C

Cadillac Tax: An Offset to the Tax Subsidy for Employer-Sponsored Health Insurance

Jane G. Gravelle
Congressional Research Service, Washington, DC, USA

Abstract

This entry will discuss the Cadillac tax imposed on high-cost employer health insurance (in excess of a dollar floor), its objectives as part of the Affordable Care Act (health reform) in 2010, and its subsequent modification in 2015. The history of the Act suggests that it was an alternative to limiting the exclusion of health insurance compensation from payroll and income taxes of employees to a dollar cap. The objective of the tax, in addition to providing financing for health reform, was to discourage the provision of high-cost insurance coverage and reduce health care spending. These effects, in turn, depend on the magnitude of the tax, the scope of coverage over time (which is expected to increase) and how the tax compares to the value of the exclusion of the benefits to employees from income tax and payroll taxes. Although the tax is imposed on insurers, its burden is expected to be passed on to labor income. Taxes will rise whether firms keep the high-cost insurance (and pay tax directly) or reduce insurance coverage and substitute taxable wages. The tax, currently imposed at 40%, is imposed on a tax-exclusive basis (as a percentage of the cost before taxes) while tax rates on employee wages are imposed on a tax-inclusive basis (as a percentage of cost inclusive of wages). For some employees the tax burden is smaller if the Cadillac tax is retained, while for others it is better to reduce insurance coverage. Those instances in which retaining the Cadillac tax is better have increased with the provision making the tax deductible from income tax, adopted in 2015. Only in circumstances where coverage is reduced will potential reductions in health care spending and efficiency gains from reductions in moral hazard be realized.

The Cadillac tax is a US excise tax on high-cost employer-provided or union-provided health insurance plans that imposes a tax on the excess cost above a dollar amount with the intent of reducing the generosity of health plan coverage and health care expenditures. It was first included in the Affordable Care Act and was set to commence 6 years after the ACA went into effect in 2018. Under this plan the tax is imposed at a 40 percent rate on the excess cost above a dollar threshold adjusted for the health cost adjustment percentage. The Consolidated Appropriations Act 2016 (enacted at the end of 2015) delayed the implementation to 2020. Were the tax to have been in effect in 2018, it would have applied to health insurance costs in excess of $10,200 for single coverage and $27,500 for non-single coverage. The Consolidated Appropriations Act provided that the 2018 amounts be adjusted by the consumer price index plus 1% for 2019, and for the consumer price index in each following year. Assuming a CPI-U of 2.3% per year, these amounts will be $10,800 for single (self-only) coverage and $29,100 for family coverage in 2020.

The tax base includes both employer and employee contributions to insurance premiums, various health savings or flexible spending accounts (flexible spending accounts, health savings accounts, health reimbursement accounts and medical savings accounts), self-employed plans with tax-deductible premiums and on-site medical clinics that provide more than de minimus medical care. The base does not include other fringe benefits, such as coverage under a separate policy for dental and/or vision care, or coverage for long-term care.

The threshold can be adjusted upwards for employers based on demographic characteristics. This adjustment would apply to employers with age and gender characteristics of employees significantly different from the national average. An upward adjustment can also be made for employees in risky professions defined in the statute, such as firefighters and paramedics, longshoremen and workers in construction, mining, agriculture, forestry and fisheries. An adjustment can also be made for retirees over 55 without Medicare coverage. For the latter two categories, retirees and high-risk professions, the dollar limits are increased by $1,650 for single coverage and $3,430 for family coverage.

The tax is legally imposed on the insurer in the case of group health plans offered by a fully insured employer. For contributions to a health savings plan (HSA) or an Archer MSA (medical savings account), the employer is responsible for the tax. For firms that are self-insured, the plan administrator is responsible. The expectation is that, in cases where firms retain their high-cost coverage, the tax would be passed on to employees through lower wages. In cases where employers reduce health insurance coverage to avoid the tax, wages would be expected to rise by the reduced benefit.

The Cadillac tax was enacted as part of the Patient Protection and Affordable Care Act of 2010, which made a number of changes in health insurance designed both to make affordable health insurance available to the uninsured and to contain the cost of health care. The Cadillac tax served two purposes: to raise revenue to finance costs of the Affordable Care Act (such as subsidies to low and moderate income families) and to discourage excessive spending on health care due to generous health insurance policies that limited the out-of-pocket costs (and thus health care prices) faced by consumers.

The Cadillac Tax and the Exclusion for Employer Sponsored Insurance (ESI)

The origins of the Cadillac tax are rooted in discussions to reform the tax subsidies for employer-provided health insurance. Amounts paid by firms on behalf of their employees for health insurance are excluded from wages and are subject to neither income nor payroll taxes. These health insurance benefits include purchase of group insurance on behalf of employees or self-insurance, where employers pay claims. Health coverage may also be selected as part of a “cafeteria” plan where employees choose among a menu of benefits. Deductible contributions may occur through specialized health savings accounts (HSAs) and flexible spending accounts (FSAs). All of these expenses can be excluded from taxable income.

These subsidies rank as one of the largest (if not the largest) income tax subsidies and, additionally, benefit from exclusions from payroll taxes (such as those paid for Social Security and Medicare). The value of these tax benefits was estimated by the Joint Committee on Taxation (2016) at $323.3 billion for 2016: $198.3 billion for exclusion from the income tax, $124.5 billion for exclusion from payroll taxes and $0.5 billion from exclusion from the additional Medicare tax of 0.9% on high income earners.

This exclusion has long been a part of the tax code. The Revenue Act of 1918 allowed the exclusion for employer provided health plans, and in 1943, the IRS ruled that direct contributions by employers to group health plans could be excluded from compensation. Miller (2014) links this ruling to a regulation by the War Labor Board that allowed employers to provide fringe benefits to avoid wage controls. The status of contributions to individual plans remained uncertain and IRS ruled in 1953 that they should be taxed. This ruling has a brief existence as Congress provided a broad exclusion of all employer contributions in 1954. Over time other types of benefits, such as flexible spending accounts and health savings accounts, were made exempt.

The exclusion has grown in relative size, compared to other tax expenditures and to the economy. When the first tax expenditure estimates for the income tax were compiled in 1968 (U.S Department of the Treasury 1969), the exclusion of medical insurance premiums, while a significant tax expenditure, was smaller than many other provisions: about a third of the size of the exclusion for pensions, and half the size of the deduction for charitable contributions. In the latest tax expenditure estimates (by the Joint Committee on Taxation 2015), it was the largest tax expenditure, 12% larger than pensions, and 3.3 times charitable contributions. This change in position was due to overall growth in the coverage of employer health insurance: the tax expenditure increased from 0.1% of GDP in 1968 to 1.1% in 2015. The tax expenditure for pensions also grew, although not as much, from 0.4% of GDP to 0.7%, while charitable contribution deductions remained about the same, at 0.25% of GDP.

Carasso (2005) plots the growth in the tax expenditure after the Tax Reform Act of 1986, through 2005, adjusted for both the consumer price index and the health cost price index, showing that a major reason for the growth of the exclusion is the rising cost of health care.

The exclusion of employer-sponsored insurances significantly reduces the relative price of health insurance. The magnitude depends on payroll taxes, which are 6.2% each on the employer and the employee for Social Security and 1.45% for Medicare (hospital insurance), as well as income taxes. While there is no cap on wages subject to Medicare taxes, wages for Social Security tax purposes are capped, currently (2016) at $118,500. Income tax rates are imposed at 10, 15, 25, 28, 33 and 39.6%. For certain high-income workers there is an additional 0.9% tax on wages. Based on the taxable income amounts, it is possible to have single individuals and two-earner married couples paying income tax at marginal rates as high as 28% while still being subject to the full payroll taxes. The most common marginal tax rate, however, is 15% (based on distributional data provided by the Joint Committee on Taxation 2009).

The assumption is generally made that, although half of the payroll tax is imposed by statute on the employer, the burden falls on workers through reduced wages. The lower wage causes the tax base to be smaller, so that the price differential cannot be calculated by adding the payroll and income tax rate. With fixed labour compensation (setting aside other fringe benefits), the wage can be determined by the relationship $W(1 + p) + B = F$, where W is the wage, p is the payroll tax rate, B is the health insurance benefit and F is a fixed amount. This relationship means that if benefits rise by one unit, wages fall by $1/(1 + p)$. When p is 0.0765 (the sum of the Social Security and Medicare tax rates for employees below the ceiling), wages fall by 7.1%, which is the amount of the payroll tax paid by the employer ($p/(1 + p)$). The employee also pays a tax of $p/(1 + p)$ and the income tax at $t/(1 + p)$, where t is the marginal tax rate. Thus the tax subsidy for health benefits relative to wages is $(2p + t)/(1 + p)$.

For employees below the Social Security payroll tax ceiling, p is 0.0765, and the subsidy, in

percentages, is 40.2, 37.4, 28.1, 23.5 and 14.2 for marginal income tax rates of 28, 25, 15, 10 and 0%. For employees above the ceiling, $p = 0.0145$, and the subsidy, in percentages, is 42.8, 38.2, 36.3 and 31.3, for tax rates of 39.6, 35, 33 and 28%. The first three of these also include the additional 0.9% tax on high incomes. Thus, for most employees the subsidies are close to or above 30%.

Data provided by the Urban Brookings Tax Policy Center (2016) indicated that 70% of the benefit of the tax exclusion accrues to the top 40% of the income distribution and 45% to the top quintile. These measures correspond (based on incomes in 2018 above $81,631 for the fourth quintile and above $143,318 for the highest quintile) to expected income tax rates of 25% or more. About 20% of the burden falls on the middle quintile, which would likely fall in the 15% or 25% income tax rate.

The payroll tax exclusion modifies the tendency of the tax subsidies to rise with income, because at the ceilings for Social Security, the payroll tax subsidy declines. At the same time, the subsidy arising from the exclusion from income of the payroll tax for Social Security is overstated, since the reduction in payroll taxes reduces future Social Security benefits. The Congressional Budget Office (2013) reported that individuals have lifetime Social Security benefits that are roughly equal to payments at a 3% discount rate. If subsidies below the payroll tax ceilings were restricted to the 1.45% Medicare tax (which is not tied to future benefits), the subsidy for tax rates from 28% down to 0% would be, in percentages, 30.5, 27.5, 17.6, 12.7 and 2.9%.

Subsidizing employer-provided health insurance has both desirable and undesirable features. Provision of health insurance suffers from an important market failure, adverse selection, where the inability of insurers to have full information on health status tends to overprice policies for healthier individuals and drive them out of the market. The pooling that arises in employer health plans help to reduce this market failure. In addition, in a private market, individuals with a preexisting health condition or health risks (such as age) may not be able to purchase affordable insurance, or any insurance at all, which may be undesirable from a social welfare perspective. At the same time, health insurance once purchased causes its own market failure, moral hazard, in that individuals who do not face the full cost of health care tend to overconsume it. In addition, because of health care coverage individuals may be less risk-averse.

Some participants in the Senate Committee on Finance roundtable discussion of health reform (2009) advocated eliminating or reducing the tax subsidies for employer-provided health insurance because of the effect on consumption and the "upside down" nature of the subsidy which tends to favour higher income taxpayers (especially if Social Security taxes are not considered).

Early on during the Senate Committee on Finance roundtable discussion (2009), Chairman Max Baucus made it clear that the elimination of health insurance subsidies was not on the table. At the same time, he expressed concern about its distributional effects and the incentive to buy too much health insurance. Members of this discussion group (committee members and outside experts) considered eliminating the exclusion for amounts above a dollar ceiling or a percentile of the actuarial value of the average plan.

Practically speaking, limiting the tax exclusion could face administrative challenges, including undesirable side effects for society. The pooling mechanism that was a benefit of employer health insurance creates problems for imputing income from employer-financed health insurance. If income were to be imputed based on the characteristics of the employees (the value of the insurance to them), the amount of income included could be onerous for some individuals, such as older employees. The simpler method of dividing costs by the number of employees means the imputed value subject to tax would depend on the health status of all the employees of the firm and could differ for employees with identical health plans and health conditions.

Whether for reasons of political optics or complications of imputing income, the Finance Committee ultimately proposed an excise tax on excess insurance costs to be paid by the insurance company (or the employer, in the case of self-insured plans). Because the tax is imposed at a flat rate, it

cannot offset the subsidy, which depends on graduated income taxes and flat payroll taxes with a ceiling on wages for Social Security.

The first proposal was at a 35 percent rate, but the rate was eventually raised to 40% and the tax was delayed until 2018. The original excise tax was not deductible for income tax purposes; revisions made in the Consolidated Appropriations Act of 2015 allowed deductibility and delayed the tax until 2020.

Penalties Imposed by the Cadillac Tax

The tax's success in discouraging high-cost health care plans with greater coverage depends on the size of the penalty. While a 40 percent rate appears to be high compared to the existing tax subsidies calculated earlier, it is not comparable to the existing subsidy rates because it is imposed on a tax-exclusive basis, in the same way as a sales tax (imposed on a base exclusive of the tax). Income and payroll tax subsidies are tax inclusive (imposed on a base inclusive of the tax). Thus a tax of 40% imposed on a tax inclusive basis is the equivalent of a 28.57 percent rate (0.4/1.4) on a tax-inclusive basis.

The excise tax is expected to be passed on to the worker as lower wages and will be offset by the tax savings on the lower wage. An additional dollar in benefits will cause wages to fall by 1.4/(1 + p), and this wage reduction will reduce the payroll and income taxes. The total tax effect reduction in wages is $-1.4(1-[(2p + t)/(1 + p)])$. This amount of reduced net wages can be decomposed into $1-(2p + t)/(1 + p)] + 0.4–0.4 [(2p + t)/(1 + p)]$. Tax effects include the tax subsidy on a dollar of benefits from the exclusion of benefits (noted above) of $(2p + t)/(1 + p)$ as well as a penalty from the excise tax and its accompanying wage offset of $0.4(1-[(2p + t)/(1 + p)])$. When $[(2p + t)/(1 + p)]$ is equal to 28.57%, the tax effects are zero, with the excise tax offsetting the subsidy from exclusion.

In many cases, the excise tax is too small to offset the initial subsidy, at least after the revision allowing deductibility of the tax. For the cases under the payroll ceilings where p is equal to 7.65%, the subsidy or penalty (denoted as a negative, showing a net tax), in percentages, is 16.3, 12.4, −0.6, −7.1 and −20.1 for marginal income tax rates of 28, 25, 15, 10 and 0%. For employees above the ceiling, $p = 0.0145$, the subsidy, in percentages, is 18.6, 12.3, 9.5 and 2.6, for tax rates of 39.6, 35, 33 and 28%. At a 15 percent rate, the income tax subsidy and the Cadillac tax penalty largely offset each other. For higher rates, the Cadillac tax is not large enough and a subsidy, albeit smaller, remains in effect. Within a payroll tax category, the initial subsidy from the tax savings for benefits is larger the higher the tax rate, while the Cadillac penalty is smaller, reflecting the offsetting effect of taxes on reduced wages on the tax.

Data provided by the Urban Brookings Tax Policy Center (2015) indicated that two-thirds of the burden of the Cadillac tax accrues to the top 40% of the income distribution and 37% to the top quintile. These measures correspond (based on incomes above $81,000 for the fourth quintile and above $143,000 for the highest quintile) to expected income tax rates of 25% or more. About 20% of the burden falls on the middle quintile, which would likely fall in the 15 or 25% income tax rate bracket. Thus, most high-cost plans would continue to receive a subsidy. The Cadillac tax burden is somewhat less concentrated in the higher income classes than the employer exclusion.

As noted earlier, the share of the payroll tax that finances Social Security benefits might be considered as funding an annuity, not a tax. In this case, the subsidy net of the payroll tax for marginal rates from 28% to 0% is, in percentages, 2.6, −1.5, −15.3, −22.2 and −36.9. Excluding this part of the payroll tax increases the regressiveness of the Cadillac tax (due to the more progressive income tax dominating income and payroll taxes) and results in a net penalty for most tax rates.

Allowing deductibility of the tax significantly reduced the size of the initial Cadillac tax. Wages and payroll taxes are deductible from the corporate or business profits tax base. If compensation is fixed at $W(1 + p)(1 - u) + B(1 - u) + .4B$, where u is the corporate tax rate, then the tax will cause a dollar of benefits to decrease wages by $1.4/[(1 - u)(1 + p)]$ without deductibility, rather than

0.4/(1 + p) with deductibility. The total effect can be decomposed into a tax of 0.4, a corporate tax on the fall in wages of 0.4u/[(1 − u)(1 + p)], an employer payroll tax savings which is deductible of p(1 − u)/[(1 − u)(1 + p)] and individual payroll and income taxes of (p + t)/[(1 − u)(1 + p)]. Setting u at 35%, for the cases under the payroll ceilings where p is equal to 7.65%, the subsidy or penalty (denoted as a negative, showing a net tax), in percentages, is 3.4, −1.1, −16.2, −23.6 and −38.7 for marginal income tax rates of 28, 25, 15, 10 and 0%. For employees above the ceiling, p = 0.0145, the subsidy, in percentages, is 5.7, −1.7, −4.9 and −12.3 for tax rates of 39.6, 35, 33 and 28%, with the first three including the 0.009 additional individual Medicare tax. The Cadillac tax, as initially designed, largely offset the subsidy from the exclusion of income and in many cases led to a net penalty.

Allowing deductibility provided more equal treatment of firms with differing tax rates (including tax exempt non-profit and government employers) but diminished the effect of the Cadillac tax in discouraging high-cost plans as well as reducing the revenue yield.

If the Social Security payroll tax is disregarded for this calculation, the subsidy rates for income tax rates from 28% to 0%, in percentages, are −12.3, −17.1, −33.0, −41.0 and −56.9 and thus all subject to penalties.

Growth of the Tax

The effect of the Cadillac tax depends on its burden and also on the scope of coverage. Because the Cadillac tax floor is indexed for inflation, the share of health insurance policies potentially subject to the tax will grow over time if the rate of growth in health insurance costs is greater. This expectation is evident from revenue effects as reported by the Congressional Budget Office (2016), with projected revenues rising from $2 billion in FY2020 to $20 billion in FY2025.

Lowry (2015) projects the growth in the percentage of plans covered using a lower growth assumption (4.6%), a moderate growth assumption (5.0%) and a high growth assumption (7.0%). Under the moderate growth scenario, in 2018, the tax would have affected about 10% of insurance plans for singles and about 8% for family plans; by 2025, these shares are over 20% for singles and around 20% for family plans and by 2030 the shares for single plans are around 40% and for family plans about 35%. Moreover, not only does the share of plans affected grow, but a greater share is subject to the tax over time.

The study also estimated the point at which the floor would be equal to the premium paid by the basic option Blue Cross Blue Shield (BCBS) plan offered by the Federal government (the lower cost of the two BCBS options). With moderate growth, for single plans, this point would be reached around 2030; with lower growth a year or two later, and with high growth by around 2023. For the family plan, the point would be reached around 2032 with moderate growth, around 2037 with low growth and around 2026 with high growth.

Geographic Differentials

One of the concerns with the Cadillac tax is the differential effects across states, since the tax threshold is not adjusted for geographical variations in health costs. Lowry (2015) also investigated these effects for 2018, using the lower growth scenario. For single plans, nationwide, 10.2% are subject to the tax. In Alaska, the share was projected at 29.6%, followed by Wyoming at 17.6%, Massachusetts at 15.8%, Montana at 15.7% and Delaware at 14.8%. Generally the states with larger shares were in the Northeast and Midwest, along with California. The smallest share was in Iowa at 4.7%, followed by Idaho, with 4.9% (although those data had a large standard error, suggesting caution), Hawaii and Alabama at 5.3%, Arkansas at 5.5% and Mississippi at 5.6%. For family plans with a national average of 6%, Alaska was 19.7%, followed by Connecticut at 12%, New Jersey at 9.7% and Maryland at 8.7%. States with higher shares were generally in the northeast. The states with the lowest shares were Idaho, at 1.6% (again with a large standard error),

Colorado at 2.3%, Louisiana at 2.4% and Mississippi and Arkansas at 2.5%. Generally, southern and western states (with the exception of Georgia, Nevada and Missouri) were below average.

Effect on Health Spending

One objective of the Cadillac tax was to address moral hazard: to discourage health plans that covered a larger proportion of health costs because consumers facing lower costs would be encouraged to consume too much. That effect would only occur if the tax caused employers to substitute wages for high cost plans.

Data from the Congressional Budget Office (2016), Gravelle (2015) and the Centers for Medicare and Medicaid Services (CMS) are used to derive a rough estimate of the potential effects on health spending. The Congressional Budget Office reports a $20 billion revenue gain for 2025, with 20–25% of that amount from the Cadillac excise tax and the remainder from changes in income and payroll taxes. Gravelle (2015) uses an assumption consistent with the Treasury Department that the sum of the individual payroll and income tax (p + t) for purposes of considering the Cadillac tax is 35%. If the payroll tax is 7.65%, it implies an income tax rate of 27.35% and the total subsidy amount (2p + t)/(1 + p) is 40%. If a 1.45% payroll tax is assumed, the value is 36%. Gravelle (2015) also uses an assumption that the out-of-pocket costs of health care are equal to 19% of the total.

The share of plans subject to the Cadillac tax should be smaller than the share of revenue because of the tax offset. If x is the share of plans that retain the high cost insurance, with others substituting the high cost insurance with wages, each dollar of revenue is equal to x0.4(1−(2p + t)/(1 + p))+(1 − x)(2p + t)/(1 + p). (These estimates assume that tax rates are the same for those plans that retain the high-cost insurance and those that eliminate it.) Using the mid-point of the JCT share, 0.225 and the mid-point of the subsidy rate, 0.38, 0.4x = 0.225 and 0.38*(1 − x) − 0.4x*0.38 = 0.775. Thus x is estimated at 0.199. Returning to the revenue amount and substituting the values for x and (2p + t)/(1 + p), each dollar of revenue is 0.199*0.4*(1 − 0.38) + 0.801*0.38. The share of revenues accounted for by the last term is 0.801/(0.199*0.4*(1 − 0.38) + 0.801*0.38), or 86%.

If the tax subsidy is 0.38, then each dollar of revenue represents 1/0.38, or $2.63 of income. The change in the subsidy for 2025 is 2.63*0.86*$20 billion, or $45 billion. This $45 billion is the change in the subsidy paid by insurance. Currently consumers face a price of P(1 − s), where P is the market price of health services and s is the share paid for by insurance (81%).

The Center for Medicare and Medicaid Services projects total health expenditures covered by private insurance for 2025 at $1752.6 billion. If the out-of-pocket share is 19%, the total expenditure is 1752.6/0.81 or 2163.7 and the out of pocket amount is $411.1 billion. So the percentage reduction in the subsidy is $45/$411 or 10.9%.

Consider two cases (as outlined in Gravelle 2015) of the effects of changing the subsidy of price and quantity in the health care market. Both rely on a demand elasticity of −0.2, with a supply elasticity of infinity in one case, and of 1.5 in the other. The percentage change in quantity is equal to 0.2 times the change in the market price plus the change in the subsidy (−10.9%). When the supply elasticity is infinity (i.e., perfectly elastic), the market price does not change and the percentage change in quantity is 2.2%. If the supply elasticity is 1.5 the market price falls with a reduction in quantity, and the change in the market price is the demand elasticity divided by the sum of the supply and demand elasticity times the percentage change in the subsidy. Thus, the market price falls by (0.2/(0.2 + 1.5)) times 10.9% or 1.3%. The quantity could be estimated from either the demand or supply curve, but using the supply curve, quantity falls by the supply elasticity times the percentage change in price, or 1.5 times (−1.3%), or 1.9%.

In the case of an infinitely elastic supply curve, total expenditure on health (in the private market) falls by 2.2%. In the case of a supply elasticity of 1.5, expenditure falls by the sum of the percentage

change in price (1.3%) and the percentage change in quantity (1.9%), or by 3.2%.

The effects of the Cadillac tax on health spending, absent revision, will tend to grow because the share of employer health insurance subject to the tax is projected to grow over time.

Conclusion

Although having the appearance of a high tax rate, the Cadillac tax rate, being expressed as a tax exclusive rate, allowed a net tax subsidy in most cases for retaining high-cost plans once it became deductible for income tax purposes. Eliminating the rule disallowing deductibility was a significant change. Nevertheless, economists at the Congressional Budget Office project that the tax will be effective at discouraging high-cost plans, perhaps because receiving income in cash is more desirable than minimizing premiums and co-pays.

According to the Department of the Treasury projections of effective tax rates, the income level of the recipient of the current benefits for these high cost plans is relatively high, although the employer-provided health insurance tax subsidy (or the Cadillac tax) does not rise with income as some other benefits (such as pensions and some itemized deductions) do. The tax should also reduce the size of the tax expenditure for employer-provided health insurance.

The reduction in high-cost health plans is expected, in turn, to reduce quantities, price, and expenditures on health costs for individuals covered by the private insurance market: the last could potentially fall by 3% or more. The Cadillac tax was perhaps the most important of the provisions of the Affordable Care Act targeted at reducing spending on health care, by discouraging use without raising market prices, and this aspect distinguishes it from other revenue-raising taxes and fees.

Cairnes was born at Castlebellingham, County Louth, Ireland. At the height of his career he was probably the best-known political economist in England after John Stuart Mill, whose friend and associate he was from 1859 onwards; but his interest in economic questions developed relatively late, after periods spent working in his family's brewing business and in journalism. In 1856 he competed in the examination by which the Whately professorship of political economy at Trinity College, Dublin, was then filled, and was appointed for a five-year term. In 1859 he was also appointed Professor of Political Economy and Jurisprudence at Queen's College, Galway, a post which he held until 1870. However, he employed a deputy to perform his duties in Galway after he himself moved to London in 1865. In 1866 he became Professor of Political Economy at University College, London, but was forced to resign in 1872 by the progress of the rheumatic disease which left him almost completely paralysed before his death in 1875.

Cairnes has often been described as 'the last of the classical economists'. He always worked within the framework of the Ricardo–Mill tradition, devoting himself to refining and strengthening it and seeing no necessity for any radical reform or reconstruction. Within these self-imposed limits and in a career of less than 20 years as a professional economist, he succeeded in making contributions to both theoretical and applied economics which earned him a high reputation among his contemporaries and a definite place in the history of economic thought.

Cairnes's first work in economics proved to be one of his most enduring contributions to the subject. This was *The Character and Logical Method of Political Economy* (1857; 2nd edition, 1875) which is still regarded as one of the best statements of the verificationist methodology of the English classical school. Following the lines laid down by Senior and Mill, Cairnes stressed the neutrality of economic science, emphasized the value of the deductive method and characterized the subject as a hypothetical science 'asserting, not what *will* take place, but what *would* or what tends to take place' ([1857] 1875, p. 55).

It was in the use of the deductive method to develop the central areas of economic theory that Cairnes's main interest came to lie. Yet it was through his work on applied economics and current issues of policy that he first came to be nationally and internationally known. In September 1859 Cairnes published the first of a series of 'Essays towards a solution of the Gold Question' in which he sought to 'apply the principles of economic science' in an attempt to 'forecast the directions in which the course [of trade and prices] would be modified by the increased supplies of gold'. This a priori approach was almost precisely the opposite of that used by Jevons to deal with the same problem, but their results coincided remarkably.

It was another application of this approach which first made Cairnes's work known to a much wider audience. In *The Slave Power* (1862) he sought to explain on economic grounds the appearance of slavery in the southern parts of the United States, tracing out both the conditions for and the consequences of the operation of a slave economy. As an indictment of the political economy of the

Confederate States it strongly influenced public opinion in Britain towards support of the Northern states in the American Civil War.

Between 1864 and 1870 Cairnes wrote a number of articles on the problems of land tenure in Ireland, in which he argued in favour of proposals to fix rent by law and contended that this was not inconsistent with classical rent theory. There is evidence that his views on this and other questions of the day, such as Irish university education, exerted considerable influence on (and through) Mill and Fawcett.

Cairnes's most important contribution to economic analysis, *Some Leading Principles of Political Economy Newly Expounded* (1874), was also to be his last work and that by which he came to be most widely known and judged. In it he restated, but with significant modifications, the essentials of classical doctrine on the central questions of value, distribution and international trade. His most important innovation was to show that the existence of 'non-competing groups' in labour markets implied that the cost of production theory must be supplemented by the analysis of reciprocal demand in the theory of domestic as well as international values.

Nevertheless his unsympathetic review of Jevons's *Theory of Political Economy (Fortnightly Review,* N.S., vol. 11, 1872) showed that he lacked interest in and understanding of the subjective approach to value theory which was then developing. Cairnes's treatment of distribution in the *Leading Principles* echoed Mill in showing sympathy for the position of the labourer combined with pessimism based on acceptance of Malthusian population theory; but it was chiefly notable for an elaborate but ultimately unsuccessful attempt to rehabilitate the wages-fund doctrine abandoned by Mill himself in 1869. The verdict of Schumpeter (1954, p. 533) still seems appropriate: Cairnes 'expounded the old analytical economics and explicitly distanced himself from the new'.

Calculus of Variations

Morton I. Kamien

JEL Classifications
C61

The development of the calculus of variations is attributed to Euler and Lagrange, although some of it can be traced back to the Bernoullis. A history of the calculus of variations is provided by Goldstine (1980). The calculus of variations deals with the problem of determining a function that optimizes some criterion that is usually expressed as an integral. This problem is analogous to the differential calculus problem of finding a point at which a function is optimized, except that the point in the calculus of variations is a function rather than a number. The function over which the optimum is sought is usually

restricted to the class of continuous and at least piecewise differentiable functions.

A typical calculus of variations problem is of the form

$$\max_{x(t)} \int_{t_0}^{t_1} F[t, x(t), x'(t)]\mathrm{d}t. \ \text{s.t.} x(t_0) = x_0, \quad (1)$$

where $x'(t) = \mathrm{d}x/\mathrm{d}t$, and t, $x(t)$, and $x'(t)$ are regarded as independent arguments of the function F. The necessary conditions for $x^*(t)$ to maximize (1) are the Euler equation

$$F_x = \mathrm{d}F_{x'}/\mathrm{d}t, \quad (2)$$

F the Legendre condition

$$F_{x'x'} \leq 0 \quad (3)$$

and the transversality conditions

$$F_{x'} = 0 \text{at} t_1, \ \text{if } x(t_1) \text{ is free}, \quad (4a)$$

$$F - x'F_{x'} = 0 \text{ at } t_1, \ \text{if } t_1 \text{ is free}, \quad (4b)$$

where F_x and $F_{x'}$ refer to the partial derivatives of F with respect to x and x', respectively, and $F_{x'x'}$ is the second partial derivative of F with respect to x and x'. The Euler Eq. 2 is in general a nonlinear second order differential equation. The initial condition $x(t_0) = x_0$ and the transversality condition (4a) provide the means for determining the two constants of integration that arise in solving the Euler equation. The optimal value of the upper limit of integration, t_1, if it can be chosen, is determined by the transversality condition (4). The problem posed in (1) can be extended to include additional arguments of the function F, to include a variety of additional constraints, and to involve double integrals (see Kamien and Schwartz 1981). Concavity of F with respect to $x(t)$ and $x'(t)$ assures that the necessary conditions are also sufficient.

The earliest application of the calculus of variations to the analysis of an economic problem appears to have been attempted by Edgeworth (1881), who seems to have been greatly impressed by its successful employment in deriving some of the basic laws of physics. He sought to employ it to find a function for distributing income and assigning work among the members of society so as to maximize total social welfare. Many applications of the calculus of variations to economic problems have been conducted since then, a few of which will be described.

As the calculus of variations deals with the problem of finding a function or a path that maximizes some criterion, its major application in economics has been to problems involving optimal decision making through time where an entire course of actions is sought rather than a single action. One of the earliest and most influential applications along these lines is by Ramsey (1928). The question he addressed is how much should a nation save out of its national income through time so as to maximize its overall welfare over time. Ramsey argued that the discounting of future utilities was 'ethically indefensible' as it means that we give less weight to the utility of future generations than to our own. He posited, therefore, a maximum level of net utility, the utility of consumption minus the disutility of work, that he called bliss. This bliss level of utility is the asymptotic limit of the achievable level of net utility. Ramsey then sought the savings rate through time that would minimize the integral over the indefinite future of the difference between the bliss level of utility and the actual net utility level at each point in time, subject to the constraint that savings plus consumption equal total output at each instant of time. The rule he derived for the optimal savings rate, through the Euler equations, is that the 'rate of saving multiplied by the marginal utility of consumption should always equal bliss minus actual rate of utility enjoyed'. This is essentially a marginal sacrifice today equals marginal benefit tomorrow rule. The rationale for taking the upper limit of integration to be infinite in the objective function is that while individuals have finite lives, society as a whole goes on forever. Ramsey also took up the case where future utilities are discounted at a constant positive rate and derived what may be regarded as the fundamental equation of optimal consumption through time, namely that the proportionate rate of change of marginal utility of consumption should equal the

C

difference between the marginal productivity of capital and the rate at which future utility is discounted. The Ramsey model became the basis for optimal growth theory that was intensely investigated in the late 1950s and 1960s.

Strotz (1956) addressed the question of the circumstances under which an individual would continue today to follow the optimal consumption plan through time that he had determined at an earlier date. In other words, he asked for the conditions under which an optimal consumption plan through time would be consistent. He found the necessary and sufficient conditions for consistency to be that 'the logarithmic rate of change in the discount function must be constant'. Exponential discounting at a constant rate satisfies this criterion.

Yaari (1965) addressed the question of an individual's optimal consumption plan through time when his lifetime is uncertain. He also allowed for the possibility that the individual derives utility from a bequest to his heirs. Yaari found that a major effect of the presence of uncertainty about one's lifetime is the same as an increase in the rate at which future utilities are discounted. Thus, the 'effective' rate at which future utilities are discounted has a risk premium term added to the discount rate in the absence of uncertainty about one's lifetime. The risk premium term is the instantaneous conditional probability of dying in the next instant given survival to the present. The presence of the risk premium means that the rate of consumption at any point in time is higher than it is in its absence. Uncertainty about one's lifetime increases one's rate of current spending, if there is no bequest motive.

While Ramsey applied the calculus of variations to the problem of optimal savings through time, Evans (1924) appears to have been the first to have employed it for determining the optimal rate of output through time. Evans used, as his vehicle for making the problem of choosing the level of output so as to maximize a monopolist's profit over an interval of time nontrivial, i.e. just simple maximization of profit at each instant of time, the assumption that the demand function for a good depended both on its current price and the rate of change of price. In particular, he assumed that the demand function was linear in price and its first derivative, and that the cost of production was a quadratic function of the level of output. Under these assumptions Evans sought the level of production that would maximize the integral of profits over a finite horizon. He was able to characterize this path and to show that a particular solution to the second order differential equation stemming from the Euler equation was the static monopoly profit maximizing level of output. Indeed, it is not difficult to show that when the problem is posed as one of maximizing the present value of an infinite horizon profit stream that the static monopoly profit maximizing level of output and the corresponding monopoly price constitute a steady-state towards which the output and price paths converge through time. This, of course, is intuitively plausible, as in the steady-state the rate of change of price with respect to time is zero, and so the demand function depends only on the current price level. Evans's work was extended by Roos (1925) to the case of duopolistic producers of a homogeneous product seeking to maximize their individual profits through time. The Roos paper may be regarded as the earliest analysis of what has come to be known as a differential game (see Fershtman and Kamien 1987).

The last paper that deserves special mention because of its important application of the calculus of variations is Hotelling's (1931), dealing with the rate at which a mineral resource such as coal, copper or oil should be extracted from a mine and sold so as to maximize the present value of its profits. Hotelling derived the fundamental equation for optimal extraction, under competitive production of the resource, namely that the extraction rate be such as to equate the percent change in price through time with the rate of interest at each instant in time. The intuitive reason for this is that if the percent change in the price of the resource exceeds the interest rate then it pays to extract and sell more today, because the alternative of extracting less and earning the interest on the revenue from that level of extraction yields less. The increase in the current rate of extraction, however, causes price to decline until the percent change in the price through time is equalized with the rate of interest. A similar analysis yields that current extraction will decline if

the percent change in price is below the interest rate, which in turn will cause price to rise until equality is achieved. Along the optimal extraction path the mine owner is just indifferent between extracting an extra unit of resource today and extracting it tomorrow. A similar analysis can be carried out for a monopolistic mine owner, with the percent change in marginal revenue through time being equated with the interest rate.

There have been a very large number of applications of the calculus of variations since these early ones. Many have employed optimal control methods and dynamic programming methods, both of which constitute generalizations of the calculus of variations. As long as decision making though time is regarded as an important subject of economic analysis, the calculus of variations will continue to find use in economics.

Calibration

Edward C. Prescott and Graham V. Candler

C

Abstract

The methodologies used in aerospace engineering and macroeconomics to make quantitative predictions are remarkably similar now that macroeconomics has developed into a hard science. Theory provides engineers with the equations, with many constants that are not well measured. Theory provides macroeconomists with the structure of preference and technology and many parameters that are not well measured. The procedures that are used to select the parameters of the agreed upon structures are what have come to be called 'calibration' in macroeconomics.

Keywords

Calibration; Elasticity of intertemporal substitution; Equity premium; Impatience; Lucas critique; Measurement; Neoclassical growth theory; Risk aversion; Total factor productivity

JEL Classifications

D4; D10

What is calibration? In the dictionary definition, calibration is the act of calibrating a measurement instrument so that it gives the correct measurement for some known conditions. When calibrating a thermometer that will be used to measure the air temperature, calibration would involve setting it to read 100 degrees Celsius when submerged in boiling water at sea level and zero degrees when submerged in ice water. Because the boiling point of water varies with altitude, the calibration would be different in Mexico City, which is more than a mile above sea level.

