suggests another advantage of export orientation: it imposes a powerful market test on domestic output. Since exports must meet the quality and pricing tests of the global market, export-led growth limits potential distortions induced by 'growth promoting' domestic policies. Specifically, it prevents Soviet Union-type superficial economic growth induced by forced investment, growth that may result in inferior products that would be wiped out in the absence of protection. Export-oriented growth also forces countries to move faster towards the technological frontier in order to survive competitive global pressures.

Some of the obstacles preventing countries from taking off arise from political economy factors. Specifically, as growth is frequently associated with the emergence of new sectors and new elites, incumbent policymakers opt to block development in an attempt to preserve their rents and their grip on power. This phenomenon was vividly illustrated at the micro level by De Soto (1989), and was shown to be a major impediment to growth (see Parente and Prescott 2005). As the burden of the low growth would mostly affect future generations, the low growth equilibrium may persist with limited opposition. Proponents of this view point out that free commerce, both internal (between provinces or states in a union) and international, provides a powerful constraint on an incumbent's ability to block development.

The importance of external financing and financial integration in the development process remains a hotly debated topic. Advocates of financial liberalization in the early 1990s argued that external financing would alleviate the scarcity of saving in developing countries, inducing higher investments and thus higher growth rates. In contrast, Rodrik (1998) and Stiglitz (2002) questioned the gains from financial liberalization. Indeed, the 1990s experience with financial liberalization suggests that the gains from external financing are overrated – the bottleneck inhibiting economic growth is less the scarcity of saving and more the scarcity of good governance. This can be illustrated by tracing the patterns of self-financing ratios, measuring the share of tangible capital financed by past national saving (see Aizenman et al. 2004). Higher self-financing rates of the nation's stock of capital are associated with a significant *increase* in growth rates. Remarkably, the wave of financial reforms in the 1990s led to deeper diversification, where greater inflows from the OECD financed comparable outflows from developing countries, with little effect on the availability of resources to finance tangible investment.

These findings are consistent with several interpretations. The first deals with risk: agents in various countries may react to exposure to financial risk differently. The desire to diversify these risks may lead to two-way capital flows,

with little change in net positions (see Dooley 1988). The ultimate obstacles limiting external financing may be related to acute moral hazard and agency problems – sovereign states, decision makers and corporate insiders pursue their own interests at the expense of outside investors (see Gertler and Rogoff 1990; Stulz 2005). An alternative interpretation follows Caroll and Weil (1994), who found that statistical causality runs from higher growth rates to higher saving rates. They conjectured that the growth-saving causality may be explained by habit formation, where consumers' utility depends on both present and past consumption. 'Habit formation', however, may be observationally equivalent to adaptive learning in the presence of uncertainty in countries where private savings are taxed in arbitrary and unpredictable ways, credibility must be acquired as an outcome of a time-consuming learning process. In these circumstances, a higher growth rate provides a positive signal about the competence and the intentions of the administration, increasing saving and investment over time. Consequently, agents in countries characterized by greater political instability and polarization would be more cautious in increasing their saving and investment rates following a reform. Hence, accomplishing take-offs in Latin America may be much harder than in Asia, explaining Latin America's relatively low growth rate. (Various studies pointed out that policy uncertainty and political instability reduce private investment and growth; see Ramey and Ramey 1995; Aizenman and Marion 1999).

I close this review with an outline of open issues. The positive association between the equality of institutions and growth is well documented, yet the precise role of institutions in the development process remains debatable. Acemoglu et al. (2003) inquired how the colonial history of a developing country affects the quality of institutions, concluding that distortionary macroeconomic policies are more likely to be symptoms of underlying institutional problems rather than the main causes of economic volatility. Yet this interpretation does not satisfactorily explain the role of institutions in the growth process. The remarkable take-offs of China and India in recent decades, episodes directly affecting about a third of the global population, cannot obviously be explained by reference to institutional changes. This suggests that there is no simple correspondence or causality between growth and institutions. A tentative answer is provided by Rodrik (1999), who identifies a nonlinear interaction between shocks, polarization of a society and the quality of institutions. This argument suggests the key importance of the capacity of societies to adjust policies to shocks. A deeper understanding of the interaction between history, geography, polarization and institutions remains a challenge awaiting future research.

The exciting developments associated with the emergence of a growing class of (formerly) poor countries that took off implies that the rewards for adopting the proper growth incentives are high. A remaining challenge is how to facilitate the widening of the emerging market club, and how to minimize the prospects of new conflicts associated with the emergence of new economic powers like China and India.

Empirical Likelihood

Yuichi Kitamura

Abstract

Empirical likelihood (EL) is a method for estimation and inference without making distributional assumptions. Viewed as a nonparametric maximum likelihood estimation procedure (NPMLE), it approximates the unknown distribution function with a discrete distribution, then applies the ML estimation method. Alternatively, EL can be regarded as a minimum divergence estimation procedure. EL works well for estimating moment condition models, though it applies to other models as well. The large deviation principle (LDP) and other techniques show that EL has many optimality properties.

Introduction

Empirical likelihood (EL) is a method for estimation and inference without making distributional assumptions. The main feature of EL is the use of a discrete distribution to approximate the unknown distribution function nonparametrically, where the approximating discrete distribution is

typically supported by empirical observations. Owen (1988) and subsequent papers considered applications of this approach to moment condition models. Their important discovery is that EL, which can be interpreted as a nonparametric maximum likelihood estimation (NPMLE) method, possesses many desirable asymptotic properties that are analogous to those of parametric likelihood procedures. To describe more details of empirical likelihood, consider i.i.d. data $\{z_i\}_{i=1}^n$, where each z_i is distributed according to an unknown probability distribution F_0. Suppose the expectation of an $\mathbb{R}^q$-valued function $g(z,\theta_0)$, which is known up to the finite-dimensional parameter θ_0 in $\Theta \subset \mathbb{R}^k$, is restricted to be zero:

$$E[g(z,\theta_0)] = \int g(z,\theta_0)\mathrm{d}F_0(z) = 0. \quad (1)$$

Let Δ denote the simplex $\{(p_1,\ldots,p_n) : \sum_{i=1}^n p_i = 1,\ 0 \le p_i, i = 1,\ldots,n\}$. Each vector $(p_1, \ldots, p_n) \in \Delta$ 'parametrizes' the unknown distribution F_0 by $\hat{F}_n(z) = \sum_{i=1}^n p_i 1\{z_i \le z\}$, $z \in \mathbb{R}$ ($1\{\cdot\}$ signifies the usual indicator function). This is the approximating discrete distribution mentioned above. The nonparametric loglikelihood function to be maximized is

$$\ell_{\mathrm{NP}} = \sum_{i=1}^n \log p_i,\ \sum_{i=1}^n g(z_i,\theta)p_i = 0,\ (p_1,\ldots,p_n) \in \Delta, \theta \in \Theta.$$

Let $\left(\hat{\theta}_{\mathrm{EL}}, \hat{p}_{\mathrm{EL1}}, \ldots, \hat{p}_{\mathrm{ELn}}\right)$ denote the value of $(\theta, p_1, \ldots, p_n) \in \Theta \times \Delta$ that maximizes ℓ_{NP}. This is called the (maximum) empirical likelihood estimator. The NPMLE for θ and F are $\hat{\theta}_{\mathrm{EL}}$ and $\hat{F}_{\mathrm{EL}} = \sum_{i=1}^n \hat{p}_{\mathrm{EL}i} 1\{z_i \le z\}$ One might expect that the high dimensionality of the parameter space $\Theta \times \Delta$ makes the above maximization problem intractable for any practical application. Fortunately, that is not the case, if one uses the following nested procedure. First, fix θ at a value in Θ and consider the loglikelihood with the parameters $(p_1, \ldots, p_n)$ 'profiled out':

$$\ell(\theta) = \max \ell_{\mathrm{NP}}(p_1,\ldots,p_n) \text{ subject to } \sum_{i=1}^n p_i = 1,\ \sum_{i=1}^n p_i g(z_i,\theta) = 0. \quad (2)$$

A straightforward application of the Lagrange multiplier method shows that $\ell(\theta)$ is represented by

$$\ell(\theta) = \min_{\gamma \in \mathbb{R}^q} -\sum_{i=1}^n \log(1 + \gamma' g(z_i,\theta)) - n\log n \quad (3)$$

(see, for example, Kitamura 2006). The numerical evaluation of the function $\ell(\cdot)$ is easy, because (3) is a low-dimensional convex maximization problem, for which a simple Newton algorithm works. Second, obtain the empirical likelihood estimator $\hat{\theta}_{\mathrm{EL}}$ as the maximizer of (3). The maximization of $\ell(\theta)$ with respect to θ is typically carried our using a nonlinear optimization algorithm.

Basic properties of the empirical likelihood procedure are now well-understood. The EL estimator $\hat{\theta}_{\mathrm{EL}}$ is $n^{1/2}$-consistent and asymptotically normal. Let D and S denote $E[\nabla_\theta g(z, \theta_0)]$ and $E[g(z,\theta_0)g(z,\theta_0)']$, then its asymptotic distribution is given by $\mathrm{N}(0,(D'SD)^{-1})$. Also, suppose R is a known $\mathbb{R}^s$-valued function of θ, and the econometrician poses a hypothesis that θ_0 is restricted as $R(\theta_0) = 0$, where the s restrictions are independent. This can be tested by forming a nonparametric analogue of the parametric likelihood ratio statistic. Let $r = -2(\sup_{\theta : R(\theta) = 0}\ell(\theta) - \sup_{\theta \in \Theta}\ell)$, then this obeys the chi-square distribution with s degrees of freedom asymptotically under the null. The factor r is called the empirical likelihood ratio (ELR) statistic. ELR also applies to testing overidentifying restrictions: see section "EL and the Large Deviation Principle". These properties and other basics of EL and related methods have been studied extensively in the literature (see Qin and Lawless 1994; Imbens 1997; Kitamura 1997; Kitamura and Stutzer 1997; Smith 1997; Imbens et al. 1998; Newey and Smith 2004).

An alternative way to motivate EL is to use a minimum divergence estimation framework. Let f and g denote the density functions or the probability functions of distribution functions F and G. Define a 'divergence measure' between F and G to be

$$D(F,G) = \int \varphi\left(\frac{f(z)}{g(z)}\right) g(z)\mathrm{d}z, \tag{4}$$

for a convex function φ. It is easy to see that $D(\ ,G)$ is minimized at G. Let

$$\mathcal{F}(\theta) = \left\{F : \int g(z,\theta)\mathrm{d}F = 0, F \text{ is a CDF}\right\}$$

Then $\mathcal{F} = \cup_{\theta\in\Theta}\mathcal{F}(\theta)$ is the set of all probability distributions that are compatible with the moment restriction (1). Now consider the problem of minimizing the divergence $D(F,F_0)$ with respect to $F \in \mathcal{F}$. In other words, a distribution that is 'closest' to the true distribution F_0 in the class of distributions $\mathcal{F}$ is sought. Pick a value $\theta \in \Theta$ and define

$$v(\theta) = \inf_F D(F,F_0) \text{subject to} \int g(z,\theta) f\mathrm{d}z = 0, \int f\mathrm{d}z = 1. \tag{P}$$

The value $v(\theta)$ is regarded as the minimum divergence between F_0 and the set of distributions that satisfy the moment restriction with respect to $g(z,\theta)$. The nonnegativity of f is maintained if φ is modified so that $\varphi(z) = \infty$ for $z < 0$ (see Borwein and Lewis 1991). The primal problem (P) has a dual problem

$$v^*(\theta) = \max_{\lambda\in\mathbb{R},\gamma\in\mathbb{R}^q}\left[\lambda - \int \varphi^*(\lambda + \gamma' g(z,\theta))\mathrm{d}F_0(z)\right], \tag{DP}$$

where φ^* is the convex conjugate (or the Legendre transformation) of φ, that is $\varphi^*(y) = \sup_x[xy - \varphi(x)]$. (DP) is a finite-dimensional unconstrained convex maximization problem. The Fenchel duality theorem implies that $v(\theta) = v^*(\theta)$. Since the true value θ_0 minimizes $v(\theta)$ over Θ, it follows that

$$\theta_0 = \mathrm{argmin}_{\theta\in\Theta} v^*(\theta). \tag{5}$$

Note that the integral in the definition of v^* is the expected value of $\varphi^*(\lambda + \gamma' g(z,\theta))$ with respect the true distribution F_0, which is unknown in practice. A feasible procedure is obtained by replacing the expectation with the sample average, that is

$$\hat{v}(\theta) = \max_{\lambda\in\mathbb{R},\gamma\in\mathbb{R}^q}\left[\lambda - \frac{1}{n}\sum_{i=1}^n \varphi*(\lambda + \gamma' g(z_i,\theta))\right]. \tag{6}$$

Corresponding to (5), an appropriate minimum distance estimator takes the form

$$\hat{\theta} = \mathrm{argmin}_{\theta\in\Theta}\hat{v}^*(\theta).$$

This minimum divergence framework yields empirical likelihood as a special case with $\varphi(x) = -\log(x)$ (or equivalently, $\varphi^*(x) = -1 - \log(-y)$). Other choices for φ are, of course, possible. For example, $\varphi(x) = x\log(x)$ yields the 'exponential tilt' estimator (Kitamura and Stutzer 1997), while $\varphi(z) = \frac{1}{2}(x^2 - 1)$ corresponds to the continuous updating GMM estimator (CUE) (Hansen et al. 1996). A convenient parametric family of convex functions known as the Cressie–Read family (Read and Cressie 1988) subsumes these three important cases. If φ belongs to the Cressie–Read family, one can show that the minimum divergence estimator can be written as

$$\hat{\theta} = \mathrm{argmin}_{\theta\in\Theta}\max_{\gamma\in\mathbb{R}^q}\left[\frac{1}{n}\sum_{i=1}^n \kappa(\gamma' g(z_i,\theta))\right] \tag{7}$$

where $\kappa(y) = -\varphi(y+1)$. This is essentially equivalent to the generalized empirical likelihood (GEL) estimator by Smith (1997). Smith (2004) provides a detailed account for GEL.

E

EL and the Large Deviation Principle

Like the conventional asymptotic method, the large deviation principle (LDP) offers first order approximations for various estimators and tests. Unlike the conventional theory, which produces local linear approximations, the LDP provides global nonlinear approximations. It is the latter feature that enables the LDP to yield results not obtained by the conventional linear approximations. For example, the LDP shows that EL enjoys many optimality properties that are not shared by, for example, the conventional GMM estimator.

To introduce the concept of the LDP in the context of moment condition models, suppose the econometrician observes i.i.d. data $(z_1, \ldots, z_n)$, where z_i satisfies the restriction (1). Let A_n be an event as a result of estimation or testing: for example, if one uses an estimator θ_n to estimate θ_0, one may consider $A_n = 1\{\|\theta_n - \theta_0\| > c\}$ for a constant c. Then $\Pr\{A_n\}$ is the probability of the estimator missing the true value by a margin larger than c. Or, in testing a null hypothesis H_0, A_n can represent the event that H_0 is accepted. If the null is incorrect, $\Pr\{A_n\}$ is the probability of type II errors. In either way, $\lim_{n \to \infty} \Pr\{A_n\} = 0$ if the estimator or the test is consistent. The LDP also deals with asymptotic properties, but it is concerned with the limit of the form $\lim_{n\to\infty} \frac{1}{n} \log \Pr\{A_n\}$. (If the limit does not exist, one needs to consider lim inf or lim sup, depending on the purpose of analysis.) Let $-d \leq 0$ denote the above limit so that $\Pr\{A_n\} \approx e^{-nd}$, which characterizes how fast $\Pr\{A_n\}$ decays. The goal is to obtain a procedure that maximizes the speed of decay d.

Kitamura and Otsu (2005) study the estimation of models of the form (1) using the LDP. One complication in the application of the LDP to an estimation problem in general is that an estimator that maximizes the limiting decay rate d with $A_n = 1\{\|\theta_n - \theta_0\| > c\}$ uniformly in unknown parameters does not exist in general, unless the model belongs to the exponential family. A possible way around this issue is to pursue minimax optimality, rather uniform optimality. See Puhalskii and Spokoiny (1998) for a general discussion on such a minimax framework. Note that the probability of the event $A_n = 1\left\{\left\|\hat{\theta}_n - \theta_0\right\| > c\right\}$ depends on θ_0 and F_0, therefore the worst case scenario is given by the pair (allowed in the model (1)) that maximizes $\Pr\{A_n\}$. Suppose an estimator θ_n minimizes this worst-case probability, thereby achieving minimaxity. The limit inferior of the minimax probability provides an asymptotic minimax criterion. Kitamura and Otsu (2005) show that an estimator that attains the lower bound of the asymptotic minimax criterion can be obtained from the EL objective function $\ell(\theta)$ in (2) as follows:

$$\hat{\theta}_{\mathrm{ld}} = \underset{\theta \in \Theta}{\operatorname{argmin}}\, Q_n(\theta), Q_n(\theta) = \sup_{\theta* \in \Theta: \|\theta* - \theta\| > c} \ell(\theta*).$$

Calculating $\hat{\theta}_{\mathrm{ld}}$ in practice is straightforward. If the dimension of θ is high, it is also possible to focus on a low-dimensional sub-vector of θ and obtain a large deviation minimax estimator for it, treating the rest as nuisance parameters.

Kitamura (2001) shows that empirical likelihood dominates other methods in terms of the LDP when applied to overidentifying restrictions testing. Researchers routinely test overidentifying restrictions of the form

$$\int g(z, \theta) \mathrm{d}F = 0 \text{ for some } \theta \in \Theta \text{ and}$$
$$\text{for some distribution function } F, \qquad \text{(O)}$$

with $\dim(\Theta) = k$ and $g \in \mathbb{R}^q$, $q > k$. The log empirical likelihood under the restriction (O) is $\sup_{\theta \in \Theta} \ell(\theta)$; without the restriction, it is $-n \log n$. The ELR test statistic for (O) is the difference of the two multiplied by -2. It is asymptotically distributed according to the χ^2 distribution with $q - k$ degrees of freedom under (O) (Qin and Lawless 1994). Using the notation in the previous section, rewrite the above null in an equivalent form: $(\mathrm{O})' : F_0 \in \mathcal{F}$. It turns out that ELR for $(\mathrm{O})'$ has a property of being uniformly most powerful in an LDP criterion. To state this optimality property of ELR formally, let F denote the set of all probability distribution functions. Practically all reasonable tests for (O) (or $(\mathrm{O})'$) can be represented by a partition $\Omega = (\Omega_1; \Omega_2)$ of F,

such that if the empirical distribution function F_n falls into Ω_1 (Ω_2) one rejects (accepts) (O). It is a straightforward exercise to show that the ELR test rejects the null if the Kullback–Leibler divergence $K(F_n,G)$ between F_n and G, minimized over $G \in \mathcal{F}$, is too large. Therefore ELR is represented by the following partition of F : $\Lambda = (\Lambda_1; \Lambda_2)$, $\Lambda_1 = \{F : \inf_{G \in F} K(F,G) < \eta\}, \Lambda_2 = \Lambda_2 = \Lambda_1^c$ for a positive number η. Following Owen (2001), for an event A_n that involves observations $z_1,\ldots, z_n$ that are randomly sampled from F, let $\Pr\{A_n; F\}$ denote the probability of the event. By applying a mathematical result called Sanov's theorem, it can be shown that

$$\sup_{F* \in \mathcal{F}} \limsup_{n \to \infty} \frac{1}{n} \log \Pr\{F_n \in \Lambda_2; F*\} \leq -\eta.$$

Kitamura (2001) also shows that if the following inequality holds for a test $\Omega = (\Omega_1; \Omega_2)$ that satisfies some regularity conditions (see Kitamura 2001, for the regularity conditions):

$$\sup_{F* \in \mathcal{F}} \limsup_{n \to \infty} \frac{1}{n} \log \Pr\{F_n \in \Omega_2; F*\} \leq \eta,$$

then it must be that

$$\limsup_{n \to \infty} \frac{1}{n} \log \Pr\{F_n \in | \, \Omega_1; F**\} \geq \limsup_{n \to \infty} \frac{1}{n} \log \Pr\{F_n \in \Lambda_1; F**\}$$

for every $F** \notin \mathcal{F}$. The first two of the above three inequalities mean that the ELR test Λ and the arbitrary regular test Ω are comparable in terms of its LDP property of type I error probabilities. But the third inequality implies that the ELR test is no less powerful than the arbitrary test if the LDP of type II error probabilities are used to measure the asymptotic powers of the tests. Note that the third inequality holds for every $F** \notin \mathcal{F}$: that is, it holds uniformly over alternatives. Since the test (Ω_1, Ω_2) is arbitrary, this shows that ELR is uniformly most powerful in an LDP sense. Such a property is sometimes referred to as the Generalized Neyman–Pearson (GNP) optimality.

Higher-Order Asymptotics

An alternative way to see why EL works well is to analyse it using higher-order asymptotics. Newey and Smith (2004) investigate higher-order properties of the GEL family of estimators. To illustrate their findings, it is instructive to look at the first-order condition that the EL estimator satisfies, that is $\nabla_\theta \ell\left(\hat{\theta}_{\mathrm{EL}}\right) = 0$. A straightforward calculation shows that this condition, using the notation $\hat{D}(\theta) = \sum_{i=1}^n \hat{p}_{\mathrm{ELi}} \nabla_\theta g(z_i, \theta)$ and $\hat{S}(\theta) = \sum_{i=1}^n \hat{p}_{\mathrm{ELi}} g(z_i, \theta) g(z_i, \theta)'$, can be written as

$$\hat{D}\left(\hat{\theta}_{\mathrm{EL}}\right)' \hat{S}^{-1}\left(\hat{\theta}_{\mathrm{EL}}\right) \overline{g}\left(\hat{\theta}_{\mathrm{EL}}\right) = 0; \qquad (8)$$

see Theorem 2.3 of Newey and Smith (2004). The factor $\hat{D}\left(\hat{\theta}_{\mathrm{EL}}\right)' \hat{S}^{-1}\left(\hat{\theta}_{\mathrm{EL}}\right)$ can be interpreted as a feasible version of the optimal weight for the sample moment $\overline{g}(\theta) = \frac{1}{n} \sum_{i=1}^n g(z_i, \theta)$. Equation (8) is similar to the first-order condition for GMM, though there are important differences. Notice that the Jacobian term D and the variance term S are estimated by $\hat{D}\left(\hat{\theta}_{\mathrm{EL}}\right)$ and $\hat{S}\left(\hat{\theta}_{\mathrm{EL}}\right)$ in (8). It can be shown that these are semiparametrically efficient estimators of D and S under the moment restriction (1). This means that they are asymptotically uncorrelated with $\overline{g}(\theta_0)$, removing the important source of the second-order bias of GMM. Moreover, the EL estimator does not involve a preliminary estimator, thereby eliminating another source of the second-order bias in GMM. Newey and Smith (2004) formalize this intuition and obtain an important conclusion that the second-order bias of the EL estimator is equal to that of the infeasible method-of-moments estimator that optimally weights $\overline{g}$ by the unknown factor $D'S^{-1}$. In contrast, the first-order condition of GMM takes a similar form, but the terms that correspond to D and S are inefficiently estimated, causing bias. Newey and Smith (2004) note that the first-order conditions of GEL estimators have a form where D is efficiently estimated but S is not, leaving a source of bias that is not present for EL.

Higher-order properties of ELR tests have been studied in the literature as well. One of the significant findings in the early literature of empirical

likelihood is the Bartlett correctability of the empirical likelihood ratio test, discovered by DiCiccio et al. (1991). Consider the ELR test statistic for H_0:$\theta = \theta_0$ in the model (1) with $q = k$. DiCiccio et al. (1991) show that the accuracy of the χ^2 asymptotic approximation for the distribution of the ELR statistic can be improved from the rate n^{-1} to the much faster rate n^{-2} by multiplying it by a factor called the Bartlett coefficient.

Some Variations of EL

EL is applicable to many problems other than (1), but they sometimes require extending and modifying the standard EL method described so far. For example, suppose economic theory implies that the conditional mean of $g(z,\theta_0)$ given a vector of covariates x is zero:

$$E[g(z,\theta_0)|x] = 0 \tag{9}$$

This restriction is stronger than (1). Though one can choose an arbitrary function $a(x)$ of x as an instrument, this can be problematic since (*a*) choosing an instrument that delivers strong identification may be a difficult task, and (*b*) an arbitrary instrument does not achieve efficiency in general. Kitamura et al. (2004) use the kernel regression technique to incorporate the information in the conditional moment restriction into empirical likelihood. Their estimator achieves the semiparametric efficiency bound of the model (9) under weak regularity conditions. While there exist estimators that achieve efficiency in the model, the EL-based estimator has an advantage that finding a preliminary estimator that is consistent is not necessary. A simulation study in Kitamura et al. (2004) indicates that the conditional EL estimator and tests based on it work remarkably well in finite samples. Donald et al. (2003) propose an alternative estimator for (9). Their idea is to use a sequence functions of x as a vector of instruments, then apply EL to the resulting unconditional moment restriction model. By letting the dimension of the instrument vector grow with the sample size in such a way that it spans the 'optimal instrument' asymptotically, their procedure also achieves the semiparametric efficiency bound.

A topic that is closely related to the above is nonparametric specification testing. Suppose, for example, one is interested in testing the specification of a parametric regression model $E[y|x] = m(x, \theta_0)$, where m is parametrized by a vector $\theta_0 \in \Theta$. The null hypothesis of correct specification can be written in terms of a conditional moment restriction for the function $g(z, \theta) = y - m(x, \theta)$; $z = (x', y)'$:

$$E[g(z,\theta)|x] = 0 \text{ for some } \theta \in \Theta \tag{C}$$

Tripathi and Kitamura (2003) shows that a conditional version of the ELR test applies to the above problem. They propose a simple procedure: reject (C) if the maximized value of the conditional empirical likelihood function, which is essentially the one used in Kitamura et al. (2004), is too small. They also calculate the asymptotic power of their test. Their analysis shows that the EL-based testing procedure has an asymptotic optimality property in terms of an average power criterion.

Another example in which EL needs an appropriate modification is a time series model. Suppose the researcher observes a strictly stationary and weakly dependent time series $\{z_1, \ldots, z_t\}$, and each z_t satisfies the moment condition $E[g(z_t, \theta_0)] = 0$, $\theta_0 \in \Theta$. Applying EL to this model ignoring dependence is inappropriate; it leads to efficiency loss, and the chi-square asymptotics of the ELR test break down.

There are at least three alternative ways to deal with the problem caused by dependence. The first approach is to parametrize the dynamics using a reduced form time series model such as a vector autoregression (VAR) model (Kitamura 2006). While straightforward, this approach involves the risk of mis-specifying the dynamics, and reduces the appeal of EL as nonparametric likelihood. The second approach is the blocking method proposed by Kitamura and Stutzer (1997) and Kitamura (1997). The idea is to form data blocks by taking consecutive observations, and apply EL to them. This is termed blockwise

empirical likelihood (BEL). BEL preserves the dependence information in the data, in a fully nonparametric manner. The third approach is a hybrid of the first and the second approaches (Kitamura 2006). That is, one applies a low order parametric filter to lessen the degree of dependence in the data, then apply BEL to the filtered data. While this does not change the desirable asymptotic property of BEL, it appears to have advantages in finite samples when applied to a time series that is highly persistent.