Sometimes macroeconomists calibrate a measurement instrument – that is, a model – in this narrow sense. But calibration has gained a broader meaning in economics and is what

macroeconomists do when using theory to derive *quantitative theoretical inference*. Prescott emphasizes that calibration is not estimation. Calibration is a process that uses theory to construct a model – that is, an instrument – which will be used to provide a quantitative answer to a question.

Clearly, instruments are not measured; rather, they are calibrated so that they can be used to accurately answer quantitative questions. The nature of questions varies. Examples of questions are as follows: what is the welfare benefit or cost of changing the currently employed policy arrangement to another one? What will happen to a spacecraft when it enters the atmosphere of Mars?

To predict the quantitative consequences of a particular policy, theory and observations are used to select a model economy, and the equilibrium behaviour of that economy is determined for the proposed policy. Theory provides a set of instructions for selecting the model economy. *This selection process is what calibration in economics has come to mean*. Needless to say, the nature of the application of theory and the availability of economic statistics dictate which model economy is selected.

Before proceeding, a little history of the development of macroeconomics is needed. The modern national accounts were developed by the NBER staff in the 1920s, with Simon Kuznets playing the leading role. In the 1950s and 1960s, macroeconomists searched for *the dynamic system* governing the behaviour of these accounts. The controls for this dynamic system were policy actions. Not having much theory, this activity was largely empirical. Macroeconomists would write down a parametric set of models and find the one that best *fitted* the national accounts, augmented with other statistics. This search for *the dynamic system* failed because, as established in the Lucas critique, the existence of such a policy invariant dynamic system is inconsistent with dynamic economic theory.

The failure of this search led to a vacuum in quantitative macroeconomics. The profession did not want to go back to conjecturing and storytelling that characterized pre-war business cycle theory. As a result, the 1970s was a frustrating decade for quantitative macroeconomists given the failure of the empirical approach and the lack of needed tools and theory to quantitatively study macroeconomic behaviour.

This vacuum was filled in the early 1980s when the extended neoclassical growth model was used to study business cycles. The national accounts had to be modified to be consistent with the model. The most important modification in the study of business cycles is treating consumer durable expenditures as an investment and imputing consumption services to the stock of consumer durables as is done for owner-occupied housing. The secular growth observations with constancy in shares of output led to a constant elasticity structure with share and elasticity parameters. The fact that capital share of income displayed no trend even though the relative price of labour increased secularly led to a unit elasticity of substitution aggregate production function with share parameters equal to income shares. The depreciation rate, for example, was calibrated to average depreciation share of product. The national accounts use prices of used capital goods to estimate depreciation.

This methodology is used in virtually all quantitative theoretical aggregate studies. We emphasize that quantitative theoretical research and empirical research are fundamentally different activities and fundamentally different tools are needed. If the objective of the research is to derive the quantitative implications of the neoclassical growth theory for business cycle fluctuations, the use of statistical tools to select the parameters that best fit the business cycle observations is not sound scientific practice.

In this short article macroeconomist Prescott will describe what he does when addressing macroeconomic issues and aerospace engineer Candler will describe what he does when addressing the problem of making predictions of what will happen when a capsule enters the atmosphere of Mars. These predictions are relevant to the design of the capsule. Prescott will conclude by comparing the approaches and argue that these scientific approaches are essentially the same. We begin with what aerospace engineers do so that comparison can be made with what they do and what macroeconomists do.

Candler: The Aerospace Engineer

I work in the field of aerodynamics, and specifically I try to predict what happens when a spacecraft enters the atmosphere of a planet. For example, one of my current projects involves predicting how the Mars Science Laboratory capsule will fly as it enters the Martian atmosphere. What is the peak heat transfer rate to the spacecraft? How much heat shield is required to protect it from the extremely high temperature gas that surrounds it during atmospheric entry? Will it produce enough lift so that it will fly along the planned trajectory? Will the uncertain state of the atmosphere cause the capsule to veer off course? These questions must be answered to a known level of accuracy before the spacecraft can be designed. Failure to predict heating levels or aerodynamic performance can result in a well-publicized and expensive loss of the mission. At the same time, excessive conservatism in the design reduces the useful payload of the spacecraft and increases the cost of the mission.

How do we go about modelling this complex problem? We cannot fly a statistical ensemble of missions and empirically extrapolate to the flight conditions of interest. Instead, we must rely on ground-based wind-tunnel testing and theory-based simulations. However, experiments have a number of limitations: it is impossible to test the full-scale capsule; it is usually impossible to produce the actual flight conditions; and we cannot produce the actual intense heating levels for realistic periods of time. On the other hand, we can use numerical simulations to predict the flow field around the full-scale spacecraft at critical points in the entry trajectory. In principle, these calculations can predict the heat transfer rates and aerodynamic forces, and provide accurate data for the spacecraft designers. Of course, these simulations are only as accurate as the underlying equations being solved, and herein lies the problem. We cannot rely on purely empirical measurements to test a spacecraft design, yet simulations require a set of governing equations that must be validated by realistic flight experiments.

Interestingly, the basic set of governing equations that describes the flow over a spacecraft entering a planetary atmosphere is well established. However, there are many parameters in these equations that are the subject of intense debate within my field. We do not have an accurate understanding of the chemical reaction rates in the flow field; we do not know how to model transition to turbulence in the flow near the surface; we cannot predict how much turbulent flow enhances the heat transfer rate; and we do not understand how the high-temperature gas interacts with the spacecraft surface. A complete model of the flow over a spacecraft entering the atmosphere of Mars has well over 100 model constants that must be determined before the equations are fully specified. Clearly, with our limited experience base and with the limitations of the ground-based testing facilities, it is fundamentally impossible to determine these model constants with the available data. Rather, we must impose a rigorous theoretical basis for the choice of these model parameters. Also, we must understand the sensitivity of the critical results (heat transfer rate and aerodynamic forces) to the choice of the parameters. For example, there is no sense in investing a lot of time and money to accurately determine a model parameter that has a one per cent effect on the lift at relevant conditions.

So what do we do? We attack the problem from two sides. First, we break the full problem into well-defined parts and use theory and experiment to determine specific parameters under controlled conditions. For example, we might be concerned with how high-temperature oxygen molecules attack a particular heat-shield material. We would commission experiments to address this specific issue at conditions that are as close as possible to the flight conditions. Typically, it is impossible to exactly reproduce the conditions, and we would then perform experiments in different test facilities to help bound the parameters. Theory would then be used to extrapolate from the test conditions to those encountered in flight. We always try to use a theoretical basis to provide discipline to this process. We never perform atheoretic variations of parameters to try to match the data – if it is necessary to break the laws of physics, there is usually something wrong!

The second approach to modelling the flow field is to determine what parameters really matter to the design. A very useful approach is to use theory and experience to bound the range of all parameters in the model. Then a large number of simulations are performed, sampling from the distribution of each parameter. With enough simulations, it is possible to determine the sensitivity of the spacecraft design to each of the modelling parameters. Usually with this parametric uncertainty analysis it is possible to isolate several critical parameters that require particular attention. For example, Wright, Bose and Chen (2007) determined that eight modelling parameters out of several hundred were responsible for 90% of the uncertainty in the design of a proposed spacecraft. New experiments were then designed and carried out to reduce the uncertainty in these critical parameters.

Another engineering perspective is worth noting. We fully recognize that our representation of the world will never be 100% per cent accurate. Rather, we must quantify the level of accuracy of a given model and determine if we can fly a mission with that implied level of risk. We must quantify levels of uncertainty in a design and recognize that a spacecraft that will never fail will be excessively expensive or will carry so little payload as to be worthless. Thus, there is a calculated risk associated with the uncertainty in our modelling parameters. Of course, we try to reduce this uncertainty, but ultimately we are always forced to live with some level of risk if we want to fly an interesting mission.

Prescott: The Macroeconomist

The selection of parameters in quantitative theory is not measurement. However, quantitative theory is often useful in measurement. It is also useful in making predictions and in accounting for observations. Some examples of successful application are as follows.

The Lucas (1978) asset pricing model with the Markov process on the growth rate of endowments places restrictions on the joint behaviour of asset returns and consumption given two parameters that specify the stand-in household's preference ordering. The first parameter is the degree of risk aversion and the second parameter is the degree of impatience. These restrictions hold in worlds in which there are no transaction costs, no taxes, and no intermediation costs. Whether abstracting from certain factors is reasonable or not depends upon the question.

Mehra and Prescott (1985) used this asset-pricing model economy to estimate how much of the historical equity premium is a premium for bearing aggregate risk. We selected a Markov aggregate endowment growth-rate process whose first two moments matched the historical experience. We used observations and theory to restrict the values of the two preference parameters, including numerous observations on household behaviour. This process of restricting these parameters is part of the calibration process. We found that only a small part of the historical equity premium was a premium for bearing aggregate risk for *any* value of the parameters in the restricted range. This model economy is ill suited for measuring the curvature and impatience parameter of the stand-in household, but it was well suited for determining how much of the historical equity premium is for bearing aggregate risk.

I turn now to a case where a key economic parameter was estimated accurately using a calibrated *set* of model economies. The neoclassical growth model used to study business cycles was used to estimate the leisure intertemporal elasticity of substitution parameter. This parameter is crucial for evaluating tax policies. Because the income and substitution effects roughly offset secularly, balanced growth observations say nothing about the magnitude of this elasticity parameter. If the neoclassical growth model is accepted as a good abstraction for studying business cycles, business cycle observations tie down this parameter. But the profession was reluctant to accept this theory as a useful one for studying business cycles and therefore did not accept the business cycle-based estimate of this elasticity.

This important parameter was tied down by cross-country and cross-time observations on tax rates and labour supply. Tax rates, broadly defined to be those features of policy that affect the households' budget constraint, account for virtually all

the large differences in labour supply across the large advanced industrial countries and across time for France, Italy and Germany. That this estimate is the same one found in the study of business cycles gave confidence to the view that business cycles are in major part optimal responses to real shocks including productivity, taxes, and terms of trade. As established theory and measurement were used in this study, this is calibration.

I turn now to a specific application of the neoclassical growth model to the study of the aggregate value of the stock market, which also entailed calibration. The study that began in late 1999 was motivated by the question of whether the stock market was overvalued and about to crash. At that time people did not know how to use this theory to obtain an accurate answer to this question and relied on historical relations such as price–earnings ratios to answer the question.

To address this issue neoclassical growth theory as developed in the study of business cycles was used. The model economy had to be modified in three important ways. First, there had to be at least two production sectors, a corporate and a non-corporate sector. To have a reason for having two producing sectors, the outputs of the sectors must be different and must be aggregated in some way. McGrattan and Prescott (2005) use the standard procedure of introducing an aggregator of the sector outputs that produces a composite final output good. This aggregator has a share parameter that must be *calibrated* to some observation. The observation selected is the average relative outputs of these two sectors. This is a crucial dimension for the model to mimic reality, given the issue being addressed. The conclusion turned out to be insensitive to the elasticity of substitution between these inputs, which was fortunate given there is not good information on this elasticity. Second, the tax and regulatory system had to be modelled explicitly. For example, we set the model's tax rate on corporate distributions equal to the average marginal tax rates on distributions. This is calibration because in the model world this tax rate is the same for all individuals when in fact it is not. Third, we deal with the fact that corporations have large stocks of unmeasured productive assets and that these assets are an important part of the value of corporations, being stocks of knowledge resulting from investment in research and development, organization capital and brand capital. We figure out how to estimate this stock of unmeasured capital using national account data and the equilibrium conditions that the after-tax return on measured and unmeasured capital are equal.

A theory is tested through successful use. The theory correctly predicts the great variation in the value of the stock market in relation to GDP, which varied by a factor of 2.5 in the United States and by a factor of three in the United Kingdom in the 1960–2000 period. Little of this variation is accounted for by the obvious factors, namely after-tax earnings in relation to GDP and the debt–equity ratio, which varied little over time. The secular behaviour of the stock market value, with its large variation in relation to gross national income, turned out to be as predicted by theory and is not due to animal spirits.

Another example of successful calibration is Hayashi and Prescott (2002), who examined why Japan lost a decade of growth. The neoclassical growth model used in their study is the one used in the study of business cycles. The exogenous parameter paths were working-age populations, capital income tax rates, and total factor productivity parameters (TFP). The TFP parameters were determined residually from the production function given the quantities of the factor inputs and the output. Given these exogenous elements the equilibrium path was computed. The finding is that the Japanese economy behaved as predicted by the theory. The reason for the lost decade of growth was the failure of TFP to grow. This led to the important question of why Japanese TFP failed to grow as it did in western Europe and North America in this period.

Similarities and Differences Between Aerospace Engineering and Macroeconomics

Both Candler and Prescott study and model aggregate phenomena. Neither can find the answers empirically through trial and error and both must rely on theoretical computer simulations restricted

by measurement. We both test for the robustness of our predictions when making predictions as to what will happen in situations never experienced. In one case the prediction is what will happen to a spacecraft that will be sent to Mars. In the other case it is what will be the consequences of implementing a proposed policy arrangement. Both rely on established theory and measurement to draw quantitative inference.

A difference is that the engineers have the equations, while macroeconomists have statements about preferences and technology. A consequence of this is that macroeconomists have the added step of determining the equilibrium equations of their model. Another minor difference is that computational intensity is much greater in aerospace engineering than in macroeconomics.

Cameralism is the specific version of mercantilism taught and practised in the German principalities (*Kleinstaaten*) in the 17th and 18th centuries. Becher (1635–82), von Justi (1717–71) and von Sonnenfels (1732–1817) are the principal figures who contributed to a vast cameralist literature of about 14,000 titles (Humpert, 1935). The subject matter of *Kameralismus* reflected the political and economic phenomena and problems in the German territorial states. As a branch of 'science' it is a fiscal *Kunstlehre,* that is, the practical art of how to govern an autonomous territory efficiently and justly via financial measures designed to fill the state's treasury. Its subject matter includes economic policy, legislation, administration and public finance. While there is no unifying analytical foundation of cameralism, it did develop in two distinct phases (a younger and an older branch) with varied emphasis on its different elements, and since the rising state was, in theory and reality, the focus and *ultima ratio* of political, economic and ethical (occasionally promotive) speculation, cameralism takes on a unitary form (*Gestalt*) only when viewed in retrospect.

The term 'cameralism' itself originates in the management of the state's or prince's treasure (*Kammer, caisse, camera principis*), seen as the principal instrument of economic and political power. In the age of enlightened absolutism, German–Austrian cameralism, based on a somewhat obscure natural-law philosophy, emphasized the paternalistic character of the governments'

centralized fiscal policy (not, as is sometimes mistakenly thought, a Keynesian short-run instrument but rather a regulator for development which was to serve the general happiness of the subjects (*Untertanen*), that is, an eudaemonistic utilitarianism). English and French mercantilism, on the other hand, stressed much more the wealth or 'riches' of the sovereign as an end.

The princely bureaucrats had been trained in their own universities (for example, Halle, Frankfurt/Oder, Vienna) in 'fiscal jurisprudence' (von Stein) – a mixture of both formal budget and tax 'principles' – and a highly pedantic and descriptive systematization of facts and definitions. Analytical economics, insights into the laws of the market and the study of the interaction between market and state (or even of the bureaucratic and political mechanism) are relatively unknown in the simple textbooks of the cameralists, which show otherwise sound common sense. Statistics, important for census and grasping foreign trade, became a new discipline of the cameral curriculum.

The *practical* policy of cameralism concentrated on the development of a country which had been devastated and depopulated in the 30 Years' War and impoverished by the discovery of the sea route to India and the fall of Constantinople. Under these abnormal circumstances a political and bureaucratic monopoly attempted to reconstruct the economic foundations of the country by an active population policy, the establishment of state manufactures and banks, the extension of infrastructure (canals, bridges, harbours and roads) and the promotion of modernization. It strictly regulated the still important agricultural sector, as well as trade and commerce.

The state protected the trades (*Gewerbe*) by means of high tariffs to restrict imports of unnecessary raw materials and it facilitated exports of manufactures and import substitution. On the other hand, the government removed internal trade barriers by abolishing the medieval guild organization and by unifying the law for municipalities. Mercantilist efforts to augment the state treasure via trade surplus and money policy were, of course, another main cameralistic aim. Finally, it is notable that its monetary policy was inconsistent, in so far as the hoarding of precious metals as opposed to their circulating function was not clearly distinguished.

To set cameralism in secular perspective, the famous arguments of Smith and the Physiocrats against the 'mercantile system' seem to be *mutatis mutandis* valid for neo-mercantilism, which also justifies both state intervention in the market and a greater GNP government share and often reverts to the regulatory rules and the principles of planning in this former epoch. However, neo-mercantilism fails to prove seriously both the state's competence to ensure efficiency and equity in the public sector and its ability to regulate the market reasonably. Some writers tend to overlook that in our times the basic conditions in the state and the economy are radically different from those of three centuries ago. For example, economic, political and administrative conditions in the German principalities differed strikingly from Ludwig Erhard's situation after the Second World War. And the wide gap between the Great Depression of the 1930s and the technologically influenced stagflation of the 1980s was obviously so fundamental that the regulatory Keynesian budget and employment theory, with its then unrealistic assumptions, became rather obsolete. Thus any attempt to revive the strict regulating prescriptions of all-embracing cameralism, which lacks sufficient analysis and empirical testing, would apparently be a violation of both reason and experience. In this case we would use analytically poor (and old) tools to repair the wrong (and modern) machine.

Campaign Finance, Economics of

Scott Ashworth

Abstract

This article surveys recent work aimed at evaluating the welfare effects of campaign finance reform. The theoretical literature distinguishes two types of contributor: those who desire ideological policies and those who want personal favours. A series of models shows that these different types of contributor have different implications for campaign finance regulation. The models also give some suggestions about the sort of empirical evidence that would argue for or against certain campaign finance regulations. These suggestions have been followed up by recent empirical work.

Campaign finance is a contentious issue in American politics. Reformers charge that a system in which interest groups provide the funds for campaigns creates opportunities for corruption, while others argue that restrictions on donations would limit the provision of information to voters. For an economist, the natural way to evaluate such arguments is to construct a model that explicitly treats the preferences and beliefs of the voters, to deduce the conditions under which the model predicts welfare improvements from regulation, and to check empirically if these conditions hold in actual elections. This article surveys a recent body of literature that does just that.

First-Generation Models

Early work on campaign finance took a reduced-form approach to the link between campaign activity and votes (Austen-Smith 1987; Baron 1989, 1994; Grossman and Helpman 1996; Snyder 1990). This literature identified two ideal types of contributor: position-induced contributors, who help ideologically compatible candidates win office, and service-induced contributors, whose contributions are analogous to purchasing contingent claims on favours provided to the buyer at the expense of citizens in general.

This literature yielded several important insights. For example, Baron (1989) finds that trades of contributions for promises of favours have interesting implications for the incumbency advantage (see, for example, Gelman and King 1990, and Ansolabehere and Snyder 2002, for empirical work on the incumbency advantage in US elections). A candidate with an exogenous advantage is more likely to be able to deliver the promised favours, making the promise more valuable. Thus an advantaged candidate can raise funds on more favourable terms, reinforcing the advantage. Morton and Myerson (1992) show that this mechanism can even lead to multiple equilibria, where predictions that one candidate will win become self-fulfilling because contributions flow to the presumptive winner.

As the comprehensive survey of this literature by Morton and Cameron (1992) emphasizes, this approach cannot address the welfare qsts raised by proposals for campaign finance reform. We now turn to more recent research that ‘opens up the black box’ and provides some welfare analysis.

Microfounded Models

A bare-bones model illustrates the main points of the literature. The game has four players: two candidates, a voter, and an interest group.

Each candidate has some level of 'quality', which could be either ability or ideological similarity to the voter. The key is that quality is valued by the voter. Candidate i's ability is θ_i. It is common knowledge that $\theta_1 = 1$, and that θ_2 is equally likely to be 0 or 2. Each candidate maximizes his probability of winning.

At the start of the game, the candidates learn θ_2, but the voter does not. At cost $c \in (0, 1)$, candidate 2 can truthfully reveal θ_2. Candidates have no funds of their own. The interest group has sufficient funds to pay for the information transmission, if it wants to.

Even without specifying the group's payoffs, we can derive two benchmarks. *The no-campaign solution*. First, assume the interest group is prohibited from funding candidate 2's campaign. Then the voter goes to the polls not knowing θ_2. Thus she is indifferent between the two candidates, and gets expected payoff 1 no matter how she votes. The natural voting rule is to have her toss a fair coin. (This would be the outcome if there were a mean-zero popularity shock prior to the election.) In this case, each candidate gets payoff 1/2.

The voter's optimum. Second, assume there is a planner who can observe the true θ_2 and communicate it to the voter, paying for the communication with a lumpsum tax on the voter.

Announcing the true θ in only one of the states suffices for complete communication, and allows for a cost savings compared with always announcing the state. So the planner announces θ_2 if and only if $\theta_2 = 2$, and the voter votes for 2 if there is an announcement and for 1 if not. Her payoff is

$$\frac{1}{2} + \frac{1}{2}(2 - c) = \frac{3}{2} - \frac{1}{2}c > 1.$$

Thus the voter is better off than in the no-campaign solution. Furthermore, each candidate still wins with *ex ante* probability 1/2, so the policy represents an *ex ante* Pareto improvement over the no campaign solution.

This scheme would be hard to implement, because it is vulnerable to collusion between the regulator and candidate 1. Thus we are interested in whether or not interest-group finance can improve on the no-campaign benchmark.

Position-Induced Contributors

Now assume the interest group wants candidate 2 to win independent of θ, perhaps because it shares the candidate's ideology. Formally, the group's payoff is

$$bw - k,$$

where $b > 0$ is the payoff to the group from having 2 win, w is an indicator variable equalling 1 if and only if candidate 2 wins, and k is the contribution to candidate 2. The timing is:

1. The candidates and the group learn θ_2.
2. The group chooses a contribution $k > 0$.
3. If $k \geq c$, the candidate decides whether or not to advertise θ.
4. The voter sees any ads purchased, and then selects the winner.

Proposition 1 *If $b > c$, then there is a perfect Bayesian equilibrium (PBE) in which*

- *the group contributes c if and only if $\theta_2 = 2$* and
- *the voter chooses candidate 2 if and only if she sees an ad certifying that $\theta_2 = 2$.*

The idea is simple. The group is better off if 2 wins. If $\theta_2 = 2$, the group can ensure that 2 wins by funding a campaign informing the voter of her true preference for 2. And if the benefit from having 2 win (b) exceeds the cost (c), the group wants to do this. Finally, the group does not contribute to a low type of candidate 2 – this cannot help the group because the candidate cannot lie.

If there are contributions in equilibrium, then the voter gains over the no-campaign solution, having a payoff of $3/2 > 1$. Thus banning contributions reduces the voter's welfare. Furthermore, the equilibrium without contributions is Pareto dominated by the following matching fund policy. Fix γ strictly between 0 and b. If the group donates γ to candidate 2, then the regulator kicks in $c - \gamma$, paid for by a lump-sum tax on the voter. The group's *ex ante* payoff increases from 0 to $(b - \gamma)/2$ and the voter's payoff increases from 1 to $3/2 - (c - \gamma)/2 > 1$. The candidates are indifferent at the *ex ante* stage.

Coate (2003) elaborates on this story in two ways. First, the voter is uncertain about both ideologies, and both candidates can receive contributions. Second, and more importantly, candidates are selected by the party's median member, who has different preferences from the median in the electorate. (Here quality is the inverse of distance from the median.) The interest group prefers less moderate candidates. However, the groups prefer to fund more moderate candidates – campaign ads are effective only when the ad reveals that the candidate is more moderate than a non-advertising candidate. This gives the party an additional incentive to choose moderate candidates, because moderate candidates can raise funds and thus do well in the election. In equilibrium, the party mixes between moderate and extremist candidates.

In this environment, simply banning contributions creates both winners and losers. Moderate voters lose. First, they must make their choices with worse information, as in the bare-bones model above. Second, candidates are less likely to be moderate. Members of the interest groups, on the other hand, are better off. They save the cost of the contributions, and policy is no worse in expectation – the extra probability that policy is extreme in the wrong direction is exactly offset by the increased probability that policy is close to the group.

Service-Induced Contributors

Now assume the group does not care directly who wins the election. Instead, the group values transfers from the winner. The group and candidate 2 can sign a contract specifying that candidate 2 receives c from the group, and, if he wins, he transfers the amount t to the group. This transfer if financed by a tax on the voter of $(1 + \lambda)t$, where λ represents the deadweight loss of the transfer.

The timing is:

1. The candidates and the group learn θ_2.
2. Candidate 2 makes a take it or leave it offer of a contract t to the group.
3. The group accepts or not.
4. If the contract is accepted, the candidate decides whether or not to advertise θ.
5. The voter sees any ads purchased, and then selects the winner.

Proposition 2 *If* $(1 + \lambda)c \leq 1$*, then there is a PBE in which the group funds the campaign if and only if* $\theta_2 = 2$ *and the voter selects candidate 2 if and only if she sees an ad certifying* $\theta_2 = 2$.

Again, the basic idea is simple. If the voter sees an ad, she learns two things. First, she learns that $\theta_2 = 2$, which improves her evaluation of candidate 2. Second, she learns that the group and the candidate have made a deal, so electing candidate 2 costs her $(1 + \lambda)c$. This tradeoff is acceptable if $(1 + \lambda)c \leq 1$.

In such an equilibrium, the voter's payoff is

$$\frac{1}{2} + \frac{1}{2}(2 - (1 + \lambda)c) = \frac{3}{2} - \frac{(1 + \lambda)c}{2}.$$

This payoff is lower than the voter-optimal benchmark payoff by $\lambda c/2$.

Again, matching funds can help. Assume again that the regulator pays $c - \gamma$ of the cost. This policy reduces the welfare loss compared with the benchmark to $\lambda\gamma/2 < \lambda c/2$.

Most papers in the literature introduce some uncertainty in the voting stage. With this addition, Prat (2002), Coate (2004) and Ashworth (2006) show that the candidate might promise so much that the voter actually *loses* from the campaign. To see the intuition, consider the candidate's incentive to advertise. Without probabilistic voting, the incentive to expand transfers is limited – once the voter's cost of transfers passes 1, the probability of election changes discontinuously from 1 to

0. With probabilistic voting, by contrast, small changes in transfers have similarly small effects on the re-election probability. In this case, candidates have an incentive to expand transfers all the way to the point where the voter is indifferent between a high-quality candidate with transfers and a low-quality candidate with no transfers. In such a case, the voter actually loses from the possibility of a campaign, and would be better off if contributions were banned outright – the likelihood of getting a high-quality winner is no lower, and the voter escapes the cost of favours.

The key to the inefficiency here is that the voter's knowledge that ads imply favours to interest groups makes the ads less effective at ensuring a high-quality candidate is elected.

Again, matching funds might be a better solution. In Coate (2004), the scale of the campaign can vary continuously. Greater spending increases the fraction of the (large) electorate that is informed. Matching funds come into play if the benefit from winning is low enough that ads are not rendered totally ineffective. In that case, a limit on contributions reduces the amount of favours, preserving the effectiveness of the ads. And the matching funds allow the scale of the campaign to be unchanged from the unregulated case.

So far, matching funds have seemed like a great policy. But they have a cost in asymmetric contests. In Ashworth (2006), the scale of campaigns is fixed (as in the bare-bones model above), but candidate 2 has an advantage independent of advertising. For moderate levels of the advantage, the advantaged candidate mounts a costly campaign even though the value of the information to the voter is less than the cost the voter pays *ex post*. For greater values of the advantage, no campaign takes place in equilibrium – the possible increase in the voter's evaluation is too small to outweigh the promised favours. Matching funds can increase the likelihood of an active campaign in such cases, even though reducing their likelihood would be efficient.

Hard vs. Soft Information

The literature focuses on two mechanisms that make advertisements informative. The first is the one we have relied on above, namely, the candidate may have verifiable information, information that cannot be falsified. The second, studied by Gerber (1996), Prat (2002), and Potters et al. (1997), is indirectly informative campaigns. Interest groups observe the quality of the candidates, but voters do not. If groups condition their contributions on quality, then voters can learn about quality by inverting the contribution schedule. Gerber and Prat show that equilibria with informative advertising exist, even thought the ads have no direct informational content. As in the case with hard information, service-induced contributions imply that a ban on contributions can benefit the median voter. On the other hand, public financing would have no value with indirectly informative advertising – there's no signal if the election regulator hands out funds to everyone. Thus a non-trivial policy problem of public financing arises only with directly informative advertising.

Empirics

Do Contributions Buy Favours?

Contributors' motivations played a key role in the welfare conclusions above. What do the data say about these motivations? The most direct approach to this question looks at correlations between donations from interest groups and votes that those groups care about. For example, we could regress votes in favour of increasing the minimum wage on contributions from unions. Of course, a positive correlation on its own does not discriminate between the theories – are the union contributions changing votes or do unions just contribute to exogenously union-friendly candidates? The many studies that try to disentangle these forces affecting roll-call votes find only weak evidence that contributions buy votes (Ansolabehere et al. 2003). One interpretation is that contributions are positioninduced rather than service-induced.

However, focusing on roll calls misses much Congressional activity (Hall 1996). Thus researchers have also looked to more indirect evidence. For example, Gordon and Hafer (2005) find that firms making large donations are less

monitored by agencies, suggesting that donations induce members of Congress to interfere in regulatory oversight. Many papers have shown that political action committees (PACs) direct their contributions in ways more consistent with service-induced motivations than with position-induced motivations (Kroszner and Stratmann 1998; Romer and Snyder 1994; Snyder 1990). Perhaps the most convincing is McCarty and Rothenberg (1996), who document that individual PACs made significant shifts in donations from Democrats to Republicans after the Republicans took control of Congress in 1994, suggesting that the contributions were not ideological.

Attempts to directly estimate the impact of contributions on policy have not reached a consensus, except that the effects are smaller than public outcry might suggest (Ansolabehere et al. 2003). The next subsection turns to a more theory-driven approach to evaluating the potential for welfare gains from regulation.

Spending and Election Outcomes

A substantial empirical literature has tried to estimate the effect of campaign spending on electoral outcomes. Cross-sectional analyses that do not condition on incumbent quality show that challenger spending is associated with better electoral performance, but incumbent spending is unrelated to success. (See the discussion in Jacobson 2001, ch. 3, which summarizes the extensive empirical work initiated by Jacobson 1978.) Of course, interpreting these correlations is difficult because of an endogeneity problem – candidates spend more when they expect the race to be competitive. Several researchers have tried to deal with this endogeneity issue (Green and Kranso 1988; Levitt 1994; Gerber 1998; Erikson and Palfrey 1998; 2000). These papers all find that spending is roughly equally effective for both incumbents and challengers, but there is no consensus about the size of the effects. (Looking across several of the most prominent estimates, Gerber 2004, calculates an implied cost for a House incumbent to get one additional vote ranging from $15 to $367.)

Prat (2000) points out that, even when one controls for candidate quality, there is an identification problem in these regressions. Simply put, the functional relationship between spending and election outcomes (with quality held fixed) depends on the way funds are raised. To see this, consider the models of service-induced contributions discussed previously. In all of the models, an exogenous increase in quality has two effects. First, the candidate raises more funds and informs the voters of his high quality, which helps his electoral chances. Second, the voter infers that the funds were given in exchange for promises of favours, which hurts his electoral chances. Thus the regressions estimate 'the effect on electoral outcomes of an extra dollar of campaign spending net of the political cost of persuading lobbies to donate the extra dollar' (Prat 2006, p. 60).

In addition to providing an important critique of the standard inpts of the empirical evidence, the prediction that the effectiveness of advertising is decreasing in the degree of service-induced contributing provides a way to test empirically for the possibility of welfare-improving policy. In particular, the theoretical models suggest that limits on contributions and (perhaps) matching funds can improve welfare precisely when campaign spending is ineffective. Thus the prediction of reduced effectiveness speaks directly to the welfare implications of the models.

Stratmann and colleagues have been leaders in testing these implications. Houser and Stratmann (2006) carry out laboratory experiments modelled after the theoretical set-up of Coate (2004) and Ashworth (2006). High-quality candidates are more likely to win in a public financing treatment than in a privately financed treatment. They also find that margins of victory are greater in the public financing treatment. In a treatment with caps on contributions, they find that voter welfare goes up, but the probability of electing a high-quality incumbent does not. These experiments support the theoretical predictions, suggesting that voters are capable of inferring that interest-group financed ads imply that the candidate has promised favours.

Stratmann (2006) exploits state-level variation in campaign finance laws to see whether the theoretical predictions hold up in field data. He first estimates standard vote-share/spending

regressions for each state's House elections. He then examines the relationship between the effectiveness of spending and the existence of limits on contributions. As predicted by the theory, he finds that effectiveness is lower when campaign finance regulations are more liberal. These results hold for all of incumbents, challengers, and open-seat candidates. Stratmann and Aparicio-Castillo (2006) show that states that limit giving subsequently have lower incumbent vote shares. This finding is consistent with Baron's (1989) and Ashworth's (2006) theoretical finding that the financing process can exaggerate incumbency advantages.

Canada, Economics in

Robert W. Dimand and Robin F. Neill

Abstract

In the first half of the 20th century, economics in Canada was primarily economic history, and its contribution was the staple theory of Canadian economic development. After the Second World War Keynesian macroeconomics swept the nation and, despite its British origin, it indigenized into a theory of primary product export-based growth, and a Western Marxist theory of the staple trap. In the last quarter of the century, positivism, monetarism, and neoconservative new classical economics swept north from the United States, leaving only the specific domestic circumstances to which it was applied as the distinctive thing about economics in Canada.

The pre-history of economics in Canada begins with the description of the society and products of New France by Pierre Boucher (1664), a former governor at Trois Rivieres and the founding seigneur of Boucherville, writing in the political arithmetic tradition of Boisguilbert and Vauban. The most notable of such descriptive works was, after the British conquest, the vast, disorganized, but often incisive *Statistical Account of Upper Canada* by the political dissident Robert Gourlay (1822), whose criticism of unrepresentative and corrupt government led to his exile as an undesirable alien - on the grounds of his birth in Scotland rather than England (Dimand 1992). Although, apart from Boucher and Gourlay, early descriptive writings about settlement and economic conditions in Canada tended to have little economic analysis, Boucher displayed an intuitive sense of economies of scale, urging that policy should encourage concentration of settlement in small areas, where mutually beneficial exchange would lead to a surplus product. Independently, Gourlay later formulated a linear relationship between land values and the number of inhabitants per acre. He urged the government to borrow to fund increased immigration and settlement, paying off the loan by taxing the resulting increase in land value. The influence of Gourlay's theorizing about the appropriate structure of property rights to promote population density in a newly settled colony (such as

limiting the size of land grants to avoid dispersion of settlers) was acknowledged by Edward Gibbon Wakefield, the English theorist of colonization who wrote Appendix B on land policy for Lord Durham's report on Canada after the 1837 rebellion and then served in the Canadian legislature before taking a leading role in the settlement of New Zealand (Wakefield 1968; Goodwin 1961, ch. 1; Neil 1991, ch. 1). One Canadian topic, the playing card currency of New France, so often cited by later economic historians (for example, Shortt 1987), attracted the attention of one of the great early economists, the philosopher David Hume, as British charge d'affaires in Paris after the Seven Years War and then as Under-Secretary of State; Hume negotiated the settlement of the outstanding paper money of New France after the British Conquest (Dimand 2005).

John Rae was an outstanding 19th-century economic theorist who wrote his *New Principles of Political Economy* (1834) while headmaster of the Gore District Grammar School in Upper Canada (now Ontario). Rae, although born and educated in medicine in Scotland, eventually became a district judge in the Kingdom of Hawaii before dying in Staten Island. For decades, he was known primarily through John Stuart Mill's citation of his statement of the infant industry argument for protection: although Sir John A. MacDonald, Canada's first prime minister, cited Rae in support of his national policy of tariff protection for manufacturing, he seems to have known of Rae only through Mill (MacDonald, quoted in Neill 1991, pp. 85–91). C.W. Mixter's new, rearranged edition of Rae's book in 1905 revealed Rae's analysis of 'effective desire of accumulation' as a pioneering capital theory, and two years later Irving Fisher dedicated The Rate of Interest 'to the memory of John Rae who laid the foundations upon which I have endeavored to build', acknowledging Rae for foreshadowing both time preference and internal rate of return over costs. Rae has since been celebrated for his discussions of conspicuous consumption, more than six decades before Thorstein Veblen, and of endogenous technical change (James 1965; Hamouda et al. 1998). University of Toronto mathematics professor John Bradford Cherriman (educated at St John's College, Cambridge, a few years before Alfred Marshall) made another striking, but isolated, contribution to economic theory: a ten-page review article and exposition of Cournot's essay in mathematical economics of 19 years before, endorsing the mathematical approach to political economy, hailing Cournot's work as more important than Ricardo, and long antedating Joseph Bertrand's 1883 article that was long thought to be the first review of Cournot's 1838 volume (Cherriman 1857; Dimand 1988, 1995). More characteristic of this period than the theorizing of Rae and Cherriman were the numerous practical and descriptive discussions of economic affairs, economics in the context of action (see Goodwin 1961; Neil 1991; Neill and Paquet 1993).