Employment, Theories of

M. Bronfenbrenner

Theories of employment are actually concerned with involuntary unemployment. They deal with the definition, nature, and causes of such unemployment, and also with economic polices to reduce or alleviate it. They consider such questions as:

How serious is the problem of involuntary unemployment, both in the short and in the longer run?

Is such unemployment a feature of economic equilibrium, or is it an exclusively disequilibrium phenomenon?

Is there a 'natural' or 'normal' or 'non-inflation-accelerating' unemployment rate?

Is there a trade-off between unemployment and inflation rates? If so, what are the terms of trade-off, and are they stable?

Under what circumstances, if any, can assurance of long-term high employment be combined with assurance of price-level stability (or non-accelerating inflation)?

Opposed Positions

Two basic and opposed positions of economists on employment theory may be summarized as follows:

(1) Applying standard supply-and-demand analysis to labour markets makes unemployment a disequilibrium phenomenon, resulting from the prevalence and persistence of real and money wage rates higher than the demand for labour will support. Its solution is the lowering of real wage rates to market-clearing levels, rather than any arbitrary removal of certain classes of workers from the labour supply. Public support for the unemployed may perhaps subsidize search for desirable jobs, but it should not subsidize withdrawal from the labour force. Intentional stimulation of labour demand, as by monetary expansion or fiscal deficits, is apt to kindle or accelerate inflation, and/or to raise interest rates and discourage investment. Limitation of labour-saving technical progress will slow economic growth at the expense of future generations.

(2) Unemployment results from equilibrium between aggregate supply and demand for the national output at a level too low to require the productive services of the full labour supply. The appropriate remedy is expansion of demand by fiscal and monetary measures – increased public spending, lower taxes, accelerated monetary growth, lower interest rates. Removal of particular groups from the labour market – youth, the elderly, secondary workers in families with employed breadwinners -and moratoria on labour-saving innovations may be legitimate devices to reduce unemployment in the short run, as may the export of unemployment by export subsidies and protection against imports.

Variants of the first of these positions – sometimes called neoclassical, but actually much older than the 'neoclassical revolution' of the 1870s – dominated economic orthodoxy in Western countries prior to the 1930s. Variants of the second position, articulated by John Maynard Keynes's General Theory of Employment Interest and Money (1936, esp. ch. 19) are called Keynesian, although none of the basic ideas was precisely new in 1936. (Marx, for example, had gone far beyond Keynes in regarding a 'reserve army of the unemployed' as highly functional in capitalism, its function being to hold wage rates at an established subsistence level.) But much as persistent depression unemployment threatened neoclassicism, persistent and accelerating inflation has later threatened Keynesianism. Revolts against Keynesian neoorthodoxy have taken two opposite tacks; towards reformulated neoclassicism on one side, and towards 'incomes policies' of employment guarantees (with regulated prices and usually also wages) at the opposite end of the spectrum. The current (mid–1980s) situation is variously described as fluid, as chaotic, and as 'in shambles'. It cannot be called 'cut and dried'!

Conflict between neoclassicals and Keynesians is exacerbated by denunciation in each group of the other's policy proposals as dangerously harmful. To the confirmed neoclassicist, artificial demand stimulus, repeated and anticipated, soon raises society's (unofficial) 'discomfort index' by raising the inflation rate more than it lowers the measured unemployment rate. To the confirmed Keynesian, the immediate effect of any real or money wage cut is to deepen recession by shifting purchasing power from 'spenders' (the working class) to 'savers' (capitalists and corporate treasuries).

Neoclassical Employment Theory

Mature neoclassical employment theory, as represented by A.C. Pigou's *Theory of Unemployment* (1933), draws its analysis from Alfred

Marshall's *Principles of Economics* (1890). There had been little formal employment theory in Marshall himself, the most nearly relevant materials being the treatment of derived demand (Book V, ch. vi) with reference to the building trades, rather than the 'wages' chapters of Book VI. Book V includes Marshall's famous 'four laws' governing the extent to which a rise in the demand and price of an output (houses) causes a rise in the demand and wage of an input (building workers). In today's economic terminology and Marshall's order, these laws state that the rise in demand for the input will increase more, the lower the elasticity of substitution between that input and other inputs, the lower the elasticity of demand for the output, the less the importance of that input in the production process for the output, and the less the elasticities of supply of substitute inputs. This seems far removed from employment theory, but Pigou, in successive editions of his *Economics of Welfare* (1920, 1st edition entitled *Wealth and Welfare*, 1912) restated Marshall's laws as conditions under which workers might obtain higher wages, presumably after union organization, with minimum losses of employment. A full mathematical statement, combining all four laws in a single formula for the elasticity of the derived demand for a labour input, dates from J.R. Hicks's *Theory of Wages* (1932). Denoting by E, η, σ, e the respective elasticities of labour demand, output demand, substitution between labour and 'capital', and supply of 'capital', the Hicks equation is:

$$E = \frac{\sigma(\eta + e) + k\sigma(\eta - e)}{\sigma(\eta + e) + k(\eta - e)}$$

with k representing the relative importance of labour in production as measured by the proportionate share of wage payments in total cost. (The equation ignores shifts of consumer demand between more and less labour-intensive commodities.) From Hicks's equation, Marshall's laws follow immediately, with the possible exception of the third one on 'the importance of being unimportant'.

We come now to Pigou's *Theory of Unemployment*. Based on the Marshallian structure and appearing in mid-Depression, this volume is remembered chiefly as the fuse that lit Keynes's *General Theory*, but deserves a better fate. Much of it can be interpreted as standing Pigou's earlier argument on its head, so as to provide us an exposition of conditions under which employment can be *restored* most rapidly in a depression, and with *minimum* cuts in real wages. These conditions are embodied in devices to *raise* the elasticity of demand for labour. These several devices involve shifts in aggregate demand, private and (especially) public from what Pigou calls 'centres' where (1) σ is low to others where it is high, (2) from centres where η is low to others where it is high, (3) from centres where k is low to others where it is high – surely the most important quantitatively – and finally (4) from centres where e is low to others where it is high.

On the more aggregative plane, Pigou seems wavering and inconsistent in the light of fifty years' additional development of macroeconomic theory. Over the long term, he argues in the second chapter of Part V, increases in aggregate demand serve only to raise prices and wages without increasing employment. In the short run, however, they can be helpful if not carried too far. This apparently implies that Say's Law is valid as a long-run proposition, but inoperative in the short run.

Pigou's approach may seem naïve in transferring microeconomic analysis to the macroeconomic plane, and in its failure to examine Say's Law more intensively than it does. But it is far from the labour-and union-bashing that neoclassical economic argumentation is often supposed to represent.

Keynesian Employment Theory

Despite its title, Lord Keynes's *General Theory* is a treatise on the macroeconomic theory of income determination. Its employment theory is confined largely to attacks on the Marshall-Pigou tradition, under the assumption (too obvious to require either stress or detailed development) that aggregate real income and the unemployment rate are inversely related under any given state of technology.

Strengthening and specifying of the Keynesian relation between income on the one hand, and employment and unemployment on the other, came only after advances in econometrics and in computer technology. A standard specification has been contributed by Arthur Okun. 'Okun's Law' or the 'Okun curve', as it is variously known, may be written in disguised differential-equation form. For example, let us denote by $\hat{U}$ the percentage change in the measured unemployment rate over a given period and by $\hat{Y}$ the percentage change in a real-income measure like deflated GNP or GDP over the same period.

$$-\hat{U} = a\left(\hat{Y} - \overline{Y}_0\right) \quad \text{or} \quad \hat{U} + a\left(\overline{Y} - \hat{Y}_0\right) = 0$$

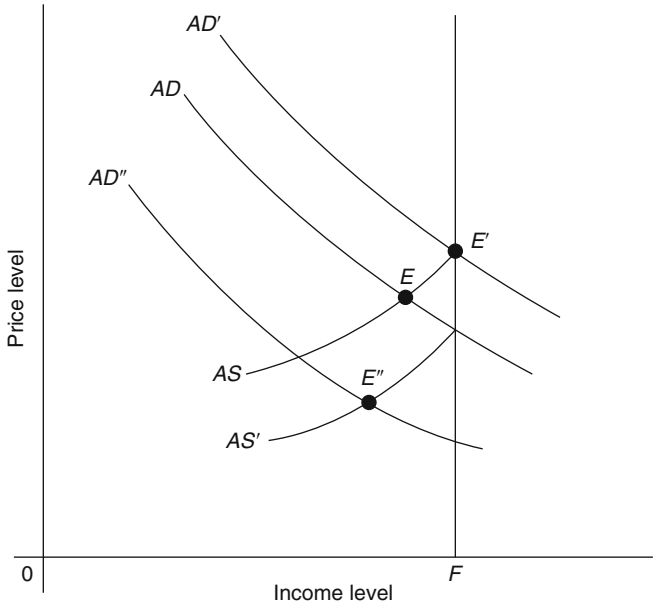
Here a is a statistical parameter, while $\overline{Y}_0$ is the income growth rate estimated to be required if the unemployment rate is not to rise. Neither real nor nominal wage rate movements are taken into explicit account. (The estimates of $\overline{Y}_0$ are based on regressions of high-employment points only, and the slope of this regression is called the country's potential growth rate. The area between such a regression and the country's actual growth path is sometimes called an 'Okun gap'.)

The $\left(a, \overline{Y}_0\right)$ values may of course vary widely, both across countries and over time. For the US 1949–60, Okun's estimate of a was about 0.3, and his estimate of $\overline{Y}_0$ about 3.75 per cent. The usefulness of the widely used Okun analysis is questionable, however, in the presence of supply shocks, wage 'explosions', and similar disturbances. (A productivity jump, for example, might be expected to lower a and raise $\overline{Y}_0$. The combination of these shifts increases the income growth rate required to reduce an existing unemployment rate or to keep that rate from rising.)

Shifting from the empirical to the analytical side, a fruitful development of Keynesian unemployment theory was the distinction between high and low full employment, introduced by A.P. Lerner's *Economics of Employment* (1951, ch. 13). By 'low full employment' Lerner meant essentially what was later called NAIRU in the United Kingdom, namely the non-inflation-accelerating rate of unemployment. By 'high full employment', on the other hand, Lerner meant 100 per cent of the labour force, minus only the frictional lacunae consequent upon job changing. Lerner set low rather than high full employment as the preferred target of employment policy, and outlined a detailed (but probably impractical) scheme of wage controls for attaining and maintaining it. (Most professed Keynesians, more ambitious than Lerner, would strive for high full employment.)

The 'expository Keynesianism' of the textbooks stresses primarily the *shapes* and *parameters* of such relations as the consumption, marginal efficiency, and liquidity functions which determine the level of income in the Keynesian scheme. At a more advanced level, the emphasis appears to be changing, to stress rather the *volatility* of these functions as expectations fluctuate. Leijonhufvud (1968) calls the newer view 'the economics of Keynes' as distinguished from the 'Keynesian economics' of the textbooks. The change in emphasis may also result from the defence of Keynesian macroeconomics, with its employment-theory appendage, against its critics, whose argument can be paraphrased: 'The aggregate demand for the national output depends inversely on the general price level, as the demand for a single commodity depends upon its price. If human wants are insatiable at a zero price level, it follows that there exists a positive price (and likewise wage) level at which full-employment output can be absorbed.' (The critics could not, however, prove that the market-clearing set of full-employment wage rates was at or above 'subsistence', however defined.)

The Keynesian rebuttal, due largely to Clower (1965), introduced the distinction between actual and 'notional' demands for output and especially for labour. In a recession, the demand function for output is weaker than the 'notional' full-employment demand function would be. At the same time, the actual demand for labour is less than the notional one which would prevail were potential employers reasonably sure of selling full-employment output at profitable prices. The impasse or vicious circle could be broken when the demand for output (see Fig. 1) could rise from



Employment, Theories of, Fig. 1 Investment and saving in a 2-period model

AD to *AD′* by public policies which improved the state of confidence – without reference to the multiplier mechanism of the Keynesian textbooks. The equilibrium position could move from point *E*, possibly all the way to point *E′* at the full-employment income level *F*, with money wages remaining the same and with no need to press aggregate supply *AS* vertically downward to *AS′* as by a wage cut.

Now suppose, in the same recession, there was to be a complete 'hands-off' policy. As unemployment continued with nothing done about it beyond calls for wage reductions, notional aggregate demand would fall, perhaps as far as *AD″* if the policy were to lead to budget-balancing and monetary contraction. Even if hard times and wage concessions from labour eventually forced aggregate supply to the *AS′* position, the result would be hyper-deflation rather than recovery. (The Hoover debacle of 1931–2 in the United States and the contemporaneous Brüning one in Germany are cases in point.) By the time aggregate supply had reached *AS′*, the equilibrium point *E″* would prevail, with output (and therefore employment) below those at *E*, even though deflationary cost-cutting would have restored high employment had aggregate demand remained at *AD*.

Equilibrium is then not unique. Depending upon the state of notional as well as actual demand, there are an infinite number of possible equilibria at as many levels of income and employment. We cannot be sure *a priori* that wage deflation will produce increases in employment.

Conclusion

The British Broadcasting Company featured in December 1944 a series of postwar-planning programmes entitled *Jobs for All*. These were inspired not only by Lord Keynes's *General Theory* but by the extensions and applications proposed by Michal Kalečki in the Oxford Institute of Statistics' *Economics of Full Employment* (Burchardt et al. 1944). (Kalečki, who would later assume temporary leadership of British Keynesianism after Keynes's own death in 1946, had proposed 'incomes policies' and income redistribution as preferable to either deficit finance or stimulation of private investment as a route to full employment.) A junior member of that Oxford team, and a speaker in the BBC *Jobs for All* series, was G. D. N. Worswick. In July 1984,

the same G.D.N. Worswick, now Professor at Oxford and President of the Royal Economic Society, delivered his presidential address on 'Jobs for All?', later published in the *Economic Journal* (Worswick 1985). It was the same subject, but note the question mark.

The substance of Worswick's address was that, unfortunately, that question mark belonged in his new title, and could not be expunged even after forty additional years of planning, theorizing, and experimentation. We quote from his final paragraph (p. 14):

> When it comes to action, *[The Economics of Full Employment]* was already too optimistic. We assumed that trade unions would readily accept some limitations on free collective bargaining as a small price to pay for ending unemployment. There was too little recognition that it is my restraint which is necessary to secure your employment. Is it possible to devise schemes which are not only of advantage for the national economy, or for workers as a whole, but can also be seen to be to the advantage . . . of members of trade unions who are already in employment? This is a task for the new generation of economists to undertake. Until a lasting solution is found, the question mark after my title must remain.

Empty Boxes

N. F. R. Crafts

'Empty Economic Boxes' is the title of a famous article in the *Economic Journal* of 1922 and a phrase which has subsequently entered the language of economics as a shorthand for 'abstract theory without practical relevance'. The paper was written by J.H. Clapham, the leading British economic historian of the interwar years and first Professor of Economic History at Cambridge University.

As an economic historian, Clapham showed a 'special predilection for hard and tangible facts' (Postan 1946, p. 57). His classic text, *An Economic History of Modern Britain* (3 vols.: 1926; 1932; 1938) is notable for its pioneering insistence on presenting facts as far as possible in detailed quantitative form. Clapham is especially remembered for his statement on the methodology of economic history subsequently eagerly embraced by 'new economic historians': Every economic historian should, however, have acquired what might be called the statistical sense, the habit of asking in relation to any institution, policy, group or movement the questions: how large? how long? how often? how representative? (1931, p. 328).

Clapham was not (nor was any of his contemporaries), however, a new economic historian, in that his work was not characterized by the use of formal economic analysis or econometrics. His approach to economic history echoes his 1922 article in finding little of practical relevance in the economic theory of his day. In effect, Clapham revealed a preference for a shift in the balance of economists' research programmes away from pure, abstract theory towards collection of better economic data.

The 1922 article was directed particularly towards Pigou's (1920) proposals for taxation of decreasing returns and subsidy of increasing returns industries. Clapham argued that 'the Laws of Returns have never been attached to specific industries; that the boxes are, in fact, empty' (1922, p. 312). In effect, Clapham criticized the lack of evidence on long-run cost curves for both firm and industry and on learning effects. He also expressed scepticism about the prospects for empirical work in this area. Pigou's reply (1922) expressed the belief that evidence would be forthcoming and that, in any case, economic thinking was useful as a method of analysis in policy questions.

Ironically, Pigou's work gave rise to a considerable body of theoretical rather than empirical literature, which left relatively little of his initial proposals intact. Notable articles by Knight (1924), Robertson (1924), Viner (1931) and Ellis and Fellner (1943) made clear, for example, the distinctions between external diseconomies and transfer payments to fixed factors and between externalities from irreversible learning effects and minimum efficient scale on a given long-run average cost curve.

Already by the end of the interwar period Pigou's hopes for empirical research were starting to be fulfilled by pioneering investigations into production functions, cost curves and learning effects, which are reviewed in Walters (1963), Johnston (1960) and Alchian (1963). It should be said that econometric work has by now achieved far more than Clapham believed possible, and the results are seriously considered in the context of antitrust policy (e.g. Cmnd. 7198, 1978), if not in taxation policy. At the same time, industrial economics textbooks still offer very substantial reservations about the precision of available estimates (Hay and Morris 1979, ch. 2).

In economic history also, there has been progress in applying Pigou's ideas as revised by the subsequent theoretical literature. By far the most interesting study is that of David (1975, ch. 2), which found econometric evidence of external economies from irreversible learning effects in the American cotton textile industry before 1825 and *also* that thereafter there was no justification for infant-industry protection.

David's paper is an excellent example of the 'new economic history', with its stress on use of theory and hypothesis testing. In fact, new economic history has generally used models based on mainstream neoclassical economics and, in general, this has undoubtedly proved fruitful – much more so than a sceptic like Clapham would have imagined. For example, discussions of the slave economy in the United States and entrepreneurial behaviour in late Victorian Britain have been substantially enriched.

Nevertheless, there is cause for concern about the one-way relationship which has developed in the past quarter-century between economics and economic history. There is a danger not so much of inevitably empty boxes as of forcing historical examples into particular boxes; that is, of operating with priors that are too tight. In particular, as McClelland (1975, p. 125) has emphasized, new economic historians should be wary of automatically believing that the marginal equivalences of the neoclassical model are tolerably achieved in all situations.

Perhaps, also, economists have more to learn from economic history than they seem presently to believe. Obviously, the past offers a much wider array of facts and institutions than the present, evidence which at present is underutilized. In addition, the study of history necessarily involves seeking to understand particular events, and exposure to the difficulties of this can give an interesting perspective on modern economic analysis. Economic historians like David would argue that the past is characterized by pervasive learning effects and technical interrelatedness so as to

produce path-dependent sequences of economic changes. If in fact the increasing-returns box is as full as initial investigations in technological history suggest it could be, then critics of orthodox theory like Kaldor (1972) will find their positions strengthened.

Moreover, in such a world the past matters in ways that neoclassical theory ignores, and the balance of research in economic history should be different; for example, less emphasis in research on the rationality of individual entrepreneurs in Victorian Britain and more on the impact of an 'early start' on subsequent economic performance.

A modern-day Clapham would still say that we do not know enough about 'increasing returns', but rather than turning his back on the concept, he would surely insist on the importance of economic history in establishing how full this box is and would now recognize that to some extent the importance of economic history depends on the answer. He would also find common cause with applied economists and econometricians like Leontief (1971) and Hendry (1980) in wishing that more resources were devoted to gathering information on economies past and present.

Encompassing

Grayham E. Mizon

Abstract

The concept of encompassing is defined and the role that it and congruence have in econometric modelling is discussed. Empirically, more than one model can appear to be congruent, but that which encompasses its rivals is dominant and will encompass all models nested within it and accurately predict the

mis-specifications of non-congruent models. These results are consistent with a general-to-specific modelling strategy being successful in practice. Alternative forms and applications of encompassing tests are discussed.

Introduction and Motivation

Imaginative and productive disciplines like economics generate many new theories, partly to extend the range of phenomena that they embrace but also to improve on existing theories. New theories require rigorous evaluation to establish their worth if they are to be relevant, reliable, and robust. In addition to checking their logical consistency and relevance it is important to assess their coherence with observation. The latter usually involves the development of a model that embodies the essential characteristics of the theory and has observable implications.

The analysis presented here concentrates on the evaluation of empirical models. Numerous criteria have been proposed for assessing the coherence of an empirical model with observation. Measures of goodness of fit and selection criteria based on likelihood functions (usually degrees of freedom adjusted) are common (Schwarz 1978), and are often used both to assess coherence with observation and to select the preferred model. Probably the most comprehensive and demanding criterion for data coherence is that of congruence (Hendry 1995; Bontemps and Mizon 2003), which requires a model to be a valid reduction of whatever process actually generates the observed data – the data generation process (DGP). When $\mathbf{x}_t$ contains the full set of variables involved in an investigation, let the DGP be denoted by the joint density $D_x(\mathbf{x}_t|\mathbf{X}_{t-1}, f)$ for $\mathbf{x}_t$ conditional on its history $\mathbf{X}_{t-1}$ with parameters φ. Knowledge of the DGP endows one with omniscience and in particular the ability to derive the properties of all models involving the same variables such as $f_x(\mathbf{x}_t|\mathbf{X}_{t-1}, x)$, but, alas, for practical purposes it is unattainable. In empirical modelling, therefore, congruence means that, given the available information, the model is indistinguishable from the DGP for the chosen variables, that is, no evidence has been evinced that the model is not the DGP. Testing the latter requires that extensive, not limited, searching is done for evidence of non-congruence. This leads to the adoption of statistical tests of model mis-specification (for example, wrong functional form, heteroskedastic or serially correlated residuals) as indirect but practical tests of congruence (Hendry 1995; Mizon 1995). Since in practice a congruent model will not be the DGP, it will not necessarily be able to explain the properties of other models, and in particular those that constitute the current best knowledge and practice. Thus, a valuable part of the evaluation of a model is an assessment of whether it represents an advance on existing knowledge. 'The encompassing principle is concerned with the ability of a model to account for the behaviour of others, or less ambitiously, to explain the behaviour of relevant characteristics of other models' (Mizon 1984, p. 136). A well-known illustration in physics, discussed by Okasha (2002), for example, is provided by Newton's laws of motion and gravitation that encompassed Kepler's laws of motion and gravitation as well as Galileo's law of free-fall, and as a result the same laws explained the motion of bodies in both the terrestrial and the celestial domains. This added credence to Newton's laws, as it does for all models that encompass their rivals. It was widely believed for a long time that Newton's theory revealed the workings of nature and had the ability to explain everything in principle. However, Newton's laws have been superseded or encompassed by Einstein's relativity theory and quantum mechanics. This illustrates the fact that modelling, like discovery, is not a once-for-all event, but a continuous process of development. Progress in science, however, is achieved in many

ways, with confidence and persistence playing a role in some instances as a consequence of rejection not being accepted as final or corroboration of models that are subsequently superseded not being taken as definitive.

Background

The idea underlying the encompassing principle has a long pedigree; for example, the comparison of competing theories has been long recognized as a basic ingredient of a scientific research strategy (Nagel 1961). The implementation via a statistical contrast equally has a long history; Cox (1961, 1962) are the most significant early examples. These papers introduced statistical tests for separate families of hypotheses, and discussed several examples to illustrate their practical relevance. The tests were later developed in the literature on non-nested hypothesis testing (Pesaran 1974; Davidson and MacKinnon 1981), and encompassing (Mizon 1984). The latter paper contains a general presentation of the concept of encompassing and discussion of numerous applications, and Mizon and Richard (1986) provides a theoretical framework for encompassing, on which other theoretical papers have built extensions. Davidson et al. (1978) is one of the first attempts to develop a framework for a scientific comparison of alternative economic theories and econometric models implementing them. Different econometric models for the series of UK consumption, which rely on different economic hypotheses about consumption behaviour, were embedded in a general model and shown to imply different testable restrictions on its coefficients.

Distinguished natural scientists have expressed surprise that social scientists are able to learn anything from empirical observation when they rarely have experimental evidence. However, the encompassing principle provides precisely the analogue of the physical experiment. Experiments enable physicists and chemists to sift through alternative theories by evaluating the veracity of their implications or predictions in controlled conditions, and thus to eliminate those theories whose predictions perform badly. Congruence is the analogue of setting up controlled experimental conditions. The need to distinguish between alternative theories that each appear to be coherent with outcomes, experimental or non-experimental, leads to the search for dominant theories. For disciplines that are largely non-experimental, having a principle such as encompassing is essential for discriminating between alternative models. Typically, alternative empirical models use different information sets and possibly different functional forms, and are thus separate or non-nested. This non-nested feature enables more than one model to be congruent with respect to sample information – each can be congruent with respect to its own information set – and so it is important to assess their relative merits. Using the encompassing principle, Ericsson and Hendry (1999) analyse this issue and show that the corroboration of more than one model can imply the inadequacy of each, and Mizon (1989) provides an illustration by comparing a Keynesian and a monetarist model of inflation. Hence, congruence and encompassing are inextricably linked; in particular, encompassing comparisons of non-congruent models can be misleading. For example, general models will not always encompass simplifications of themselves even though that might seem to be an obvious characteristic of a general model, but a congruent general model will always encompass simpler models (Hendry 1995; Gouriéroux and Monfort 1995; Bontemps and Mizon 2003).

Principle

Underlying all empirical econometric analyses is an information set (collection of variables or their sigma field), and a corresponding probability space. This information set has to be sufficiently general to include all the variables thought to be relevant to the empirical implementation of theoretical models in the form of statistical models. It is also important that this information set include the variables needed for all competing models that are to be compared. When these variables are $\mathbf{x}_t$ the

DGP for the observed sample is the joint density $D_x(\mathbf{x}_t|\mathbf{X}_{t-1},f)$ at the particular parameter value $\varphi=\varphi_0$. Let a parametric statistical model of the joint distribution be $M_f=\{f_x(\mathbf{x}_t|\mathbf{X}_{t-1},x)x\in\Xi\subset R^k\}$. Let $\hat{x}$ be the maximum likelihood estimator of $\boldsymbol{\xi}$ so that $\hat{x}\xrightarrow[M_f]{P}x$ and $\hat{x}\xrightarrow[DGP]{P}x(f_0)=x_0$ which is the pseudo-true value of $\hat{x}$.

Note that the parameters of a model are not arbitrary in that M_f and its parameterization $\boldsymbol{\xi}$ are chosen to correspond to phenomena of interest such as elasticities and partial responses within the chosen probability space. For the two alternative models $M_1=\{f_1(\mathbf{x}_t|\mathbf{X}_{t-1},q_1),q_1\in\Theta_1\subset R^{p_1}\}$ and $M_2=\{f_2(\mathbf{x}_t|\mathbf{X}_{t-1},q_2),q_2\in\Theta_2\subset R^{p_2}\}$ the concept of parametric encompassing, in accordance with the approach in Mizon (1984), Mizon and Richard (1986), and Hendry and Richard (1989), can be defined as follows. M_1 encompasses M_2 (denoted $M_1\mathscr{E}M_2$) if and only if $q_{20}=\mathbf{h}_{21}(q_{10})$ when θ_{i0} is the pseudo-true value of the maximum likelihood estimator $\widehat{q}_i$ of $q_i i=1,2$, and $\mathbf{h}_{21}(q_{10})$ is the binding function given by $\widehat{q}_2\xrightarrow[M_1]{P}\mathbf{h}_{21}(q_{10})$ (Mizon and Richard 1986; Hendry and Richard 1989; Gouriéroux and Monfort 1995). Note that this definition of encompassing applies when M_1 and M_2 are non-nested as well as nested. However, Hendry and Richard (1989) showed that when M_1 and M_2 are non-nested $(M_1\mathscr{E}M_2)$ is equivalent to M_1 being a valid reduction of the minimum completing model $M_c=M_1\cup M_2^{\perp}$ (so that $M_1,M_2\subset M_c$) when $M_2{}^{\perp}$ is the model which represents all aspects of M_2 that are not contained in M_1. When this condition is satisfied, M_1 is said to parsimoniously encompass M_1 $\left(M_1\mathscr{E}_pM_c\right)$. Parsimonious encompassing is the property that a model is a valid reduction of a more general model. When a general-to-simple modelling strategy is adopted, the general unrestricted model (GUM) will have been chosen to embed the different econometric models implementing rival economic theories for the phenomenon of interest. Hence searching for the model that parsimoniously encompasses the congruent GUM is an efficient way to find congruent and encompassing models in practice. Hendry and Krolzig (2003) describe and illustrate the performance of a computer program that implements a general-to specific modelling strategy.