The Rise of Academic Economics in Canada

Although a few courses had been offered previously, economics in Canadian universities began in 1888 with the appointment of the English historical economist W.J. (later Sir William) Ashley as professor of political economy and constitutional history at the University of Toronto and of Adam Shortt (previously tutor in philosophy, instructor in botany, and demonstrator in chemistry) as lecturer in political economy at Queen's University, Kingston (promoted to Sir John A. Macdonald Professor of Political Science in 1891). Professorial appointments at the university were then made by Order in Council by the provincial government, and candidates were interviewed by the Premier of Ontario and by the chancellor of the University. No classical or neoclassical theorist would have been appointed, lest they promote free trade in their lectures, but the English Historical School was acceptable (Drummond 1983). When Ashley departed in 1892 to become professor of economic history at Harvard (and later dean of commerce in Birmingham), he was succeeded by James Mavor, Scottish economic historian of Russia and friend to Tolstoy, Kropotkin, and the Doukhobors (see Mavor 1923), and until 1970 the Department of Political Economy was led by a succession of distinguished

economic historians (apart from one sociologist), notably Harold Innis and William Easterbrook, and the historian of economic thought Vincent Bladen (see Drummond 1983; Bladen 1978). Under Ashley's sponsorship, the University of Toronto published the first academic economic writing by a Canadian woman, Jean Scott Thomas (1889), 'The conditions of female labour in Ontario'. As in other disciplines and elsewhere in the Dominions and the British Empire, several early professors of economics in English-speaking Canadian universities, notably Ashley and C.R. Fay in Toronto and A.W. Flux at McGill, were British scholars who had finished their careers in Britain, as was James Bonar, Deputy Master of the Mint in Ottawa and authority on Malthus. The British Association for the Advancement of Science met in Montreal in 1884; in other years it met in Dublin, Cape Town, or Sydney. The following year, the association commemorated its meeting with *Canadian Economics,* a volume of 27 papers by Canadian and American authors that, according to Goodwin (1961, p. 116), 'marked the end of an era when description and analysis were carried out by interested persons in all walks of life and before there were any professional economists in government and the universities' . The Canadian Political Science Association met in September 1913, with Adam Shortt as president, and published a volume of proceedings, but the September 1914 meeting was cancelled when the First World War broke out, and the association lapsed until 1929.

Long after the social sciences separated in Britain and the United States, they remained institutionally linked in Canada, sharing a single Department of Political Economy at the University of Toronto until 1982 (the equivalent term at McGill and the University of Saskatchewan was Department of Economics and Political Science), a single Canadian Political Science Association and the *Canadian Journal of Economics and Political Science* (first published in 1935) until 1966 (the sociologists and anthropologists seceded in 1963), with the economists departing only much later from the joint annual conferences of the Learned Societies (now the Humanities and Social Science Congress). As Taylor (1960, p. 8) remarks, 'Shortt, Skelton, Mavor, and Leacock throughout their careers could almost equally well be described as historians or political scientists.' While the economic historian Harold Innis headed Toronto's Department of Political Economy during the 1930s and 1940s, scholars in the various disciplines there, not all of them within the department, were linked by their historical approach and by Innis's influence, in historical sociology (S.D. Clark), history of political thought (C.B. Macpherson), history of economic thought (Vincent Bladen), economic history (John Dales, William Easterbrook), historical geography (Andrew Hill Clark), history of communications (Marshall McLuhan), Canadian history (Donald Creighton, Innis's biographer). Formal economic theory, in contrast, was conspicuously absent, except that A.F.W. Plumptre, before joining the public service, taught Keynes's *Treatise on Money,* having studied in Cambridge while that book was being written. When the University of Saskatchewan opened in 1910, economics was taught by the professor of history, using texts by Richard T. Ely, an American economist influenced by the German Historical School, and by Ashley, Archdeacon William Cunningham, and J. Kell Ingram of the English Historical School, but not Marshall or Jevons (Spafford 2000). One consequence of multidisciplinary sharing of departments, association, and journal was that after the humorist Stephen Leacock, trained in political science and author of a successful textbook in that field, succeeded Flux as Dow Professor of Economics and Political Science at McGill in 1908, he acquired public credibility for his economic pronouncements, such as advocating a tariff union for the British Empire to end the Great Depression.

Growing numbers of academics, and the gains from division of labour in scholarly research and publication as in other activities, led the social sciences in Canada to become increasingly separate after the Second World War, well in advance of formal institutional separation. The British connection and the emphasis on a historical approach also faded in the same decades, as Canadian economics became more grounded in formal theory

and quantitative methods and more attuned to intellectual developments in the United States.

The teaching of economics emerged later in French Canada. The journalist Etienne Parent (1846), an admirer of Adam Smith and Jean-Baptiste Say, was unusual in declaring political economy a science and urging the enlightened publication of the principles it taught, notably free trade and the respectability of commerce and industry as occupations. Although Parent became Under-Secretary of State when the Dominion of Canada was created in 1867, his views on the study of economics had little influence. Political economy was widely identified with doctrinaire free traders (such as Parent) and with the secular pursuit of material gain, and did not often find a place in the curriculum of the Jesuit classical colleges in Quebec, which steered promising students towards law, medicine and the Church. Attitudes toward social and economic research in Quebec changed following papal social encyclicals such as *Rerum Novarum* in 1891 (an influence that ceased to dominate intellectual life in Quebec after the 1960s). The École des Hautes Études Commerciales (HEC) was established in Montreal in 1911, and its journal *Actualité Ėconomique* began publication in 1925. Such HEC professors as Esdras Minville (1979), Edouard Montpetit (1939–42), and François-Albert Angers were concerned with the economic independence and distinctive cultural values of French Canadian society, beyond the technical aspects of the economics that Montpetit had studied under Charles Gide at the Sciences-Po in Paris, and the concerns of French Canadian economists were shaped by the uneasy relationship of their intellectual milieu and society with the rest of Canada and North America (see Falardeau 1944; Angers 1961; Parizeau 1968; and the extensive oral history in Paquet 1989 on the emergence and evolution of francophone economics in Canada).

The Staples Thesis

The two outstanding figures of inter-war Canadian economics, William A. Mackintosh (1923, 1939), of Queen's University, and Harold A. Innis (1930, 1940, 1956), of the University of Toronto, developed a distinctive approach to understanding Canada's economic development, the staples thesis (see also Mary Quayle Innis 1935; Creighton 1937; Neill 1972). Rejecting the universal applicability of neoclassical analysis of the market determination of relative prices, the staples thesis drew on a wide range of influences (including American institutionalists, notably Veblen) to argue that a newly settled, peripheral economy could not be studied in the same way as the core economies of the world economy. The keys to analysing Canadian economic development were the geographical setting (especially regional differences and the transport routes such as the St Lawrence Valley/Great Lakes) and the characteristics of the staple commodities such as cod, fur and wheat that successively dominated an export-oriented peripheral economy. The core-periphery distinction in the staples thesis was mirrored in the structure of interwar Canadian economics discipline: Mackintosh and Innis at the leading universities in the industrial and commercial heartland of Ontario developed the dominant interpretation of Canadian development as whole, while George Brittnell (1939) and Vernon Fowke (1946) at the University of Saskatchewan focused on the locally dominant staple, wheat, and maritime economists such as Stanley Saunders (1939) were concerned with the maritime provinces as an economically backward region within Confederation. This historical and institutional approach, which had parallels in later Latin American dependency theory, received considerable attention beyond Canada: at the time of his death in 1952, Innis had been elected president of the American Economic Association, the only foreigner or non-resident ever so honoured. Except for Creighton on the merchant class, the staple literature paid little attention to class until H. Clare Pentland's Toronto dissertation on the emergence of Canada's industrial working class, finished in 1961 and published posthumously 20 years later, but largely written at the University of Toronto before Innis's death (Pentland 1950, 1981). Canadian political economy influenced by Innis and Pentland continues to flourish in the disciplines of political science and sociology (and Innis 1951, is influential in

communications studies in Canada), but has largely disappeared from economics departments, as Canadian economics has become part of an international mainstream in which the old (or original) institutional economics, widespread in the interwar United States, has been marginalized.

Economists in and on Government in Canada

The Dominion Bureau of Statistics (now Statistics Canada) became a leading centre of quantitative research under Robert Coats, for 25 years the first Dominion Statistician, an achievement recognized internationally by the election of Coats as president of the American Statistical Association in 1938 (see Coats 1932; Keyfritz and Greenway 1961). Economists at Queen's and McMaster Universities produced two volumes of *Statistical Contributions to Canadian Economic History* in 1931. Economists became deeply involved in other areas of government, more so than in many other countries. After exploring Canada's monetary and banking history in a long series of articles in the *Journal of the Canadian Bankers Association* (reprinted as Shortt 1987), Adam Shortt, the first economics professor at Queen's University, came to Ottawa to head the Civil Service Commission and then to superintend the publication of numerous documents on monetary history (see Shortt 1976). His student and successor at Queen's, Oscar D. Skelton, winner of the Hart Shaffner & Marx Prize for a study of socialism (Skelton 1911), was Under-Secretary of State for External Affairs from 1925 until his death in 1941, an especially important position because the External Affairs portfolio was held by the prime minister, so that Skelton was the prime minister's deputy minister. Skelton in turn recruited another Queen's economics professor, W. Clifford Clark, as Deputy Minister of Finance from 1932 until Clark's death in 1952. Noteworthy anniversary surveys of the progress of economic scholarship in Canada were written by the Under-Secretary of State for External Affairs (Skelton 1932) and the Deputy Minister of Finance (Taylor 1960), rather than by academics, and economic research in Quebec was surveyed by a future separatist Finance Minister and Premier of Quebec (Parizeau 1968).

The Great Depression of the 1930s, which was especially severe in the Prairie provinces, and the Second World War expanded the role of the government in the economy, and of economists in government, notably with the creation of the Bank of Canada in 1934 and of a system of national accounts during the war. The extent of popular dissatisfaction with existing economic arrangements was shown in 1935 when Alberta gave 56 of the 63 seats in its provincial legislature (and, later that year, all 15 of its seats in the federal House of Commons) to Social Credit, a movement devoted to the heterodox monetary doctrines of Major C.H. Douglas (Ascah 1999). Keynesian macroeconomic policy offered a way to stabilize the economy and avoid depressions without recourse to central planning or inflationary Social Credit (see Brecher 1957, on interwar monetary and fiscal discussions in Canada). William A. Mackintosh of Queen's, nominally only a wartime special assistant to Clifford Clark but de facto head of the Economic Advisory Committee, drafted the federal government's 1945 White Paper on post-war employment policy. The White Paper made a commitment to macroeconomic demand management to maintain full employment that lasted in one form or another for three decades, until in 1975 Bank of Canada Governor, Gerald Bouey, announced the bank's conversion to targeting monetary aggregates to control inflation.

Keynesian ideas reached Canada through Keynes's wartime visits to Ottawa en route to and from the United States, and especially through a group of leading civil servants including some of his former students at Cambridge (Granatstein 1982; Owram 1986). A.F. Wynne Plumptre, who had studied with Keynes in the late 1920s, headed the economics division of the Department of External Affairs and then was Assistant Deputy Minister of Finance (1954–65) before returning to the University of Toronto. Robert Bryce, after attending Keynes's lectures for three years while Keynes was writing *The*

General Theory, was secretary to the Economic Advisory Committee during the war, Secretary to the Cabinet and Clerk of the Privy Council (1954–63), and Deputy Minister of Finance (1963–70). Keynesian macroeconomics reached Canadian academic economists through Mabel Timlin's *Keynesian Economics* (1942). Timlin, a secretary at the University of Saskatchewan, began writing that remarkable book as a Ph.D. dissertation for the University of Washington as early as 1935, before the publication of Keynes's *General Theory,* when Benjamin Higgins arrived in Saskatoon with a copy of Robert Bryce's summary of Keynes's lectures, which Bryce had presented to Hayek's seminar at the London School of Economics, where Higgins was studying. Timlin's book, her first publication at the age of 50, led to a distinguished academic career at the University of Saskatchewan, the presidency of the Canadian Political Science Association, the executive committee of the American Economic Association, and being the first woman in the humanities or social sciences elected to the Royal Society of Canada (see Alexander 1995, on the history of women in economics in Canada). After the war, Timlin wrote a series of review articles in the *Canadian Journal ofEconomics and Political Science* on welfare economics and the applicability of general equilibrium methods to public policy analysis, helping introduce Canadian economists to advances in economic theory elsewhere.

Mabel Timlin was also an early academic critic of the Bank of Canada for permitting inflation during the Korean War by failing to pursue Keynesian stabilization policy. A few years later, many Canadian economists denounced the Bank of Canada Governor, James Coyne, for being more concerned about inflation than with expansionary Keynesian policy to end a recession (Gordon 1961). Economists at the University of Western Ontario, notably David Laidler, Michael Parkin, and Thomas Courchene, later brought to Canada monetarist arguments that the Bank of Canada should adopt a monetary policy rule designed to combat inflation rather than pursuing Keynesian discretionary stabilization policy (Courchene 1975–80).

After the Second World War

The Canadian economics profession expanded along with the great expansion of Canadian universities that began in the 1960s and also with the growing employment of economists in the business community (Parish 1997). Along with the growth of numbers came specialization, first between the different Canadian social sciences (previously sharing departments, conferences and a journal), then between fields within economics. Canadian economics became increasingly theoretical and econometric, and decreasingly historical, in line with changes elsewhere, especially in the United States. Since the rise of academic economics in Canada, Canadian economists had studied in the United States (for example, Innis had taken his Ph.D. at the University of Chicago, with a thesis on the Canadian Pacific Railway) and taken part in American associations, but increasingly Canadian economics, like the rest of Canadian intellectual life, became more oriented towards the United States than to Britain (except that Quebec academics were very conscious of intellectual developments in France). Post-war Canadian economists made noteworthy contributions to economics, particularly the economics of natural resources (Gordon 1954; Scott 1955; Easterbrook 1959; George 1989) and international economics (for example, the effects of trade liberalization), but while Canada's position as a resource-based, small open economy guided the choice of topics, the analytical approaches taken were shared with the international community of economists. Many outstanding economics graduates of Canadian universities pursued careers outside the country, mostly in the United States, but among these, Jacob Viner, John Kenneth Galbraith, Harry Johnson, and Robert Mundell retained close ties to Canada, paid attention to Canada's distinctive economic experience (very large capital inflows relative to GDP before 1914, a floating exchange rate from 1950 to 1962), and took part both in Canadian policy debates and in influencing the development of the Canadian economics profession (for example, Viner 1924; Johnson 1963, 1968).

French mathematician and economist, Canard was born in Moulins, near Vichy, around 1750, and died there in 1833. Little is known about his life other than the fact that he taught mathematics at the Ecole Centrale de Moulins. His other interests included economics, jurisprudence and meteorology.

Canard's reputation as an economist rests on his *Principes d'économie politique* (1801), a study of the incidence of taxes, which, however, has drawn more attention for its use of mathematics in economic analysis. Written in the year of Cournot's birth, the *Principes* was honoured by the French Institute, the same body that refused to recognize the later efforts of Cournot and Walras. Cournot (1877, p. i) reviled Canard's work as 'false', even as he admitted that it provided him an important starting point for his own researches. Other harsh critics were Francis Horner, J.B. Say, Joseph Bertrand, W.S. Jevons, and Léon Walras. Despite this rejection by French and English economists, Canard had considerable influence in Italy, where a group of writers, led most conspicuously by Francesco Fuoco, defended his method and adopted some of his ideas. In the present century, Seligman (1927, pp. 159–62) has credited Canard with the diffusion theory of taxation, Schumpeter (1954) has discounted his contribution completely, while Theocharis (1983) has defended him.

The *Principes* was influenced by Cantillon and to a lesser extent by the Physiocrats, whose doctrine Canard sought to refute. Cantillon's influence is obvious in two major areas. First, without using the terms, Canard advanced both an 'intrinsic' and a 'market' conception of price. He held that everything derives its value from the quantity of labour bestowed upon it. Different (unmeasurable) qualities of labour, however, render labour quantity an unsatisfactory measure.

Therefore, one must look to the market to discover the determinants of price. Canard developed an equilibrium theory based on the relative bargaining power of buyer and seller, which he related to need and competition. (Clearly recognizing the forces of monopoly and monopsony, he nevertheless failed to develop a bilateral monopoly model.) Second, Canard revived Cantillon's 'three rents', and wove them into a general equilibrium conception of the economy, which he used to trace the effects of taxation (in the process, adumbrating the Ricardian theory of land rent).

Canard argued that the imposition of a new tax produces disequilibrium and sets in motion certain equilibrating adjustments which take time to work themselves through the economy. Each person who initially pays the new tax will attempt to pass it on to the purchaser of the good, but his success in doing so depends upon the 'forces' encountered; or as we would say today, the tax is shifted in proportion to the elasticities of demand and supply. Canard's maxim that 'every old tax is good, every new tax is bad', must be judged in this context.

Cannan, Edwin (1861–1935)

Murray Milgate

Cannan's name is linked inextricably with two great economic institutions: Adam Smith and the London School of Economics. His edition of the *Wealth of Nations* first appeared in 1904 and remains in print today (1986). Before the publication of the Glasgow edition of Smith's works in 1976, there was nothing that could even lay claim to being its rival. His association with the LSE began as a lecturer in 1895 (the year the School was founded), and continued (in the role of Professor from 1907) until his retirement in 1926.

Cannan was born on 2 February 1861 in Madeira, his mother having gone there on medical advice. Within three weeks of Edwin Cannan's birth his mother had died, and the family returned to Bournemouth where Cannan spent his boyhood. In 1880 he went to Balliol College, Oxford, and took his BA in 1884. He resided in Oxford for the remainder of his life although he was only once formally associated with that city's university when, in 1931, he held the Sidney Ball lectureship. Having a private income from a substantial family fortune, at no time in his life did Cannan have to rely upon securing paid employment for his living. Even after his appointment at the LSE, Cannan was in London on no more than two or three days a week. Cannan was twice President of Section F of the British Association (1902 and 1931), President of the Royal Economic Society (1932–4), and held honorary degrees from Glasgow (LL.D) and Manchester (Litt.D).

To Smith scholarship Cannan bequeathed not only his edition of the *Wealth of Nations* (1904) but also an edition of Smith's Glasgow lectures on jurisprudence (1896). Of the first of these, it is perhaps sufficient to note that subsequent scholarship has modified Cannan's editorial speculations as to its origins in only one major respect – concerning Smith's acquaintance with the work of Turgot – to demonstrate its value. The only other peculiarity of Cannan's commentary concerns his view of the theory of distribution, and it will be necessary to return to this point later. The publication of Smith's Glasgow lectures allowed scholars to observe for the first time just how many of Smith's subsequent views were to be found in his work on economics before his visits to France.

Cannan's original work in the history of economic thought is presented in a number of works, of which two call for separate attention: *A History of Theories of Production and Distribution in English Political Economy 1776–1848* (1893) and A *Review of Economic Theory* (1929). The former is the more carefully considered and better documented of the two, and although it would be difficult to agree with Hugh Dalton who in 1927 claimed that 'no one need ever do this particular piece of work again' (in Gregory and Dalton 1927, p. 11), it is nevertheless the case that both books can be consulted with advantage even by modern students.

It seems that Cannan worked full-time on *Theories of Production and Distribution* from 1890 onwards. In the process of preparing the manuscript, he accumulated a personal library rich in materials form the 18th and 19th century (a library which was subsequently to contain, among other things, a collection of tracts by those Cannan called 'currency cranks' and all editions of Smith's *Wealth of Nations* down to 1900). Many of Cannan's original, if somewhat singular, views gain expression therein. There are two that warrant mention here: the claim that a theory of distribution properly understood requires an explanation of the *shares* of wages, profits and rent in total production (and not an explanation of their respective *rates*, which he calls pseudo-distribution), and the implied definition of

'classical economics' as the period between (and including) Smith's *Wealth of Nations* and the first edition of John Stuart Mill's *Principles* in 1848.

The former opinion is re-iterated in his introduction to the *Wealth of Nations* where it is argued that 'the theory of distribution . . . is no essential part of the work and could easily be excised by deleting a few paragraphs in Book I, chapter vi, and a few lines elsewhere' (1904, p. xxxix). On Cannan's reading, Smith was sidetracked from what should have been his real target (a theory of distribution proper) into a discussion of distribution 'as a mere appendage or corollary of his doctrine of prices' (1893, p. 186), so that 'though Adam Smith had declared that the whole of annual produce is distributed into wages, profit, and rent, obviously meaning thereby total wages, profits, and rent, the last four chapters of Book I of the *Wealth of Nations* deal with wages per head, profits per cent, and rent per acre' (p. 231). Quite how Cannan felt that one might go about explaining his 'distribution properly understood' without a theory about the rates of wages, profits and rent, is impossible to determine from his extant writings. Indeed, his tenacious adherence to this peculiar conception introduces what is perhaps the only real blemish into his editorial introduction of the *Wealth of Nations*. As Higgs observed in his review of that edition in the *Economic Journal* for 1904, Cannan had not so ruthlessly abstained from introducing his own opinions about economic theory as might have been hoped.

Though Cannan does not use the epithet 'classical' to describe either the economics or the economists with which he deals in *Theories of Production and Distribution*, his implied definition of that school in terms of the work on economics in the years between 1776 and 1848 runs counter to the views of those historians of economic thought who prefer to construct a definition of classical economics in terms of some shared set of analytical precepts (a procedure which does not, of course, require that all classical economists reached the same conclusions). It should be noted, however, that Cannan did not subscribe to the view then beginning to emerge that there was a fundamental continuity in the history of economics from 1776 down to the present day. Indeed, like most historians of thought at the time, he was highly critical of Marshall's attempt to establish such continuity in Appendix I of his *Principles* which discusses Ricardo; such views were 'in defiance of all evidence' (1929, p. 177n) as far as Cannan was concerned. There will be cause to return to Cannan's reaction to Marshall later.

The *Review of Economic Theory* (1929) was based on Cannan's LSE lectures to second- and third-year undergraduates (see 1929, p. v). It is an interesting book perhaps more because of what is not said in it rather than what is. It contains no formal presentation of the formula for the elasticity of demand, the treatment of the theory of marginal utility is exceedingly brief, there is no discussion of equilibrium and no reference to the work of Cournot, Pareto, Edgeworth or Wicksell. These latter omissions are striking lacunae – the more so for a book written in the late 1920s. They take on even more significance when it is remembered that this book was an explicit attempt to supplement *Theories of Production and Distribution* with a consideration of work which followed it.

Indeed, it seems that Cannan was no great admirer of the mathematical school, and his opinion of Marshall was to say the least somewhat ambivalent (see, for example, Robbins 1935, p. 396). On this latter point, one may take as an indication his article in *Economica* for 1924 which expresses no great admiration for the quintessentially Marshallian concept of consumer's surplus: it is a method which involves, not a single hypothesis, but an indefinite number of different hypotheses, each of which is inconsistent with all the others as well as with the actual facts . . . inconsistent hypotheses which no one would ever have thought of it if it had not been suggested by the 'space' which happens to be included under the curve of a demand schedule (pp. 23–4). Furthermore, in *An Economist's Protest* (1927) Cannan imagines Adam Smith to comment as follows on 'modern' economics:

> The very ingenious speculations of Mr Jevons, Mr Marshall, Mr Edgeworth and others, . . . have introduced a sort of algebra or geometry into the science

> .... The followers of that system are very numerous; and as men are fond of appearing to understand what surpasses the comprehension of ordinary people, the cypher, as it may be called, in which they have concealed, rather than exposed, their doctrine, [they have] perhaps contributed not a little to increases the number of its admirers (p. 334).

It is doubtful whether the designers of the main doors of the new post-Cannan LSE building understood the irony of their decision to inscribe upon them the now familiar Marshallian demand-and-supply cross diagram.

No account of these two books should omit to mention the ample evidence they provide of Cannan's almost obsessive concern with the etymology of the terms used by economists. Sometimes this propensity led to interesting points, on other occasions it degenerated into farce.

Another of Cannan's contributions to the history of economic thought which may be singled out is his reprint of the Bullion Report (1810), which he published under the title *The Paper Pound* in 1919. The text of the Report runs to 72 pages, Cannan's introduction to it occupies 49 pages. It is of interest not only as an account of the debates which led up to the resumption of specie payments in England with the Act of the Elder Peel in 1819, but also as an indication of the position Cannan was to adopt in the monetary debates of the 1920s and 1930s.

This position was to lead him into head-on collision with the views of Keynes on the question of the advisability of Britain's return to the gold standard after the First World War at the pre-war parity, and his adherence to it, in fact, helps to explain why *The Times* obituary for Cannan was headed 'An Orthodox Economist'. Moreover, the timing of its publication, as Cannan himself observes (1919b, p. xxxix), brings out very clearly the parallels between these two episodes in British monetary history.

Put bluntly, Cannan was probably one of the most strident advocates of the old-fashioned quantity theory around at the time, his solution to inflation being captured in his more than half-serious motto: 'Burn your paper money, and go on burning it till it will buy as much gold as it used to do' (1919b, p. xli). The experience of the policies adopted to deal with the inflation of the post-Napoleonic period were confirmation of the soundness of the return to gold after World War I. Cannan had no sympathy for the idea (still perfectly admissable under the quantity theory) of stabilizing the domestic price level through the management of the domestic supply of money, instead of fixing the exchange rate as the return to gold required. Indeed, it is not always clear from his writings that he understood that the two possibilities were part and parcel of the theory he so vigorously defended.

Nor, it seems, was Cannan prepared to admit the seriousness of the short-run consequences of a policy of deflation on the domestic distribution of income, output and employment as a reason for being cautious about the return to gold – a factor which even someone like Pigou (the official adviser to the Cunliffe Committee and therefore no opponent of the return to gold) was more than prepared to take into account. According to Cannan the necessary adjustments 'must be regarded in the same light as those which a spendthrift or a drunkard is rightly exhorted by his friends to face like a man' (1919b, p. 105).

In addition to the works mentioned above (and those listed in the accompanying bibliography), Cannan contributed twenty-five entries to the original edition of this Dictionary, including those on 'capital' and 'profit'. The latter was cited by Friedman and Savage in their celebrated application of utility analysis to risk. Edwin Cannan was, it is said, a keen bicyclist; though in *Who's Who* he listed his recreation as work. He died on 8 April 1935.

Cantillon, Philip (fl. 1725–1759)

Henry Higgs

Author of '*The Analysis of Trade, Commerce, Coin, Bullion, Banks, and Foreign Exchanges:* . . . Taken chiefly from a Manuscript of a very ingenious Gentleman deceas'd, and adapted to the present situation of our Trade and Commerce. By Philip Cantillon, late of the City of London, Merchant, London, 1759'. This Philip was the eldest son of James Cantillon of the city of Limerick, who was first cousin of Richard Cantillon, author of the *Essai sur la Nature du Commerce*. Philip carried on a banking business with David Cantillon at Warnford Court, Throgmorton Street, London, at least as early as 1725. In 1738 he was a director of the Royal Exchange Assurance: in 1742 became bankrupt: in 1747 was trading alone as insurance agent and policy broker: in 1753 was partner with one Thomas Mannock in the same business: and in 1759 had retired. He married, 14 July 1733, Rebecca, daughter of William Newland of Gatton, Surrey, by whom he had two daughters. There is reason to think that he was engaged for a short time at Richard Cantillon's bank in Paris, but that his litigious character made him unamiable and brought about his speedy return. On the death of Richard, Philip intervened in the management of his estate, and thus obtained possession of several papers, including probably the English manuscript of the Essay, which professedly served as the groundwork of the *Analysis of Trade*. He must, however, have mutilated the manuscript almost beyond recognition. Much of the closely packed original is omitted, and much is replaced by vague and general summaries, most unskilfully made, with the result that little indeed of the *Analysis* fairly represents the views of Richard Cantillon. Philip added a preface on the history and importance of commerce, some strictures upon close corporations, new matter on inland and foreign trade, bankers and banks, and exchanges, interspersed with quotations from Hume's *Essays*, and from *The Universal Merchant*, etc., concluding with a criticism of the law relating to bills of exchange.

The book was reviewed in the *Monthly Review* or *Literary Journal* for April 1759, London, vol. xx. 309. Sir James Steuart (*Works*, 1805 edn, iii. 22) says, 'Mr. Cantillon, in his *Analysis of Trade*, which I suppose he understood by practice as well as by theory, has the following passage,' etc.

'A small treatise of Arithmetic,' explaining the foreign exchanges 'vulgarly and decimally'

without 'unintelligible jargon,' was designed by the author of the *Analysis* (p. 85), but does not seem to have ever been published.

Selected Works

1759. *The analysis of trade, commerce, coin, bullion, banks, and foreign exchanges*. London.

Cantillon, Richard (1697–1734)

One Richard Cantillon, son of Philip Cantillon of Ballyheigue, County Kerry, was born in Ireland. Joseph Hone argued convincingly that this was the economist, on the ground that this Richard married Mary Ann Mahony, daughter of Lady Clare, and had with her a daughter Henrietta, who married Lord Farnham (after the death of her first husband, the Earl of Stafford). Earlier writers had estimated Cantillon's birth to have been as many as 17 years earlier, but subsequent scholars have tended to accept Hone's evidence; for example, Joseph J. Spengler (1954, p. 283) and Anita Page (1952, p. xxiv).

Richard Cantillon's close association with France has often been noted, but certain facts about his family go far to explaining this connection. An Anglo-Irish county family whose establishment in Ireland was Elizabethan or later would of course be Protestant, and the term 'Anglo-Irish Protestant ascendancy' would then apply strictly. But those families which came to Ireland in Norman times were Catholics, and some of these remained so for hundreds of years, in spite of dungeon, fire and sword (to use an old phrase). They often became Jacobites, and in that case Europe was for them a place of refuge and support. These were the 'Wild Geese', who joined foreign flags after one or other Irish rebellion failed. Often educated in Europe, their ideas were cosmopolitan, their eyes on Paris and on Rome.

The Cantillons were established in Ireland in Norman times and remained Catholics, although not always very good ones. And in later centuries they became, and long remained, devoted to the Stuart cause. Roger Cantillon of Ballyheigue married Elizabeth Stuart in 1556, and his grandson Valentine fought for Charles I at Naseby, while his great-grandson Richard was wounded at the Boyne, went to France with James II and was made a chevalier for his pains. The chevalier, clearly more notable for gallantry than for worldiness, is said to have become banker to the Stuart Pretender in Paris (Spengler 1954, p. 284) and died insolvent, a not unpredictable fate, in 1717. Our Richard appears to have come to the rescue of his uncle's honour, paying off most of the poor old Jacobite soldier's debts, many of which, indeed, were to him. This was not the end of the family's Stuart involvement; a James Cantillon, believed by Hone to be the young future economist's brother, followed King James to France and was decorated for valour, while a nephew, Thomas, mentioned in the economist's will, was with the Irish Brigade at Lauffelt. Migration to France and beyond was in the blood of these wild geese. It should cause no surprise that our Cantillon had houses in seven European cities, or that he lived much in Paris.

He was there, active in banking, between 1716 and 1720. Brilliantly anticipating the fate of John Law's scheme, he was also daring enough to profit immensely by it and, if the sources consulted by W. Stanley Jevons can be believed, 'made a fortune of several millions in a few days, but still, distrusting Law, prudently retired to Holland'

(Jevons 1881, p. 336). He appears again in Paris between 1729 and 1732, and seems to have had to engage in litigation with people who had lost through the collapse of Law's scheme, and blamed Cantillon for his part in this. Henry Higgs, after surveying the evidence, commented that Cantillon appeared 'to have triumphed in the Courts over all his opponents' (Higgs 1931, p. 373). One gets the feeling as one reads of rather ordinary people playing a game for stakes they could not afford with a master they could not match. Bankers fell like autumn leaves in Paris between 1717 and 1720, and as Higgs remarks, 'Their losses were probably very heavy in 1720 and much of them went into Cantillon's pocket' (1931, p. 370).

Back in London in 1734, Cantillon's luck ran out. At the height of his success and his brilliance, he was robbed and murdered, left in the flames of his townhouse in Albermarle Street, Mayfair, during the early morning of 14 May. His precious manuscripts, the Marquis de Mirabeau tells us, perished with him (Higgs 1931, p. 382). Lady Penelope Compton, who lived opposite, tells us that 'it burnt very feirce two houses intirely down before they could get any water' (1931, p. 374). Given this furious blaze, the really remarkable thing to the modern reader is that even despite the primitive state of the forensic science of the day, evidence of foul play was nevertheless found. Higgs, who read the account of the subsequent trial at the Old Bailey, observes that

> it was soon evident that he had been murdered before the house was set on fire. His body was burned to ashes. The Journals for 6 June 1734 say 'Yesterday the refiners finished their search into the ashes of the late Mr Cantillon's house, when no plate, money, or jewels had been found; an undeniable circumstance of a robbery previous to the burning of the house'. (1931, p. 374)

Cantillon's servants were tried for murder, but quickly acquitted. Suspicion then fell on a Frenchman, Joseph Denier, alias Lebane, who, we are told by Higgs, had been Cantillon's cook for 11 years, but apparently had been dismissed a little more than a week before the murder. The French chef, whether in fact guilty or not, fled to Holland and thus evaded arrest.

So it came about that we possess only one work of Cantillon's, and that in what it has been claimed is a rough French translation. Even now its early publishing history is shrouded in mystery. The *Essay on the Nature of Trade in General* (1755) is thought to have been written between 1730 and Cantillon's death, but it was not published in a complete version until 1755, and then in the French translation, claiming on the title page to have been printed in London by Fletcher Gyles, a claim reasonably disputed by Jevons (1881, p. 341). The Marquis de Mirabeau, who revealed that the French translation was in his possession for 16 years, insisted that Cantillon 'never intended that the work should appear in French and only translated it for a friend' (Higgs 1931, p. 383).

Yet, as we have seen, there would be nothing odd in someone of Cantillon's family background and personal habits *writing* a book in French and publishing it in Paris. It would appear, however, that an English original must have existed, and had been in the hands of Malachy Postlethwayt, since the latter incorporated large parts of Cantillon's *Essay* in publications beginning in 1749. The first complete English translation from the French text, which was printed alongside it, was that of Higgs in 1931. Higgs, incidentally, collated his English translation with parallel passages from Postlethwayt. In addition we now have the scholarly French edition, edited by Alfred Sauvy (1952) with a number of studies and commentaries.

Since the 'discovery' of Cantillon by the English-speaking world following Jevons's enthusiastic article (1881), no less than justice has been done to the merits of the *Essay* on those topics treated by Cantillon whose significance can be expressed satisfactorily in broadly neoclassical terms. Over these topics we may pass quickly. Jevons himself noted that Cantillon had presented a treatment of currency, foreign exchanges, banking and credit which, judged against the work of its period, he felt to be 'almost beyond praise' (Jevons 1881, p. 342). This enthusiasm has proved infectious, and we find Joseph Spengler, 73 years later, writing that Hume, assuming he knew Cantillon's work, missed 'the

import of Cantillon's brilliant analysis (which compares favourably with Keynes's) of the response of the price structure to changes in the quantity of money' (Spengler 1954, p. 283). Spengler was not quite as impressed by Cantillon's treatment of the international specie flow mechanism, but Joseph A. Schumpeter found it a brilliant performance and insisted that 'the automatic mechanism that distributes the monetary metals internationally is ... almost faultlessly described' (1954, p. 223).

It was likewise recognized as early as Jevons that Cantillon had set out the leading ideas of Adam Smith's 'important doctrine concerning wages in different employments' (Jevons 1881, p. 343), and that the *Essay* contained what Jevons (somewhat exaggeratedly) called 'an almost complete anticipation of the Malthusian theory of population' (p. 347). Jevons, with remarkable objectivity considering his own views on the formation of value, also singled out Cantillon's treatment of 'the whole doctrine of market value as contrasted to cost value' (1881, p. 345). It was also customarily recognized by neoclassical scholars later than Jevons that Cantillon made important contributions to the founding of allocation theory.

To intellectual historians approaching the *Essay* in terms of the neo-Walrasian class of models for general equilibrium theory, it became natural to construe Cantillon's land and labour as given resources. In the *Essay,* however, while land is a given non-produced input, labour is a *produced commodity* available in return for subsistence. A reproduction structure thus exists, and surplus may be defined. Cantillon is largely concerned with the allocation of surplus output. This was understood by the first classical theorist to read Cantillon, François Quesnay. For all his one-sided preoccupation with *agricultural* surplus, Cantillon's French successor picked up the importance of the role of surplus, embodied it in a formal model and passed it on to later classical economists.

From a *modern* classical point of view Cantillon made several important contributions, which are not always stressed by traditional scholars. For one thing, he offered an early analysis of the respective roles of produced and non-produced inputs in a more than minimally viable commodity reproduction structure. Developing Sir William Petty's concept of a 'par' between land and labour, Cantillon investigated the assumptions upon which a reduction of labour to land is legitimate. But, of course, Cantillon was reducing labour to the *produce* of land; that is, to corn. He noted that 'as those who labour must subsist on the produce of the Land it seems that some relation might be found between the value of labour and that *of the produce* of the Land' (Cantillon 1755b, p. 31; emphasis added). Cantillon had entered an area which even today bristles with problems, which would nowadays be described as concerning the aggregation of heterogeneous objects. Cantillon was well aware of some of them. He used a concept of subsistence, that of the 'meanest Peasant' (p. 39), as his unit of labour, but he was well aware that this differed all over Europe, and had apparently offered statistical material on this in the lost supplement. It is then necessary to be able to express units of more skilled labour in terms of common labour. He argues that 'it is easily seen that the difference of price paid for daily work is based upon natural and obvious reasons' (p. 23). Even today not much progress has been made on this problem, and highly sophisticated models blithely assume it out of existence by using a single homogeneous labour input. Land is also heterogeneous, as Cantillon was well aware; furthermore, any given kind of land can be used to grow different crops. But the analysis of heterogeneous land in the case of a single crop was not developed until Ricardo's period, and the formal analysis of the case where *different crops* are grown had to wait for Piero Sraffa (1960, pp. 74–8), and more recent work on the relations between produced and non-produced means of production, such as that of Alberto Quadrio Curzio (1980, pp. 218–40).

Leaving aside the difficulties of heterogeneous labour and heterogeneous land with multiple uses, the par is the quantity of corn needed for the subsistence of a labourer and his family during a given period. To get a consistent model, corn must be treated as the only commodity strictly necessary to the reproduction system (the only 'basic'

in the Sraffian sense). Other outputs have to be treated as luxury goods (non-basics), so that one can accommodate the changing modes and fashions of Cantillon's prince and landowners. Cantillon in fact allowed even his meanest peasant a number of commodities: 'the married Labourer will content himself with Bread, Cheese, Vegetables, etc., will rarely eat meat, will drink little wine or beer' (Cantillon 1755b, p. 37).

To accept this and retain the par, only two options seem open. The poor peasant's commodities other than bread (or other things made in the household from corn, labour, and any free ingredients) could be regarded as non-basic. Or one could construct a composite commodity, containing bread, cheese, vegetables, and so on, in fixed proportions, and use this as the unit of measurement for the par. Then, if one is to avoid the problems of different crops, one must assume that any parcel of the uniform land can produce these commodities in the standard proportions. Cantillon stressed how much even peasant consumption varied from country to country in Europe in his day. But it was not absurd to suppose, as he did, that consumption habits were fixed and traditional among the peasants of a *particular* area. None of this is meant to deny the justice of Marian Bowley's claim that 'the "par" between land and labour could only be found under special and unrealistic assumptions' (1973, p. 105).

In a model where corn is the only basic, or where a unit of composite commodity is always consumed in fixed proportions, one can express the surplus as corn output minus necessary corn input (seed, subsistence, feed for animals), or alternatively one can express surplus as net output of the composite commodity. Passages such as the following are then consistent with the measurement of the surplus in terms of com (or units of the composite commodity) as required for the par:

> The Farmers have generally two thirds of the Produce of the Land, one for their costs and the support of their Assistants the other for the Profit of their Undertaking ... The Proprietor has usually one third of the produce of his Land and on this third he maintains all the Mechanicks and others whom he employs in the City as well, frequently, as the Carriers who bring the Produce of the Country to the City. (Cantillon 1755b, pp. 43–5)

Cantillon's treatment of surplus strongly implies that it arises only in agriculture. All those in a state, we are told more than once, subsist at the expense of the proprietors of land. There are isolated passages where he seems to be recognizing that profits (in the sense in which these reflect the existence of surplus) can arise in manufacturing. Perhaps the classic case is the description of the master hatter, who, we are told, besides his upkeep, ought also to find 'a profit like that of the Farmer who has his third part for himself' (1755b, p. 203). Certainly Cantillon believed (unlike the Physiocrats) that farmers kept two-thirds of the total produce, one-third representing their *profit.* But Cantillon used his term 'undertaker' (entrepreneur) to cover chimneysweeps and water-carriers, and Samuel Hollander is probably correct in saying that, in Cantillon, 'profits and wages were said to have a common source in, or to be dependent upon, the property of landowners' (1973, p. 40, n. 48). The concept of surplus throughout *industry*, and the dual concept of a rate of profit tending to equality across all sectors, including industrial sectors, would not be clearly and systematically expressed until the mature work of Adam Smith (see Walsh and Gram 1980, pp. 40–77).

Cantillon, however, did pioneering work in developing the theory of the allocation of surplus. His model is remarkably sophisticated. It is an isolated economy – one might think of it as an island – ruled by a prince or landowner. Cantillon is perfectly clear that the prince's significant freedom of choice concerns only that part of output which constitutes the surplus he receives after providing for necessary inputs. He remarks that the prince, deciding on the use of the estate, 'will necessarily use part of it for corn to feed the Labourers, Mechanicks, and Overseers who work for him, another part to feed the Cattle, Sheep and other Animals' (Cantillon 1755b, p. 59). The consumption pattern of workers is fixed, just like fodder for the animals: 'Labourers and Mechanicks who live from day to day change their mode of living only from necessity' (p. 63).

Cantillon is far from assuming, however, that the composition of *surplus* output is unchanging. Indeed, changes in the allocation of surplus,

dictated by changes in the demands of the prince and any other landowners, are his explanation of deviations of current market prices from natural prices, or intrinsic values. In the original classics, and indeed as late as Alfred Marshall (as Pierangelo Garegnani has noted), natural prices are centres of gravitation towards which market prices *tend* (Garegnani 1976). This idea is clearly present in Cantillon. The prince or landlord, who is assumed to have a third of the produce of each of the farms he owns, and is mainly responsible for luxury consumption, is 'the principal Agent in the changes which may occur in demand' (Cantillon 1755b, p. 63). If a few prosperous farmers engage in some luxury consumption, they will imitate the tastes of the prince. Thus changes in fashion were the leading cause of 'the variations of demand which cause the variations of Market prices' (p. 65). Cantillon is well aware that good or bad harvests, extraordinary consumption resulting from foreign troops, and so on, can disturb the gravitation of market prices towards natural prices, but he eliminates such accidents 'so as not to complicate my subject, considering only a State in its natural and uniform condition' (p. 65). This is precisely the concept of a long-period position common to all the great classical economists.

Even more surprisingly, Cantillon shows that he is quite aware that a planned economy directed by the prince, and a system of prices, can each achieve the identical allocation of surplus output – a result whose formal proof had to wait until the 20th century, and which lay fallow after Cantillon as classical political economy developed in other respects.

Cantillon, of course, was by no means the first to make *some* kind of distinction between market and natural prices. The Schoolmen had distinguished between the price ruling at a given moment on a market and the just price, sometimes relating the latter to costs. But in Cantillon the distinction between market and natural price is an integral part of a whole economic model. The natural price, or intrinsic value of a commodity 'is the measure of the quantity of Land and of Labour entering into its production' (1755b, p. 29). Labour is then reduced, through the par, to subsistence units, which, as we have seen, can either be measured in corn or in quantities of a composite commodity. These intrinsic values are assumed to be invariant (p. 31). Market prices may deviate from intrinsic values following a change in demand, as we have seen, but the actions of profit-maximizing capitalist farmers will then lead to supply changes, initiating the gravitation process. If the farmers 'have too much Wool and too little Corn for the demand, they will not fail to change from year to year the use of the land till they arrive at proportioning their production pretty well to the consumption of Inhabitants' (pp. 61–3).

Notice that since we are considering a change in *demand* for corn and wool, these goods are here being used for *luxury* consumption. Corn can be fed to servants and musicians, and wool makes fine garments. What is more, Cantillon can allow for the existence of a number of agricultural sectors producing *only* luxuries: fine wines, silks, blood horses, and so on. His model clearly implies that there is a tendency towards a long-period position in which capitalist farmers in each of these sectors would receive profits at the uniform rate of one-third of the intrinsic value of their total output. Thus the extraction of surplus, and its reflection in a uniform intersectorial rate of profit, is certainly understood by Cantillon for those sectors where capitalist production relations were firmly established in his period. It remained for Adam Smith to extend this analysis to the newly widespread phenomenon of his time, capitalist production throughout industry.

Capital as a Factor of Production

K. H. Hennings

The role played by capital in production has frequently been in dispute: 'When economists reach agreement on the theory of capital they will shortly reach agreement on everything else' (Bliss 1975, p. vii). Disagreements are due as much to divergent definitions, or uses, of the term 'capital' as to different views about what should be considered a factor of production. But above all there have been differing views about whether, and in what sense, capital can be said to be productive. In particular, there has been disagreement about whether it can be said that a more capital-intensive production method is more productive than a less capital-intensive one. Preclassical, classical, neoclassical and neo-neoclassical economic theory have given different answers to these questions. These will be considered below, but the discussion will be confined to the role of capital as a factor of production. It should be noted in particular that the problem why capital earns its owner an income depends as much on the social institution of ownership and the institutional organization of production as on the role capital plays in production. It is only the latter, in a sense technical, problem which will be addressed here.

Terminology

Capital goods are produced commodities which are required for production no matter how much or how little they are subject to wear and tear. A stock (at a point of time; see Fisher 1906) of different capital goods is a *capital*; this concept is to be taken in a vector sense. As long as they are required in production, all capital goods can be valued, even when they are not traded on markets, as many of them are. Because of their heterogeneity, different capital goods cannot be aggregated, but their values can. A *capital value* is therefore the sum of the capital values of those capital goods which constitute a capital. Note that this is a book-keeping term, which depends on the valuation of the capital goods involved; the capital value can change although there is no change in the stock of capital goods. The term *money capital* will be used in a similar sense, but with a somewhat different connotation: it denotes the sum of money necessary to buy a specified stock of capital goods. Real counterparts in a scalar sense to a given capital value or money capital can be constructed in principle (Hicks 1974, p. 151), but not in an unambiguous manner.

Production: Basic Notions

Production is the transformation of inputs into outputs. Inputs are those things which need to be increased in order to obtain more output by the same method of production, where the latter is defined as a blueprint which details what inputs are required when and in which proportions to produce a unit bundle of outputs. As there may be more than one method to produce the same unit bundle of outputs, a production process is defined as a particular method of production to produce a particular unit bundle of outputs. A production process always uses inputs in fixed proportions; variable proportions are represented by different production processes. If there exist various different production processes with which the same unit bundle of outputs can be produced, they will differ in the proportions in which they use various inputs; but in general it will not be possible to compare them from a purely technical point of view. Different production processes are comparable only if their costs are computed and related to the value of the outputs obtained. In general, however, any ordering obtained in this way need not be unique: two different production processes may have the same unit costs. Moreover, if the prices of inputs change a given ordering need not be preserved. Such difficulties affect the choice between different production processes; they do not, however, affect the role of capital in production, or its status as a factor of production.

Production typically is roundabout, i.e. proceeds in stages: what is produced as output in one production process is used as an input (alongside others) in another. If all these intermediate products (outputs which are used as inputs) are specific in the sense that they have only one possible use, all production processes required to produce a particular bundle of outputs can be strung together into a sequence of production processes. Consolidating all stages, one can view the sequence as transforming 'primary' inputs into 'final' outputs. Here primary inputs are these which are not produced within the sequence of production processes, if indeed they can be produced at all; final outputs are those which are not used, or used up, within the sequence.

Not all intermediate products are specific in the sense that they have only one possible use. In this case all interlocking sequences can be combined into a production system which again can be viewed as transforming primary inputs into final outputs. Without loss of generality one can assume that such a production system comprises all production processes in operation in an economy. Consolidating them amounts to adopting a 'black box' view of production. Disregarding the internal structure of the production system and of the production processes which constitute it, one links directly primary inputs to final outputs, and disregards all inputs produced and used, or used up, within the production system. The advantage of this procedure is that it reduces the number of inputs to be considered.

The definition of what is a primary input, or a final output, depends on the level of aggregation as well as the nature of the production processes involved. Production on a barren island will require many inputs as primary ones which are intermediate products in a production system comprising all production processes operating in a continent rich in resources. Similarly the final outputs produced by the island economy's production system may be confined to what are intermediate products in the production system of a continent.

By definition, an increase in output can only be obtained by an increase in inputs in fixed proportions. From this one can infer that all required inputs together are productive, and have a non-negative marginal production. This cannot, however, be inferred for any single input. This can only be done if either there are at least two different production processes for the production of the same unit bundle of outputs because then it is possible to calculate the marginal net value product of an input (Bliss 1975, ch. 5); or if there are alternative uses for all inputs in production processes which produce other unit bundles of outputs (Uzawa 1958). Only when there exists only one production process for a particular unit bundle of outputs and there are no alternative uses for some of the inputs it requires is it impossible to calculate their marginal contribution to the outputs obtained individually; it is of course still possible to calculate their contribution as a group of inputs.

Factors of Production

In modern usage, all primary inputs can be called 'factors of production'. Conventionally, however, primary inputs are considered, following Senior (1836), the services of agents or stocks, and the term 'factor of production' is reserved for the latter. If they are the services of natural agents or human beings, they are called 'original factors of production'; they are called simply 'factors of production' if they also include the services of stocks of durable commodities. Factors of production can therefore be defined as those agents or durable stocks the services of which are primary inputs in production processes.

Factors of production are productive and have a non-negative marginal product if their services are productive and have a non-negative marginal product.

The definition of factors of production just given is reasonably precise as far as natural agents and human beings are concerned. Land and labour have been considered factors of production at least since Petty (1662). Land was often understood, if tacitly, to include all beneficial powers of nature; the term 'natural agents' was introduced by Senior (1836). In preclassical theory durable stocks were called simply 'stocks' (see, e.g., Barbon 1690), but usage of the term was often confined to trade and commerce. When production came to be seen as the dominant economic activity, produced means of production, considered as a factor of production, came to be called 'capital'. This term had been in use for a long time (see Hohoff 1918–19; Salin 1930; Assel 1953), but now acquired a new meaning, thus inviting confusion and controversy. It will be useful, therefore, to trace historically the use made of that term, and the notions attached to it.

Preclassical Theories of Capital and Production

There is very little about production and its relation to capital in economic writings before the mid-18th century. Barbon (1690) provides an early, but singular, instance of an analysis in which a surplus is seen to arise from the use of what he calls a 'stock' (of capital goods) in trade as well as in the production of commodities. In a similar vein, Hume used the term 'stock' somewhat indiscriminately to denote both a store of commodities and a sum of money. But he did distinguish, as had Barbon, between profits from 'stock' and interest on money (1752, p. 313), thus separating the investment of money from the productive use of 'stock', e.g. capital goods, although he is none too clear about the latter.

The Physiocrats were probably the first to develop a clear view of production and the role of capital in it. But they did not use the term 'capital'. Cantillon (1755) strongly emphasized the need for accumulated sums of money required to buy stocks of goods in which to trade, or with which to produce. But he called them 'funds' not 'capital'. Thus he speaks of the farmer who needs to have enough funds (*assed de fond*) to conduct his business. Quesnay used the term 'advances' (*avances*) in a similar way in the sense of money capital. Behind his usage is a clearly drawn picture of agricultural production which uses land and labour to produce output, and needs money capital to finance the lag between the expenditure on inputs and the sale of the output obtained. Probably deliberately, Quesnay eschewed the term 'capital'. Where he used it (1766b), he spoke explicitly of money capital (*capital d'argent*), but conceived it as invested in buildings, implements, stores of grain, cattle, and so on (1766a, pp. 172–3). These, however, he clearly conceived as productive. Moreover, his argument centres on the idea that larger advances would permit more productive production methods to be used (see Eltis 1984, chs. 1 and 2).

Turgot (1770) was the first to develop a specific theory of capital as a factor in production when, possibly under the influence of Hume's ideas, he generalized Quesnay's theory. Quesnay had shown that advances were necessary for agricultural production. Turgot, in an attempt to develop Quesnay's theory of a society dominated by agriculture into a theory of a commercial society, places commerce and manufacture on an equal footing with agricultural production, and emphasized that advances are required in all branches of

economic activity. Such advances are paid out of capital, which is defined as 'accumulated values' (1770, § LVIII). If account is taken of the various degrees of risks involved, the rates of return on all possible investments are equalized by competition between the owners of the various capitals (Turgot uses the plural, *capitaux*) such that the rate of interest can 'be regarded as a kind of thermometer of the abundance or scarcity of capitals in a Nation, and of the extent of the enterprises of all kinds in which it may engage' (1770, § LXXXIX). At the same time, Turgot argues emphatically that some return on all these kinds of investment is necessary in order to keep production on the same level; if the rate of return were lowered, capitals would be withdrawn, and production could not be kept on the same level as before (1770, § XCVI). Thus to Turgot 'capitals' are money capital. Money capital is required because production is roundabout and thus needs capital goods as well as original factors of production. Like Quesnay, Turgot assumed that larger amounts of money capital make possible higher levels of production. One might be inclined to argue that therefore money capital, i.e. advances, are productive; but although Turgot is not entirely clear on this point it seems that he considered not so much advances as the capital goods which represent them as productive.

The Classical Theory of Capital and Production

The classical view of the role of capital in production was worked out by Adam Smith. He began by emphasizing the division of labour, but then switched to a detailed consideration 'Of the Nature, Accumulation, and Employment of Stock' (1776, book II) in which he effectively adopted the theory put forward by Quesnay and Turgot. His attempts to integrate these two approaches were not entirely successful (Bowley 1976); although the division of labour retained its status as a device which enhances the productivity of labour in classical economic theory, the emphasis was shifted to the accumulation of capital as the prime force making for growth. This was of course linked to the idea that production needs advances, and the proposition that labour was the more productive the larger these advances. Smith also changed the emphasis in another respect: he formally defined 'capital' as that part of a person's stock of commodities which is expected to yield an income. Smith described its function as assisting labour in production: fixed capital (machines, buildings, land improvements, and 'acquired and useful abilities') 'facilitates' labour by increasing its effectiveness; circulating capital (money, raw materials, goods in process and goods in stock) 'abridges' by providing (material) advances.

This distinction is ambiguous, but characteristic for Smith's position. Fixed capital, he argued, yields an income, i.e. is productive, by being used 'without changing masters': while circulating capital needs to be either given up (in trade) or be destroyed (in production) in order to be productive (1776, pp. 279–83). What is considered are capital goods; but only money capital can circulate in the way Smith described their circulation. The two approaches can be reconciled; but the way in which Smith expressed himself invited confusion between money capital on the one hand, and capital in the sense of capital goods on the other. In fact, Smith needed both concepts. James Mill (1821), Rae (1834) and other classical writers often used the term 'instrument' when emphasizing that they meant capital goods, and continued to speak of capital in the sense of money capital. Money capital played indeed an important role in classical economic thought for it permitted classical writers to argue, in a rather loose way, that production methods were the more productive, the more money capital they required. It is for this reason that Hicks (1974) called them 'Fundists'. At the same time, however, they also considered the role of capital goods in production processes (Sraffa 1960), and thus maintained a 'real capital doctrine' (Corry 1962, p. 18).

The view that capital assists labour was attacked by Lauderdale (1804), who pointed out that capital could, and frequently did, supplant labour when circulating capital was substituted for fixed capital. This initiated the debate on the

'machinery question', and confirmed the role of capital as a factor of production: what can supplant a factor of production surely must be considered as belonging to the same species.

Smith had separated a person's stock of commodities into durable consumer goods and capital by requiring that the latter be expected to earn an income. This led to many attempts to show that not only capital goods used in production are expected to yield an income (i.e. Hermann 1832, or Menger 1888). These discussions often confused the role of money capital in investment processes with the role of capital goods in production processes, and contributed to the survival of the concept of money capital as a factor of production referred to above.

The view that production requires advances in the form of capital goods was so dominant that the role of fixed capital was often pushed into the background. Thus Ricardo spoke of production as 'the united application of labour, machinery, and capital' (1817, p. 5), thus equating capital with circulating capital. As Smith had subsumed the consumer goods required for the maintenance of labour under circulating capital stocks, this particular part of the total stock of commodities in an economy acquired, under the name of the 'wages fund', a pivotal role in all discussions of the role of capital in production. Following a precedent set by Smith, the wage fund was seen to be derived from, and increased by, saving, i.e. non-consumption or 'abstinence', as Senior (1836) was to call it. Destined to supply the consumption goods required as advances while production processes continue, the concept was used as a theory of wage determination on the assumption that the wages fund was given at least in the short run and thus determines the wage level when workers compete freely for employment.

In spite of all the attention Smith gave to the accumulation of capital as a factor making for economic growth, he reserved a special role for human labour as the prime factor of production, expecially in those passages in which he set out his conjectural history. This emphasis, which is clearly based on the view that production requires advances, remained a feature of the classical theory of capital, and was a mainstay of the labour theory of value as developed by Ricardo and others. It is symptomatic that from this point of view the use of 'machinery and other fixed and durable capital' was considered no more than an (admittedly considerable) modification of the labour theory of value by Ricardo (1818, p. 30). More radical writers, such as Hodgskin (1827) emphasized the notion of capital goods as 'stored-up' labour (i.e. outputs produced by past labour) that had been worked out by James Mill (1821) and Ricardo (1817) and on its basis denied fixed capital the status as a factor of production.

The special role Smith has reserved for labour did not prevent him from juxtaposing labour, stock and land to parallel wages, profits and rent (1776, p. 69). This juxtaposition was elaborated into a strict parallelism between factors of production and their earnings by Say (1814) which became generally accepted by the middle of the 19th century. Thus when J.S. Mill (1848) summarized the classical theory of capital into his four propositions, he still adhered to the view that production required advances in the form of capital goods. But when he comes to discuss the laws of increase of factors of production, he treats them on an equal footing (though in exactly the order Smith had listed them: and not the land–labour–capital order which Say had made familiar). At the same time, however, Mill often gives the impression that he means money capital when he speaks of 'capital', especially in those passages in which he argues that competition will establish a uniform rate of return on capital because capital will be transferred from one industry to another.

In a similar way Marx (1867) used the term capital to mean both a stock of commodities, and a sum of values. In addition, Marx insisted that capital goods are capital only in a capitalistic society, and thus used the term also to describe a particular organization of production in society.

Finally, the view that production requires advances in the form of capital goods which Smith had expounded, and which most classical writers accepted, was developed by a few of them into a theory which strongly emphasized the time element in production. There are some traces of this in Ricardo (1817), especially in his recognition that all the difficulties he encountered in his

theory of value are due to the temporal aspect of production processes. The view was worked out in detail by Rae (1834), by Longfield (1834), and also by Senior (1836). Their work foreshadows one aspect of the neoclassical theory of capital.

Classical economic theory considered three factors of production: land, labour, and capital. Each had its own dimension: land was a stock, labour a flow, and capital was money capital in the form of a stock of capital goods. In the original conception their standing was not equal: labour worked on land with the help of capital. Hence the capital intensity of production mattered: the more money capital was invested, the more productive was labour in its efforts to work up the bounty of nature into consumable output. These notions were not, however, made very precise: that was left for neoclassical theorists. Thünen's early discussion of the marginal productivity of capital (1850) remained an exception.

The Neoclassical Theory of Capital and Production

Neoclassical economic theory was not a coherent construct: up to the 1930s there were different versions of neoclassical theory as far as the treatment of capital as a factor of production is concerned (Stigler 1941).

Perhaps the most contentious version was the Austrian one as worked out by Böhm-Bawerk (1889). To some extent it had been foreshadowed by Jevons (1871), even though Jevons had little to say about production. But there is a clear picture in Jevons of the necessity of money capital which is 'invested' in the form of advances in time-consuming production processes. What is more, Jevons formulated, very much *ad hoc*, a temporal production function which postulated that there are diminishing marginal returns to the length of investment of such advances: and used it to derive the marginal product of an extension of that length, which clearly is a measure for the capital intensity of production.

Böhm-Bawerk, by contrast, consciously and explicitly developed a theory of production. It very much follows classical lines: production requires time, and hence needs advances in the form of capital goods. Capital goods are seen as produced means of production, and at the same time as stored-up land-and-labour, even though they derive their value not, as the classics had maintained, from the fact that they represent land and labour services spent in the past: but from their prospective usefulness in the production of future output. Nevertheless Böhm-Bawerk emphatically denied that capital goods can be productive, and insisted that only the production processes which they make possible are productive. Although this could have meant that the notion of productiveness was transferred from factors of production to production processes, Böhm-Bawerk did not take this step. He seems to begin by saying that only land and labour should be called productive, and ends by postulating something very much like a productivity of the length of the period of production. As in Jevons (1871), this view is based on a temporal production function in which the degree of roundaboutness of production processes is explicitly taken as a measure for the capital intensity of the production processes in operation. Böhm-Bawerk attempted to overcome in this manner the difficulty of deriving any such measure from diverse sets of capital goods. The roundaboutness of production processes was turned into a variable which was chosen by profit-maximizing entrepreneurs subject to a given amount of money capital.

The relationship of this construction to classical economic thought is obvious. Nevertheless Böhm-Bawerk's attempt to provide a temporal theory of production based on the notion of capital as a derived factor of production, or intermediate good, turned out to be very contentious. The theory of interest which he had been built upon it was turned into what became the standard (neoclassical) theory of interest by Fisher (1907, 1930) – but only after it had been cut loose from its production-theoretic underpinnings: and after Fisher had substituted instead an analysis of investment opportunities based on the concept of money capital. Various attempts to reformulate Böhm-Bawerk's theory of the role of capital in production (Wicksell 1893; Strigl 1934; Hayek

1940) generated much debate, but did not manage to rescue it.

The Austrian theory of capital is much more traditional than other versions of neoclassical theory which gave up the 'advances' view of capital. Thus Wicksteed (1894) placed all factors of production on an equal footing, including all kinds of capital goods, and postulated that 'The Product being a function of the factors of production we have $P = f(a, b, c, \ldots)$' (1894, p. 4) without even mentioning whether production takes time or not. Being considered akin to any other input in this respect, capital goods are of course productive; but nothing can be said about the capital intensity of production. Marshall (1890) argued in a similar way, although he kept to the classical tradition by reserving a place for money capital alongside the capital goods used in production. Taking up a distinction first made, it seems, by Menger (1888, p. 44), Marshall distinguished between capital goods which earn quasi-rents, and money capital which earns interest. In essence this is the distinction between production and investment: capital goods are used in production, and if used productively, earn quasi-rents; money capital is invested, and if invested successfully, earns interest. Clark (1899) equally rejected the advances view of production. In his view, production did not require advances once production processes were properly set up, or synchronized. As in Wicksteed, capital is a factor of production on an equal footing with land or labour. At the same time, Clark separated clearly between material capital goods or produced means of production, on the one hand, and capital as a 'quantum of productive wealth' (1899, p. 119), measured in money, which is invested in capital goods. Although Clark calls this 'a material entity' (1899, p. 119), his 'capital' is money capital, just as it was in Marshall (or Menger for that matter). Knight (1933) continued in this vein, but emphasized money capital, considered as a 'material entity', so much that capital goods were almost lost sight of. As a result, 'capital' came to be seen more and more as a homogeneous mass which was created by saving decisions, which could be invested in one industry and transferred to another, which was productive in the sense that is has a non-negative marginal product if used properly, and which guaranteed higher productivity if employed in larger amounts in relation to other factors of production. Not surprisingly, this conception was attacked by the heirs to the Austrian tradition in capital theory, especially Hayek (1936, 1940), as a 'mythology of capital'. But their own position was so much bound up with the deprecated notion of a period of production that Knight's conception (1933, 1934, 1935, 1936) became the dominant doctrine.

The notion of capital as a 'material entity' was formulated rigorously by Pigou, who provided a sophisticated definition of a capital stock, consisting of heterogeneous capital goods, which 'is capable of maintaining its quantity while altering its form' (1935, p. 239). This was possible only by making some rather strong assumptions on the way the capital stock was maintained. Thus Pigou assumed, among other things, that any item of a constant capital stock that needs to be replaced is replaced by another capital good yielding equal quasi-rents at the time of replacement. Later changes in quasi-rents are disregarded. While such assumptions may be objected to, they do make it possible in principle to give precise meaning to the notion of a capital stock as a changing 'material entity' without aggregating heterogeneous capital goods, i.e. without negating its quality as a vector.

Walras (1874–7) and Pareto (1909) treated capital very much as Wicksteed had done: as yet another factor of production in a production system which was fully synchronized and which was not in need of advances. As they used production functions and thus assumed, as Wicksteed had done, that there always exist many production processes for the production of the same unit bundle of outputs, the productivity of capital goods was no problem for them. But because they espoused the black box view of production they somewhat lost sight of the internal structure of production, and hence of the character of capital goods as produced means of production: capital goods are in their conceptual scheme simply part of the endowment which economic agents use to maximize their satisfaction. Moreover they could not form a notion of the capital intensity

of production as they had no way of aggregating capital goods in an unambiguous manner.

Wicksell, finally, in his later treatment of the matter (1901) attempted to provide a synthesis of neoclassical capital theory by combining the general equilibrium framework of Walras and Pareto with the Austrian view of production as a time-consuming process. This led him to emphasize capital goods and their productivity. But when he came to close his system he took refuge, as Böhm-Bawerk had done, in the idea of a given fund of money capital. The importance of a given fund of money capital which acted as a constraint on entrepreneurial choices between different degrees of roundaboutness of production processes was also emphasized by Schumpeter (1911) and Cassel (1918).

Neoclassical economists have in common that they attempted to formulate a theory of production; but they differed in their conceptions (Hennings 1985). Böhm-Bawerk and those who followed him made an attempt to formulate more precisely what they saw as the gist of the classical theory of the role of capital in production: but their efforts were not generally accepted. All other neoclassical writers except Wicksell jettisoned the advances view of capital, and were in consequence faced with the necessity of formulating a measure for the capital intensity of production if they wished to uphold the proposition that more capital-intensive methods of production were more productive. Wicksteed as well as Walras and Pareto did not do so, and simply refrained from making such statements. Marshall, Clark, and Knight in one way or another attempted to solve the problem by taking refuge in a concept of capital which is in essence a notion of money capital, and which cannot unambiguously serve for that purpose. Only Pigou formulated an unambiguous concept of capital as a changeable 'material entity'.

The Neo-neoclassical Theory of Capital in Production

The neo-neoclassical view of the role of capital in production is based on the work of Viner (1930), Stackelberg (1932), Schneider (1934) and others, who worked out the theory of production as well as a theory of production costs, and the syntheses later provided by Hicks (1939) and Samuelson (1947) of the various neoclassical theories on the basis of the Walras–Pareto theory of general equilibrium (Arrow and Hahn 1971). Originally strongly microeconomic in nature, capital goods held and stage. But as this theory was essentially static, little thought was given to dynamic considerations (Hicks (1939) was the exception), and hence to the problems that arise if concrete capital goods are shifted from one industry to another. Where such problems came up, refuge was taken in the Clark–Knight conception of capital as a fairly homogeneous and amorphous mass which could take on different forms. With the growth of macroeconomic one-sector thinking – Hicks (1932) is one of the earliest examples in this part of economic theory – this conception was more and more resorted to. It received the seal of approval in Samuelson's textbook (1948), and in numerous empirical studies based on the macroeconomic production function first proposed by Cobb and Douglas (1928). It was of course realized that capital consisted of capital goods: but their aggregation into a more or less homogeneous aggregate was considered an index number problem which could be solved in principle as well as in practice. It was against these notions that opposition arose in the 1950s and 1960s.

Recent Debates

As Joan Robinson (1954, 1956) pointed out, the Clark–Knight concept of capital cannot serve in a macroeconomic production function à la Cobb–Douglas because it is essentially a monetary measure. Surprisingly, this contention engendered a major debate in capital theory. Essentially two answers were given to Robinson's objection. On the one hand it was argued that one should search for appropriate indices that can be used to aggregate heterogeneous capital goods into a scalar measure (Champernowne 1954).

This created a specialist literature on aggregation problems which demonstrates that in general

conditions for consistent aggregation are rather restrictive, although in many cases appropriate indices exist (Green 1964). On the other hand, it was argued that macroeconomic analyses should be abandoned in favour of microeconomic ones if heterogeneity (which after all exists in land and labour as well as in capital goods) is the issue (Swan 1962).

In the course of the debates referred to above it was demonstrated that the value paradoxes Joan Robinson had pointed out may invalidate the idea that different production processes can be brought into a continuous ordering which corresponds to their respective capital intensities. While this point was eventually accepted, its importance is still under dispute (see Harcourt (1972) and Blaug (1974) for summaries and evaluations from divergent points of view). To some, such demonstrations completely invalidate neoclassical and in particular neo-neoclassical economic theory, because both are considered to be founded on the idea that marginal products of factors of production need to be calculated on the basis of technical data alone. Others accept such demonstrations as exceptions to a general rule. What is sometimes lost sight of in these assessments is the fact that reswitching of production processes, capital revaluations, Wicksell effects, *et hoc genus omne* do not invalidate all propositions in capital theory (whether neoclassical or not). One can well do without capital in the sense of capital value (i.e. as a scalar magnitude) for some purposes (see, e.g. Nuti 1970). Moreover, it should be appreciated that Robinson's objections do not apply to Pigou's notion of capital as a changeable 'material entity' even though it is not at all obvious that such a concept would serve well in a macroeconomic production function.

Another attack on neoclassical capital theory was made by Garegnani (1960, 1970, 1976). The gist of his argument seems to be that the Walrasian model of general equilibrium, if properly extended to include the production of capital goods, cannot generate equilibrium as well as a unique rate of return on all capital goods for all possible initial endowments. As Garegnani has not specified the dynamic adjustment processes he envisages, his claim is difficult to adjudicate. Nor is it clear in what respect, if any, it invalidates received notions of the role of capital in production processes. Recent debates (Hahn 1982; Duménil and Lévy 1985) have not thrown much light on these issues.

Conclusion

Capital always consists of heterogeneous capital goods; indeed it is useful precisely because goods are heterogeneous and specific in the sense that they cannot be used for all purposes. Attempts to represent them by some kind of aggregate are useful only if they preserve this aspect of capital goods. In classical economic theory the notion of advances was used as such an aggregate, although in a rather loose fashion, with an awareness of the heterogeneity of the capital goods that assisted labour in time-consuming production. Austrian neoclassical economic theory attempted unsuccessfully to make this notion more precise in the form of a temporal theory of production. Non-Austrian neoclassical and neo-neoclassical economic theory sacrificed the heterogeneity of capital goods together with the time element in production, and developed an atemporal theory of production on the basis of a concept of capital value, or money capital. Yet, as Wicksell pointed out (1901, p. 149), the valuation of capital goods in terms of prospective output is a 'theoretical anomaly'; it is nevertheless appropriate in view of their character as produced means of production. It is not surprising, therefore, that anomalies result when such concepts are used. The alternative is obviously to analyse the role of capital goods in a framework which admits their heterogeneity and permits them to be used for different purposes, i.e. in a general equilibrium framework. Such analyses have so far been mainly confined to stationary states. Some of the essential characteristics of capital goods, however, such as their specificity, are of importance only in non-stationary states. Much remains to be done, therefore, before the role of capital and of capital goods as factors of production can be said to be completely elucidated.

Capital as a Social Relation

Anwar Shaikh

Taken by itself, a sharp stone is simply a relic of some ancient and inexorable geologic process. But appropriated as a cutting instrument, it is a tool or, in a somewhat more murderous vein, a weapon. As a stone, it is a natural object. But as a tool or weapon, it is an eminently social object

whose natural form is merely the carrier of the social relations which, so to speak, happen to have seized upon it.

Even any particular social object, such as a tool, can enter into many different sets of social relations. For instance, whenever a loom is used to weave cloth, it is a part of the *means of production* of a cloth-making labour process. However, because any such labour activity is itself part of the social division of labour, its true content can only be grasped by analysing it as part of a greater whole. For instance, the cloth-making process may be part of the collective labour of a family or community, in which the cloth is intended for direct consumption. Alternately, the very same people may end up using the same type of loom, in a capitalist factory in which the whole purpose of the labour process is to produce a profit for the owners. In the case of cloth produced for direct use, it is properties such as quality and durability which directly concern the producers. But in the case of cloth produced in a capitalist factory, the salient property of the cloth is the *profit* it can generate. All other properties are then reduced to mere vehicles for profit, and as we know only too well, the packaging of the product can easily displace its actual usefulness. This at any rate establishes that even two labour processes which are technically identical can nonetheless have substantially different dynamics, precisely because they exist within very different social frameworks.

The above result also applies to the tools of the labour process. For instance, in both communal and capitalist production, the loom serves as means of production in a labour process. But only in the latter case does it also function as *capital*. That is to say, for its capitalist owners, the significance of the loom lies not in its character as means of production, but rather in its role as means towards profit; while for the workers labouring alongside it, the loom functions not as their own instrument but rather as a proper capitalist tool. Indeed, if we look more closely at the capitalist factory, we will see that not only the loom, but also money, yarn, and even the capacity to labour all serve at various points as particular incarnations of the owners' capital. This is because *capital is not a thing*, *but rather a definite set of social relations* which belong to a definite historical period in human development, and which give the things enmeshed within these relations their specific content as social objects. To understand Capital, one must therefore decipher its character as a social relation (Marx 1894, ch. 48; Marx 1867, Appendix, II–III).

C

Capital and Class

Human society is structured by complex networks of social relations within which people exist and reproduce. The reproduction of any given society in turn requires not only the reproduction of its people, but also of the things they need for their existence, and of the social relations which surround both people and things.

The things which people need for their daily existence form the material base of society. Although the specific character of these things, and even of the needs they satisfy, may vary according to time and circumstance, no society can exist for long without them. Moreover, in all but the most primitive of societies, the vast bulk of the necessary social objects must be produced through human labour. Production, and the social allocation of labour upon which it rests, thus emerge as absolutely fundamental aspects of social reproduction. But social labour involves acting on nature while interacting with other people, in-and-through specific social relations. Thus, the labour process ends up as crucial not only in the production of new wealth, but also in the reproduction of the social relations surrounding this production, as well as of any other social relations directly contingent upon them.

The preceding point assumes particular significance in the case of class societies. In effect, a class society is structured in such a way as to enable one set of people to live off the labour of the others. For this to be possible, the subordinate classes must not only be able to produce more than they themselves appropriate, they must also somehow be regularly induced to do so. In other words, they must be made to work longer than that required by their own needs, so that their surplus labour and corresponding surplus product can be

used to support their rulers. Thus, the very existence of a ruling class is predicated on the *exploitation of labour*, and on the reproduction of the social and material conditions of this exploitation. Moreover, since any such process is a fundamentally antagonistic one, all class societies are marked by a simmering hostility between rulers and ruled, punctuated by periods of riots, rebellions, and revolutions. This is why class societies always rely heavily on ideology to motivate and rationalize the fundamental social cleavage upon which they rest, and on force to provide the necessary discipline when all else fails.

Capitalism is no different in this respect. It is a class society, in which the capitalist class exists by virtue of its ownership and control of the vast bulk of the society's means of production. The working class is in turn comprised of those who have been 'freed' of this self-same burden of property in means of production, and who must therefore earn their livelihood by selling their capacity to labour (labour power) to the capitalist class. As Marx so elegantly demonstrates, the *general social condition* for the regular sale of labour power is that the working class as a whole be induced to perform surplus labour, for it is this surplus labour which forms the basis of capitalist profit, and it is this profit which in turn keeps the capitalist class willing and able to re-employ workers. And as capitalism itself makes abundantly clear, the struggle among the classes about the conditions, terms and future of these relations has always been an integral part of its history (Marx 1867, Part II and Appendix).