The comparison of Gaussian linear regression models provides a simple and convenient framework to illustrate the main ideas. Consider the two models M_1 and M_2 defined in:

$$\begin{array}{ll} M_1\backsim\mathbf{y}=\mathbf{Z}_1b+\mathbf{u}_1, & \mathbf{u}_1\backsim N\left(0,s_1^2\mathbf{I}_n\right)\\ M_2\backsim\mathbf{y}=\mathbf{Z}_2g+\mathbf{u}_2, & \mathbf{u}_2\backsim N\left(0,s_2^2\mathbf{I}_n\right)\\ M_c\backsim\mathbf{y}=\mathbf{Z}_1\mathbf{b}+\mathbf{Z}_2\mathbf{c}+e & e\backsim N\left(0,s_c^2\mathbf{I}_n\right)\end{array}\quad(1)$$

when $\mathbf{y}$ is $n\times1$, and $\mathbf{Z}_i$ is $n\times k_i(i=1,2)$ containing n observations on the independent and two sets of explanatory variables respectively with no variables in common. The explanatory variables are distributed independently of the error vectors $\mathbf{u}$, $\mathbf{v}$, and ε. When M_1, M_2 and M_c are each hypotheses about the distribution of $y|\mathbf{z}$, the models M_1 and M_2 are non-nested in that neither is a special case of the other, whereas both M_1 and M_2 are nested within M_c. A test of the hypothesis that M_1 encompasses M_2 $(M_1\mathscr{E}M_2)$ is possible using the contrast $\widehat{\psi}_\gamma=\widehat{\gamma}-\widehat{\gamma}_1=\left(\mathbf{Z}_2'\mathbf{Z}_2\right)^{-1}\mathbf{Z}_2'\mathbf{Q}_1\mathbf{y}$ with $\mathbf{Q}_1=\left(\mathbf{I}_n-\mathbf{Z}_1\left(\mathbf{Z}_1'\mathbf{Z}_1\right)^{-1}\mathbf{Z}_1'\right)$ between the maximum likelihood estimator of γ, $\widehat{g}=\left(\mathbf{Z}_1'\mathbf{Z}_2\right)^{-1}\mathbf{Z}_2'\mathbf{y}$, and an estimate $\widehat{g}_1\left(\mathbf{Z}_2'\mathbf{Z}_2\right)^{-1}\mathbf{Z}_2'\left(\mathbf{Z}_1'\mathbf{Z}_1\right)^{-1}\mathbf{Z}_1'\mathbf{y}$ of the pseudo-true value of $\hat{g}$ under M_1 given by $g_1=plim_{n\to\infty M_1}(\widehat{g})$. The sample complete parametric encompassing test statistic is given by $\eta_c=\widehat{\psi}_\gamma'\left(\mathbf{Z}_2'\mathbf{Z}_2\right)\left(\mathbf{Z}_2'\mathbf{Q}_1\mathbf{Z}_2\right)^{-1}\left(\mathbf{Z}_2'\mathbf{Z}_2\right)\widehat{\psi}_\gamma/k_2\widehat{\sigma}_c^2$ when $\widehat{\sigma}_c^2=\mathbf{y}'\left(\mathbf{I}_n-\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\right)\mathbf{y}/(n-k_1-k_2)$ is the unbiased estimator of σ_c^2 with $\mathbf{Z}=(\mathbf{Z}_1,\mathbf{Z}_2)$. Under the complete parametric encompassing hypothesis $H_c:\psi_\gamma=\gamma-\gamma_1=0$ the statistic η_c is distributed as $F(k_2,n-k_1-k_2)$: Mizon and Richard (1986) showed that this is precisely the same statistic as that for testing the hypothesis $\mathbf{c}=0$ in (1), that is, the test statistic for $(M_1\mathscr{E}M_2)$ is exactly the same as that for $M_1\mathscr{E}_pM_c$ in this case. Variance encompassing is based on the contrast $\widehat{\psi}_{\sigma_2^2}=\widehat{\sigma}_2^2-\widehat{\sigma}_{21}^2$ between $\widehat{\sigma}_2^2$ and an estimator of $\sigma_{21}^2=\sigma_2^2+\left(\sigma_1^2/n\right)b_1'\left(\mathbf{Z}_1'\mathbf{Q}_2\mathbf{Z}_1\right)b_1$

E

the pseudo-true value $\widehat{\sigma}_2^2$ under M_1 when $\mathbf{Q}_2 = \left(\mathbf{I}_n - \mathbf{Z}_2\left(\mathbf{Z}_2'\mathbf{Z}_2\right)^{-1}\mathbf{Z}_2'\right)$. Mizon and Richard (1986) showed that the resulting variance encompassing test statistic is asymptotically equivalent to each of the one degree of freedom non-nested test statistics developed by Cox (1961, 1962), Pesaran (1974), and Davidson and MacKinnon (1981), among others. The fact that variance dominance is a necessary but not a sufficient condition for variance encompassing highlights a serious limitation of choosing models on the basis of goodness-of-fit selection criteria rather than comparing the alternative models using encompassing test statistics.

Further Developments

This analysis illustrates the fact that the choice of statistic for the encompassing contrast is very important, and may depend very much on the purpose of the analysis or the nature of the models being investigated. For example, when the GUM is not easily available or the calculation of pseudo-true values for other encompassing test statistics is difficult, comparison of the forecasting abilities provides an alternative basis for an encompassing test. Although selecting models on the basis of forecast performance can be very misleading for some purposes in a non-stationary environment with regime shifts (Hendry and Mizon 2005), the concept of forecast encompassing is a valuable method of model comparison. Forecast encompassing statistics were presented by Chong and Hendry (1990), and Ericsson (1993) and Lu and Mizon (1991) extend this analysis in several directions, including multi-step ahead forecasts from nonlinear dynamic models with estimated coefficients. Similarly, when the analytic calculation of pseudo-true values is intractable simulation methods may be used to estimate the pseudo-true values and hence compute the non-nested test statistics (Hendry and Richard 1989; Pesaran and Pesaran 1993). Gouriéroux et al. (1993) developed a comprehensive framework for such simulation known as indirect inference, which allows choice of auxiliary functions as the basis for parameter estimation. A consistent estimator of the parameters involved in the encompassing contrast can be obtained when a correction based on the simulated pseudo-true values of the testing statistics is applied. This approach has the potential to extend the application of the encompassing principle enormously. The relationship between encompassing and conditional moment or m-tests (Newey 1985) is discussed in White (1994) and Lu and Mizon (1996). The possibility that the encompassing principle be used as a generator of test statistics is discussed in Mizon and Richard (1986). Govaerts et al. (1994) consider the application of encompassing in dynamic models, and Hendry and Mizon (1993) apply it to the comparison of alternative dynamic simultaneous equations models containing integrated and cointegrated variables. A Bayesian approach to encompassing is presented in Florens et al. (1996) and, as a result of using statistical procedures rather than pseudo-true values as in Mizon and Richard (1986), argues that encompassing can be interpreted as a property of model specificity analogous to that of sufficiency for statistics. The encompassing relationship between nonparametric models is considered in Bontemps et al. (2006). Finally, Hendry et al. (2008) contains a comprehensive statement and analysis of encompassing as well as many applications of the principle.

Endogeneity and Exogeneity

John Geweke

Abstract

Endogeneity and exogeneity are properties of variables in economic or econometric models. The specification of these properties in

variables is an essential component of the process of model specification. This article considers their application in the specification of, in turn, deterministic and stochastic models.

Keywords

Cowles Commission; Endogeneity and exogeneity; Model specification; Simultaneous equations models; Statistical inference

Endogeneity and exogeneity are properties of variables in economic or econometric models. The specification of these properties for respective variables is an essential component of the entire process of model specification. The words have an ambiguous meaning, for they have been applied in closely related but conceptually distinct ways, particularly in the specification of stochastic models. We consider in turn the case of deterministic and stochastic models, concentrating mainly on the latter.

A deterministic economic model typically specifies restrictions to be satisfied by a vector of variables **y**. These restrictions often incorporate a second vector of variables **x**, and the restrictions themselves may hold only if **x** itself satisfies certain restrictions. The model asserts

$$\forall \mathbf{x} \in R, \;\; \mathrm{G}(\mathbf{x}, \;\; \mathbf{y}) = 0.$$

The variables **x** are exogenous and the variables **y** are endogenous. The defining distinction between **x** and **y** is that **y** may be (and generally is) restricted by **x**, but not conversely. This distinction is an essential part of the specification of the functioning of the model, as may be seen from the trivial model,

$$\forall \mathbf{x} \in \mathbf{R}^1, \;\; x + y = 0.$$

The condition $x + y = 0$ is symmetric in x and y; the further stipulation that x is exogenous and y is endogenous specifies that in the model x restricts y and not conversely, a property that cannot be derived from $x + y = 0$. In many instances the restrictions on **y** may *determine* **y**, at least for $x \in R^* \subset R$, but the existence of a *unique* solution has no bearing on the endogeneity and exogeneity of the variables.

The formal distinction between endogeneity and exogeneity in econometric models was emphasized by the Cowles Commission in its path-breaking work on the estimation of simultaneous economic relationships. The class of models it considered is contained in the specification

$$\begin{aligned} \mathbf{B}(L)\mathbf{y}(t) + \Gamma(L)\mathbf{x}(t) &= \mathbf{u}(t); \\ \mathbf{A}(L)\mathbf{u}(t) &= \boldsymbol{\varepsilon}(t); \\ \mathrm{cov}[\boldsymbol{\varepsilon}(t), \mathbf{y}(t-s)] &= \mathbf{O}, s > 0; \\ \mathrm{cov}[\boldsymbol{\varepsilon}(t), \mathbf{x}(t-s)] &= \mathbf{O}, \text{all } s; \\ \boldsymbol{\varepsilon}(t) &\sim \mathbf{IIDN}\left(\mathbf{O}, \sum\right). \end{aligned}$$

The vectors **x**(t) and **y**(t) are observed, whereas **u**(t) and **ε**(t) are underlying disturbances not observed but affecting **y**(t). The lag operator L is defined by $L\mathbf{x}(t) = \mathbf{x}(t-1)$; the roots of $|\mathbf{B}(L)|$ and $|\mathbf{A}(L)|$ are assumed to have modulus greater than 1, a stability condition guaranteeing the non-explosive behaviour of **y** given any stable path for **x**. The Cowles Commission definition of exogeneity in this model (Koopmans and Hood 1953, pp. 117–20) as set forth in Christ (1966, p. 156) is as follows:

> An exogenous variable in a stochastic model is a variable whose value in each period is statistically independent of the values of all the random disturbances in the model in all periods.

All other variables are endogenous. In the prototypical model set forth above **x** is exogenous and **y** is endogenous.

The Cowles Commission distinction between endogeneity and exogeneity applied to a specific class of models, with linear relationships and normally distributed disturbances. The exogenous variables **x** in the prototypical model have two important but quite distinct properties. First, the model may be solved to yield an expression for y(t) in terms of current and past values of **x** and **ε**,

$$\mathbf{y}(t) = \mathbf{B}(L)^{-1}\mathbf{\Gamma}(L)\mathbf{x}(t) + \mathbf{B}(L)^{-1}\mathbf{A}(L)\varepsilon(t).$$

Given suitably restricted **x**(t) (for example, all **x** uniformly bounded, or being realizations of a stationary stochastic process with finite variance) it is natural to complete the model by specifying that it is valid for all **x** meeting the restrictions, and this is often done. The variables **x** are therefore exogenous here as **x** is exogenous in a deterministic economic model. A second, distinct property of these variables is that in estimation $\mathbf{x}(t)$ $(-\infty < t < \infty)$ may be regarded as fixed, thus extending to the environment of simultaneous equation models methods of statistical inference initially designed for experimental settings. It was generally recognized that exogeneity in the prototypical model was a sufficient but not a necessary condition to justify treating variables as fixed for purposes of inference. If **u**(t) in the model is serially independent (that is, $\mathbf{A}(L) = \mathbf{I}$) then lagged values of y may also be treated as fixed for purposes of the model; this leads to the definition of 'predetermined variables' (Christ 1966, p. 227) following Koopmans and Hood (1953, pp. 117–21):

> A variable is predetermined at time t if all its current and past values are independent of the vector of current disturbances in the model, and these disturbances are serially independent.