Capital as Individual Versus Dominant Social Relation

In the preceding section we spoke about already constituted capitalist society. But no social form springs full blown into being. Instead, its constituent elements must either already exist within other societies, albeit in disassociated form, or else they must arise and be nurtured within the structure of its direct predecessor. This distinction between elements and the whole is important because it allows us to differentiate between capital as an individual social relation, and capitalism as a social formation in which capital is the *dominant* social relation.

Capital as an individual social relation is concerned most of all with the making of profit. In its most general form, this means advancing a sum of money M in order to recoup a larger sum of money M'. The general *circuit of capital* is therefore always attended by the two poles M and M', and their span is always the overall measure of its success. Note that money functions here as a means of making money (i.e. as money-capital), rather than merely as a means of purchasing commodities to be consumed (i.e. as money-revenue). Marx draws many significant and powerful implications from the above functional difference between money-capital and money-revenue.

Even within the circuit of capital, there are three distinct routes possible between its two poles. First, money capital M may be advanced as a loan, in return for a subsequent repayment M' which covers both the original advance and an additional sum over and above it. This is the circuit $M–M'$ of financial capital, in which an initial sum of money appears to directly beget a greater sum, through the apparently magical device of interest. Second, money capital M may be utilized to buy commodities C, and these very same commodities may then be resold for more money M'. This is the circuit $M–C–C–M'$ of commercial capital, in which the double appearance of C as an intermediate term signifies that it is the same set of commodities which first exists as the object of purchase of the capitalist, and then later as their object of (re)sale. Here, it is the acumen of the capitalist in 'buying cheap and selling dear' which appears to generate the circuit's profit. Finally, money capital M may be advanced to purchase commodities C comprising means of production (materials, plant and equipment) and labour power, these latter elements set into motion as a production process P, and the resultant product C' then sold for (expanded) money capital M'. This is circuit $M–C\ldots P\ldots C'–M'$ of industrial capital, in which the characteristic intermediate term is that of the production process P. Now, it is the capitalist's ability to keep the productivity of

labour ahead of the real wage which appears as the fount of all profit.

The most prevalent early incarnations of capital are those of usurer's capital $M–M'$ and merchant capital $M–C–C'–M'$. Both of these are virtually as old as money itself, and have existed over the millennia within many different civilizations. However, they almost always appear as parasitic relations, either within a particular host society or between two or more cultures. Often despised and occasionally feared, these individual activities were nonetheless generally tolerated as long as they conformed to the overall structure of the social formation within which they existed. It is only in feudal Europe, particularly in England, that these antediluvian forms of capital fused together with industrial capital to form the entirely new social formation that we call the capitalist mode of production. Only then, on the foundation of surplus labour extracted directly by itself and for itself, do we find capital as the dominant social relation and its individual forms as mere particular moments of the same overall process (Marx 1858, p. 266, 1867, Appendix).

General Laws of Capital

The social dominance of capital gives rise to certain patterns which are characteristic of the capitalist mode of production.

We have already encountered the first of these, which is that the class relation between capital and labour is a fundamentally antagonistic one, marked by an intrinsic struggle over the conditions and terms of the extraction of surplus labour. Though ever present, this antagonism can sometimes erupt with a force and ferocity which can shake the very foundations of the system itself.

Second, capitalism as a form of social organization pits each element against the other in a generalized climate of conflict: capitalist against worker in the labour process, worker against worker in the competition for jobs, capitalist against capitalist in the battle for market position and sales, and nation against nation in the world market. Like the class struggle, these other conflicts also periodically erupt into acute and open combat between the participants, whether it be the battles of strikers against scabs, or capitalists against their rivals, or even of world wars between one set of capitalist nations and another. It is precisely this real conflict which the bourgeois notion of 'perfect competition' is designed to conceal (Shaikh 1982).

Thirdly, the relations among people are mediated by relations among things. This stems from the very nature of capitalist production itself, in which individual labours are undertaken solely with the aim of making a profit on their product. The various individual labours are thus articulated into a social division of labour only under the 'objectified husk' of their products. It is the products which therefore step to the fore, and the producers who follow behind. From this derives the famous Fetishism of Commodity Relations, i.e. exchangeability appears to be a natural property of all objects, rather than a historically specific way of evaluating the social content of the labour which produced them.

The fourth point follows directly from the third. As noted above, under capitalist relations of production individual labour processes are undertaken in the hope of private gain, with no prior consideration of a social division of labour. But any ensemble of such labours can survive only if they happen to collectively reproduce both the material and social basis of their existence: capitalist society, like all society, requires a particular pattern of labour in order to reproduce its general structure. Thus, under capitalist production, the various individual labours end up being *forcibly articulated into a moving social division of labour*, through a process of trial-through-error, of overshooting and undershooting, of discrepancy, disruption and even occasional ruptures in the process of reproduction. This pattern of apparent anarchy regulated by inner laws of motion is the characteristic form of capitalist reproduction. Notice how different this concept is from that of general equilibrium, where the whole process is reduced to one of immediate and perfect stasis.

The fifth point stems from the fact that capitalist production is driven by profit. Each capitalist is compelled to try and widen the gap between the

initial advance M and the final return M'; those who are most successful prosper and grow, those who fall behind soon face the spectre of extinction. Within the labour process, this shows up in the tendency to stretch the length and intensity of the working day to its social limits, while at the same time constantly seeking to reshape the labour process along lines which are ever more 'rational' from the point of view of capital. This compulsion is directly responsible for capitalism's historically revolutionary role in raising the productivity of labour to new heights. And it is the associated capitalist rationality which is most perfectly expressed in the routinization of production, in the reduction of human activities to repetitive and automatic operations, and in the eventual replacement of the now machine-like human labour by actual machines. As Marx notes, the so-called Industrial Revolution is merely the signal, not the cause, of the advent of capitalist relations of production. And whereas earlier the tool was an instrument of labour, now it is the worker who is an instrument of the machine (Marx 1867, Parts III–IV).

The Conception of Capital Within Orthodox Economics

Within orthodox economics, the term 'capital' generally refers to the means of production. Thus capital, along with labour, is said to exist in every society. From this point of view, social forms are to be distinguished from one another by the manner in which they 'bring together' the factors of production, the capital and labour, at their respective disposals. Capitalism is then defined as a system which utilizes the market to accomplish this task, in the context of the private ownership of the means of production (Alchian and Allen 1983, chs 1 and 8).

By treating human labouring activity as a factor of production on a par with raw materials and tools, *hence as a thing*, orthodox economics succeeds in reducing the labour process to a technical relation between so-called inputs and outputs (e.g. a production function). All struggles over the terms and condition of labour thereby disappear from view.

Moreover, once labour is defined as a factor of production, every (able-bodied) individual is an owner of at least one factor. Of course, some may be fortunate enough to also own large quantities of capital. But that is a mere detail of the distribution of 'initial endowments', and on such things orthodox economics remains studiously neutral. What matters instead is that under capitalism the notion that everybody owns a factor of production bespeaks of an inherent equality among individuals. Any reference to the concept of class is therefore blocked from the start.

Next, because labour is merely one of the factors of production which individuals are free to utilize in any manner they choose, this labour-as-thing cannot be said to be exploited. The exploitation of labour thus drops out of sight, to be replaced by the notion of the cooperation of Capital and Labour, each of which contributes its component to the product and receives in turn its commensurate reward (as in marginal productivity theories of distribution). With this, the sanctification of capitalism is complete.

The Historical Limits of Capital as a Social Relation

The last general point has to do with the historical specificity of capitalist production. On the one hand, capitalism is a powerful and highly flexible social structure. It has developed its forces of production to extraordinary heights, and has proved itself capable of dissolving or destroying all previous social forms. Its inherently expansive nature has led to the creation of vast quantities of wealth, and to a dominion which extends all over the globe. But on the other hand, this very same progressive aspect feeds off a dark and enormously destructive side whose nature becomes particularly clear when viewed on a world scale. The capital-labour relation is a profoundly unequal one, and the concentration and centralization of capital which attends capitalist development only deepens the inequality. The competitive struggle of all against all creates an alienated and selfish social character, imprisons each in an atmosphere of suspicion and stress, and heaps its

miseries precisely on those who are in the weakest positions. Finally, as capitalism develops, so too does its level of mechanization, so that it is progressively less able to absorb labour. In the developed capitalist countries, this manifests itself as a growing mass of unemployed people at any given 'natural' rate of unemployment. In the Third World, as the incursion of capitalist relations lays waste to earlier social forms, the mechanized processes which replace them are able to pick up only a fraction of the huge numbers previously 'set free'. Thus the rising productivity of capitalist production is accompanied by a growing pool of redundant labour all across the globe. The presence of starving masses in the Third World, as well as of floating populations of unemployed in the developed capitalist world, are bitter reminders of these inherent tendencies.

The above perspective forcibly reminds us that capitalism is only one particular historical form of social organization, subject to deep contradictions which are inherent in the very structure of its being. Precisely because these contradictions are built-in, any successful struggle against their destructive effects must move beyond reform to the rejection of the structure itself. In the 20th century such efforts have taken a variety of forms, ranging from so-called parliamentary socialism to socialist revolution. Whatever we may think of the strengths and weaknesses of these various fledgling social movements, the general tendency is itself part of an age-old human process. History teaches us that no social form lasts forever, and capital as a social relation is no exception to this rule.

Capital Asset Pricing Model

M. J. Brennan

Abstract

Two general approaches to the problem of valuing assets under uncertainty may be distinguished. The first approach relies on arbitrage arguments of one kind or another, while under the second approach equilibrium asset prices are obtained by equating endogenously determined asset demands to asset supplies, which are typically taken as exogenous. The capital asset pricing model (CAPM) is an example of an equilibrium model in which asset prices are related to the exogenous data, the tastes and endowments of investors, although the CAPM is often presented as a relative pricing model.

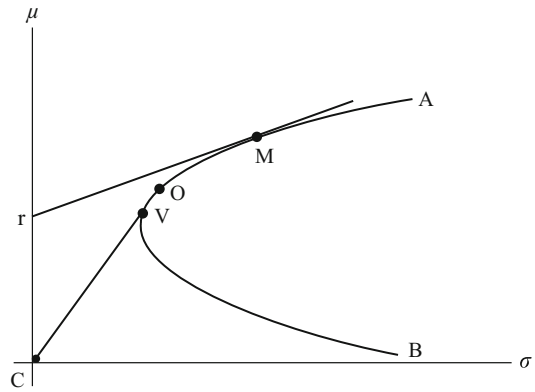
If they are to be of practical use, equilibrium asset pricing models must be parsimonious in their

parameterization of asset demands. To date this parsimony has been achieved only by a choice of assumptions which leads to universal portfolio separation: this is the property that the asset demand vector of every agent can be expressed as a linear combination of a set of basis vectors which may be thought of as portfolios or mutual funds. The distinguishing feature of the set of models which is collectively known as the capital asset pricing model (CAPM) is that each of these basis portfolios can be interpreted as the solution to a particular constrained portfolio variance minimization problem.



Capital Asset Pricing Model, Fig. 1 The efficient frontier and the CAPM

Historical Perspective

The assumption that uncertainty about future asset returns can be described in terms of a probability distribution is at least as old as Irving Fisher (1906), although Hicks (1934b) appears to have been the first to suggest that preferences for investments could be represented as preferences for the moments of the probability distributions of their returns, and to propose that, as a first approximation, preferences could be represented by indifference curves in mean-variance space. Von Neumann and Morgenstern (1947) were the first to place the theory of choice under uncertainty on a rigorous axiomatic basis.

The story of modern portfolio theory really begins, however, with Markowitz (1952, 1958) who assumed explicitly that investor preferences were defined over the mean and variance of the aggregate portfolio return, related these parameters to the portfolio composition and the parameters of the joint distribution of security returns, and for the first time applied the principles of marginal analysis to the choice of optimal portfolios.

Both Markowitz and Tobin (1958) showed that mean-variance preferences can be reconciled with the von Neumann–Morgenstern axioms if the utility function is quadratic in return or wealth. This assumption is objectionable since it implies negative marginal utility at high wealth levels. Tobin also showed, however, that mean-variance preferences could be derived by restricting the probability distributions over which choices are made to a two-parameter family. After some initial confusion it was recognized that, since portfolio returns are weighted sums of security returns, the two-parameter family must be stable under addition, and the only member of the stable class with a finite variance is the normal distribution. Subsequently Merton (1969) and Samuelson (1970) showed that mean-variance analysis is applicable for a broad class of continuous asset price processes if the trading interval is infinitesimal.

The major part of Tobin's analysis deals with the choice between a single risky asset and cash, but he demonstrated that nothing essential is changed if there are many risky assets, for they will always be held in the same proportions and can be treated as a single composite asset. This, the first separation theorem in portfolio theory, is illustrated in Fig. 1, which plots mean returns, μ, against the standard deviation, σ. In this figure the curved locus AMOVB corresponds to the set of portfolios offering the lowest standard deviation for each level of mean return: the positively sloped segment is referred to as the efficient frontier, for points along it offer the highest μ for a given σ. In the absence of any riskless investment opportunities, risk-averse mean-variance investors will select portfolios corresponding to the points at which their indifference curves in (μ, σ) space are tangent to the efficient frontier (Tobin shows that the indifference curves of risk averters will have the requisite curvature). Point C

represents cash which has zero risk and return. By combining cash with the portfolio of risky assets corresponding to the tangency portfolio O, investors are able to attain the (μ, σ) combinations along the line segment CO, and all investors who find it optimal to hold cash will find it optimal to combine their cash with the same risky portfolio O: their portfolio decisions can be *separated* into the choice of the optimal combination of risky asset (O) and the choice of the cash–risky asset ratio.

Six years elapsed before the equilibrium implications of the Tobin separation theorem were exploited by Sharpe (1964) and Lintner (1965). The reason for delay was undoubtedly the boldness of the assumption required for progress, namely, that all investors hold the same beliefs about the joint distribution of security returns. Nevertheless, this assumption of homogeneous beliefs, combined with the further assumption that all investors can borrow as well as lend at the riskless rate, r, leads to the powerful conclusion that all investors hold the same portfolio of risky assets, denoted by M in the figure. Then the only risky assets that will be held by investors in equilibrium are those contained in portfolio M, and M must be the market portfolio of all risky assets in the economy. This identification of the tangency portfolio M with the aggregate market portfolio is the essence of the Sharpe–Lintner CAPM.

The interest of this result derives from the restriction that it imposes on expected asset returns: the excess of μ_j, the expected return on any security j, over the risk-free rate r, must be proportional to the covariance of the security return with the return on the market portfolio, σ_{jM}:

$$\mu_j - r = \theta_M \sigma_{jM} \text{ for all } j \tag{1}$$

where θ_M is a measure of aggregate risk aversion. The intuition behind this important result is that if investors are content to hold portfolio M, the marginal rate of transformation between risk and return obtained by borrowing to invest in a risky security must be the same for all risky securities. Frequently the unknown risk aversion parameter, θ_M, is eliminated and the relative pricing result is obtained:

$$u_j - r = \beta_j(\mu_M - r) \text{ for all } j \tag{2}$$

where μ_M is the expected return on the market portfolio and $\beta_j \equiv \sigma_{jM}/\sigma_{MM}$ is the 'beta' coefficient, which corresponds to the slope of the regression line relating the return on the security to the return on the market portfolio.

During the first half of the 1970s extensive progress was made in relaxing the strong assumptions underlying the original model, and new separation theorems and models were obtained. At the same time, extensive empirical investigations made possible by the development of new stock-price databases found results which were interpreted as favourable to the model. The model also has an influence on practical investment management and corporate finance.

A turning point was reached with the publication of a paper by Roll (1977); this argued that the market portfolio of the theory, which includes all assets, could never be empirically identified, and that therefore the CAPM, which simply asserts the efficiency properties of this portfolio, could never be empirically tested. This argument had substantial influence, and for some time played a major role in shifting attention away from the CAPM to the newly emerging arbitrage pricing theory (APT) of Ross (1976). However, since the early 1990s growing acceptance of the empirical importance of time variation in investment opportunities has led to a resurgence of interest in Merton's (1973) intertemporal version of the CAPM which is formally similar to the APT but is able to provide an economic interpretation of the return factors that are priced in equilibrium.

The CAPM is of great historical significance, not only because it was the first equilibrium model of asset pricing under uncertainty, but also because it showed the importance of portfolio separation for tractable equilibrium models; and, being derivable from assumptions of either quadratic utility or normal distributions, it revealed that the requisite separation properties could be obtained by restrictions either on preferences or on distributions. Cass and Stiglitz (1970) clarified

the rather restrictive assumptions necessary for preference-based separation, and equilibrium models based on this have been constructed, for example, by Rubinstein (1976). Ross (1978) has identified the distributional assumptions required for separation in the absence of restrictions on preferences, and the arbitrage pricing theory is based on a generalization of his separating distributions. Chamberlain (1983) discusses spherical distributions, the subclass of separating distributions for which the expected utility is a function of the portfolio mean and variance. Both preference-based and distribution-based models of capital market equilibrium are lineal descendants of the CAPM.

A pricing kernel is a non-negative weighting function for asset returns under which the expected returns on all assets are equal to the risk-free interest rate; the kernel corresponds roughly to the marginal utility of a representative investor and the existence of a pricing kernel is a necessary and sufficient condition for arbitrage free security markets. Modern treatments of asset pricing such as Cochrane (2005) treat the general problem of asset pricing as that of specifying an appropriate pricing kernel: the CAPM specifies a class of pricing kernels that are linear in the aggregate market return.

An unfortunate consequence of the one-period nature of the CAPM was a concentration of attention on equilibrium rates of return, rather than on prices, which are the fundamental variables of interest. However, Merton (1973) placed the CAPM in an intertemporal context, and his necessary condition for equilibrium rates of return forms one cornerstone (the other being an assumption of rational expectations) for partial differential equations for asset prices which, following Cox et al. (1985), has tended to unify the pricing theories for bond and equity markets.

Formal Models

While a complete asset pricing model endogenizes the riskless interest rate as well as the prices of risky securities, the CAPM adds nothing new to the theory of interest rate determination, and we shall simplify by taking the interest rate and current consumption decisions as given, concentrating our attention on portfolio decisions and the pricing of risky securities.

In considering the various versions of the CAPM we shall pay particular attention to the implied demands of investors. It will be seen that in all cases in which risks are freely traded asset demands exhibit the separation property, and even when there are restrictions on trading as in the Mayers (1972) asset pricing model, an approximate separation property obtains.

The Sharpe–Lintner Model

Consider a setting in which each investor $i(i = 1,\ldots,m)$ is endowed with a fraction $\overline{z}_{ij}$ of security $j(j = 1,\ldots,n)$ and (a) investor utility is defined over the mean and variance of end of period wealth; (b) securities are traded in a competitive market with no taxes or transactions costs; (c) investors share homogeneous beliefs or assessments of the joint distribution of payoffs on the securities; there are no dividends; (d) there is an exogenously determined interest rate $r = R - 1$ at which investors may borrow or lend without default; (e) there are no restrictions on short sales.

Then define:

$\overline{p}_{j1}$ expected end of period value of security j;
$\overline{p}_{j0}$ initial value of security j;
ω_{jk} covariance between end of period value of j and k;
$\overline{W}_i, S_i^2$ expectation and variance of end of period wealth of investor i;
$V_i(\overline{W}_i, S_i^2)$ utility of investor i with
$V_{i1} \equiv \partial V_i / \partial \overline{W}_i > 0, V_{i2} \equiv \partial V_i / \partial S_i^2 < 0.$

The investor's decision problem may be written as

$$\max_{z_{ij}} \; V_i\left(\overline{W}_i, \mathrm{S}_i^2\right) \tag{3}$$

$$\text{s.t. } \overline{W}_i = \sum_j z_{ij}\overline{P}_{j1} - R\sum_j \left(z_{ij} - \overline{z}_{ij}\right)P_{j0} \tag{4}$$

$$S_i^2 = \sum_j \sum_k z_{ij} z_{ik} \omega_{jk}. \tag{5}$$

The first order conditions for an optimum are

$$V_{i1}\left(\overline{P}_{j1} - RP_{j0}\right) + 2V_{i2}\sum_k z_{ik}\omega_{jk} = 0, \quad (j = 1, \ldots, n) \tag{6}$$

and the second conditions are satisfied by virtue of the assumption of risk aversion. Defining $\mathbf{\Omega}^*$ as the variance covariance matrix $[\omega_{jk}]$ and using boldface type to denote vectors, the vector of fractional asset demands may be written

$$\mathrm{z}_i = \theta_1^{-1}\mathbf{\Omega}^{*-1}\left(\overline{\mathbf{P}}_1 - R\mathbf{P}_0\right) \tag{7}$$

where $\theta_i^1 \equiv -V_{i1}/2V_{i2}$ is a measure of the investor's risk tolerance. Equation (7) is a statement of the Tobin separation theorem, that investor demands for risky assets differ only by a scalar multiple.

Market clearing requires that $\sum_i \mathbf{Z}_i = 1$where **1** is a vector of units. Then the equilibrium initial price vector is obtained by summing (7) over i and imposing the market clearing condition:

$$\mathbf{P}_0 = \frac{1}{R}\left\{\overline{\mathbf{P}}_1 - \theta_m \mathbf{\Omega}^* 1\right\} \tag{8}$$

where $\theta_m \equiv \left(\sum_i \theta_i^{-1}\right)^{-1}$. In this form the CAPM expresses equilibrium asset prices in terms of the exogenous variables, the distribution of end of period prices, investor risk aversion parameters and the interest rate, although it should be noted that in general the market risk aversion parameter $\theta_m$will depend upon the endogenously determined distribution of wealth. This formulation corresponds to that of Lintner (1965) and emphasizes the one-period nature of the model and the exogeneity of the end of period prices. However, the CAPM is most often written as a necessary condition for the equilibrium rates of return, although this obscures the distinction between endogenous and exogenous variables.

In what follows we shall work with the rate of return formulation; thus define $x_{ij} \equiv z_{ij}P_{j0}$, the amount invested in security j; $\mu_j \equiv \overline{P}_{j1}/\mathrm{P}_{j0} - 1$, the expected rate of return and$\sigma_{jk} \equiv \omega_{jk}/P_{j0}P_{k0}$, the covariance of the rates of return between securities j and k. Making these substitutions in (4) and (5), the first order conditions (6) become

$$V_{i1}\left(\mu_j - r\right) + 2V_{i2}\sum_k x_{ik}\sigma_{jk} = 0, \quad (j = 1, \ldots, n). \tag{9}$$

Then, defining $\mathbf{\Omega}$ as the variance covariance matrix of rates of return, the vector of asset demands $\mathbf{x}_i$ may be expressed as

$$\mathbf{x}_i = \theta_i^{-1}\mathbf{\Omega}^{-1}(\boldsymbol{\mu} - r1). \tag{10}$$

This is an alternative statement of the Tobin separation theorem and the portfolio $\mathbf{\Omega}^{-1}(\boldsymbol{\mu} - r1)$ corresponds to the point of tangency in Fig. 1. This portfolio itself may be decomposed into the two portfolios $\mathbf{\Omega}^{-1}\boldsymbol{\mu}$ and $\mathbf{\Omega}^{-1}1$. The former is the solution to the problem of finding the minimum variance portfolio of risky assets with a given expected payoff, and the latter is the solution to the problem of finding the global minimum variance portfolio of risky assets; these two portfolios plot at points O and V in the figure. As Merton (1972) has shown, the whole locus may be constructed from just these two portfolios.

Let Vm denote the aggregate market value of all assets in the market portfolio and let $\mathbf{v}_\mathrm{m}$ denote the vector of market proportions. Combining the market clearing condition $\sum_i \mathbf{x}_i = V_m\,\mathbf{v}_\mathrm{m}$ with (10) yields

$$\boldsymbol{\mu} - r1 = \theta_m V_m \mathbf{\Omega}\mathrm{v}_m. \tag{11}$$

This form of the CAPM expresses asset risk premia as proportional to the covariances of their returns with the returns on the market portfolio; this of course is no more than the condition for the market portfolio to correspond to the tangency point in Fig. 1. Equation (11) contains the market risk aversion parameter θ_m. This can be eliminated by pre-multiplying (11) by $\mathbf{v_m}$ and solving for $\theta_m = (\mu_m - r)/\sigma_m^2$, where μm and $\sigma_m^2$are the

C

expected return and variance of return on the market portfolio respectively. Then, substituting for θ_m in (11) we have the equation of the 'security market line':

$$\mu_j - r = \beta_j(\mu_m - r) \tag{12}$$

where $\beta_j \equiv \sigma_{jm}/\sigma_m^2$. In this form the CAPM is a relative pricing model which relates the risk premium on individual securities to the risk premium on the market portfolio. The proportionality factor, β_i, often referred to as the 'beta coefficient', is the coefficient from the regression of $\tilde{R}_j$, the return on security j, on $\tilde{R}_m$, the return on the market portfolio:

$$\tilde{R}_j = \alpha_j + \beta_j \tilde{R}_m + \tilde{e}_j \tag{13}$$

where $\tilde{e}_j$is an orthogonal error term. Taking expectations in the market model Eq. (13), the asset pricing Eq. (12) is seen to imply the restriction $\alpha_j = (1 - \beta_j)r$. This restriction, and the existence of a positive risk premium on the market portfolio, are the major empirical predictions of the Sharpe–Lintner model. They have been the subject of extensive empirical tests.

Taxes and Restrictions on Riskless Transactions

The absence of short sales restrictions is not critical to the Sharpe–Lintner model, since in equilibrium all investors hold the market portfolio, which does not involve short sales. The assumption is critical, however, for all the remaining models we shall consider which involve more than a single basis fund of risky securities.

Thus, following Black (1972) and Brennan (1970), assume that there are no opportunities for riskless borrowing or lending, and that each security pays predetermined dividends which are taxed in the hands of the investor at the rate $t_i (i = 1, \ldots, m)$. Denoting the dividend yield by δ_j, and assuming that investor preferences are defined over the moments of after tax wealth, the first order conditions corresponding to (9) are

$$V_{i1}\left(\mu_j - t_i\delta_j - \lambda_i\right) + 2V_{i2}\sum_k x_{ik}\sigma_{jk} = 0, \quad (j = 1, \ldots, n). \tag{14}$$

where λ_i is the Lagrange multiplier associated with the constraint that all wealth be invested in risky securities. The vector of asset demands may be written as

$$x_i = \theta_i^{-1}\boldsymbol{\Omega}^{-1}\boldsymbol{\mu} - \left(\theta_1^{-1}\lambda_1\right)\boldsymbol{\Omega}^{-1}1 - \left(\theta_1^{-1}\mathbf{t}_1\right)\boldsymbol{\Omega}^{-1}\delta. \tag{15}$$

Note first that if $t_i = 0$ the optimal portfolio for any preferences can be constructed from the two mutual funds $\boldsymbol{\Omega}^{-1}\boldsymbol{\mu}$ and $\boldsymbol{\Omega}^{-1}\mathbf{1}$. Heterogeneous taxation of dividends introduces the third mutual fund, which can be interpreted as the solution to the problem of finding the minimum variance portfolio with a given total dividend. Aggregating the demand vectors, and imposing the market clearing conditions, yields an asset pricing equation which contains three utility dependent parameters, λm, θ_m and t_m, corresponding to the three funds in (15):

$$\boldsymbol{\mu} - \lambda_m 1 = \theta_m V_m \boldsymbol{\Omega} \mathrm{v}_m + t_m \delta \tag{16}$$

t_m, the market tax rate, is a weighted average of the personal tax rates, and λ_m, the market shadow interest rate, is referred to for historical reasons as the zero beta return. When $t_m = 0$, (16) is just the condition for the market portfolio to be the tangency portfolio when the interest rate is λ_m. Thus the Black model, which does not include taxes, differs from the Sharpe–Lintner model only in leaving unspecified the relevant (shadow) riskless interest rate.

Non-marketable Assets

Mayers (1972) has considered the effect of introducing an extreme form of market imperfection, namely, an absolute prohibition on trading certain assets. This is important, for a substantial part of total wealth is not held as part of well-diversified portfolios, on account either of prohibitions on trade (human capital), or of market imperfections

such as transactions costs and information asymmetries. Thus let $\overline{h}_i$ denote the expected payoff on the non-marketable wealth (human capital) of investor i, and let σ^i_{jh} denote the covariance between the return on marketable security j and the human capital of investor i. Then the expression for $\overline{W}_i$ must be increased by $\overline{h}_i$ and the variance of end of period wealth becomes $S_i^2 = \sum_j \sum_k x_{ij} x_{ik} \sigma_{jk} + 2\sum_j x_{ij}\sigma^i_{jh} + \sigma$. The asset demand vector can then be written as

$$\mathbf{x}_i = \theta_i^{-1} \mathbf{\Omega}^{-1}(\boldsymbol{\mu} - r1) - \mathbf{b}_i \tag{17}$$

where $\mathbf{b}_i = \mathbf{\Omega}^{-1}\sigma^i_n$ is the vector of coefficients from the regression of the return on human wealth on the marketable security returns. Defining $\mathbf{x}^e_i \equiv \mathbf{x}_i + \mathbf{b}_i$ as the vector of effective asset demands, we see from (17) that effective asset demands exhibit the standard separation property. This reflects the fact that, while the returns on human capital are not directly marketable, the component of the return which is linearly related to the returns on the marketable securities is indirectly marketable by appropriate offsetting positions in the marketable securities. The asset holdings of the individual may be represented as the sum of effective asset holdings $\mathbf{x}^e_i$ and an investment in the component of human wealth whose return is orthogonal to the returns on marketable assets. We refer to this as approximate portfolio separation since the first component exhibits portfolio separation, and the second component has no effect on the relative demands for marketable assets.

The Mayers model leads to an asset pricing equation which is identical to that of the Sharpe–Lintner model if the market portfolio is defined as the sum of the effective investment vectors $\mathbf{x}^e_i$.

Inflation and International Asset Pricing

Stochastic inflation has no effect on the foregoing results, provided that a common inflation rate can be defined for all investors and returns are restated in real terms. However, the international asset pricing models of Solnik (1974) and Stulz (1981) distinguish between nationalities precisely on the basis of their price indices, which may differ on account of either a violation of commodity price parity or differences in tastes and consumption baskets (see Adler and Dumas 1983).

Define $\widetilde{\pi}_i$ as the inflation rate in the numeraire currency for investor i. Then, to a high order of approximation, which becomes exact as the time interval approaches zero, the mean and variance of real wealth can be written as

$$\begin{aligned}\overline{W}_i = &\sum_j x_{ij}(\mu_j - r) \\ &+ W_{0i}\left(1 + r - \widetilde{\pi}_i + \sigma^i_{\pi\pi}\right) \\ &- \sum_j x_{ij}\sigma^j_{j\pi}\end{aligned} \tag{18}$$

$$\begin{aligned}S_i^2 = &\sum_j \sum_k x_{ij}x_{ik}\sigma_{jk} - 2W_{0i}\sum_j x_{ij}\sigma^i_{k\pi} \\ &+ W^i_{0i}\sigma^i_{\pi\pi}\end{aligned} \tag{19}$$

where W_{0i} is the investor's initial wealth.

The asset demand vector is then

$$x_i = \theta_i{}^{-1}\mathbf{\Omega}^{-1}(\boldsymbol{\mu} - r1) + \mathbf{b}_i \tag{20}$$

Where $\mathbf{b}_i \equiv W_{0i}\,\mathbf{\Omega}^{-1}\,\sigma^i_x$ is the vector of coefficients from the regression at the individual's aggregate inflation risk, $W_{0i}\widetilde{\pi}_i$, on security returns. If we compare (20) with (17), it is apparent that this international asset pricing model is isomorphic to the Mayers' non-marketable wealth model with individual inflation risks playing the same role as human capital.

Black (1974) has modelled segmentation in international capital markets by introducing a tax on foreign security holdings for residents of one country. This model is isomorphic to Brennan's (1970) tax model, if the foreign securities are thought of as paying dividends on which only domestic residents are taxable. Stulz (1981) extends Black's model by prohibiting negative taxes on short sales: as one might expect, this causes some indeterminacy in the pricing relations

since the marginal conditions of portfolio optimality are no longer always satisfied.

Intertemporal Models

Merton (1973) showed that the classical one-period CAPM can be extended to an intertemporal setting in which investors maximize the expected utility of lifetime consumption. With continuous trading and suitable restrictions on the stochastic process of asset prices, the essential mean-variance analysis is retained, the major innovation being that at each instant the individual may be represented as maximizing the expected utility of a derived utility function, defined over wealth and a set of S state variables describing the future investment and consumption opportunity sets. The state dependent derived utility function induces $(S + 1)$ fund separation in the risky asset portfolio, and the vector of risky asset demands may be written

$$x_1 = \theta_i^{-1}\mathbf{\Omega}^{-1}(\boldsymbol{\mu} - r1) - \sum_{s=1}^{S} \gamma_{is}\mathbf{\Omega}^{-1}\xi_s \quad (21)$$

where ξ_s is the vector of covariances of asset returns with the change in state variable S and γ_{is} depends on the utility function. Aggregation of asset demands and the imposition of the market clearing condition lead to an asset pricing equation in which asset risk premia are a linear function of covariances with aggregate wealth *and* covariances with changes in the state variables or factors that described the investment opportunity set. In the absence of prior information about the relevant state variables this model is empirically indistinguishable from the arbitrage pricing theory. Breeden (1979) showed that if consumption preferences are time separable this 'multi-beta' pricing model can be collapsed to a single beta measured with respect to changes in aggregate consumption, the 'consumption' CAPM(CCAPM), and much effort has been expended on testing this form of the model despite the difficulties of measuring consumption flows.

Campbell (1993) developed a model with recursive utility which, unlike the standard time-additive utility function defined over consumption, does not satisfy the von Neumann–Morgenstern axioms but does allow the intertemporal marginal rate of substitution to vary independently of risk aversion. This model contains elements of both the CAPM and the CCAPM in that expected returns depend on the covariances of asset returns with both consumption and the market return.

Recent Empirical Developments

During the 1990s renewed interest in Merton's (1973) 'intertemporal' CAPM (ICAPM) was generated by the empirical failures of both the CAPM and the CCAPM, the increasing evidence of time variation in investment opportunities, and the empirical success of an atheoretical three-factor model of security returns developed by Fama and French (FF) (1992, 1993) to account for high returns on small firms and the low returns on growth stocks relative to value stocks. The FF model could be interpreted as a version of either the APT or the ICAPM if no restrictions were placed on the types of factors that could enter these models. However, the factors that are important for pricing in the APT are those that explain the covariance of (one-period) returns, while the factors in the ICAPM are those that forecast future returns. Merton (1973) had suggested the interest rate as an example of an ICAPM state variable, and Nielsen and Vassalou (2006) showed formally that the only state variables that are relevant for the ICAPM are those with information about the current and future interest rate and the slope of the capital market line which is shown as rM in Fig. 1. Brennan et al. (2004) constructed a version of the ICAPM in which the interest rate and slope of the capital market line follow a joint Markov process, and showed that its empirical performance was at least as good as that of the FF model. Brennan and Xia (2006) used this framework to derive expressions for the prices of cash flow claims which depend explicitly on current capital market conditions as measured by the interest rate and the slope of the capital market line, as well as on the characteristics of the underlying cash flow. This implies that stock prices vary with discount rates as well as cash flow expectations, and Campbell

and Vuolteenaho (2004) showed that, if market betas are decomposed into components due to changes in cash flow expectations and to changes in discount rates, then risk premia are associated primarily with the cash flow component of beta. These models attribute the low returns on growth stocks to the greater proportion of their risk arising from discount rate changes.

The classic CAPM may hold even with time variation in investment opportunities. Constantinides (1980, 1982) has identified two sets of sufficient conditions for the simple CAPM to hold with a time varying interest rate. In his models the social investment opportunity set is stationary and consists only of risky investments: stochastic variation in the interest rate then does not affect the CAPM relation if there is either demand aggregation or full Pareto efficiency of asset markets. Either condition is sufficient for prices to be determined as though there existed a single representative individual; for such an individual stochastic variation in the interest rate is irrelevant since the interest rate represents only a shadow price and not a real investment opportunity. Finally, the single period nature of the CAPM is retained if individuals behave myopically, ignoring stochastic variation in the investment opportunity set: this occurs if and only if the utility function is logarithmic.

Time variation in the distribution of asset returns can affect tests of asset pricing models even if the CAPM is true. For example, if betas and risk premia are time varying, then average returns need not be related to average betas as predicted by the CAPM even if period by period returns and betas are. Lettau and Ludvigson (2001) argued that the predictive power of the CCAPM is considerably enhanced by allowing the covariances of asset returns to depend on a measure of the aggregate consumption–wealth ratio. However, Lewellen and Nagel (2006) argued that time variation in risk premia is unlikely to be sufficient to account for the observed value anomaly.

Capital Budgeting

E. Solomon

A sub-field within economics and finance, the principal concern of capital budgeting is the optimal deployment of funds into capital expenditures. The mainstream of the field, developed essentially in the 1950s and 1960s, consists of two threads of inquiry. (1) How should a company measure the investment worth of a capital expenditure proposal? (2) How should a company set the minimum required rate of return for a capital expenditure proposal?

Historical Evolution

The concept of a *capital budget*, as opposed to an *operating budget*, originated in public finance. Many governments – the United States Federal government is a notable exception – have long maintained separate accounts for capital expenditures; that is, expenditures on capital assets that provide benefits over relatively long time periods.

In the private sector, separate budgeting for capital expenditure has an almost equally long history. The development, however, of the coherent body of thought now known as *capital budgeting* began only after World War II. Three forces drove that development:

(1) A dramatic postwar increase in private capital spending that led to increased interest in how such expenditures should be made.
(2) The postwar development of national income accounts which provided a vehicle for plausible economic projections, a necessary condition for rational choice.
(3) The publication in 1951 of two seminal books: *Capital Budgeting*, by Joel Dean, and *The Theory of Investment of the Firm*, by Friedrich and Vera Lutz.

Rational capital budgeting requires a correct basis for measuring the investment worth of each capital expenditure proposal.

Although capital expenditure decisions have long been regarded as one of the critical responsibilities of top-management (and, indeed, of Corporate Boards of Directors), before the 1950s the decisions themselves had been made on the basis either of intuitive judgements or poorly defined standards. Such inadequate approaches have been supplemented and, in some companies, supplanted by more robust and more quantitative criteria.

The Pay-Back Period

One of the earliest quantitative yardsticks used for assaying the investment worth of a capital expenditure proposal (and one that is still in use) is the project's pay-back period – the number of years required to recoup the initial outlay. Because the measure ignores the size and duration of benefits beyond the pay-back period itself, it is a poor proxy for 'profitability'. Nonetheless, it provides a quick screening device for rejecting some proposals as well as for selecting among alternative investment proposals that involve purchases of equipment having approximately equal lives.

The Average Rate of Profit

The earliest measure used for a project's expected profitability is the ratio of the average annual flow of profit expected from the project to the average investment dedicated to the project – both measured in conventional accounting terms. The measure has been increasingly discarded because it is a poor proxy for true profitability on two counts: (1) it ignores the *timing* of expected benefits, and (2) it is subject, both with respect to the numerator and the denominator, to the vagaries of depreciation accounting.

The DCF Rate of Return

The discounted cash-flow rate-of-return measure (hence DCF), which relates the incremental cash inflows attributable to a project to the incremental cash outlays required by it, has gradually supplanted the average-rate accounting measure. In principle, the DCF rate of return (or internal rate of return) is identical to the long-used financial measure for the effective yield to maturity on a bond; that is, it is the rate at which the present value of all incremental cash or equivalent benefits expected from an investment is equal to the incremental outlays required by that investment.

Net Present Value

If a company has a correct estimate for the rate of return that is required by the market on an investment with a given degree of riskiness, the DCF return offered by that investment proposal provides an infallible guide to whether or not it should be accepted. Exactly the same result can be achieved by an alternative process: if the present value of a project's net cash flows, discounted at its required rate of return, *exceeds* the present value of the outlays it entails, then the proposal should be accepted; that is, all proposals that have a positive *net* present value should be undertaken. Although both approaches yield the same correct result for accept–reject decisions, the net-present-value approach is a superior one in two special situations. (1) Some investment proposals (especially those designed to accelerate cash-inflows) have more than one DCF rate of return solution. In such cases (i.e. those with two or more positive solutions), none is a correct measure of the project's expected profitability. (2) When more than one proposal is acceptable by either standard, but only one can be executed because the two are mutually exclusive, the net-present-value approach invariably provides a better answer to the 'which is better?' question.

The Required Rate of Return

Both the DCF approach and the Net-Present-Value approach to investment decisions require a correct estimate of the required rate of return (or applicable discount rate) on the investment outlay that is being assayed. A number of increasingly sophisticated approaches to the estimation of that rate (also known as the appropriate 'cost of capital') have been developed. All such measures are now based on observable rates of return demanded in the marketplace by holders of the debt and equity securities that jointly finance the assets of the corporation. This rate, adjusted up or down for any differential riskiness of the particularly project that is being assayed, is now widely used as the 'hurdle' that any proposal must pass in order to be acceptable.

The rationale is a straightforward one. An investment that yields a *higher* rate of return than the market-determined cost of the funds it requires, has a positive net present value; that is, it creates wealth for the owners as well as for society as a whole. That is how Adam Smith's 'invisible hand' gets translated into practice.

Capital Controls

Kristin J. Forbes

Abstract

Capital controls can take many different forms and are broadly defined as any restrictions on the movement of capital across a country's borders. This article focuses on the debate on the merits of capital controls for emerging markets and developing economies. It describes the potential costs and benefits of capital controls, focusing on the recent empirical literature evaluating the impact of capital controls.

Capital controls are any restrictions on the movement of capital into or out of a country. Capital controls can take a wide variety of forms. For example, capital controls can be quantity-based or price-based, or apply to only capital inflows, only capital outflows, or all types of capital flows. Capital controls can also be directed at different types of capital flows (such as at bank loans, foreign direct investment or portfolio investment) or at different types of actors (such as at companies, banks, governments or individuals).

Most developed countries believe that the benefits from the free movement of capital across borders outweigh the costs, and therefore have very limited (if any) capital controls in place today. For emerging markets and developing economies, however, there has been a long-

standing debate on the desirability of capital controls. Assessing the impact of capital controls is complicated due to a number of factors, including the various forms in which they can be structured. This article discusses the recent debate on capital controls, focusing on the theoretical arguments for and against controls and the existing empirical evidence on their impact.

History of the Debate

Throughout the 20th century, economists have regularly expressed concerns about international capital flows. For example, in the 1940s Ragnar Nurkse worried about 'destabilizing capital flows' and in the 1970s Charles Kindleberger described the role of capital in driving 'manias, panics and crashes' (see Nurkse 1944; Kindleberger 1978). When the world's leading economies met at Bretton Woods in 1944 to formulate rules governing the international financial system, John Maynard Keynes and other delegates debated the role of capital controls. The resulting compromise required that members of the International Monetary Fund (IMF), one of the newly created international monetary institutions, allow capital to be freely exchanged and convertible across countries for the purpose of all current account transactions, but permitted members to implement capital controls for financial account transactions. Most countries had capital controls in place at this time.

Over the following years, however, many developed countries gradually removed their capital controls, so that by the 1980s most had few controls in place. In the early and mid-1990s, many emerging markets and developing countries also began to lift their capital controls. The impact initially appeared to be positive – capital flowed into countries with liberalized capital accounts, investment and growth increased, and asset prices rose. In fact, support for lifting capital controls was so widespread that in 1996–7 leading policymakers discussed amending the rules agreed to at Bretton Woods to extend the IMF's jurisdiction to include capital movements and make capital account liberalization a goal of the IMF. In mid-1997, however, a series of financial crises started in Asia and spread across the world, appearing to disproportionately affect emerging markets that had recently liberalized their capital accounts. This series of crises sparked a reassessment of the desirability of capital controls for emerging markets and developing economies.

In a sharp sea change, many leading policymakers and economists began to support the use of capital controls for emerging markets in some circumstances, especially taxes on capital inflows. Much of this support was based on the belief that controls on capital inflows could reduce a country's vulnerability to financial crises. From 2002 to 2005, several emerging markets (such as Colombia, Russia and Venezuela) also implemented new controls on capital inflows, largely to reduce the appreciations of their currencies. Over the same period, however, several large emerging markets (such as India and China) moved in the opposite direction and lifted many of their existing controls.

Benefits and Costs of Capital Controls

The free movement of capital across borders can have widespread benefits. Capital inflows can provide financing for high-return investment, thereby raising growth rates. Capital inflows – especially in the form of direct investment – often bring improved technology, management techniques, and access to international networks, all of which further raise productivity and growth. Capital outflows can allow domestic citizens and companies to earn higher returns and better diversify risk, thereby reducing volatility in consumption and income. Capital inflows and outflows can increase market discipline, thereby leading to a more efficient allocation of resources and higher productivity growth. Implementing capital controls can reduce a country's ability to realise these multifaceted benefits.

On the other hand, the free movement of capital across borders can also have costs. Countries reliant on foreign financing will be more vulnerable to 'sudden stops' in capital inflows, which can cause financial crises and/or major currency depreciations. Large volumes of capital inflows

can cause currencies to appreciate and undermine export competitiveness, causing what is often called the 'Dutch disease'. The free movement of capital can also complicate a country's ability to pursue an independent monetary policy, especially when combined with a fixed exchange rate. Finally, capital inflows may be invested inefficiently due to a number of market distortions, thereby leading to overinvestment and bubbles that create additional challenges. Capital controls could potentially reduce these costs from the free movement of capital.

Empirical Evidence on Capital Controls

Since capital controls can have costs and benefits, evaluating the desirability and aggregate impact of capital controls is largely an empirical question. (See Eichengreen 2003, on the potential costs and benefits of capital controls.) Not surprisingly, an extensive literature has attempted to measure and assess the effects of capital controls.

The most studied experience with capital controls is the Chilean *encaje* – a market-based tax on capital inflows from 1991 to 1998 so structured that the magnitude of the tax decreased with the maturity of the capital flow. Chile's experience with capital controls is generally viewed positively, largely due to Chile's strong economic performance during the period the controls were in place. Empirical studies of the impact of Chile's capital controls, however, have reached several general conclusions. First, there is no evidence that the capital controls moderated the appreciation of Chile's currency (which was the primary purpose of the capital controls). Second, there is little evidence that the controls protected Chile from external shocks. Third, there is some evidence that the controls raised domestic interest rates (at least in the short term). Fourth, there is some evidence that the controls did not affect the volume of capital inflows, but did lengthen the maturity of capital inflows. Finally, the capital controls significantly raised the cost of financing for small and medium-sized firms and distorted the mechanisms by which Chilean companies procured financing. The general conclusion from this work is that Chile's strong economic performance during the 1990s resulted from sound macroeconomic and financial policies, not the capital controls, and that the capital controls had both costs and benefits. (See Forbes 2007, for more information on this literature and the Chilean capital controls.)

A second major branch of literature examining the impact of capital controls focuses on the effects of lifting capital controls (that is, capital account liberalization). The majority of this work uses macroeconomic data, typically focusing on how capital account liberalization raises economic growth using cross-country growth regressions. Prasad et al. (2003) is a detailed survey of this literature and shows that, although several papers find a robust, positive effect of capital account liberalization on growth, other papers find no significant effect, and most papers find mixed evidence. This literature is generally read as showing weak evidence that lifting capital controls may have some positive effect on growth.

There are several explanations for the inconclusive results in this macroeconomic literature assessing the impact of capital controls. First, it is extremely difficult to measure capital account openness and to capture the various types of capital controls in a simple measure that can be used for empirical analysis. Second, different types of capital flows and controls may have different effects on growth and other macroeconomic variables. For example, controls on portfolio investment may be more beneficial than other types of capital controls. Third, the impact of removing capital controls could depend on a range of other factors that are difficult to capture in cross-country regressions, such as a country's institutions, financial system, corporate governance or even the sequence in which different controls are removed. Fourth, capital controls can be very difficult to enforce (especially for countries with undeveloped financial markets) so the same capital control may have different degrees of effectiveness in different countries. Finally, most countries that remove their capital controls undertake simultaneously a range of reforms and undergo structural changes, so that it can be difficult to isolate the impact of removing the controls.

(For additional details on the challenges in measuring the impact of capital controls, see Eichengreen 2003; Forbes 2006; Magud and Reinhart 2006; Prasad et al. 2003.)

Given these challenges in measuring the impact of capital controls, it is not surprising that the empirical literature has had difficulty documenting their effects on growth at the macroeconomic level. To put these results in perspective, however, the current status of this literature is similar to the literature in the 1980s and 1990s on how trade liberalization affects economic growth. Economists generally believe that trade openness raises growth, but most of the initial work on this topic also focused on cross-country, macroeconomic studies and reached inconclusive results. At a much earlier date, however, several papers using microeconomic data and case studies found compelling evidence that trade liberalization raises productivity and growth.

Similarly, recent work based on microeconomic data has been much more successful than the macroeconomic literature in documenting the effects of capital controls. Forbes (2006) surveys this new literature, which covers a variety of countries and periods, uses a range of approaches and methodologies, and builds on several different fields. This literature has, to date, reached five general results. First, capital controls reduce the supply of capital, raise the cost of financing, and increase financial constraints – especially for smaller firms and firms without access to international capital markets. Second, capital controls reduce market discipline in financial markets and the government, leading to a more inefficient allocation of capital and resources. Third, capital controls distort decision-making by firms and individuals as they attempt to minimize the costs of the controls, or even evade them outright. Fourth, the effects of capital controls vary across different types of firms and countries, reflecting different pre-existing economic distortions. Finally, capital controls can be difficult and costly to enforce, even in countries with sound institutions and low levels of corruption. Therefore, this series of microeconomic studies suggests that capital controls have widespread and pervasive costs, but has not yet provided significant evidence of the benefits of capital controls.

Conclusions

The debate on the effects and desirability of capital controls is likely to continue and to motivate new academic research. Most economists agree that countries should gradually lift their capital controls as they grow and develop, and that developed countries should have few (if any) capital controls in place. Most economists also believe that the free movement of capital can have widespread benefits, but that in countries with weak financial systems, poorly developed institutions, and vulnerable macroeconomies the free movement of capital can also generate distortions and increase a country's vulnerability. As a result, emerging markets and developing countries that currently have capital controls should work to address the shortcomings in their economies as they liberalize their capital accounts. There continues to be widespread disagreement, however, on the exact sequencing of these reforms and the optimal pace of capital account liberalization for emerging markets and developing economies.

Capital Flight

Brendan Brown

This term describes the phenomenon of funds fleeing across the national frontier in search of greater safety. The driving forces behind capital flight include actual or feared monetary instability, confiscatory taxation, war and revolution. Examples of the phenomenon can be found through several centuries. A low level of liquidity and high costs of international communication at first limited the potential scope of capital flight. The earliest 'modern' example was the largescale movement of French funds to London during the Franco-Prussian war. Capital flight has reached in the twentieth century a frequency and importance previously unseen.

The first major episode was the flight of capital during World War 1 out of France, Italy and the Central Powers, into the neutral countries – principally Switzerland, the Netherlands, and Sweden. The capital movements were 'accommodated' to a large extent by speculators in the neutrals buying the belligerent currencies at big discounts to their theoretical gold pars in the hope that large gains would be made once peace was restored.

Defeat brought a new outpouring of capital from Central Europe. Funds fled the Austro-Hungarian crown out of fear that the Successor States would 'nationalize' crowns on their own territory – blocking a substantial share of private holdings and insisting on tax-registration before converting the remainder into the new national money. At first, buyers of the Austro-Hungarian notes could be found in Italy's new territories (acquired from Austria–Hungary) in the expectation (correct) that the Italian authorities would ultimately convert its new subjects' holdings into liras at a favourable rate. Then buyers appeared in the form of tourists attracted in swarms to Vienna during 1920–1921 by the cheap crown.

The flight out of the mark was at first driven by fear that hurge taxes would be levied by the new Republic to meet the internal and external costs of defeat. After a brief respite in the last three-quarters of 1920, capital flight got new impetus from the gathering reparations crisis. The German government was suspected of deliberately inflating to demonstrate the 'impossibility' of paying reparations, whilst the danger of a French invasion of the Ruhr increased. Germany was again the source of huge capital flight in the years 1929–1931, driven this time by the spectre of political instability (from mid-1929, the Nazi vote in elections rose strongly) and of national bankruptcy.

The next major episode of capital flight was from France. The fascist riots in February 1934, then the prospects of a 'Front Populaire' government coming to power (May 1935) and of a large devaluation of the franc to reflate the economy, unleashed a huge outflow of funds. The formation of a Centre–Centre Right government under Daladier in spring 1938 marked the turning point. In the next 18 months, funds returned to France despite the growing menace of war. For Britain and the European neutrals (Holland, Belgium and Switzerland), by contrast, spring 1938 marked the start of a period of capital flight as funds sought refuge in the USA. There were three great waves and a final smaller wave between mid-1938 and the end of 1939: autumn 1938 (Munich crisis), spring 1939 (German occupation of Prague), August 1939 (Nazi-Soviet Pact and invasion of Poland) and November 1939 (feared invasion of the Low Countries). The Bank of England financed the outflows by undertaking massive dollar sales.

Capital flight changed direction dramatically as soon as France sued for an armistice (June

1940). Investors in Axis Europe and in the remaining European neutrals (particularly Switzerland) feared that the USA would freeze their funds and these were transferred into Swiss francs or to Latin America. For the next decade, Switzerland was the principal recipient of refuge funds – which in the early post-war years came largely from France. The USA was not regarded as a safe-haven – not just because of its wartime freeze of most foreign assets, but also because of the cooperation of the US authorities with European governments in securing the repatriation of flight capital.

In general, the postwar industrial world has not been struck by the huge waves of capital flight driven by political fears which marked the years 1914–1940. The mid and late 1970s were a period of large movements of flight capital, but these were driven primarily by inflation. The inflows to Switzerland from France, Italy and Britain in 1976 reflected largely the high inflation in these countries and the non-indexation of their tax structures (particularly with respect to capital). During 1978, the spectre of high and rising inflation in the USA caused international funds to flee the dollar. Just when inflation fears began to moderate following the turn in US monetary policy of October 1979, a new fillip was given to capital outflows from the USA by the freezing of Iranian assets. Investors in much of the Third World, particularly OPEC, feared that if revolution brought to power a government unfriendly to Washington, their dollar assets might not be safe.

In almost all the episodes of capital flight mentioned, foreign investors and creditors have played a disproportionately large role. Foreign capital is less tied down by 'convenience factors'. Domestic residents in general have less to lose than foreigners from the introduction of exchange restrictions. Whereas foreigners might not be able to buy anything with frozen balances (except, perhaps, tourist services), residents would be able to use their funds freely on a normal range of goods – albeit possibly curtailed by import controls.

A general property of capital flight driven by fears of future disaster is that it occurs in waves, not continuously. The wave-like motion reflects discontinuous changes in the probability of the possible 'bad state of the world' becoming reality. News – a frequent cause of shifts in probability assessments – is by its nature sudden. Alarming new information causes investors to revise upwards the share of hedge-assets (usually foreign) in their portfolio. During the period of portfolio-adjustment a wave of capital flight becomes apparent. Once adjustment is complete, the wave subsides. Under a floating exchange rate system, the waves are sublimated into abrupt fluctuations in currency values. The exchange rate falls to a point where investors see sufficient return on holding the 'troubled' money at the margin to delay re-arranging their portfolio. As trade flows respond to the exchange rate change, the portfolio adjustment begins to take place.

Capital flight can reach such a force as to cause national bankruptcy (meaning that foreign credits are frozen and exchange restrictions introduced). For example, the official foreign exchange reserves may have become exhausted; foreign loans be impossible to obtain; interest rate rises (which in principle might stem capital outflows) be infeasible because they would intensify deflation, increasing the risk of domestic political tumult or bank failures; a downward float of the currency be ineffective in strengthening the capital account because it gives rise to a wage–price spiral or invites retaliation by other nations concerned with 'unfair' competition in trade. Governments sometimes pre-empt a forced bankruptcy by coming to a 'voluntary' re-scheduling arrangement with foreign creditors and imposing a range of controls on domestic capital exports. Such measures are costly. The country's credit-rating would be adversely affected for decades to come. A tradition of economic and political liberalism might well be damaged irreparably. In some respects, a liberal government which prevents its citizens from protecting their wealth against the coming to power of a dictatorship or against a foreign invader is already in league with the enemy.

The fear of forced bankruptcy is not the only motive for government to seek to limit capital

flight. Measures may be introduced as a 'sop' to labour when economic policy is being tightened. Alternatively, the authorities may hope that the measures will raise the level of domestic investment and employment of real wages. A reduced degree of capital flight should mean that interest rates can settle at a lower level. In general, though, measures against capital flight are largely ineffective, unless policed by methods inconsistent with a liberal society. Traffic in banknotes is one obvious loophole, especially where the given country has land frontiers and is a tourist centre. Other loopholes include false invoicing in trade and compensation payments.

Such transactions often lie behind the large negative 'errors and omissions' items in balance of payments statistics for countries susceptible to capital flight. They may also be responsible for the positive 'errors and omissions' for the countries receiving flight capital. The positive errors could reflect foreign hoarding demand for the domestic currency (for example, Swiss franc notes accumulated outside Switzerland) or inflows of flight capital being hidden behind domestic names for fear of freezing (for example, much of the inflows to the USA in 1939–1940 were disguised behind US names and gave rise to a large positive errors item in the US balance of payments at that time).

Measures against capital flight might indeed increase its extent. Domestic investors would realize that they could not quickly raise the proportion of foreign currency in their portfolio. Hence, if the political and economic climate at home worsened, they could be 'underprotected' for a long time. To hedge this possibility, they might painstakingly via available loopholes accumulate foreign holdings to a level higher than justified simply by present risks.

Capital Gains and Losses

E. Malinvaud

Abstract

How capital gains and losses are distinct from income raises subtle and unresolved issues. Whereas national accountants measure income as the sum of the value of production and net current transfers, thus excluding stock revaluations that change the level of wealth, Hicks's definition implies that expected stock revaluations count as income. Such revaluations due to inflation benefit net debtors but mean losses for households. Irreversible environmental damage and depletion of non-renewable resources are often treated as capital loss, but great uncertainty affects the estimation of consequences, rendering the emergence of an objective methodology for economic decisions is particularly difficult.

National accounting has made the definition of capital gains and losses rather precise in practice,

but fundamentally their distinction from income raises quite subtle issues, about which great economists have long been wavering. Whenever it becomes important, inflation gives to some of these issues a fresh relevance. Much remains to be learned, moreover, on how capital gains affect economic behaviour and how the allocation of resources ought to deal with the capital losses resulting from current activity.

Definition

Although the reference books such as United Nations (1969) are not explicit enough about this basic notion, national accounting systematically applies the following

$$\Delta W = Y + CT + CG - C \qquad (1)$$

where ΔW is the variation of wealth between the beginning and end of the period under consideration, Y is income, CT the net capital transfer received (gifts, bequests, capital taxes and subsidies), CG the net capital gain and C consumption. The identity applies to any agent or group of agents. This identity may be taken as the de facto definition of net capital gains (that is, gains *minus* losses), to the extent that well- defined rules are used for the flows Y, C and CT, which appear in the current accounts, and to the extent that wealth is assumed to be unambiguously determined.

Looking carefully at the existing rules, one, however, realizes that the distinction between income and net capital gain is conventional to a large extent. It is precisely on the choice of this convention that some important questions about the definition of incomes lie.

Chapter 7 of Fisher (1906) shows that defining the concept of income was not an easy task for economists. Fisher's own preferred definition, 'the services of capital', may not seem quite clear, but it can be identified with consumption. This would make the whole of investment belong to capital gains, a solution that was seriously discussed by Samuelson (1961) but has hardly any advocate today. At the other extreme, the 'comprehensive definition of income', also called the Haig–Simons definition, was proposed by economists studying income taxes (Haig 1921; Simons 1938); income would be equal to the sum of consumption and wealth increase, thus leaving neither capital gains, nor capital transfers in Eq. 1. One now most commonly refers to the definition introduced by Hicks (1939 p. 172), 'A man's income is the maximum value which he can consume during a week, and still expect to be as well off at the end of the week as he was at the beginning'.

National accountants, however, measure income as the sum of the value of production and net current transfers. Production is essentially computed from physical outputs and inputs, valued at current prices and aggregated. This means that stock revaluations that explain part of the change of wealth are not incomes but capital gains or losses. Hicks's definition, on the contrary, implies that expected stock revaluations belong to income. In Eq. 1 only windfalls would be true capital gains. But whether the change of value of an asset should be classified as expected or not is most often not clear. (How long in advance should it have been expected? Should an outside observer be able to make sure that the asset holder had expected the change?) The distinction between expected and unexpected capital gains or losses, however, remains essential in economic analysis.

Inflation

The most sizeable asset revaluations result from changes of the price level. When inflation is important, a good proportion of these revaluations are, moreover, expected by all agents. Their occurrence then plays a role in the determination of the equilibrium of all exchanges and economic operations, inducing in particular high interest rates. On the other hand, the change of nominal wealth becomes of little interest in comparison with the change of real wealth; 'real capital gains' should then be distinguished from nominal ones. Hence, inflation perturbs the significance of normal accounting rules; new measurements are required for correct assessments of income flows (Jump 1980).

This applies first to business accounting, in which reference to historical costs underestimates physical assets and depreciation of fixed capital, while it overestimates net returns from financial assets. This explains the search for new or alternative accounting rules that would be better suited in cases of fast inflation and would more correctly draw the line between income and capital gains or losses. This search went as far as the stage of implementation in the United Kingdom (see Walton 1978).

At the level of the whole economy, when the rules of national accounting are applied, real capital gains and losses resulting from variations of the general level of prices are important. Typically they benefit enterprises and government, which are net debtors, whereas they mean large losses for households. When all these capital gains and losses are imputed to incomes, on the ground that they must have been expected, the current accounts of firms and government appear substantially more favourable, whereas sizeable redistribution is also found as between groups of households (see Bach and Stephenson 1974; Babeau 1978; Wolff 1979).

The question has been considered whether national account practices should not be revised so as to better record true incomes in times of inflation (see Hibbert 1982). A prerequisite is the regular production of national balance sheets. When this is done, important capital gains and losses, due for instance to booms in real estate or share prices, also appear beyond those due to changes of the general price level.

Capital Gains in Economic Behaviour

Most econometric studies tend to neglect capital gains as flows, although wealth and indebtedness are often taken into account. The role of capital gains on the consumption behaviour of households has, however, been studied. Up to now the results have been rather inconclusive (Bhatia 1972; Peek 1983; Pesaran and Evans 1984).

In all likelihood the difficulty comes from the fact that some capital gains are purely transitory, whereas most of them have some degree of permanence, but this degree varies widely from one to the other. A pure windfall is comparable to an exceptional gift; accidental losses or war damages occur once for all, whereas capital losses due to an inflation that is expected to last may appear to be as permanent as interest incomes, even sometimes as wage incomes. But to classify capital gains according to their supposed permanence is far from being an obvious operation.

Gains on the value of corporate shares have a permanent component following from the firms' policy of retaining part of their profits. This is why increases of retained earnings have been considered as likely to increase household consumption, but not as much as an increase of permanent income would, since the size of undistributed profits varies a good deal with business conditions (Feldstein and Fane 1973; Malinvaud 1986).

The problem becomes still more complex when capital gains are correlated with cost changes for items of household wealth. An extreme case occurs when prices of residential real estate increase: owners of houses make a capital gain, but simultaneously the cost of housing increases by the corresponding amount; whether houses are let or used by their owners, a stimulating effect on real consumption is doubtful.

Capital Losses, Conservation and Welfare

The existence of capital gains and losses raises a number of issues for the theory of allocation of resources, for instance what should be the taxation of capital gains (David 1968; Green and Sheshinski 1978), or how best to organize insurance against capital losses. But particular attention nowadays concerns the damages that economic activity causes to the environment and to reserves of exhaustible resources (Fisher 1981).

Not all environmental effects mean capital losses; many of them are just externalities in the normal course of economic activity. But irreversible damages to the forests, the soil or even the climate must also be recognized and are usually not recorded as consumption or as inputs to

production. Depletion of non-renewable reserves is similarly often treated as capital loss.

The detrimental effects of many of these losses will appear mainly in a rather distant future. Whether or not losses should be accepted – what for instance should be the optimal speed of depletion of natural resources – raises difficult questions of intergenerational equity, on which economists have uncomfortably to enter the field of social philosophy.

The problem cannot be discarded here on the ground that proper discounting makes the distant future negligible. Indeed, in the purest case, the shadow discounted price of an exhaustible resource is as high in the future as it is now, for as long as the resource will remain used (Hotelling 1931). The remote future must then be taken into account for present decisions.

It is moreover notorious that enormous uncertainties affect the purely physical estimation of the consequences involved. Neither the effects of carbon dioxide emission on the climate, nor the existing reserves of fossil fuels, nor the future emergence of appropriate technologies for the wider use of renewable energy can be securely assessed. Under such circumstances, the emergence of an objective methodology for economic decisions is particularly difficult.

Capital Gains Taxation

William Gentry

Abstract

Capital gains taxation is the taxation of gains or losses from owning assets, usually as part of an income tax. Typically, tax systems measure capital gains or losses upon realization so that capital gains are taxed only when assets are sold. These realization-based tax rules create a number of behavioural incentives. Investors have an incentive to maximize the value of tax

deferral by delaying the sale of assets. Capital gains taxes can also affect incentives for investing in risky assets. The realization-based tax rules also complicate the estimation of the revenue consequences of changing the tax rate on capital gains.

Keywords

Capital gains and losses; Capital gains taxation; Inflation; Tax base; Tax incentives for saving; Tax planning; Taxation of corporate profits

JEL Classifications

H2

Capital gains taxation involves the taxation of changes in asset values, usually in the context of an income tax rather than as a separate tax. Under a pure income tax, these gains or losses would be measured on a periodic basis (for example, annually) and would be adjusted for inflation. However, actual tax systems tend to deviate in several important ways from this hypothetical treatment. The most important of these deviations is that capital gains are typically measured upon the realization of the gain or loss rather than under accrual accounting. The taxation of capital gains creates a wide variety of incentive issues, especially given the deviations between their tax treatment under a pure income tax and their treatment under actual tax rules.

Administrative Issues

While the concept of a capital gain or loss from the ownership of an asset is straightforward, administering a tax on capital gains is a complicated part in the income tax codes of most countries. The primary difficulty arises from the challenge of measuring the size of a capital gain or loss over a specified period of time. This difficulty has led to most capital gains being taxed upon realization rather than as they accrue. The exceptions to this general rule tend to be for relatively sophisticated investors (for example, brokers) on assets that are relatively liquid and easily valued (for example, publicly traded equities). Realization-based taxation means that taxpayers keep records of the purchase price of assets, known as the basis in the asset, and calculate the gain or loss as the difference between the sales price and this basis when the asset is sold. The basis in an asset can be adjusted over time, with the most common type of adjustment being for the depreciation allowances accorded to depreciable assets.

An important issue in measuring capital gains is whether the gain is adjusted for changes in purchasing power created by inflation. Countries vary in their treatment of capital gains created by inflation. Most countries include the portion of the gain that is due to inflation in the tax base, but a few countries allow the asset's tax basis to be adjusted for inflation so that the tax base includes only the real portion of the capital gain. A pure income tax would allow for an adjustment for inflation, but such an adjustment would be part of a system that adjusted all forms of capital taxation for inflation.

In many countries, capital gains face lower marginal tax rates than other sources of income. Two rationales motivate these lower tax rates. First, policymakers may want to encourage investment in activities that generate capital gains. Second, the preferential tax rates provide an ad hoc method of adjusting tax burdens for inflation in tax systems that do not index the measurement of capital gains for inflation. These preferential rates, which can include the exemption of capital gains from income taxation, often depend on meeting a minimum holding period (for example, preferential rates apply to 'long-term' capital gains that are earned on assets held for longer than one year) and may apply only to specific types of assets (for example, gains on corporate stock qualify for preferential tax rates but gains on collectibles do not).

Another cumbersome feature of capital gains taxation is the specific rules dealing with how gains and losses offset each other. Typically, these loss-offset provisions limit a taxpayer's ability to use capital losses to offset other sources of income. The motivation for these limitations is that realization-based taxation provides taxpayers with the option of deferring the tax on gains but

accelerating the deductions for losses through a strategy of holding on to appreciated assets but selling assets with losses.

In terms of administration, Auerbach (1991) and Auerbach and Bradford (2004) propose tax systems that allow for realization-based tax rules that would mimic the incentive and revenue effects of accrual taxation of capital gains. Such tax reforms would eliminate many of the complicated incentive effects created by current administrative rules for capital gains taxation.

Incentive Effects

Taxing capital gains creates a variety of incentive, or disincentive, effects. Since taxing capital gains is typically part of a broader regime to tax capital income, the tax on capital gains can affect incentives to save. As a tax on capital income, the capital gains tax reduces the return to saving, which can have a theoretically ambiguous effect on the level of savings in the economy. Of course, since many countries provide preferential tax treatment for capital gains compared with other forms of capital income, tax policy towards capital gains often increases the return to saving by reducing the effective tax rate on savings compared with a regime without preferential tax rates for capital gains.

Capital gains taxation can also affect incentives for taking risk. A tax on capital gains from risky investments reduces the expected return to these investments, which one might expect would discourage investment in risky assets. However, the tax on capital gains also reduces the variance in the payoffs to investing in risky assets and this reduction in variance may encourage investors to increase their investments in risky assets. The net effect of the reduction in both the expected return and the variance in returns may actually imply that the theoretical effect of a higher tax rate on capital gains is an increase in the amount of risk taking (see Domar and Musgrave 1944). This result, however, rests on the symmetric tax treatment of gains and losses. When loss offset rules are imperfect, such that gains face a higher marginal tax rate than losses, then the theoretical predictions are much more complicated and it becomes more likely that the capital gains tax reduces the amount of risk taking in the economy because gains face a higher tax rate than losses.

The relative tax treatment of capital gains and other forms of capital income can also affect investors' portfolio choices (see Poterba 2002; Poterba and Samwick 2002). If capital gains face lower effective tax rates, due to either preferential tax rates or the ability to defer taxes by deferring realization of income, investors may prefer to invest in assets that are likely to generate capital gains rather than assets that generate interest or dividend income. In addition to affecting portfolio decisions, the relative tax treatment of different forms of capital income may also affect relative asset prices and expected returns (see Klein 1999).

The realization-based feature of capital gains taxation creates several tax planning incentives (see Stiglitz 1983). By not selling an appreciated asset, an investor can postpone paying the tax liability on the associated capital gain. This deferral of taxation reduces the discounted value of the tax (assuming that the statutory tax rate will remain constant in the future). This incentive to delay the realization of capital gains is known as the 'lock-in' effect since the tax liability that would be triggered by selling an asset reduces the incentive for investors to sell appreciated assets and locks them into holding assets. In the United States, the incentive to defer the realization of capital gains is compounded by tax rules that allow heirs to step-up the basis of appreciated assets that they inherit, which eliminates the income tax on capital gains on bequeathed assets.

In addition to incentives to delay the realization of capital gains, realization- based taxation also creates an incentive to accelerate the realization of capital losses since these losses can reduce taxation on other types of income (though this offset is possibly limited by loss offset rules) or capital gains on other assets (see Constantinides 1983; Poterba 1987; Auerbach et al. 2000). This pattern of selective realization leads to the tax planning advice that taxpayers should sell their losers and hold their winners. In essence, realization-based taxation provides taxpayers with an option of whether to pay taxes, and it is typically more

advantageous to exercise this option for assets that have lost value.

While most of the incentives discussed above deal with decisions made by investors, the tax treatment of capital gains can also affect the supply of different assets. For example, corporations may alter their payout policies in response to the relative tax treatment of dividends and capital gains. To the extent that capital gains face a lower effective tax rate than dividends at the investor level, corporations have an incentive to retain earnings so that investors can recognize income as capital gains rather than distribute earnings as dividends. Retaining earnings due to this tax rate differential does not necessarily imply that it leads to an increase in corporate investment. Instead of increasing investment, corporations that eschew dividends can repurchase shares as an alternative mechanism to distribute cash to shareholders (see Green and Hollifield 2003). These share repurchases allow investors to time their tax liabilities since the decision to sell shares back to the firm is discretionary and, for the shareholders who sell, the income associated with the transaction faces capital gains tax rates rather than dividend tax rates.

Revenue Consequences

One of the more contentious issues surrounding capital gains taxation is the effects of capital gains taxes on government revenues. From the government's perspective, the incentive effects discussed above create opportunities for lost revenue. While the overall revenue effect of capital gains taxation depends on the whole myriad of incentives discussed above, much of the empirical literature on this issue has focused on the capital gains realization decisions of individuals. An important empirical issue has been separating how capital gains realizations respond to short-run fluctuations in the tax rate (or anticipated changes in tax rates) from how long-term realizations behaviour responds to the tax rate (or the 'permanent' response to tax changes). Auerbach (1988) examines the time series evidence in the United States and documents a large timing response of capital gains to anticipate tax rate changes but finds limited evidence of a permanent response of capital gains realizations to tax rates. Burman and Randolph (1994) examine a panel of US household taxpayers; their results also point towards a much larger transitory response than permanent response to changes in capital gains tax rates. Taken together, these studies cast doubt on the claim that reductions in capital gains tax rates can be self-financing.

Capital Goods

Harald Hagemann

Capital goods are a series of heterogeneous commodities, each having specific technical characteristics. Outside the hypothetical case where real capital consists of a single commodity, it is impossible to express the stock of capital goods as a homogeneous physical entity. As a consequence of capital's heterogeneous nature its measurement has become the source of many controversies in the history of economic thought.

The function of capital goods is production. Unlike labour ('in the raw') and (non-cultivated) land, capital goods are not given, they are themselves produced. Being an output as well as an input, the size and variation of the capital stock are intra-economic phenomena. Because real capital is not an 'original' factor of production but is the result of economic processes in which it participates as one of the determinants, the formation of real capital or investment is the central channel through which all other determinants, be they technical progress, changes in labour supply or the exploitation of natural resources, influence the long-run development of an industrial system.

A distinction is normally made between durable or fixed capital, including not only plant and machinery but also buildings and other essential parts of the industrial infrastructure which are used up only partially during the year, and circulating capital, consisting of stocks of raw materials, semi-finished goods, etc., capital which is fully used up during the production period and must therefore be replaced in full.

Capital has at least two different aspects: capital as goods and capital as value. From a technological point of view, produced means of production are a condition for the operation of any social and economic system, once Smith's early and rude state of society is overcome. It was Marx who emphasized that these necessary physical instruments of production become 'capital' only under the capitalistic rules of the game when the means of production are separated from the labourers and owned by the capitalists. Thus the means of production possess a double aspect in capitalistic societies: on the one hand 'capital' is understood to mean the total of heterogeneous goods and equipment designed for specific uses (productive concept), on the other hand it is regarded as a homogeneous fund of value and source of 'unearned' income in the form of profits (portfolio concept).