These two properties were not explicitly distinguished in the prototypical model (Koopmans 1950; Koopmans and Hood 1953) and tended to remain merged in the literature over the next quarter-century (for example, Christ 1966; Theil 1971; Geweke 1978). By the late 1970s there had developed a tension between the two, due to the increasing sophistication of estimation procedures in nonlinear models, treatment of rational expectations, and the explicit consideration of the respective dynamic properties of endogenous and exogenous variables (Sims 1972, 1977; Geweke 1982). Engle et al. (1983), drawing on this literature and discussions at the 1979 Warwick Summer Workshop, formalized the distinction of the two properties we have discussed. Drawing on their definitions 2.3 and 2.5 and the discussions in Sims (1977) and Geweke (1982), **x** is *model exogenous* if given $\{\mathbf{x}(t),\ t \le T\} \in \mathbf{R}(T)$ the model may restrict $\{\mathrm{y}(t),\ t \le T\}$, but given

$$\{\mathbf{x}(t),\ \ t \le T + J\} \in R(T + J)$$

there are no further restrictions on $\{\mathbf{y}(t),\ t \le \mathrm{T}\}$, for any $J > 0$. If the model in fact does restrict $\{\mathbf{y}(t),\ t \le T\}$, then **y** is model endogenous. As examples consider

Model 1:

$$y(t) = ay(t-1) + bx(t) + u(t),$$
$$x(t) = cx(t-1) + \upsilon(t);$$

Model 2:

$$y(t) = ay(t-1) + bx(t) + u(t),$$
$$x(t) = cx(t-1) + dy(t) + \upsilon(t);$$

Model 3:

$$y(t) = ay(t-1)$$
$$+b\{x(t) + E[x(t)|\, x(t-s), s > 0]\} + u(t),$$
$$x(t) = cx(t-1) + \upsilon(t).$$

In each case u(t) and v(t) are mutually and serially independent, and normally distributed. The parameters are assumed to satisfy the usual stability restrictions guaranteeing that x and y have normal distributions with finite variances. In all three models y is model endogenous, and x is model exogenous in Models 1 and 3 but not 2. For estimation the situation is different. In Model 1, treating x (t), $x(t-1)$ and y $(t-1)$ as fixed simplifies inference at no cost; $y(t-1)$ is a classic predetermined variable in the sense of Koopmans and Hood (1953) and Christ (1966). Similarly in Model 2, $x(t-1)$ and $y(t-1)$ may be regarded as fixed for purposes of inference despite the fact that x and y are both model endogenous. When Model 3 is reexpressed

$$y(t) = ay(t-1) + bx(t) + bcx(t-1) + u(t),$$
$$x(t) = cx(t-1) + \upsilon(t),$$

it is clear that $x(t)$ cannot be treated as fixed if the parameters are to be estimated efficiently since there are cross-equation restrictions involving the parameter c. Model exogeneity of a variable is thus neither a necessary nor a sufficient condition for treating that variable as fixed for purposes of inference.

The condition that a set of variables can be regarded as fixed for inference can be formalized, following Engleet al. (1983) along the lines given in Geweke (1984). Let

$$\mathbf{X} \equiv [\mathbf{x}(1), \ldots, \mathbf{x}(n)] \text{ and } \mathbf{Y} \equiv [\mathbf{y}(1), ..., \mathbf{y}(n)]$$

be matrices of n observations on the variables **x** and **y** respectively. Suppose the likelihood function $L(\mathbf{X}, \mathbf{Y}|\boldsymbol{\Theta})$ can be reparameterized by $\lambda = F(\boldsymbol{\Theta})$ where F is a one-to-one transformation; $\lambda' = (\lambda_1, \lambda_2)'$, $(\lambda_1, \lambda_2) \in \Lambda_1 X \Lambda_2$; and the investigator's loss function depends on parameters of interest λ_1 but not nuisance parameters λ_2. Then **x** is *weakly exogenous* if

$$L(\mathbf{X}, \mathbf{Y}|\, \lambda_1, \lambda_2) = L_1(\mathbf{Y}|\, \mathbf{X}, \lambda, \lambda_1) \cdot L_2(\mathbf{X}|\, \lambda_2),$$

and in this case *y* is *weakly endogenous.* When this condition is met the expected loss function may be expressed using only L_1 $(\mathbf{Y}|\ \mathbf{X},\ \lambda_1)$, that is, **x** may be regarded as fixed for purposes of inference.

The concepts of model exogeneity and weak exogeneity play important but distinct roles in the construction, estimation, and evaluation of econometric models. The dichotomy between variables that are model exogenous and model endogenous is a global property of a model, drawing in effect a logical distinction between the inputs of the model $\{x(t),\ t \leq T\} \in R(T)$ and the set of variables restricted by the model $\{\mathbf{y}(t),\ t \leq T\}$. Since model exogeneity stipulates that $\{\mathbf{x}(t), t \leq T + J\}$ places no more restrictions on $\{\mathbf{y}(t), t \leq T\}$ than does $\{\mathbf{x}(t), t \leq T\}$, the global property of model exogeneity is in principle testable, either in the presence or absence of other restrictions imposed by the model. When conducted in the absence of most other restrictions this test is often termed a 'causality test', and its use as a test of specification was introduced by Sims (1972). The distinction between weakly exogenous and weakly endogenous variables permits a simplification of the likelihood function that depends on the subset of the model's parameters that are of interest to the investigator. It is a logical property of the model: the same results would be obtained using $L(\mathbf{X}|\ \mathbf{Y}|\ \lambda_1,\lambda_2)$, as using $L(\mathbf{Y}|\ \mathbf{X},\ \lambda_1)$. The stipulation of weak exogeneity is therefore not, by itself, testable.

Endogenous and Exogenous Money

Meghnad Desai

The issue of endogeneity or exogeneity of money is one that runs through the history of monetary theory, with prominent authors appearing to hold views on either side. Narrowly put, those who plug for the exogeneity view take one or all among the cluster of variables – price level, interest rate or real output – as being determined by movements in the stock of money. Those who

hold the endogeneity view consider that the stock of money in circulation is determined by one or all of the variables mentioned above. This narrow definition begs several questions. The variables price level (P), interest rate (R), real output (Y) and money stock (M) are all at the macroeconomic level, i.e. in the context of a one-good economy. Some part of the continuing debate can be traced to the view held by various participants in the controversy about whether such a high level of aggregation is appropriate, e.g. is there a rate of interest? Another part of the debate refers to the choice of money stock variable. Is it commodity money (gold), fiat (paper) money, bank deposits or a larger measure of liquidity that is to stand for *the* money stock? The problem can be dealt with even at a one-good level either in the context of a closed economy or an open economy and either in an equilibrium or a disequilibrium context, static or dynamic, short run or long run. The basic issue is about the direction of causality-money to other variables or other variables to money. But as our understanding of the underlying statistical theory concerning causality and exogeneity has advanced in recent years, it must also be added that participants in the controversy conflate the exogeneity of a variable (especially of money) with its *controllability* by policy. Strictly speaking one can have exogeneity without any presumption that the variable can be manipulated by policy, for example rainfall. Also once posed in a dynamic context, we should distinguish between weak exogeneity, which allows for feedback from the endogenous to the exogenous variables over time, and strong exogeneity, which does not allow such a feedback (Hendry et al. 1983). Endogeneity or exogeneity are notions that only make sense in the context of a model. Frequently in the past, there has been a failure to specify such a model, which has then allowed the controversy to continue.

Some Definitions

To simplify matters, at the risk of putting off readers, let us begin by specifying a small model within whose context endogeneity and exogeneity can be defined. This macroeconomic model will consist of four variables P, Y, R and M whose exogenous/endogenous status is at debate. We subdivide them into the three non-monetary variables P, Y, R labelled X and money M. There are of course other truly exogneous variables – tastes, technology, international variables – which we label Z. Now we observe that the variables X and M are correlated, i.e. jointly distributed conditional upon the set of variables Z. The question of endogeneity or exogeneity of money is as to whether the correlation between X and M can be written in terms of X being a function of M and Z, or M being a function of X and Z. In econometric terms, can we partition the joint distribution of X and M into a *conditional* distribution of X on M, Z and a marginal distribution of M on Z (the exogenous money case) or a conditional distribution of M on X and Z and a marginal distribution of X on Z. Thus when we say money is exogenous it is exogenous with respect to X variables but it could still be determined by Z variables; symmetrically for the X variables being exogenous. If M is influenced by the past values of X as well as by Z though not by the current values of X, then M is said to be weakly exogenous. Thus M may be controlled by monetary authorities but they may be reacting to past behaviour of X variables. Then M is determined by a reaction function and is only weakly exogenous. The same definition of weak exogeneity extends to the Z variables. Thus even international variables, such as capital inflow, may be determined by past values of X variables in which case they are weakly exogenous (for further detail, see Desai 1981). The best way to consider the issue of exogeneity of money is to specify the type of money economy envisaged – commodity money, paper money, credit money and look at the variables likely to influence the supply of money and its relation with other variables.

Commodity Money

Historically the argument about exogeneity is constructed around the Quantity Theory of Money, which stated that the amount of money in circulation at any time determined the volume

of trade and if the amount went on increasing it would lead sooner or later to an increase in price. In the context of commodity money, the proposition concerned attempts by coining authorities to debase coinage by clipping or alloying it with inferior metal. These were ways in which the amount of money could be altered by policy manipulation and then exogenously act upon prices. But in a commodity money regime, the stock of money could also be altered by influx of precious metal through gold discoveries and greater influx. These were exogenous variations not susceptible to policy manipulation but presumed an open economy. The first statement of the quantity theory of money by David Hume starts with an illustration of an influx of gold from outside and traces its effects first on real economic activity and eventually on prices. In Hume's quantity theory, money is exogenous but not subject to policy manipulation. The opposite view (argued by James Steuart for instance) was that it was the volume of activity that elicited the matching supply of money. This could be done partly by dis-hoarding on the parts of those who now expected a better yield on their stock. It could also be altered if banks were willing to 'accommodate' a larger volume of bills (see Desai 1981). Dis-hoarding implies that a portion of the money supply in *circulation* is endogenously determined in a commodity money economy. It could be argued that even the influx of gold could have been caused by the discrepancy between the domestic and the world gold price, which in the 18th century before a world gold market existed could be substantial. In the latter case money would be weakly exogenous as long as there were lags between the appearance of discrepancy and the inflow of gold.

Inside Money

Once however one introduces banks into the scheme of things, the issue of exogeneity becomes complex. Till very recently we have lacked a theory of banking behaviour of any degree of sophistication, although in terms of institutional description we have much knowledge. If banks are willing to 'accommodate' a greater volume of trade, this can only be because they find it profitable to do so. This increased profitability may be actual or perceived but it must be a result of an increase in differential between the interest (discount) rate borrowers are willing to pay and the rate at which banks can acquire liquidity. Banks can then choose to expand the ratio of credit to the cash base and sustain a higher volume. Banks create inside money and inside money can only be regarded as endogenous. But the extent to which a single bank can create money will depend on the behaviour of the *banking system*. The banking system can by the cloakroom mechanism choose any ratio of credit to cash base. It is conceivable though not likely that in such a system of inside money, banks could arbitrarily, i.e. exogenously, increase money supply. They must however base such an action on considerations of expected profitability. We can envisage a situation in which banks guided by 'false' expectations can sustain a credit boom by a bootstraps mechanism. This is the way in which a Wicksellian cumulative process could sustain itself. An arbitrary, exogenous increase in inside money by the banking system though possible is not very likely. It runs into the problems caused by the leakage of cash either internally (finite limits to the velocity of circulation of cash) or abroad. It was the international leakage that was normally regarded as the most likely constraint since it caused outflow of gold – the International Gold Standard which provided the context for 19th-century theories in this imposed exogenous constraints on money supply by imposing a uniform gold price in all countries. In such a case, money is exogenous and not subject to policy manipulation. In as much as gold movements are triggered by internal variables, it is weakly exogenous.

Outside Fiat Money

It is the case of fiat money printed as the state's liability, i.e. as outside money, that provides the best illustration of exogenous money not subject to any constraint. In a world where only paper

currency was used and it was printed by the monetary authorities, the stock of money could be exogenously determined. This would be additionally so even if there was inside money as long as the monetary authorities could insist that banks obeyed a strict cash to deposit ratio and there were no substitutes for cash available beyond the control of the monetary authorities. It is this view of money that most closely corresponds to Keynes's assumptions in the *General Theory* and it is also in the monetarist theory of Milton Friedman. The banking system is a passive agent in this view and given the cash base is always fully loaned up. Thus given the amount of high powered money in the system providable only by the monetary authorities, the supply of money is determined. Even if the stock of money were exogenous, its impact on the non-monetary variables X can be variable. This is because the velocity of circulation which translates the stock of money into money in circulation need not be constant but variable. If the velocity of circulation were not only a variable but also a function of the X variables, then although the monetary authorities can determine the stock of money the influence of money on real variables is not as predicted by the Quantity Theory. Thus it is not the exogeneity of money issue that divides monetarists and Keynesians but the determinants of the velocity of circulation. For the monetarist, the velocity of circulation ($M/P \cdot Y$) has to be independent of P, Y, R and M. For Keynesians, the demand for money depends on the rate of interest crucially and the interest elasticity of demand for money is a variable tending to infinity in a liquidity trap.