The value of the capital goods corresponding to each system of production, even with a constant technique, will change with income distribution whichever the unit in which they are measured. Current relative prices change when the rate of profits or the real wage rate changes, so that the same physical capital represents a different value whereas different stocks of capital goods can have the same value. Furthermore, only in long-run equilibrium will a given stock of capital goods have the same value whether it be determined as the accumulated sum of past investment expenditures or as the expected future net returns discounted back to the present at the ruling rate of profits.

Another way of measuring capital goods is in terms of labour time directly and indirectly required to produce them, the appropriately dated quantities of labour compounded at the various given rates of profits. As the analyses of Joan Robinson (1956), who called it 'real capital', and Sraffa (1960) show, it is impossible to get any notion of capital as a measurable quantity independent of distribution and prices.

Whereas the individual is concerned with the extent to which he owns capital goods as a store of wealth and a source of income, society as a whole is never faced with problems of buying or selling capital goods against money or credit. Greater output unambiguously requires a greater amount of capital goods, given the degree of capacity

utilization and technology. These additional capital goods can be provided only by a process of accumulation or net investment.

Emphasis on the strategic role of the capacity to produce capital goods in the domestic economy plays a decisive role in the analyses of Fel'dman (1928) and Lowe (1955, 1976). Both authors take as their starting point Marx's famous two-departmental scheme of expanded reproduction, modifying it in an adequate way to include all activities that increase the capacity of an economy to produce output in one sector. During the Soviet industrialization debate in the late twenties, Fel'dman formalized the notion that investment-priority for the capital-goods sector was a precondition for attaining a higher growth rate. Structural incapacity to supply enough capital goods will prevent a rise in the saving ratio from being fully transformed into the desired level of investment. But it has to be taken into account that a one-sided preoccupation with this 'Fel'dman constraint' on the investment capacity side may bring the 'Preobrazhenski constraint' on the consumption side into action. If the initial capacity of the capital goods industry is just sufficient to replace the worn-out machines, growth can only take place as a result of a temporary reduction in the output of consumer goods which may be impossible for subsistence reasons. In this case a *circulus vitiosus* will emerge.

The strategic role of the machine tools sector and the compulsion to enlarge first the equipment in capital goods industries were also dealt with by economists discussing the growth and planning problems of underdeveloped countries in the Fifties and Sixties (see, for example, Dobb 1960 and Mathur 1965). Countries like India which lack a self-sufficient machine tools sector can speed up their transformation process by foreign trade. The Fel'dman constraint would be binding only if the domestic output of machine tools could not be supplemented with imports.

The perception that there is a group of fixed capital goods which hold the strategic position in any industrial system like seed corn for agricultural production, led Lowe to the conclusion that it is useful to split up the capital goods sector in the Marxian scheme of reproduction into two subsectors. In his 'tripartite' scheme of three vertically integrated sectors, the first produces primary equipment goods or 'machine tools' which are directly used for production in sectors I and II. Sector II produces the secondary equipment goods which are used as inputs only in sector III producing consumer goods, which means that the capital stock in the latter is not transferable. Thus sector I is the only one capable not only of producing machines for other sectors but also for itself; it is therefore a *self-reproducible sector.* In Sraffa's terminology, sector I represents the 'basic system'.

The sub-division of the capital goods group is relevant for investigating the structural conditions for steady growth and, even more, in addressing questions of 'traverse analysis', when the problem of structural change is moved to the centre of the stage. The decisive problem that the economy faces upon departing from a steady growth path is the inadequacy of the old capital stock. The dynamic traverse from one steady growth path to another necessarily involves a change in the whole quantity structure, especially the rebuilding of the capital stock. The economy cannot change output unless it first changes inputs, i.e. the capital goods group must provide the commodities demanded for changing the inputs to produce the new output pattern. The production of machine tools is the bottle-neck which any process of rapid expansion must overcome. The key to a higher growth rate lies in increasing the shares of sector I. The same logic requiring that the system as a whole first has to change inputs before it can change output makes such an increase dependent on the prior expansion of the capital stock of this sector. Whereas in the two-sectoral Fel'dman model this is only possible by a policy of putting a larger proportion of new machine tools into the production of more machine tools, in the Lowe model an additional *ex post* transfer of machine from sector II to sector I is possible, thereby shortening the time of adjustment. Both models come to the same result, namely that in order to increase the growth rates of total output and consumption output in the long run, at first a temporary fall in the growth rate of consumption output is necessary.

The neo-Austrian theory developed by Hicks is characterized by a completely different treatment of the durable means of production. In his neo-Austrian model, a stream of labour inputs is converted into a stream of final outputs (consumption goods). 'Capital goods are simply stages in the process of production' (Hicks 1973, p. 5), i.e. they are regarded as intermediate products which don't appear explicitly but are implied and produced within each process of 'maturing' of original inputs into the final product. Thus the intertemporal aspect of production and consumption is placed into the forefront of the analysis; time is the essence of capital in the Austrian view. By treating fixed capital as if it were working capital, Hicks does not recognize the need for a special machine-tools sector. There is no basic product in this model. Hence, the production process is not 'circular'; the neo-Austrian approach turns out to be a further variant of the production theoretic paradigm of marginalist analysis, which conceives of the production process as a 'one-way avenue that leads from "Factors of production" to "Consumption goods"' (Sraffa 1960, p. 93).

It is precisely the focus on the adjustment problems caused by the impact of technical innovations that has led Hicks to his vertical representation of the productive structure. In contrast to Leontief–Sraffa–Lowe systems, in Hicks neither intersectoral transactions, nor therefore the effects of innovation upon industrial structure, are shown. Hicks sees the decisive advantage of the Austrian method in its ability to cope with the important fact that process innovations nearly always involve the introduction of new capital goods. This would lead to insurmountable difficulties in the traverse analysis if capital goods were physically specified because 'there is no way of establishing a physical relation between the capital goods that are required in the one technique and those that are required in the other' (Hicks 1977, p. 193). A similar explanation is given by Pasinetti who develops his theory of structural change in terms of vertically integrated sectors. While conceding that the input–output model gives more information on the structure of an economic system at any point in time, he points out that because of the change of input–output coefficients and the 'breaking down' of the inter-industry system over time, the vertically integrated model is superior for dynamic analysis (see Pasinetti 1981, pp. 109–17). Measuring capital goods in units of vertically integrated productive capacity of the final commodity 'has an unambiguous meaning through time, no matter which type of technical change, and how much of it, may occur' (p. 178).

Whilst it is true that a sectorally disaggregated approach encounters difficulties when the effects of innovations connected with the introduction of new capital goods are studied, the price that Austrian-type models have to pay for their linear 'imperialism' is rather high. Technical change takes place at the industry level, a characteristic which is completely washed out in vertically integrated models. The industry-specific nature of technical change also implies that, contrary to Pasinetti's assumption, rates of productivity growth in the different vertically integrated sectors cannot be thought of as being independent of each other. How could the new capital goods be produced without the old ones existing at the beginning of the traverse? Thus the existence of a basic system remains relevant, even when the basic product(s) is(are) changing its(their) quality. Innovations introducing new consumption goods cannot be dealt with in a satisfactory way. All this does not imply that the concept of vertically integrated sectors is meaningless, on the contrary, it can be very helpful as a complementary perspective. But it illustrates that input–output models emphasizing intersectoral interdependencies retain conceptual priority.

Fixed capital has two other important dimensions: its degree of capacity utilization, and its durability. Thus the choice of cost-minimizing technique involves the choice of the 'planned' degree of capital utilization and the choice of the economic lifetime of a fixed capital good. The latter can best be dealt with on the basis of a von Neumann–Sraffa treatment of fixed capital goods (which contains Hicks's neo-Austrian model as a special case) as a joint part of the gross output, thus identifying machines of different ages as different commodities. To every technically possible lifetime corresponds a specific w-r relation

which may slope upwards over some range for a given truncation (in which case the prices of partly worn-out machines become negative and premature truncation is advantageous), whereas the w–r frontier is always downwards sloping. The analysis of the choice of the optimal lifetime or truncation period shows that with constant or increasing efficiency the maximum technical lifetime will always be chosen, independently of income distribution. With decreasing or changing efficiency, however, premature truncation may become profitable (see Hagemann and Kurz 1976). A change in the wage rate (rate of profits) will generally lead to changes in the optimal economic lifetimes of fixed capital goods. With more complex patterns of the time profile of efficiency, the return of the same truncation period at different intervals of the rate of profits is possible, a phenomenon closely linked to reswitching of techniques (see also Schefold 1974).

Capital Measurement

W. Erwin Diewert and Paul Schreyer

Abstract

Capital measures provide an indicator of wealth and of capital services, the contribution of assets to production. The wealth stock is the market value of assets, whereas capital services are measured in proportion to the quantity of past investment, adjusted for the relative efficiency of different vintages and capital goods in production. Although the two measures of capital are different, they are derived from a single theoretical framework whose centrepiece is a fundamental equilibrium relationship between stocks and flows of capital. Index number theory is used to guide the empirical implementation of stock and flow measures.

Capital measures are constructed for two main purposes: (1) to measure wealth (the market value of assets) and (2) to analyse the role of capital in production. Because capital is durable, the value of using it in any given year is not the same as the value of owning it. There are thus different measures of capital depending on the purpose of accounting. However, these different measures should be consistently derived from a single framework.

The scope of the discussion below is restricted to fixed assets and land; we do not deal with financial or intangible assets, inventories or environmental assets.

Fundamental Relations Between Stocks and Flows of Capital

In equilibrium, the *stock value* of an asset is equal to the discounted stream of future rental payments for *capital services* that the asset is expected to yield, an insight that goes at least back to Walras (1874) and Böhm-Bawerk (1888).

Let the price of an n-period old asset purchased at the beginning of period t be P_n^t. When prices change over time, it is necessary to distinguish between the observable rental prices for the asset at different ages in period t and future expected rental prices. Let f_n^t be the rental price of an n-period old asset at the beginning ofzperiod t. Then the fundamental equation relating the stock value of an asset, P_n^t, to the sequence of rental prices by age, $\{f_n^t : n = 0,\ 1,\ 2, \ldots\}$ is:

$$\begin{aligned} P_n^t = {} & f_n^t + [(1+i^t)/(1+r^t)]f_{n+1}^t \\ & + [(1+i^t)/(1+r^t)]^2 f_{n+2}^t \\ & + [(1+i^t)/(1+r^t)]^3 f_{n+3}^t + \ldots \\ n = 0,\ & 1,\ 2, \ldots \end{aligned} \tag{1}$$

where the i_n^t are expected rates of change of rental prices that are formed at the beginning of period t. For simplicity, it has been assumed that i_n^t does not depend on the asset's age. The term $1 + r^t$ is the discount factor that makes a dollar received at the beginning of period t equivalent to a dollar received at the beginning of period $t + 1$. Thus, the r_n^t are one-period *nominal interest rates* where the assumption has been made that the term structure of interest rates is constant. However, as the period t changes, r^t and i^t can change. The sequence of stock prices $\{P_n^t\}$ is not affected by general inflation provided that it affects the expected asset inflation rates i_n^t and the nominal interest rates r_n^t in a proportional manner.

The rental prices $\{f_n^t\}$ are potentially observable. In producer equilibrium, the ratio of any pair of rental prices equals the relative marginal productivity of the corresponding capital goods; see Hulten (1990).

By successive insertion for different P_n^t, (1) can be transformed into:

$$P_n^t = f_n^t + [(1+i^t)/(1+r^t)]P_{n+1}^t \tag{2}$$

or

$$\begin{aligned} f_n^t &= (1+r^t)^{-1}\left[P_n^t(1+r^t) - (1+i^t)P_{n+1}^t\right] \\ &= \left[P_n^t - (1+i^t)P_{n+1}^t/(1+r^t)\right];\ \ n \\ &= 0,\ 1,\ 2, \ldots \end{aligned} \tag{3}$$

Christensen and Jorgenson (1969) derived a version of (3) for the geometric depreciation model and end-of-period rental payments. Other variants are due to Christensen and Jorgenson (1973), Diewert (1980, 2005), Jorgenson (1989), Hulten (1990) and Diewert and Lawrence (2000).

(3) represents the *rental price* or *user cost* of an n-year old asset: the cost of using it during a period is given by the difference between the purchase price at the beginning of the period P_n^t and the value of the depreciated asset $(1 + i^t)P_{n+1}^t = P_{n+1}^{t+1}$ at the end of period t. Since this offset to the initial expense will be received only by the end of the period, it must be divided by the discount factor $(1 + r^t)$.

Depreciation, Asset Prices and User Costs

Depreciation is typically defined as the decline in asset value as one goes from an asset of a particular age to the next oldest at the same point in time; see Hicks (1939), Hulten and Wykoff (1981a, b), Hulten (1990), Jorgenson (1996) and Triplett (1996). Define the *depreciation rates* δ_n^t for an asset that is n periods old at the start of period t as:

$$\delta_n^t \equiv 1 - \left[P_{n+1}^t / P_n^t\right]; \quad n = 0, \ 1, \ 2, \ldots \tag{4}$$

Thus, given $\left\{P_n^t\right\}$, the period t sequence of $\left\{\delta_n^t\right\}$ is determined. Conversely, given $\left\{\delta_n^t\right\}$ and the price of a new asset in period t, $\left\{P_n^t\right\}$ is determined.

$$P_n^t = \left(1-\delta_0^t\right)\left(1-\delta_1^t\right)\ldots\left(1-\delta_{n-1}^t\right)P_0^t; \quad n = 0, \ 1, \ 2, \ldots \tag{5}$$

With expressions (5) and (3), the sequence of user costs $\left\{f_n^t\right\}$ can be expressed in terms of the price of a new asset at the beginning of period t, P_0^t, and $\left\{\delta_n^t\right\}$:

$$\begin{aligned} f_n^t &= (1+r^t)^{-1}\left(1-\delta_0^t\right)\ldots\left(1-\delta_{n-1}^t\right) \\ &\left[(1+r^t)-(1+r^t)\left(1-\delta_n^t\right)\right]P_0^t \\ &= (1+r^t)^{-1}\left[r^t+\delta_n^t(1+i^t)-i^t\right]P_n^t \quad n = 0, \ 1, \ 2, \ldots \end{aligned} \tag{6}$$

Thus, given any one of these sequences, all of the other sequences are completely determined. This means that assumptions about depreciation rates, the pattern of user costs by age or the pattern of asset prices by age cannot be made independently of each other. This point was first explicitly made by Jorgenson and Griliches (1967, 1972).

Aggregation

Asset prices are relevant for the construction of *wealth measures* of capital, and the user costs are relevant for the construction of *capital services measures*. Let there be N different types of assets and let the quantity of period t investment in asset i be I_i^t with a sequence of asset prices $\left\{P_{n,i}^t\right\}$. Then the value of the period t wealth stock is:

$$\begin{aligned} W_i^t \equiv{}& P_{0,i}^t \ I_i^{t-1} + P_{1,i}^t \ I_i^{t-2} + P_{2,i}^t \ I_i^{t-3} \\ &+ \ldots \ i \\ ={}& 1, \ 2, \ldots, N. \end{aligned} \tag{7}$$

To turn to capital services (we set aside issues of capital utilization), the flow of services that an asset of a particular age delivers is proportional to the corresponding quantity of past investment. The value of capital services for all ages of a given asset class i during period t using the sequence of user costs $\left\{f_{n,i}^t\right\}$ is:

$$\begin{aligned} S_i^t \equiv{}& f_{0,i}^t \ I_i^{t-1} + f_{1,i}^t \ I_i^{t-2} + f_{2,i}^t \ I_i^{t-3} \\ &+ \ldots \ i \\ ={}& 1, \ 2, \ldots, N. \end{aligned} \tag{8}$$

The value aggregates W_i^t and S_i^t can be decomposed into separate price and quantity components by standard index number methods, if each new unit of capital lasts only a finite number of periods, L. Define the period t price, user cost and quantity vectors, P_i^t, f_i^t and K_i^t respectively, as follows:

$$\begin{aligned} P_i^t &\equiv \left[P_{0,i}^t, \ P_{1,i}^t, \ldots, P_{L-1,i}^t\right]; f_i^t \\ &\equiv \left[f_{0,i}^t, \ f_{1,i}^t, \ \ldots, f_{L-1,i}^t\right]; K_i^t \\ &\equiv \left[I_i^{t-1}, \ I_i^{t-2}, \ldots, I_i^{t-L-1}\right]; \ i \\ &= 1, 2, \ldots, N. \end{aligned} \tag{9}$$

Fixed base or chain indexes may be used to decompose value ratios into price-change and quantity-change components. The values of W_i^t and S_i^t relative to their values in the preceding period, W_i^{t-1}, S_i^{t-1} have the following index number decomposition:

$$\begin{aligned} W_i^t / W_i^{t-1} = {}& P_i^W\left(P_i^{t-1}, \ P_i^t, \ K_i^{t-1}, \ K_i^t\right) \\ & Q_i^W\left(P_i^{t-1}, \ P_i^t, \ K_i^{t-1}, \ K_i^t\right); \\ i = {}& 1, \ 2, \ldots, N. \end{aligned} \tag{10}$$

$$S_i^t/S_i^{t-1} = P_i^S\left(f_i^{t-1},\ f_i^t,\ K_i^{t-1},\ K_i^t\right) \quad Q_i^S\left(f_i^{t-1},\ f_i^t,\ K_i^{t-1},\ K_i^t\right); \quad i = 1, 2, \ldots, N. \tag{11}$$

where P_i^W, P_i^S and Q_i^W, Q_i^S are bilateral price and quantity indexes respectively. In particular, Q_i^S measures the service flow of type i assets into production. It is thus an appropriate measure of capital input.

A functional form has to be chosen. For empirical work, Diewert (1976, 1992) has shown that the *Fisher* (1922) *ideal price and quantity indexes* appear to be 'best' from the axiomatic viewpoint, and can also be given strong economic justifications. The above index number approach to aggregating over vintages of capital was first suggested by Diewert and Lawrence (2000) and it is more general than the usual aggregation procedures for homogenous assets, which essentially assume that the different ages of the same capital good are perfectly substitutable so that linear aggregation techniques can be used.

However, most researchers use an index number approach to form price and quantity aggregates across *different* types of assets. The overall values of the period t wealth stock and capital services are respectively:

$$W^t \equiv P_1^{W,t}Q_1^{W,t} + P_2^{W,t}Q_2^{W,t} + P_3^{W,t}Q_3^{W,t} + \ldots \tag{12}$$

$$S^t \equiv P_1^{S,t}Q_1^{S,t} + P_2^{S,t}Q_2^{S,t} + P_3^{S,t}Q_3^{S,t} + \ldots \tag{13}$$

Akin to (10)–(11), the value aggregates W^t and S^t can be decomposed into separate price and quantity components. Define the period t price and quantity vectors, $P^{W,t}$, $P^{S,t}$ and $K^{W,t}$, $K^{S,t}$ respectively, as follows:

$$P^{W,t} \equiv \left[P_1^{W,t},\ P_2^{W,t}, \ldots, P_N^{W,t}\right]; P^{S,t} \equiv \left[P_1^{S,t},\ P_2^{S,t}, \ldots, P_N^{S,t}\right];$$
$$K^{W,t} \equiv \left[K_1^{W,t},\ K_2^{W,t}, \ldots, K_N^{W,t}\right]; K^{S,t} \equiv \left[K_1^{S,t},\ K_2^{S,t}, \ldots, K_N^{S,t}\right] \tag{14}$$

The values of W^t and S^t relative to their values in the preceding period, W^{t-1} and S^{t-1}, have the following index number decomposition:

$$W^t/W^{t-1} = P^W\left(P^{W,t-1},\ P^{W,t},\ K^{W,t-1},\ K^{W,t}\right) \quad Q^W\left(P^{W,t-1},\ P^{W,t},\ K^{W,t-1},\ K^{W,t}\right); \tag{15}$$

$$S^t/S^{t-1} = P^S\left(P^{S,t-1},\ P^{S,t},\ K^{S,t-1},\ K^{S,t}\right) \quad Q^S\left(P^{S,t-1},\ P^{S,t},\ K^{S,t-1},\ K^{S,t}\right); \tag{16}$$

where P^W, P^S and Q^W, Q^S are bilateral price and quantity indexes respectively. In particular, Q^S measures the overall service flow of capital into production.

Empirical Determination of Rates of Return and Asset Price Changes

Rates of return r^t can be based either on a balancing procedure or on market interest rates. The balancing procedure postulates that the value of capital services is equal to the value of gross operating surplus as shown by the national accounts plus the capital income of the self-employed. A rate of return is then chosen so that this equality holds. If market interest rates are used, there is still a choice between *ex ante* and *ex post* rates. Most empirical work on capital services has relied on an *ex post* balancing procedure based on Jorgenson and Griliches (1967, 1972) and Christensen and Jorgenson (1969). However, empirical problems arise when these methods yield highly volatile and sometimes negative user costs of capital. The debate has therefore continued – see Harper et al. (1989), Diewert (1980, 2005) and Schreyer (2006).

Possibilities for the choice of the asset inflation rates i^t include using the *ex post* asset price changes (consistent with the *ex post*, balancing procedure for rates of return), forecasting *ex ante* rates on the basis of *ex post* rates and assuming that expected asset price changes are equal to general inflation. The latter implies that the term $r^t - i^t$ in the user cost expression (6) becomes a real rate of return that is simple to measure and typically not too volatile. At the same time, the procedure may induce a bias in

C

user costs and capital measures if the prices of different assets move with different trends and/or if asset prices move very differently from general inflation.

Empirical Determination of Rates of Depreciation

Possibilities for determining depreciation rates include a number of approaches. First, information on market prices of assets of different age at the same point in time can be used to derive measures of depreciation. Empirical studies include Hall (1971), Beidelman (1973), Hulten and Wykoff (1981a, b) and Oliner (1996). The literature has been reviewed by Hulten and Wykoff (1996) and Jorgenson (1996). The second approach uses rental prices for assets where they exist, along with information on the rate of return and on asset prices to solve the user cost Eq. (6) for the rate of depreciation; for a review see Jorgenson (1996). The third approach is based on production function estimation where output is regressed on non-durable inputs and past investment. The estimated coefficients of the investment variable can be used to identify a constant rate of depreciation. Empirical studies using this approach include Epstein and Denny (1980), Pakes and Griliches (1984), Nadiri and Prucha (1996) and Doms (1996). The fourth method relies on insurance and other expert appraisals.

The fifth method makes assumptions about the relative efficiency sequence $\{f^t_n/f^t_0\}$ and the service life of assets, and then derives, via (1) and (5), a consistent measure of the rate of depreciation. For example, the *one-hoss shay* model of efficiency states that an asset yields a constant level of services throughout its useful life of L years: $f^t_n/f^t_0 = 1$ for $n = 0, 1, 2, \ldots, L-1$ and zero for $n = L, L+1, L+2, \ldots$. Another example is a *model of linear efficiency decline*, where the sequence $\{f^t_n/f^t_0\}$ is given by $f^t_n/f^t_0 \equiv [L-n]/L$ for $n = 0, 1, 2, \ldots, L-1$ and zero for $n = L, L+1, L+2, \ldots$.

The sixth method makes direct assumptions about the depreciation sequence $\{P^t_n/P^t_0\}$. The most frequent approaches are the *straight line depreciation model* and the *geometric* or *declining balance model*. Under the former, there is a constant amount of depreciation between every vintage: $P^t_n/P^t_0 = [L-n]/L$ for $n = 0, 1, 2, \ldots, L$ and zero for $n > L$. Under the latter, which dates back to Matheson (1910), there is a constant rate of depreciation $\delta^t_n = \delta$ for $n = 0, 1, 2, \ldots$. The geometric model greatly simplifies the algebra of capital measurement and has been supported empirically through studies on used asset markets; see Hulten and Wykoff (1981a, b). When there is only information on the average asset life L, the double declining balance method determines the rate of depreciation as $\delta = 2/[L+1]$.

Capital Perversity

Tatsuo Hatta

Neoclassical capital theory regards the interest rate as the market price of the composite factor ‘capital’. In this theory the interest rate is equal to the marginal product of capital, since the demand curve for capital is its marginal productivity schedule. Moreover, the theory assumes that capital obeys the law of diminishing returns just like any other factor, so that its demand curve is downward-sloping. In an economy where labour is the only primary factor and constant returns to scale prevail, this implies the following postulate: *as the interest rate falls, the capital – labour ratio increases*, which plays an important role in neoclassical growth theory and in comparative static analyses of interest rate determination.

Neoclassical capital theory also makes another closely related postulate: *as the interest rate falls, the output–labour ratio increases*. This postulate does not explicitly use the concept of aggregate capital. However, it too implies that ‘capital’ obeys the law of diminishing returns. For the output–labour ratio can be raised only when some input other than labour is increased behind the scenes, and in this economy capital is the only such input available.

Both postulates necessarily hold if output is produced by labour and a *single* capital input in a linear homogeneous production function, as in

the Clark–Ramsey production function. Cambridge economists, led by Robinson (1953–4, 1956), Champernowne (1953–4) and Sraffa (1960), criticized these postulates, however, for economies with heterogeneous capital goods, thus kindling the so-called Cambridge controversies in capital theory as surveyed by von Weizsäcker (1971), Harcourt (1972), Blaug (1974), and Burmeister (1980). Eventually, counter-examples that appeared in Pasinetti et al. (1966) showed irrefutably that both postulates can fail to hold in such economies. These paradoxical phenomena are called *capital perversities*. They showed very clearly that 'capital' is different from other factors in that diminishing returns do not hold for it even in contexts quite free of aggregation problems.

In order to examine the first postulate for economies with heterogeneous capital goods, one has to aggregate heterogeneous capital goods into a single dollar value of capital. Such a measure could well be specious, however, due to the index number problem involved in the aggregation, the interest rate affecting the prices of capital goods with different gestation periods differently. Since the second postulate does not depend on a particular aggregate measure of capital, it may appear a more robust characterization of diminishing returns from roundabout processes than the first. In fact, the following proposition due to Burmeister and Dobell (1970, Corollary 7.2) implies that the two postulates are equivalent once a proper price index is chosen for evaluating capital.

> Suppose than an exogenous increase in interest rate shifts one stationary-state production equilibrium to another. Then, as long as the interest rate is positive, the ratio of output to labour moves in the same direction as the ratio of 'constant-price capital' to labour, where the 'constant-price capital' is the dollar value of the new capital input vector measured at the initial input price vector.

For this reason we will examine only the failure of the second postulate to hold.

Reswitching

Capital perversity was demonstrated via examples of the so-called reswitching phenomenon; the simplest and most illuminating is Samuelson's (1966). He assumes that output this year is produced by applying labour inputs in three preceding years according to the following production function:

$$Y = y(x_1, x_2, x_3), \tag{1}$$

where Y is this year's output level and x_1, x_2, and x_3 are labour inputs one, two and three years ago, respectively. Let p_t be the present value of the wage rate t periods prior to the production year. Producers chose the cost-minimizing input vector (x_1, x_2, x_3) for the given output level under the input price vector (p_1, p_2, p_3). Samuelson also assumes free entry, so that maximized profit is zero.

Now consider a steady-state economy where Y is produced every year and prices are constant. Then we have

$$p_t = w \cdot r^t, \tag{2}$$

where w is the (constant) wage rate and r is 1 plus the interest rate. Input and output variables for each year may be shown as in Table 1. Each column shows the total amount of labour L applied in the entire production process that year as

$$L = x_1 + x_2 + x_3. \tag{3}$$

As the macroeconomist sees it, this economy as a whole produces Y every year by applying capital inputs in the form of goods-in-process and an amount L of labour.

Samuelson considered the case where the technology (Eq. 1) consists of only two techniques α and β: α's input vector (x_1, x_2, x_3) for producing a unit output is (0, 7, 0) and β's (6, 0, 2). He showed

Capital Perversity, Table 1

1986	1985	1984	1983	1982	1981	1980
			y	x_1	x_2	x_3
		y	x_1	x_2	x_3	
	y	x_1	x_2	x_3		
y	x_1	x_2	x_3			

that β minimizes cost when the interest rate lies between 50 and 100 per cent year, while α does so otherwise. As the interest rate increases from zero, therefore, the cost-minimizing technique switches first from α to β, and then back to α. This phenomenon, that as the interest rate increases, a once-abandoned technique becomes re-employed, is called *the reswitching of techniques*. It is obvious that when it happens capital perversity necessarily occurs. In Samuelson's case, for example, when the interest rate is increased past 100 per cent, technique β with $Y/L = 1/8$ is switched to α with 1/7, falsifying the second postulate. It can readily be shown that at this switching interest rate the first postulate also fails, even after the index number problem is removed.

What Causes Perversity?

Examples of reswitching had to be given for economies with discrete technologies, since it occurs with probability zero in a smoothly substitutable production function. But neither reswitching nor a discrete technology is necessary for perversity itself. Indeed, Hatta (1976) constructed an example of a smoothly substitutable and linear homogeneous function of type (Eq. 1) that behaves perversely.

To see how this might work, consider a generalized version of (Eq. 1):

$$Y = y(x_1, x_2, \ldots, x_n), \tag{4}$$

where y is quasi-concave, linear homogeneous, and differentiable. Then we have the following proposition due to Hatta (1976), which was independently hinted at by Solow (1975, p. 52):

For capital perversity to occur in Eq. 4 it must have at least one complementary input pair. (A) Equivalently, if all input pairs in Eq. 4 are (Hicksian) substitutes, perversity cannot occur.

According to a standard Hicksian demand rule (1946, ch. 3), (net) complementarity among inputs can occur in Eq. 4 only if n is greater than 2. Thus Proposition (A) implies that for perversity to occur in Eq. 4, n must be greater than 2. When $n = 2$, on the other hand, the economy has only one capital good, i.e., the one produced by the labour input applied in the previous year. Proposition (A) therefore implies that:

Heterogeneity of capital is necessary for perversity in Eq. 4. (B)

We now prove (A) for the case n = 3. The cost-minimizing input vector for output level Y under the input price vector (p1, p2, p3) is given by the following set of input demand functions:

$$x_s = a_s(p_1, p_2, p_3, Y) \quad s = 1, 2, 3.$$

We assume that the interest rate is positive, i.e.,

$$r > 1. \tag{5}$$

Noting Eq. 2 and the zero-degree homogeneity of a_s in the prices, the following must hold when cost is minimized:

$$x_s = a_s\left(1, r, r^2, Y\right) \quad s = 1, 2, 3.$$

In view of Eq. 3, therefore, the total labour movement requirement in this stationary economy is

$$L = a_1\left(1, r, r^2, Y\right) + a_2\left(1, r, r^2, Y\right) + a_3\left(1, r, r^2, Y\right)$$

By definition perversity occurs if the L necessary to produce a constant Y every year is lowered when the interest rate is raised, i.e., if

$$\partial L/\partial r < 0. \tag{6}$$

Carrying out this differentiation, we obtain

$$\frac{\partial L}{\partial r} = (r-1)a_{12} + 2\left(r^2 - 1\right)a_3 + \left(r^2 - r\right)a_{23} \tag{7}$$

where

$$a_{st} \equiv \partial a_s/\partial p_t.$$

This and Eq. 5 imply that $\partial L/\partial r$ is positive if all a_{st}'s (i.e. Hicksian cross-substitution terms) are positive. This in turn implies that for perversity

to occur, there must be at least one complementary input pair. Q.E.D.

For general n, Proposition (Eq. 6) is proved similarly, since Eq. 7 generalizes to

$$r \cdot \frac{\partial L}{\partial r} = \sum_{s=1}^{n-1} \sum_{t=s+1}^{n} (t-s)(p_t - p_s) \cdot a_{st}.$$

Now look at Samuelson's example in the light of (A). Assume that for given Y and given prices, β is cost-minimizing. Now let p_1 increase, keeping p_2 and p_3 constant. Eventually this will make β more costly than α, so α will be employed. But α uses less x_3 than β in order to produce the same output, so the rise in p_1 has caused a reduction in x_3, i.e. pair (1, 3) is complementary. Thus Samuelson's discrete model is consistent with our Proposition (A), obtained for the neoclassical production function.

Hence perversity is simply one of the many paradoxes caused by complementarity. The reason why the Clark–Ramsey production function always behaves well is now clear: it has only two inputs, which must be substitutes.

Why Complementarity?

Why does complementarity cause perversity? Note first that when $n = 3$ perversity cannot occur if either the input pair (1, 2) or the pair (2, 3) is complementary. Indeed, when $n = 3$ the following stronger version of (A) holds: For perversity to occur in Eq. 1, a_{13} must be negative, i.e., the specific input pair (1, 3) must be complementary. (C)

Just as a complementary pair of consumption goods can be regarded as a composite good, a complementary pair of inputs (e.g. truck and garage) may be treated as a composite input. When a neighbouring input pair is complementary in the production function (Eq. 1), therefore, that function can be regarded as containing just two inputs: one (composite) labour and a (composite) capital. For example, when (1, 2) is complementary, the pair (1, 2) can be regarded as composite labour. In such cases the production function is essentially of Clark–Ramsey form and so behaves well.

When (1, 3) is complementary, on the other hand, the technology's two (composite) inputs (1, 3) and 2 cannot be ranked in terms of their gestation periods. The two inputs can interchange the roles of capital and labour for different levels of interest rate, which explains why perversity can occur in this situation. Observe that (1, 3) is also complementary in Samuelson's model with a discrete technology, and the above explanation is applicable to his model.

Proposition (C) can be extended in various ways to the case where $n > 3$. For example, perversity never occurs if the structure of complementarity is such that the n inputs can be classified into one composite labour and one composite capital. Thus perversity occurs only if complementarity creates a composite input that cannot be unequivocally ranked with another (composite) input *vis-à-vis* their gestation periods. As Hatta (1976) argues, Bruno et al.'s (1966) non-reswitching condition can be interpreted in this spirit.

The proof of (C) is straightforward. Noting that $a_{11} + r\, a_{12} + r^2\, a_{13} = 0$ and $a_{31} + r\, a_{32} + r^2\, a_{33} = 0$, from the homogeneity property of the input demand functions in prices, we can rewrite (Eq. 7) as:

$$\frac{r}{w} \cdot \frac{\partial L}{\partial r} = (1-r) \cdot a_{11} + \left(r^3 - r\right) \cdot a_{13} + \left(r^3 - r^4\right) \cdot a_{33}.$$

This implies that a_{13} must be negative if perversity occurs, since r is greater than 1 and a_{11} and a_{33} are negative from the Hicksian demand rule. Thus (C) is proved.

Conclusion

To construct models of growth and the interest rate in an economy with heterogeneous capital– good inputs, the concept of 'capital' is not at all necessary: microeconomic production functions can be specified directly in terms of the physical units of those inputs. The main focus of the Cambridge controversies in capital theory was rather on the question of how well the simple Clark–Ramsey production function can approximate the

qualitative properties of a production economy with heterogeneous capital–good inputs.

It was established through these controversies that the monotonic relationship between output–labour ratio and interest rate, a basic property of the Clark–Ramsey production function, fails to hold in a world of heterogeneous capital inputs. Since this relation has nothing to do with the index number problem, the fact that it breaks down in a general model clearly contradicted that part of neoclassical capital theory which was based upon the Clark–Ramsey production function. This was a genuinely new finding that came out of the capital controversies. As we have seen, however, it is fully explicable within neoclassical theory, being no more (and no less) than one of the many intractable problems caused by the presence of complementarity.

Capital Theory

Robert A. Becker

Abstract

Capital theory examines the special role played by time in resource allocation studies. The determination of the interest rate and functional distribution of income as well as how rational agents invest are analysed within single- and multi-sector general equilibrium frameworks. Here, agents exercise perfect foresight over alternative consumption and capital accumulation programs. Efficient programs are characterized. Representative and multi-agent infinitely lived households are studied. Equivalence principles link the equilibrium programs and optimal paths. Heterogeneous agent models with borrowing constraints are reviewed. A behavioural model of intertemporal choice is also compared to its constant discounting counterpart.

Introduction

Capital theory examines the special role played by time in resource allocation studies. The determination of the rate of interest and the functional distribution of income are considered along with the development of criteria for evaluating investment decisions. Contemporary capital theory focuses on the intertemporal choices undertaken by rational actors within a general equilibrium setting where all prices and allocations are determined by market clearing. The central role played by time is that producing goods and services to supply future consumption requires withdrawing some output from current consumption in order to create the produced means of production, or capital goods, which enable future production to be undertaken in conjunction with other factors such as labour and land. That agents seek to make their investment decisions rationally is taken as a fundamental premise of capital theoretic models. The rationality hypothesis is implemented by assuming that agents maximize a utility function over paths of future consumption and that producers maximize the present discounted value of their profits. A specification of the degree of foresight must be postulated together with an assumption on which spot and futures markets are open for trade. Consumption and investment decisions are realized in a market equilibrium.

Dated Commodities and Prices

The classical general equilibrium model developed over the last half of the 20th century by Arrow, Debreu, McKenzie and their followers was sufficiently abstract that it could model any number of different economic activities by the device of *named goods*: a commodity was specified by its physical characteristics, date of availability, contingent events upon which its availability depended, as well as its location. For example, a consumption good available now was differentiated from the same physical commodity available at a different date even if the location or contingent events were the same at both dates. Capital theoretic models focused on the pure role of time assume certainty (no contingent events) and the same location. The simplest models assume that there is just one consumption good and that its characteristics are the same at each point of time. Only the date of its availability differentiates goods. These are the *deterministic models*. Agents are supposed to exercise perfect foresight over the paths of all relevant variables in this case. Other models treat both time and uncertainty by way of dated goods and contingent events. Rational expectations about the future

probability distributions of variables are assumed to describe agents' behaviour. The basic principles and issues in capital theory are most easily reviewed in the deterministic setting with risk and uncertainty treated as a non-trivial extension of the basic theory.