Modern Credit Economy

In a world with inside and outside money with a sophisticated banking system as well as a non-banking financial sector, the question of exogeneity is the most complex. In the previous case of outside fiat money we assumed, that the cash ratio was fixed and adhered to by banks. It is when the banks' reserve base contains government debt instruments – treasury bills, bonds, etc. – that the profit-maximizing behaviour of the banks renders a greater part of the money stock endogenous. Thus while the narrow money base – currency in circulation and in central bank reserves – can be regulated by the monetary authority, the connection between money base and total liquidity in the economy becomes highly variable. Banks will expand their loan portfolio as long as the cost of replenishing their liquidity does not exceed the interest rate they can earn on loans. The relation between broad money (M_3) and narrow money (M_0) becomes a function of the funding policy concerning the budget deficit and the structure of interest rates. Thus the stock of narrow money can be exogenous and policy determined. But the stock of broad money is endogenous. A crucial recent element has been the financial revolution of the last decade (De Cecco 1987). A variety of financial instruments – credit cards, charge cards, money market funds, interest-bearing demand deposits, electronic cash transfer – has made the ratio of cash to volume of financial transactions variable though with a steep downward trend. It has also increased the number of money substitutes and made the cost of liquidity lower. The non-banking financial system thus can create liquidity by 'accommodating' a larger volume of business, advancing trade credit, allowing consumer debt to increase etc. The velocity of circulation of cash increases very sharply in such a world and liquidity, a broader concept than even broad money, becomes endogenous. Here again profitability of liquidity creation becomes the determining variable. But the financial revolution has also integrated world financial markets and economies are increasingly open. Thus capital flows are rapid and respond to minute discrepancies in the covered interest parity. In such a world money is at best weakly exogenous but more usually endogenous. The issue of exogeneity or endogeneity of money thus crucially depends on the type of money economy that one is considering – commodity money, paper money, credit (mobile) money. It also depends on the sophistication of the banking and financial system within which such money is issued. Debates over the last two hundred years have used the word money to cover a variety of situations. It has also not been clarified whether the issue is exogeneity

of money or its controllability and whether it is merely the stock of money or its velocity as well which is being considered. Once these issues have been clarified, the notion of exogeneity needs to be defined in the modern econometric fashion, relative to a model in order to decide whether money can be exogenous. It seems likely that the narrower the definition of money stock, the more likely is it to fulfil the requirement of (weak) exogeneity. Such exogeneity is necessary but not sufficient to demonstrate that money determines the price level or the real economy.

Endogenous Growth Theory

Peter Howitt

Abstract

Endogenous growth theory explains long-run growth as emanating from economic activities that create new technological knowledge. This article sketches the outlines of the theory, especially the 'Schumpeterian' variety, and briefly describes how the theory has evolved in response to empirical discoveries.

Keywords

Endogenous growth is long-run economic growth at a rate determined by forces that are internal to the economic system, particularly those forces governing the opportunities and incentives to create technological knowledge.

In the long run the rate of economic growth, as measured by the growth rate of output per person, depends on the growth rate of total factor productivity (TFP), which is determined in turn by the rate of technological progress. The neoclassical growth theory of Solow (1956) and Swan (1956) assumes the rate of technological progress to be determined by a scientific process that is separate from, and independent of, economic forces. Neoclassical theory thus implies that economists can take the long-run growth rate as given exogenously from outside the economic system.

Endogenous growth theory challenges this neoclassical view by proposing channels through which the rate of technological progress, and hence the long-run rate of economic growth, can be influenced by economic factors. It starts from the observation that technological progress takes place through innovations, in the form of new products, processes and markets, many of which are the result of economic activities. For example, because firms learn from experience how to produce more efficiently, a higher pace of economic

activity can raise the pace of process innovation by giving firms more production experience. Also, because many innovations result from R&D expenditures undertaken by profit-seeking firms, economic policies with respect to trade, competition, education, taxes and intellectual property can influence the rate of innovation by affecting the private costs and benefits of doing R&D.

AK Theory

The first version of endogenous growth theory was AK theory, which did not make an explicit distinction between capital accumulation and technological progress. In effect it lumped together the physical and human capital whose accumulation is studied by neoclassical theory with the intellectual capital that is accumulated when innovations occur. An early version of AK theory was produced by Frankel (1962), who argued that the aggregate production function can exhibit a constant or even increasing marginal product of capital. This is because, when firms accumulate more capital, some of that increased capital will be the intellectual capital that creates technological progress, and this technological progress will offset the tendency for the marginal product of capital to diminish.

In the special case where the marginal product of capital is exactly constant, aggregate output Y is proportional to the aggregate stock of capital K:

$$Y = AK \tag{1}$$

where A is a positive constant. Hence the term 'AK theory'.

According to AK theory, an economy's long-run growth rate depends on its saving rate. For example, if a fixed fraction s of output is saved and there is a fixed rate of depreciation δ, the rate of aggregate net investment is:

$$\frac{dK}{dt} = sY - \delta K$$

which along with (1) implies that the growth rate is given by:

$$g \equiv \frac{1}{Y}\frac{dY}{dt} = \frac{1}{K}\frac{dK}{dt} = sA - \delta.$$

Hence an increase in the saving rate s will lead to a permanently higher growth rate.

Romer (1986) produced a similar analysis with a more general production structure, under the assumption that saving is generated by intertemporal utility maximization instead of the fixed saving rate of Frankel. Lucas (1988) also produced a similar analysis focusing on human capital rather than physical capital; following Uzawa (1965) he explicitly assumed that human capital and technological knowledge were one and the same.

Innovation-Based Theory

AK theory was followed by a second wave of endogenous growth theory, generally known as 'innovation-based' growth theory, which recognizes that intellectual capital, the source of technological progress, is distinct from physical and human capital. Physical and human capital are accumulated through saving and schooling, but intellectual capital grows through innovation.

One version of innovation-based theory was initiated by Romer (1990), who assumed that aggregate productivity is an increasing function of the degree of product variety. In this theory, innovation causes productivity growth by creating new, but not necessarily improved, varieties of products. It makes use of the Dixit–Stiglitz–Ethier production function, in which final output is produced by labour and a continuum of intermediate products:

$$Y = L^{1-\alpha}\int_0^A x(i)^{\alpha}\,di, 0 < \alpha < 1 \tag{2}$$

where L is the aggregate supply of labour (assumed to be constant), $x(i)$ is the flow input of intermediate product i, and A is the measure of different intermediate products that are available for use. Intuitively, an increase in product variety, as measured by A, raises productivity by allowing society to spread its intermediate production more thinly across a larger number of activities, each of

which is subject to diminishing returns and hence exhibits a higher average product when operated at a lower intensity.

The other version of innovation-based growth theory is the 'Schumpeterian' theory developed by Aghion and Howitt (1992) and Grossman and Helpman (1991). (Early models were produced by Segerstrom et al. 1990 and Corriveau 1991). Schumpeterian theory focuses on quality-improving innovations that render old products obsolete, through the process that Schumpeter (1942) called 'creative destruction.'

In Schumpeterian theory aggregate output is again produced by a continuum of intermediate products, this time according to:

$$Y = L^{1-\alpha} \int_0^1 A(i)^{1-\alpha} x(i)^{\alpha} di, \tag{3}$$

where now there is a fixed measure of product variety, normalized to unity, and each intermediate product i has a separate productivity parameter $A(i)$. Each sector is monopolized and produces its intermediate product with a constant marginal cost of unity. The monopolist in sector i faces a demand curve given by the marginal product: $\alpha \cdot (A(i)L/x(i))^{1-\alpha}$ of that intermediate input in the final sector. Equating marginal revenue (α time this marginal product) to the marginal cost of unity yields the monopolist's profit-maximizing intermediate output:

$$x(i) = \xi L A(i)$$

where $\xi = \alpha^{2/(1-\alpha)}$. Using this to substitute for each $x(i)$ in the production function (3) yields the aggregate production function:

$$Y = \theta A L \tag{4}$$

where $\theta = \xi^{\alpha}$, and where A is the average productivity parameter:

$$A \equiv \int_0^1 A(i)\, di.$$

Innovations in Schumpeterian theory create improved versions of old products. An innovation in sector i consists of a new version whose productivity parameter A exceeds that of the previous version by the fixed factor $\gamma > 1$. Suppose that the probability of an innovation arriving in sector i over any short interval of length dt is $\mu \cdot dt$. Then the growth rate of $A(i)$ is

$$\frac{dA(i)}{A(i)} \cdot \frac{1}{dt} = \left\{ \begin{array}{ll} (\gamma - 1) \cdot \dfrac{1}{dt} & \text{with probability } \mu \cdot dt \\ 0 & \text{with probability } 1 - \mu \cdot dt \end{array} \right\}.$$

Therefore the expected growth rate of $A(i)$ is:

$$E(g) = \mu(\gamma - 1). \tag{5}$$

The flow probability μ of an innovation in any sector is proportional to the current flow of productivity-adjusted R&D expenditures:

$$\mu = \lambda R/A \tag{6}$$

where R is the amount of final output spent on R&D, and where the division by A takes into account the force of increasing complexity. That is, as technology advances it becomes more complex, and hence society must make an ever-increasing expenditure on research and development just to keep innovating at the same rate as before.

It follows from (4) that the growth rate g of aggregate output is the growth rate of the average productivity parameter A. The law of large numbers guarantees that g equals the expected growth rate (5) of each individual productivity parameter. From this and (6) we have:

$$g = (\gamma - 1)\lambda R/A.$$

From this and (4) it follows that the growth rate depends on the fraction of GDP spent on research and development, $n = R/Y$, according to:

$$g = (\gamma - 1)\lambda \theta L n. \tag{7}$$

Thus, innovation-based theory implies that the way to grow rapidly is not to save a large fraction

of output but to devote a large fraction of output to research and development. The theory is explicit about how R&D activities are influenced by various policies, who gains from technological progress, who loses, how the gains and losses depend on social arrangements, and how such arrangements affect society's willingness and ability to create and cope with technological change, the ultimate source of economic growth.

Empirical Challenges

Endogenous growth theory has been challenged on empirical grounds, but its proponents have replied with modifications of the theory that make it consistent with the critics' evidence. For example, Mankiw et al. (1992), Barro and Sala-i-Martin (1992) and Evans (1996) showed, using data from the second half of the 20th century, that most countries seem to be converging to roughly similar long-run growth rates, whereas endogenous growth theory seems to imply that, because many countries have different policies and institutions, they should have different long-run growth rates. But the Schumpeterian model of Howitt (2000), which incorporates the force of technology transfer, whereby the productivity of R&D in one country is enhanced by innovations in other countries, implies that all countries that perform R&D at a positive level should converge to parallel long-run growth paths.

The key to this convergence result is what Gerschenkron (1952) called the 'advantage of backwardness'; that is, the further a country falls behind the technology frontier, the larger is the average size of innovations, because the larger is the gap between the frontier ideas incorporated in the country's innovations and the ideas incorporated in the old technologies being replaced by innovations. This increase in the size of innovations keeps raising the laggard country's growth rate until the gap separating it from the frontier finally stabilizes.

Likewise, Jones (1995) has argued that the evidence of the United States and other OECD countries since 1950 refutes the 'scale effect' of Schumpeterian endogenous growth theory. That is, according to the growth Eq. 7 an increase in the size of population should raise long-run growth by increasing the size of the workforce L, thus providing a larger market for a successful innovator and inducing a higher rate of innovation. But in fact productivity growth has remained stationary during a period when population, and in particular the number of people engaged in R&D, has risen dramatically. The models of Dinopoulos and Thompson (1998), Peretto (1998) and Howitt (1999) counter this criticism by incorporating Young's (1998) insight that, as an economy grows, proliferation of product varieties reduces the effectiveness of R&D aimed at quality improvement by causing it to be spread more thinly over a larger number of different sectors. When modified this way the theory is consistent with the observed coexistence of stationary TFP growth and rising population, because in a steady state the growth-enhancing scale effect is just offset by the growth-reducing effect of product proliferation.

As a final example, early versions of innovation-based growth theory implied, counter to much evidence, that growth would be adversely affected by stronger competition laws, which by reducing the profits that imperfectly competitive firms can earn ought to reduce the incentive to innovate. However, Aghion and Howitt (1998, ch. 7) describe a variety of channels through which competition might in fact spur economic growth. One such channel is provided by the work of Aghion et al. (2001), who show that, although an increase in the intensity of competition will tend to reduce the absolute level of profits realized by a successful innovator, it will nevertheless tend to reduce the profits of an unsuccessful innovator by even more. In this variant of Schumpeterian theory, more intense competition can have a positive effect on the rate of innovation because firms will want to escape the competition that they would face if they lost whatever technological advantage they have over their rivals.

Much more work needs to be done before we can claim to have a reliable explanation for why economic growth is faster in some countries and in some time periods than in others. But the fact that much of the cross-country variation in growth rates

is attributable to differences in productivity growth rather than differences in rates of capital accumulation suggests that endogenous growth theory, which aims to provide an economic explanation of these differences in productivity growth, will continue to attract economists' attention for years to come.

Endogenous Market Incompleteness

Christopher Sleet

Abstract

Endogenously incomplete models derive restrictions on asset trading from primitive constraints on the enforcement and monitoring technologies available to societies. They have been applied to a wide variety of macroeconomic problems. This article reviews some of these applications and the models that underpin them.

Keywords

Asset pricing models; Autarky; Bilateral insurance games; Commitment; Default; Dynamic moral hazard models; Endogenously incomplete markets; Equity premium; Euler equations; Incomplete markets; Information revelation; Limited enforcement models; Risk sharing; Taxation of assets

JEL Classifications

D4; D10

An asset trading arrangement is incomplete if it is too restrictive to ensure a fully Pareto-optimal allocation of risk. Endogenously incomplete models derive such trading arrangements from primitive frictions. They are to be contrasted with models that *assume* a particular incomplete asset markets structure.

Recent contributions to the endogenous incompleteness literature have emphasized imperfections in the enforcement and monitoring technologies available to societies. They derive endogenous market structures, sometimes supplemented with a tax system, as decentralizations of planning problems in which the planner faces one or both of these imperfections. These market-tax structures ensure that agents are provided with incentives to honour promises that cannot be costlessly enforced or that are contingent on states that cannot be costlessly observed. By construction they admit equilibria that are constrained efficient.

Models with endogenous incompleteness have received a variety of applications in macroeconomics. They have been used to enhance understanding of risk sharing, asset pricing and business cycles; on the normative side they have been applied to analyses of optimal fiscal policy. Here I review some of these applications and the models that underpin them.

Limited Enforcement

The canonical example of a limited enforcement model is the bilateral insurance game of Kocherlakota (1996). In this game, two risk-averse agents are endowed with random and imperfectly correlated income processes. Neither agent can be compelled to deliver resources to the other, even if they have promised to do so in the past.

Equilibrium allocations in this setting can be implemented with strategies that revert to autarky following an agent defection. Agents with high-income shocks can be induced to share some of their resources by the threat of such reversion and, when this is insufficient, by promises of extra resources in the future. Such promises introduce additional dynamics into optimal equilibrium allocations; shocks that cannot be smoothed over states are smoothed over time instead, ensuring that individual consumption is persistent even when aggregate consumption is not.

Constrained-efficient allocations in limited enforcement economies can be decentralized using a complete set of Arrow security markets coupled with endogenous debt limits (see Alvarez and Jermann 2000). Intuitively, agents can borrow only up to the amount that they are willing to pay back in the future given that the penalty for default is consignment to autarky. Thus, the limited enforcement friction provides a micro-foundation for the often-made assumption of a debt limit tighter than that implied by an agent's intertemporal budget constraint. In the limited enforcement case, however, the debt limit is state-contingent; it depends upon the value of autarky to the agent. Since this value is a function of individual and aggregate shocks, the parameters of the shock process and, in richer models, the agent's opportunities for self- or public insurance after exclusion from markets, so too is the debt limit.

When agents' endogenous debt limits periodically bind, risk sharing is disrupted; individual consumption, conditional on the aggregate state, is positively correlated with current and past individual income. Qualitatively, such departures from full risk-sharing cohere well with evidence on individual consumption. In Alvarez and Jermann's (2001) quantitative analysis of a calibrated limited enforcement model, the endogenous debt limits bind fairly often and permit relatively little risk sharing. This is consistent with evidence on the sharing of low- frequency risks. Alvarez and Jermann's analysis also has implications for asset pricing. They obtain a volatile asset pricing kernel and risk premia that are large and time varying. These implications are consistent with asset pricing data, but contrast with those of the benchmark representative agent asset pricing model.

Cross-country consumption data also exhibit apparent departures from full risk sharing. Standard models (with complete markets) imply co-movements in consumption that exceed those in output, yet the data suggests the reverse. Kehoe

and Perri (2002) show that a limited enforcement model augmented with production and physical capital accumulation can go some way to explaining this anomaly.

Recent papers have considered alternative penalties for default including the confiscation of an endogenously valued collateral asset (see, Lustig 2005) or the payment of a fixed default cost (Cooley et al. 2004). These contributions illustrate the scope of limited enforcement models: Lustig explores the implications of endogenously valued collateral for asset pricing and obtains a large and time-varying price of risk; Cooley, Marimon and Quadrini examine the role of limited enforcement frictions in propagating business cycle shocks. Cordoba (2005) and Arpad and Cárceles-Poveda (2005), however, sound cautionary notes. They provide calibrated models in which the introduction of collateral relaxes endogenous debt limits so much that agents can fully diversify risk.

Private Information

An alternative line of research has analysed environments in which risk-averse agents privately observe shocks to their endowments, tastes or productivity (see, for example, Atkeson and Lucas 1992). In this setting, agents must be provided with incentives to reveal information. The socially efficient provision of incentives requires the conditioning of current consumption on an agent's history of shock reports. Intuitively, agents are rewarded for reporting a low current need for resources with the promise of more consumption in the future. Thus, intertemporal consumption smoothing is enhanced and interstate smoothing disrupted.

Albanesi and Sleet (2006) and Kocherlakota (2005) show that optimal information-constrained allocations can be implemented with a mixture of non-contingent debt markets and taxes. Thus, these authors derive joint restrictions on the market structure *and* the tax system from primitive informational frictions. Central to their analyses is an 'inverted Euler equation'. If $\{c_t^*\}_{t=0}^{\infty}$ denotes the optimal consumption allocation, this equation is given by:

$$\frac{1}{u'\left(c_t^*(z^t,\theta^t)\right)} = \beta\lambda_{t+1}(z^{t+1})E_t\left[\frac{1}{u'\left(c_{t+1}^*\right)}|z^{t+1},\theta^t\right]. \tag{1}$$

Here θ^t denotes an agent's period t history of privately observed shocks, z and z^{t+1} denote t and $t+1$ histories of observable aggregate shocks, β is the agent's discount factor and u' her marginal utility of consumption. λ_{t+1} is a social stochastic discount factor (SSDF) that 'prices' resources delivered after each history z^{t+1}. Golosov et al. (2003) show that such equations hold in a large class of dynamic moral hazard models. They imply a wedge between an agent's conditional expected intertemporal marginal rate of substitution (IMRS) and the SSDF. This wedge provides a rationale for asset taxation; intuitively, agents must be discouraged from saving at date t since greater wealth at $t+1$ undermines incentives at that date. However, the implications for asset taxation are subtle. The optimal allocation cannot be implemented with an asset tax that merely 'matches the wedge' and equates the conditional expectation of an agent's IMRS to the SSDF. Instead, marginal asset taxes at $t+1$ are used to generate a positive covariance between the after-tax asset return and the agent's consumption that deters savings. In some cases, the expected asset tax is zero and the wedge is entirely generated by this covariance effect.

Positive analyses of dynamic moral hazard are relatively scarce. Green and Oh (1991) contrast the empirical implications of various incomplete market models, including those with moral hazard. Kocherlakota and Pistaferri (2005) identify λ_{t+1} with the market discount factor, assume that utility has the constant relative risk aversion property and use (1) to derive expressions for λ_{t+1} in terms of cross-sectional moments of the consumption distribution. They then investigate the implications of this dynamic moral hazard model for asset pricing and, in particular, the equity premium and risk-free rate. They find that plausible

values of the coefficient of relative risk aversion set the equity premium pricing error to zero.

In all of the dynamic moral hazard models described so far, the consumption of agents is observable. An alternative assumption is that agents can undertake asset trades that are hidden from society. Agents must now be given incentives to reveal information *and* save an appropriate amount. This places additional constraints on risk sharing. When agents can control their publicly observable histories and can save at the prices implied by an exogenously given sequence of SSDFs, these constraints are severe. In this case, the optimal allocation is identical to that in an economy with riskless debt (see Cole and Kocherlakota 2001). This result is important as it provides a micro-foundation for models that exogenously restrict agents to the trading of such debt.

Government Incentive Problems

Governments or mechanism designers may also have difficulty keeping their promises. There is a long tradition of considering commitment problems in Ramsey models. In these, a socially benevolent government typically has access to a restricted set of linear tax mechanisms and an asset market in which it can trade claims to resources. *Ex ante* optimal policy entails implicit promises over future allocations and, in particular, the expected value of the government's future stream of primary surpluses that it is rarely in the government's interests to keep. For example, if the government can default on its debt it will, since in this way it can avoid the distortionary taxes necessary for debt repayment. As in the limited-enforcement models described above, reversion to autarky after a default can sustain some equilibrium borrowing by the government, though typically it implies a tight endogenous debt limit (Chari and Kehoe 1993). Sleet (2004) and Sleet and Yeltekin (2006a) consider models in which the government's true spending needs are not publicly observable. Although the government has access to a complete set of contingent claims markets, in equilibrium it is required to adopt a debt-trading policy consistent with truthful revelation of its spending needs. This limits its ability to buy claims against high spending-needs states and sell them against low spending-needs ones. The outcome is enhanced intertemporal, as opposed to inter-state, smoothing of taxes.

The optimal allocations and market-tax implementations implied by dynamic moral hazard models also involve promises from a planner (or government) to an agent. These allocations often entail the absorption of almost all agents by a minimal utility immiserating state; they thus place strong demands on the planner's ability to commit. Sleet and Yeltekin (2006b) remove this ability. They show that optimal allocations without planner commitment solve the problems of *committed* planners who discount the future *less heavily* than agents. Coupling this result with the work of Farhi and Werning (2005), who directly assume a planner discount factor in excess of the agents, suggests that constrained optimal allocations can be implemented with non-contingent debt, an income tax and a progressive estate tax. Analysis of dynamic moral hazard models without societal commitment is, however, still in its infancy and much remains to be done.

Energy Economics

Robin Sickles and Hillard G. Huntington

Abstract

Energy economics studies energy resources and energy commodities. It includes forces motivating firms and consumers to supply, convert, transport, use energy resource; market and regulatory structures; distributional and environmental consequences; economically efficient use. The fact that energy use is dominantly depletable resources, particularly fossil fuels, makes this study unique. The energy industry has moved into the 21st century with promises of both profits and a short-term future. With added pressure from government, cleaner fuels are being introduced on a continual basis. Additionally, the expanding energy demand from developing countries is changing the energy market.

Energy is crucial to the economic progress and social development of nations.

Energy can be neither created nor destroyed but its form can be changed. Energy comes from the physical environment and ultimately returns there. The demand for energy is a derived demand. The value of energy is assessed by its ability to provide a set of desired services in both industry and in the household.

Energy commodities are economic substitutes. Energy resources are depletable or renewable and storable or non-storable. On a global scale the 20th century was dominated by the use of fossil fuels. According to the US Department of Energy, in the year 2000 global commercial energy consumption consisted of petroleum (39 per cent), coal (24 per cent), natural gas (23 per cent), hydro (6 per cent), nuclear (7 per cent) and others (1 per cent). In 1999, of the total sources of energy

consumed in the United States, 92 per cent were from depletable resources and only 8 per cent from renewable resources (EIA 2001). No one doubts that fossil fuels are subject to depletion, and that depletion leads to scarcity, which in turn leads to higher prices. Resources are defined as 'non-conventional' when they cannot be produced economically at today's prices and with today's technology. With higher prices, however, the gap between conventional and non-conventional oil resources narrows. Ultimately, a combination of escalating prices and technological enhancements can transform the non-conventional into the conventional. Much of the pessimism about oil resources has been focused entirely on conventional resources.

Demand for Energy

Bohi and Toman (1996) suggest a link between energy and economy. An abundance of empirical research suggests a strong correlation between increases in oil prices and decreases in macroeconomic performance for oil-importing industrialized countries. Higher import costs may lead to higher price levels and inflation.

Industrial energy demand increases most rapidly at the initial stages of development, but growth slows steadily throughout the industrialization process (Medlock and Soligo 2001). Energy demand for transportation rises steadily, and takes the major share of total energy use at the latter stages of developments.

Elasticity of Energy Demand

Is energy an essential good? In economics, an essential good is one for which the demand remains positive no matter how high its price. Energy is often described as an essential good because human activity would be impossible absent use of energy. Although energy is essential to humans, neither particular energy commodities nor any purchased energy commodities are essential goods because consumers can convert one form of energy into another.

The income elasticity of energy demand is defined as the percentage change in energy demand given a one per cent change in income holding all else constant, or

$$\varepsilon_y = \frac{\%\Delta e}{\%\Delta y} = \frac{de}{dy} \cdot \frac{y}{e}$$

where e denotes energy demand and y denotes income. 'The household sector's share of aggregate energy consumption tends to fall with income, the share of transportation tends to rise, and the share of industry follows an inverse-U pattern' (Judson et al. 1999).

The price elasticity of energy demand is defined as the percentage change in energy demand given a one per cent change in price, with all else held constant, or

$$\varepsilon_p = \frac{\%\Delta e}{\%\Delta p} = \frac{de}{dp} \cdot \frac{p}{e}$$

where p denotes the price of energy.

Cooper (2003) uses a multiple regression model derived from an adaptation of Nerlove's (1958) partial adjustment model to estimate both the short-run and the long-run elasticity of demand for crude oil in 23 countries over a 30-year period from 1971 to 2000. The estimates so obtained confirm that the demand for crude oil internationally is highly insensitive to changes in price.

Demand Substitution Between Energy Commodities and Others

Denny et al. (1981) used time-series data for 18 US manufacturing two-digit industries (1948–1971) and 18 Canadian manufacturing industry groups (1962–1975). Their results were also mixed: for both the United States and Canada, energy and capital were substitutes in the food industry, but they were complements in the tobacco industry.

Energy consumption can be modelled either as providing utility to households or as an input in the production process for firms. To express the former problem mathematically, a representative consumer maximizes utility, $U(z,e)$, which is function of energy consumption, e, and all other

consumption, z, subject to the constraint that expenditures cannot exceed income, y. Let the energy variable be a vector of n energy products, $e = (e_1, e_2, \ldots, e_n)$; we could examine the substitution possibilities across energy products. Allowing the price of good j to be represented as pj, the consumer is assumed to

$$\max_{z, e_1, \ldots e_n} U(z, e_1, \ldots e_n)$$

$$\text{subject to} : y \geq p_z Z + p_{e_1} e_1 + \ldots + p_{e_n} e_n.$$

The first order necessary conditions for a maximum for this problem can be solved to yield demand equations for each of the energy products and for all other consumption. With some adjustments, the above method can be applied to a representative firm.

Recent research focuses mainly on dynamic models. Dynamic models allow for a more complete analysis of the energy demand because they are capable of capturing factors that generate the asymmetries. In addition, dynamic models incorporate the intertemporal choices that a consumer/firm must make when maximizing utilities or profits over some time horizon. Medlock and Soligo (2002) developed a useful framework. Let z_t be multiple types of capital and e_t be multiple types of energy consumption. Denoting time using the subscript t, the consumer will maximize the discounted sum of lifetime utility, $\sum_{t=0}^{T} \beta^t U(z_t, e_t)$, subject to the constraint whereby capital goods purchases (i_t), purchases of other goods (z_t), purchases of energy (e_t), and savings (s_t) in each period cannot exceed this period's income (y_t), plus the return of last period's saving $((1 + r)s_{t-1})$. It is assumed that capital goods depreciate at a rate δ, savings earn a rate return r, the discount rate is $0 < \beta < 1$, and all initial conditions are given.

Consumers will

$$\max_{z, e, s} \sum_{t=0}^{T} \beta^t U(z_t, e_t)$$

$$\text{subject to } p_{zt} z_t + p_{et} e_t + p_{kt} i_t + s_t \leq y_t + (1 + r) s_{t-1}$$

$$i_t = k_t - (1 - \delta) k_{t-1}$$