The classical general equilibrium model assumes a finite number of commodities. In the deterministic intertemporal setting this means there are a finite number of dated commodities. Consumers have a finite planning horizon; time unfolds in discrete periods, $t = 1, 2, \ldots, T$. A finite number of goods are available at each date, indexed by $i = 1, 2, \ldots, N$. This makes for NT commodities. Consumers' preferences are defined over a commodity space contained in an NT-dimensional Euclidean space. Similarly, producers' technology sets were defined in the same commodity space. Competitive prices are established through a market mechanism on the presupposition that markets operate for all NT commodities. The classic existence of equilibrium and welfare theorems apply under appropriate assumptions on the consumption and production sectors as well as the relations between them. This formal connection between intertemporal and atemporal static general equilibrium theory offers little that is new or special to capital theory. It is the recognition that time places restrictions on preferences and technologies that specialize the abstract Walrasian model to the type more suited to answering capital theoretic questions about interest rate determination and the corresponding division of the model's output among its participating consumers and resource owners.

The distinguishing feature of capital theoretic models is their focus on infinite horizon decision problems. The motivation for this lies in the open-ended nature of the economic problem. Economies do not have foreseeable ends and the problem of saving and investing for future consumption seemingly goes on for ever, even though all the decision makers know that our planet's time is limited. But that terminal date is so far in the future that we might as well act today as if an infinite horizon is a good approximation to a very long but finite horizon. The theoretical advantage of the infinite horizon is that it allows us to draw a sharp formal distinction between the short and the long runs. The short run represents the transitional time that model solutions follow, whereas the long run constitutes the solutions' properties as time runs towards infinity. The classical focus on the stationary state, or 'long period', presumes there is a long run and that the economy evolves towards it.

Frank Ramsey (1928) modelled infinite horizons in a seminal article on optimal growth. He argued that discounting by the planner was ethically indefensible. Ramsey's modern followers from Paul Samuelson to the present day have studied both undiscounted and discounted models. Von Neumann's (1937) celebrated model of capital accumulation at a maximum balanced growth rate implicitly assumed an infinite horizon. A balanced program occurs when each type of capital good grows from one period to the next at the same constant rate. By focusing attention on balanced growth paths, it would seem reasonable that von Neumann understood those programs might correspond to that model economy's long-run position. The infinite horizon assumption has a long tradition in capital theory and finance (for example, the consol bonds issued by the United Kingdom; see Goetzmann and Rouwenhorst, 2005, for other examples).

This article concentrates entirely on the discounted case and its connection to general competitive analysis. The primary focus is taken to be the one-sector discounted Ramsey model. Capital theory is viewed as a branch of general equilibrium theory. The masterful surveys by McKenzie (1986, 1987) lay out the undiscounted as well as discounted models for many capital goods and multiple sectors in great generality. His surveys also provide details on how those models can evolve over time (the so-called turnpike theorems) as well as general comparative dynamics results.

Ramsey (1928) formulated his seminal model in continuous time. The models presented here are cast in discrete time with periods $t = 1, 2, \ldots$. This turns out to have some technical advantages over continuous time modelling as well as expositional advantages as economic concepts are more readily grasped by readers unschooled in

the calculus of variations and its modern development, optimal control theory.

Neoclassical Capital Theory: The One-Sector Model

The Discounted Ramsey Optimal Growth Model

Neoclassical capital theory is illustrated by the properties exhibited in the discrete time one-sector discounted Ramsey optimal growth model (Ramsey, 1928). This model encapsulates the fundamental consumption–investment trade-offs that a decision maker considers when choosing a consumption plan over time to achieve a maximum lifetime utility. The model is simplified in many ways. There is a single decision maker, or planner, acting over an infinite horizon. There is no uncertainty or shocks that would make output available in the future look like a random variable when viewed from the present. The model examines an aggregated economy. There is a single all-purpose consumption good produced using capital goods (carried over from the previous period) and fixed labour. The capital and consumption goods available at each time are physically identical and can be costlessly converted from consumption to capital (and vice versa) at a one-to-one rate. The planner decides how much to consume in the current period and how much to save for next period's production. Capital depreciates entirely within the period. It is *circulating* as it is used up within the production period. Extensions to include durable capital that depreciates at a fixed rate are straightforward. The planner's exogenously given initial stock of capital produces goods available in the first period. The planner obtains utility from consumption at each time and maximizes the discounted sum of future utilities. The discount factor on future utility is a given constant.

The planner's intertemporal optimization problem is:

$$\sup \sum_{t=1}^{\infty} \delta^{t-1} u(c_t) \text{ by choice of } \{c_t, k_{t-1}\}_{t=1}^{\infty}, \quad (1)$$

subject to:

$$c_t + k_t \le f(k_{t-1}) \text{ for } t = 1, 2, \ldots; \; c_t \ge 0, \quad k_{t-1} \ge 0 \text{ all } t; \; k_0 \le k, \quad \text{where } k > 0 \text{ is given.} \quad (2)$$

Feasible programs are sequences $\{c_t, k_{t-1}\}_{t=1}^{\infty}$ which satisfy (2). Assume $u : [0, \infty) \to [0, \infty)$ is strictly concave, increasing, twice continuously differentiable, $u(0) = 0$, and satisfies the Inada condition: $\lim_{c \to 0+} u'(c) = \infty$. The production function $f : [0, \infty) \to [0, \infty)$ is strictly concave, increasing, twice continuously differentiable, $f(0) = 0$, satisfies $\lim_{k \to 0+} f'(k) = \infty$, and $\lim_{k \to \infty} f'(k) < 1$ (also called Inada conditions). There is a maximum sustainable stock, $b > 0$, with $f(b) = b$ and $0 < k < b$. The discount factor, δ, satisfies $0 < \delta < 1; \delta = 1/(1 + \tilde{n})$, where $\tilde{n} > 0$ is the pure rate of time preference (or rate of impatience). There is a unique optimal program, $\{\overline{c}_t, \overline{k}_{t-1}\}_{t=1}^{\infty}$. Its discounted utility sums, $\sum_{t=1}^{\infty} \delta^{t-1} u(\overline{c}_t) < \infty$. The optimal growth problem has a *time consistency property*: The optimal sequence $\{\overline{c}_t, \overline{k}_{t-1}\}_{t=1}^{\infty}$ has the property that $\{\overline{c}_{t+\tau}, \overline{k}_{t-1+\tau}\}_{t=1}^{\infty}$ solves the optimization problem with objective starting at time τ, $\sum_{t=1}^{\infty} \delta^{t-1+\tau} u(c_{t+\tau})$, subject to $c_{t+\tau} + k_{t+\tau} \le f(k_{t-1+\tau})$ for $t = 1, 2, \ldots$ and $k_\tau = k$. Calender time is irrelevant: if the planner's objective is moved forward τ periods and the initial capital stock is maintained at the new starting time, then the optimal capital and consumption sequence are identical to the ones initiated at time $\tau = 0$. The reason for this is $\sum_{t=1}^{\infty} \delta^{t-1+\tau} u(c_{t+\tau}) = \delta^{\tau} \sum_{t=1}^{\infty} \delta^{t-1} u(c_{t+\tau})$, which is multiple of (1) and the set of feasible programs is unchanged. Hence, the optimal solution is unchanged from the same initial condition even though time has simply been reset to start at τ.

The optimal program satisfies $(\overline{c}_t, \overline{k}_{t-1}) > 0$ for each t. The Kuhn–Tucker necessary conditions for an optimum, known as the *Euler*, or *no-arbitrage conditions*, are:

$$\delta f'(\overline{k}_t) u'(\overline{c}_{t+1}) = u'(\overline{c}_t), \quad \text{for each } t. \quad (3)$$

If the planner's horizon is a finite period, T, then (3) and the complementary slackness

condition $\delta^{T-1}u'(\overline{c}_T)\overline{k}_T = 0$ obtain. The latter condition states capital's terminal value is zero. For the infinite horizon case of interest, it is natural to conjecture the *transversality condition* holds as a necessary condition for optimality:

$$\lim_{T\to\infty} \delta^{T-1}u'(\overline{c}_T)\overline{k}_T = 0. \tag{4}$$

This condition's necessity can be formally demonstrated in many problems. The conditions (3) and (4) are also sufficient conditions for optimality under the maintained hypotheses governing the concavity of the single period return function, u, and the production function, f.

Equation (3) expresses the unprofitability of the *one-period reversed arbitrages* developed below. An *arbitrage* represents a feasible change in the optimal path. Reversed arbitrages perturb the optimum for finitely many consecutive periods. Unreversed arbitrages change the optimal path permanently from some given time on to infinity. A necessary condition for an optimal path is that no arbitrage increase the discounted sum of future utilities above the optimal discounted utility. The necessity of the transversality condition can be interpreted as a type of no-arbitrage condition for *unreversed arbitrages* which never return to the optimal path.

Suppose that the consumption and capital sequences $\left(\overline{c}_t, \overline{k}_{t-1}\right) > 0$ (for each t) are optimal for the given initial capital stock. Then, the planner cannot increase utility by undertaking the following activity: at time t marginally increase the capital stock to be carried to time $t + 1$. This costs the planner $u'(\overline{c}_t)$ utils on the margin. Now invest this extra capital to obtain $f'\left(\overline{k}_t\right)$ additional units of goods in period $t + 1$ from the production sector. Convert this additional income into consumption at $t + 1$ worth $u'(\overline{c}_{t+1})$ utils on the margin. This implies the marginal benefit of this incremental investment measured at $t + 1$ is $f'\left(\overline{k}_t\right)$ $u'(\overline{c}_{t+1})$. Now discount this by the utility discount factor δ to place the marginal benefit at time $t + 1$ and marginal cost at time t in comparable utility units. The marginal benefit cannot exceed the marginal cost along an optimal solution to the household's problem. This is formally expressed by the inequality $\delta f'\left(\overline{k}_t\right)u'(\overline{c}_{t+1}) \leq u'(\overline{c}_t)$, for each t. Since the capital stock at time t is positive, then this arbitrage calculation can be repeated for an increase in consumption at time t paid for by lower consumption at time $t + 1$. In this case, the inequality is reversed and (3) holds.

This model has one special solution: it is the stationary optimal program (c^*, k^*), with $c^* = f(k^*) - k^*$ and $\delta f'(k^*) = 1$. By concavity of f, this program has the property that k^* solves the problem $\max_{k\geq 0}[\delta f(k) - k]$. This is a form of the dynamic non-substitution theorem: the stationary optimal capital stock is independent of the planner's felicity function and depends only on technology and the planner's discount factor. The equation $\delta f'(k^*) = 1$ is also the Euler equation for the program $c_t^* \equiv c^*$ and $k_{t-1}^* \equiv k^*$ for each $t \geq 1$. That is, if the initial capital stock is k^*, then it is optimal to maintain that capital stock for ever. The program $\left\{c_t^*, k_{t-1}^*\right\}_{t=1}^{\infty}$ is constant, or stationary, over time. Hence the name: the stationary optimal program (also called the *steady state*). In the case $\delta = 1$ the steady state maximizes stationary consumption over all feasible stationary consumption levels (it is the *optimal stationary consumption path*) and is called the *golden-rule consumption level* while the corresponding stationary capital stock is the *golden-rule capital stock*. For the discounted case, $0 < \delta < 1$, the steady states are also known as the *modified golden-rule consumption* and *capital stock*.

The optimal path of the infinite horizon problem with initial stocks $k \neq k^*$ converges monotonically to the stationary optimal program (c^*, k^*), with $c^* = f(k^*) - k^*$ and $\delta f'(k^*) = 1$. For example, if $0 < k < k^*$, then the optimal capital sequence, $\left\{\overline{k}_{t-1}\right\}_{t=1}^{\infty} \nearrow k^*$. Moreover, paths *do not cross*: if $0 < k < k' < k^*$, then $\overline{k}_t < \overline{k}'_t$, where $\left\{\overline{k}'_{t-1}\right\}_{t=1}^{\infty}$ is optimal from initial stocks, k'. The convergence of the optimal path implies it is bounded, and the transversality condition holds as a necessary condition for optimality in this model. Conversely, a feasible program satisfying the Euler equations and transversality condition is an optimal program. The convergence property of the optimal capital sequences is also known as the *turnpike theorem*: the optimal

C

capital sequence from any initial starting stock converges to the modified golden-rule capital stock. The corresponding consumption sequences likewise converge (monotonically) to the golden-rule consumption level. The turnpike theorem's conclusion suggests that there is a distinction between the economy's *long-run steady state* and the *short-run transitional dynamics* that describe how the economy approaches that stationary optimal program. One consequence of the turnpike theorem is that optimal programs spend infinitely many periods in any neighborhood of the steady state. In that sense, the steady state is a good approximation for the transitional dynamics over long periods of time. The choice of the analyst lies in determining how small that neighbourhood is, and hence how many periods the economy is not 'sufficiently close' to the model's long-run solution.

The Canonical Example

The *logarithmic utility, Cobb–Douglas production economy* is an important example of Ramsey's optimal growth problem. Many writers refer to it as the *canonical example* of the one-sector model since its solution is explicitly found. The planner's single period utility function is $u(c_t) = \ln c_t$ and the production function has the Cobb–Douglas form $f(x) = x^{\rho}$ where $0 < \rho < 1$ is a technology parameter (it is capital's constant share of total income in a competitive equilibrium setting). The Ramsey optimal growth problem for this specification (and no depreciation) can be solved explicitly by a variety of techniques (see Becker and Boyd, 1997, for one such approach based on symmetry techniques). The solution is described by the *consumption policy functiong*$(k) = (1 - \delta_{\rho})k^{\rho}$ and the *capital policy functionh*$(k) = \delta\rho k^{\rho}$. At each date, the policy functions tell the decision maker how much to consume and how much to save given the current level of the capital stock, k. The optimal capital and consumption sequences are given by iterating the policy functions. Carrying out that iteration for example leads to the explicit solution for the capital sequence:

$$x_t(k) = \left(\delta_{\rho}\right)^{\rho^{t-1}+\cdots+1} k^{\rho^t} \tag{5}$$

The capital and consumption policy functions in this example have constant marginal propensities to save and consume, respectively. Solow's (1956) growth model postulated savings and consumption functions of this type within a one-sector framework with a Cobb–Douglas production function in order to model the process of economic growth. Solow also assumed exogenous technological progress in the form of labour augmenting technical change, whereby each worker becomes more productive at an exponentially growing rate. Solow aimed his model at describing stylized facts of economic growth. The model was not formally set up to reflect microeconomic based optimizing behaviour at the level of individual consumption–saving decisions. The canonical version of Ramsey's discounted model provides such a microfoundation for Solow's descriptive theory in case there is no exogenous technical progress.

Let $k_t = x_t(k)$. The policy functions satisfy the no arbitrage condition. Let $c_t = (1 - \delta\rho)k_{t-1}^{\rho}$ and $c_{t+1} = (1 - \delta\rho)k_t^{\rho}$, where k_t is the capital stock at time t. The no arbitrage condition is:

$$\frac{c_t}{\delta c_{t-1}} = \frac{(1 - \delta\rho)k_t^{\rho}}{\delta(1 - \delta\rho)k_{t-1}^{\rho}} = \rho k_t^{\rho-1} = f'(k_t).$$

This solution can also be shown to satisfy the transversality condition, which takes the form here:

$$\lim_{t\to\infty} \frac{\rho k_{t-1}^{\rho-1}\delta^{t-1}}{c_t} = 0.$$

Therefore, the policy functions tell us how to find the optimal solution to this optimal growth problem. The optimal policy functions have the time consistency property as well.

The qualitative features of the optimal solution also follow from the policy functions. The most important observation is that the optimal capital sequence is monotonic as can be shown by iterating the capital policy function. Notice that each

optimal path converges to the unique positive fixed point of the capital policy function, k^*, where $h(k^*) = k^*$, which implies that:

$$k^* = (\delta\rho)^{\frac{1}{1-\rho}}.$$

This is the model's modified golden-rule capital stock. If the positive initial capital is below the modified golden rule, then the economy accumulates capital and the sequence of optimal capital stocks increases and converges to the modified golden-rule capital stock. Similarly, the optimal capital stocks decrease and converge to the modified golden rule when the starting stock is larger than the positive fixed point. If the initial capital happens to equal the modified golden-rule stocks, then it will be optimal to maintain those stocks in every period. Thus, the modified golden rule is a steady state of the dynamical system:

$$k_{t+1} = h(k_t) = \delta\rho k_t^{\rho}.$$

The corresponding consumption sequence is also monotonic since the consumption policy function is increasing in capital. The resulting consumption sequence converges to the *modified golden-rule consumption* level defined by:

$$c^* = (1 - \delta\rho)(k^*)^{\rho}.$$

The convergence of the optimal capital and consumption sequences illustrates the *turnpike theorem*. The monotonicity property for optimal capital sequences can also be viewed as a *non-crossing property*: if $k < k'$ are two different starting stocks, then $h(k) = k_1 < k_1' = h(k')$. Continuing in this way we see that, when two starting stocks are compared, the lower one always provides less capital than the higher one at any time along the optimal program.

The steady state's sensitivity to the discount factor is readily shown for $0 < \delta < 1$ for the general discounted one-sector model. Let $k^* = k^*(\delta)$ denote the steady state capital stock as a function of the discount factor. The condition $\delta f'(k^*(\delta)) = 1$ implies upon differentiation that $dk^*/d\delta > 0$. This *comparative steady state* result means that a more patient planner (there is a marginal increase in discount factor) produces a larger stationary optimal capital stock. Some writers on capital theory call this the *capital deepening* response to a change in the discount factor. The corresponding result for the consumption path $c^*(\delta) = f(k^*(\delta)) - k^*(\delta)$ states $dc^*/d\delta > 0$ as well. This is called *non-paradoxical consumption behaviour*. Note that this comparative steady state exercise does not compare the optimal program starting from k^* given the new discount factor to the optimal stationary plan k^* for the old discount factor. Comparative steady state exercises merely compare the steady states before and after a parameter change without evaluating the economy's transition path from one steady state to another.

Comparative dynamics results are available for the one-sector model which include studying the transition from one steady state to another in response to a parameter change. The planner considers all feasible plans in response to a change in one of the economy's deep taste or technology parameters. In particular, it is possible to compare the optimal programs before and after the parameter changes. For example, if the planner's discount factor increases (or, equivalently, the pure rate of time preference declines), then the planner becomes more patient. If the planner's discount factor increases from δ to δ', with $0 < \delta < \delta' < 1$, then the optimal capital paths starting from the same initial capital stock satisfy the conditions $\overline{k}'_t > \overline{k}_t$ for each time – there is a *generalized capital deepening response* because the economy's capital stock is increased at each time. Indeed, the discount factor's *initial impact* is to increase the first period's capital stocks at the expense of first period consumption since the initial capital stocks and first period output are unchanged after the discount factor increases. As the new consumption program converges monotonically to a larger modified golden-rule consumption level, $c^*(\delta')$, it follows that *eventually* (that is, in finite time) $\overline{c}_t(\delta') > \overline{c}_t(\delta)$ must obtain. These comparative dynamics results are easily verified for the canonical example with log utility and Cobb–Douglas production.

It is interesting to note that the monotonicity and non-crossing properties of the one-sector

model are robust. For example, the concavity of the production function can be relaxed while preserving these qualitative properties. The production function is *non-classical* provided there is an inflection point, $0 < k_I < b$ such that $f''(k) > 0$ for $k < k_I$ and $f''(k) < 0$ for $k > k_I$. Non-classical production functions can arise in fishery models when representing the production of a new generation of fish from the existing population. See Becker and Boyd (1997, Chap. 5) for details on the non-classical production extensions.

Generalizations of the one-sector model's turnpike property (the convergence of optimal capital sequences to the modified golden-rule stock) are also available for some multi-capital goods models, as found in McKenzie's surveys. The original turnpike theorem for many capital goods models was conjectured by Dorfman et al. (1958) in the von Neumann model framework without an explicit consumption criterion. Radner (1961) provides the first rigorous proof of a turnpike theorem for a von Neumann style model with a unique maximum balanced growth path and a finite planning horizon. Radner's theory evaluated alternative programs from a given initial vector of capital stocks according to a criterion based on the value of those stocks in the program's final time period. As with Dorfman, Samuelson and Solow's model, Radner's theorem did not apply to a Ramsey-style planner with an objective based on discounted utility. Radner's value loss technique for demonstrating the turnpike theorem did turn out to apply to undiscounted Ramsey models as well as some forms of the discounted model, as summarized in McKenzie's survey articles.

Another generalization focuses on the representation of the intertemporal utility function. Some recursive utility functions, which generalize the time consistency property of the time additive utility function, can be specified for concave production models while retaining the qualitative properties of optimal paths, such as capital monotonicity. The basic notion of a recursive utility function is illustrated below. The general theory of recursive utility functions is exposited by Becker and Boyd (1997).

Flexible time preference underlies many classic writings on capital theory – the agents discount factor depends on the underlying consumption stream. Recursive utility functions are one family of utilities that allow the steady state consumption stream to influence the corresponding discount factor. The brief development of recursive utility theory given here is grounded in a re-examination of the time consistency property of the planner's optimal choice in the one-sector discounted Ramsey model.

The discounted additive utility function, U, over infinite consumption streams $\mathbf{c} = \{c_1, c_2, \ldots\}$ is defined by the formula:

$$U(\mathbf{c}) = \sum_{t=1}^{\infty} \delta^{t-1} u(c_t)$$

where u is a bounded, strictly increasing, and strictly concave function on $[0, \infty)$ with $0 < \delta < 1$ as before. The time consistency property discussed above reflects the property that U is *recursive*: the behaviour embodied in this additive representation of utility has a self-referential property, that is, the behaviour of the planner over the infinite time horizon $t = 1, 2, \ldots$ is guided by the behaviour of that agent over the tail horizon $t = T, T + 1, T + 2, \ldots$ (for each T) hidden inside the original horizon. For this additive utility function, recursivity means the objective from time $T+1$ to $+\infty$ has the same form as the objective starting at time $T = 0$ (except for some time shifts in consumption dates). Formally, U may be rewritten as:

$$\sum_{t=1}^{\infty} \delta^{t-1} u(c_t) = \sum_{t=1}^{T} \delta^{t-1} u(c_t) + \delta^T \sum_{t=T+1}^{\infty} \delta^{t-1} u(c_{t+T}),$$

where the last sum gives the utility of the stream $\{c_{T+1}, c_{T+2}, \ldots\}$. The utility of the consumption stream $\mathbf{c}$ can be written as the function:

$$U(\mathbf{c}) = u(c_1) + \delta U(S\mathbf{c}),$$

where S is the *shift operator*: $S\mathbf{c} = \{c_2, c_3, \ldots\}$. Let the *projection operator*, π, be defined by the formula $\pi\mathbf{c} = c_1$. The general notion of a recursive

utility function is that the utility function U can be written in the form:

$$U(\mathbf{c}) = W(u(\pi\mathbf{c}), U(S\mathbf{c}))$$

for an appropriate real-valued function W defined on $[0, \infty) \times \mathcal{U}$, where $\mathcal{U}$ is the range of U. W is called the *aggregator function*. For the additive function, $W(c, y) = u(c) + \delta y$ for $y \in \mathcal{U}$. There are other examples of recursive utility functions. The Epstein–Hynes utility function developed below is generated by the *EH aggregator* $W(c, y) = (-1 + y) \exp(-v(c))$, where v is a strictly concave, increasing function of c with $v(0) > 0$.

The general theory of recursive utility functions provides a way to recover the utility function U from specification of the aggregator. Intuitively, U can be found by recursively substituting it into the equation $U(\mathbf{c}) = W(u(\pi\mathbf{c}), U(S\mathbf{c}))$. This substitution is performed by the *recursive operator* T_W defined by:

$$(T_W(U^0)(\mathbf{c}) = W(u(\pi\mathbf{c}), U^0(S\mathbf{c})),$$

where U^0 is considered the initial seed in this recursive substitution. For example, if $U^0 = 0$, the zero function that annihilates all consumption streams, then the $N^{th} - iterate$ of TW is:

$$(T_W^N 0) = W(c_1, W(c_2, \ldots, W(c_N, 0) \cdots)).$$

The recursive utility function is the unique fixed point of the operator T_W. The general theory provides conditions under which T_W has a unique fixed point and the successive iterates T_W^N converge to that fixed point independently of the choice of the initial seed function, U^0. Lucas and Stokey (1984) first proposed the specification of utility functions via aggregators and provided the basic theory of the recursion operator for bounded aggregators when consumption streams were elements of the set of all real-valued non-negative bounded sequences.

The basic ideas in recursive utility theory are readily illustrated for the case of the EH aggregator. This yields an example where the planner's utility function has flexible time preference and a recursive structure. A planner whose preferences over consumption streams is defined by the EH aggregator can be shown by recursive substitution to have the utility function U, which takes the form:

$$U(\mathbf{c}) = -\sum_{t=1}^{\infty} \exp\left(-\sum_{s=1}^{t} v(c_s)\right) \tag{6}$$

where $v : \mathbb{R}_+ \to \mathbb{R}_+$ is strictly concave, increasing, and satisfies $v(0) > 0$. Equation (6) is known as the *Epstein–Hynes (EH) utility function* after the continuous time analogue from Epstein and Hynes (1983); (6) was also studied in Epstein (1983). The EH utility from the consumption sequence's tail, $(c_{T+1}, c_{T+2}, \ldots)$, appears in the last term of the following expression breaking down the utility over the entire consumption path into segments for the first T periods and the subsequent periods:

$$\begin{aligned}
&-\sum_{t=1}^{\infty} \exp\left(-\sum_{s=1}^{t} v(c_s)\right) \\
&= -\sum_{t=1}^{T} \exp\left(-\sum_{s=1}^{t} v(c_s)\right) \\
&\quad + \exp\left(-\sum_{\tau=1}^{T} v(c_s)\right) \\
&\quad \times \left[-\sum_{t=T+1}^{\infty} \exp\left(-\sum_{\tau=T+1}^{t} v(c_s)\right)\right]
\end{aligned}$$

Hence, the utility of the tail of the program is just a time-shifted form of the utility of the original program – this is the identifying characteristic of a recursive utility function based on stationary preferences.

The steady state conditions for this economy are found by working out the no arbitrage conditions for the optimal growth problem which maximizes (6) subject to (2) and letting the consumption and capital sequences be constant sequences. Then the steady state conditions become:

$$f'(k^*) = 1/\exp(v(c^*)), \tag{7}$$

where k^* is the aggregate steady state capital stock. Since $\exp(v(0)) > 1$ and $c^* + k^* = f(k^*)$, one can solve (7) for a unique long-run capital and consumption level. The capital monotonicity property holds for the optimal solution to the problem of maximizing (6) subject to (2) when the neoclassical production function satisfies the concavity and Inada conditions for the discounted Ramsey model (see Becker and Boyd, 1997, Chap. 5, for a detailed proof and Beals and Koopmans, 1969, for the seminal article on recursive utility in optimal growth theory). In particular, if the initial capital stock is smaller than the steady state stock, then the economy's capital stock increases at each time and converges to the steady state; likewise, an initial capital stock above the steady state leads to a declining capital stock over time which converges to the steady state stock. The non-crossing property also obtains.

Equilibrium Equivalence Principles

The optimal growth model connects to the central questions of the determination of prices, including the rate of interest, and the functional distribution of income, by way of reinterpreting the optimal program as a competitive equilibrium for a fully specified dynamic general equilibrium model. This relationship is obtained by proving a version of the fundamental welfare theorems for this economy. The traditional welfare theorems based on finitely many goods must be adapted to the case of infinitely many dated commodities. There is more than one way to interpret the equilibrium model. The first interpretation is one with perfect foresight and a sequence of budget constraints, one for each time. Prices are reckoned in units of current consumption. The second interpretation links the neoclassical model with Irving Fisher's theory of interest rate determination and emphasizes his famous *separation principle*. The Fisherian equilibrium model is also one where agents act with perfect foresight.

At the core of either equilibrium model's interpretation is what Christopher Bliss (1975) called the *orthodox vision of capital theory*: an economy accumulating capital will generate rising wages and a falling rate of interest. Since capital increases over time, labour–capital complementarity implies workers are more productive and their wage rises. Diminishing returns set in and the rental rate falls as so many early writers on capital theory hypothesized in their verbal models. One of Ramsey's great contributions was to provide a consistent mathematical model of this story.

The PFCE Equivalence Principle

The competitive economy consists of an infinitely lived representative *household*, or *consumer sector*, and a *production sector*. The representative household's preferences coincide with the Ramsey style planner introduced above. The representative household is derived for an economy with a continuum of identical infinitely lived households whose preferences coincide with the Ramsey style planner. These households' preferences and endowments are identical. The total labour supply of all households has unit mass. In a *symmetric equilibrium* each household will take the same action given the same endowment, so it is sufficient to examine the decisions undertaken by a representative household who is also taken as supplying the economy's labour services to the production sector. The production sector's production function is the same as the one in the corresponding optimal growth model.

The representative consumer forecasts sequences of rental and wage rates to maximize lifetime utility subject to a sequence of budget constraints, one for each period. Formally, the household sector solves for given $\{r_t, w_t\}_{t=1}^{\infty}$ the problem:

$$\sup \sum_{t=1}^{\infty} \delta^{t-1} u(c_t)$$

by choice of the non-negative sequences $\{k_{t-1}, c_t\}_{t=1}^{\infty}$ subject to:

$$c_t + k_t = w_t + (1 + r_t)k_{t-1} \quad \text{for } t = 1, 2, \ldots \tag{8}$$

and $k_0 \leq k$. Here k is the initial capital stock (the same one as in the Ramsey optimal growth problem), r_t is the one-period rental rate on capital, and w_t is the wage rate earned by inelastically supplying one unit of labour in each time period. The prices r_t and w_t are reckoned in units of consumption available at time t.

The consumer's problem has a no arbitrage condition analogous to the one obtained in the optimal growth problem:

$$\delta(1 + r_t)u'(c_{t+1}) = u'(c_t) \quad \text{for each } t.$$

The transversality condition is necessary for equilibrium programs as defined below. The combination of the transversality condition and the no arbitrage equation is also sufficient for a consumption–capital sequence to solve the consumer's problem for a given profile of wages and rental factors.

Producers take the rental rate as given and solve the following myopic maximization problem for the production sector's capital demand at each time period:

$$\sup_{x \geq 0} f(x) - (1 + r_t)x.$$

Here, x denotes a level of aggregate capital; the profit maximizing solution is denoted k_{t-1}, the planned capital demand at time t. It only depends on the current rental rate, r_t. The problem's point input–point output structure reflects the absence of adjustment costs or other structural production lags and the fact that all forward-looking consumption–investment decisions reside in the household sector. The necessary and sufficient condition for a positive capital stock to solve the production sector's optimization problem at time t is:

$$f'(k_{t-1}) = 1 + r_t,$$

which uniquely determines k_{t-1} in terms of $1 + r_t$. The *total capital income* is $(1 + r_t)k_{t-1} = f'(k_{t-1})k_{t-1}$.

The *wage bill* is the residual 'profit' given by:

$$w_t = f(k_{t-1}) - (1 + r_t)k_{t-1}.$$

Notice that $w_t = f(k_{t-1}) - f'(k_{t-1})k_{t-1}$. In the Cobb–Douglas case with $f(k) = k^\rho$, then this economy labour's share of the total output or national product, k_{t-1}^ρ, is $1 - \rho$ and capital's share is ρ. The *total supply of goods in period t* is $f(k_{t-1})$ as a result of one-period profit maximization.

Sequences $\{1 + r_t, w_t, c_t, k_{t-1}\}_{t=1}^{\infty}$ constitute a *perfect foresight competitive equilibrium (PFCE)* provided that:

(PFCE-1) $\{c_t, k_{t-1}\}_{t=1}^{\infty}$ solve the consumer's problem given $\{1 + r_t, w_t\}_{t=1}^{\infty}$;
(PFCE-2) $f'(k_{t-1}) = 1 + r_t$, and
(PFCE-3) $w_t = f(k_{t-1}) - (1 + r_t)k_{t-1}$ for each time t.

These three conditions yield via Walras's Law the materials balance condition, $c_t + k_t = f(k_{t-1})$ for each t and $k_0 = k$.

The *equivalence principle* tells us that for this dynamic economy the *PFCE* allocation is the same as the Ramsey planner's solution. Hence, a *PFCE* allocation is an optimum and vice versa. The argument is the no arbitrage conditions for the equilibrium and optimal growth problems coincide, and the respective transversality conditions hold as necessary conditions in their respective problems. The sufficiency of these conditions is used to finish the proof.

A PFCE determines the *functional distribution of income* as the payments to each productive factor at each point in time. Labour receives its wage and capital is paid its capital income. The share of income received by each factor is a constant and time independent when production is Cobb–Douglas. The functional distribution of income at each time also yields the representative agent's personal income by adding the two source's income at each time. Multi-agent models differentiate the personal income an agent enjoys at each time from the corresponding functional distribution of income.

The Fisher Competitive Equilibrium Equivalence Principle

The capital theoretic foundation for the present value investment criterion is the *Fisher separation*

principle derived from Fisher's 'second approximation', which portrays the intertemporal consumption–investment decision of agents as a two-stage process. In the first stage, investment opportunities are exploited to realize a maximum value of initial wealth. The solution to the first-stage problem is found by maximizing the net present value over all feasible projects. Given competitive prices (and implicit discount rates), all agents whose intertemporal utility functions satisfy a mild non-satiation requirement will be led to choose the same wealth maximizing investment projects. In the second stage, those agents take their maximized wealth and access perfect capital markets to borrow and lend in order to obtain the most preferred lifetime consumption pattern.

The Fisher competitive equilibrium is the infinite horizon analogue of the Fisher separation principle. There is a single lifetime budget constraint; the savings–investment decision is separated from the consumption decision. Consumers maximize utility given their maximized wealth obtained as residual claimants to the production sector's discounted profit streams. Discounted profits are maximized within that sector. Letting $\{r_t\}$ be the sequence of interest rates and $q_t = \Pi_{\tau=1}^{t}(1+r_\tau)^{-1}$ the discounted price of time t consumption, define the profit function by $\pi(k,\{r_t\}) = \max\{\sum_{t=1}^{\infty} q_t[f(k_{t-1}) - (1+r_t)k_{t-1}] : k_0 = k\}$.

A sequence $\{r_t, c_t, k_t\}$ forms a Fisher competitive equilibrium (FCE) if:

(FCE-1) $\pi(k,\{r_t\}) = \max\{\sum_{t=1}^{\infty} q_t[f(k_{t-1}) - (1+r_t)k_{t-1}] : k_0 = k\}$;

(FCE-2) Consumers maximize $\sum_{t=1}^{\infty} \delta^{t-1}u(c_t)$ subject to the budget constraint $\sum_{t=1}^{\infty} q_t c_t = \pi(k,\{r_t\}) + k$;

(FCE-3) The market clearing condition $c_t = f(k_{t-1}) - k_{t-1}$ holds.

Once again, by matching first-order conditions and transversality conditions the sufficiency conditions for the agents' optimization problems imply that the allocation $\{c_t, k_t\}$ in a FCE $\{r_t, c_t, k_t\}$ is an optimum, and vice versa: given the optimal allocation $\{c_t, k_t\}$, there is a sequence of interest rates such that the triple $\{r_t, c_t, k_t\}$ forms a FCE. The result is the Fisher equivalence theorem.

The twin equivalence theorems for the PFCE and FCE models connect Ramsey's theory of optimal growth in an aggregate economy to Fisher's theory of consumption and investment in an intertemporal choice market model as well as to Solow's descriptive growth theory (the logarithmic utility, Cobb–Douglas production function example has a constant marginal propensity to save, as assumed in Solow's growth model). The qualitative properties of the optimal growth model carry over to the two formulations of dynamic competitive economies. In the case where the initial capital stocks are smaller than the modified golden-rule stocks, the capital monotonicity property of the optimal program implies that the consumption sequence increases, the sequence of wage rates is increasing, and the sequence of interest rates/ rental rates is decreasing. The orthodox vision of capital theory holds for the one-sector optimal growth model once the dynamic equilibrium is interpreted by way of the PFCE and FCE equivalence principles.

Many Agents

The equivalence principles for the discounted Ramsey model postulate a representative agent. The orthodox vision of capital theory carries over to some forms of neoclassical capital theory when many distinct agents replace the assumption of a representative infinitely lived household. The introduction of many distinct consumers raises interesting questions concerning the determination of equilibrium prices and the distribution of personal (and factor) income both in short and long runs.

Frank Ramsey's seminal contribution to optimal growth also addressed the long-run, or steady state, distribution in a competitive economy. He conjectured that, with households having different rates of impatience, the steady state equilibrium would have very unequal income and wealth distributions. The most patient household would enjoy the maximum sustainable consumption ('bliss' in his conception) and all other households would consume at a minimal level necessary to sustain their lives. This was not a particularly new idea at the time his paper was published. The

notion that time preference differences operating in a market economy might promote long-run differences in income and wealth can be found in the writings of such eminent economists as John Rae in 1834 and in several books by Irving Fisher beginning with his great work on the rate of interest first published in 1907. The Ramsey conjecture can be examined in two distinct neoclassical settings. The first deals with a natural extension of the optimal growth model to one of Pareto optimal growth. Agents are allowed to borrow and lend. The equilibrium version is analogous to the FCE set-up. Households have a single budget constraint expressed in present value terms. Here, long-run income distribution can be extreme if individuals have different discount factors – the relatively impatient ones receive NO income. The second formulation is one of temporary equilibrium where markets are incomplete – households are forbidden to borrow against their future labour income (each person's capital stock is constrained to be non-negative at each time) and face a sequence of budget constraints, as in the PFCE model. In this setting, the relatively impatient households consume their wage income and the most patient household consumes wage and capital income – a modern formulation of Ramsey's two-class society.

Pareto Optimal Growth with Many Agents

Suppose there are H households ($h = 1, 2, \ldots, H$) with one-period return functions u_h of the type met in the optimal growth setting. Let c_t^h denote agent h's consumption at time t and suppose that each agent's discount factor is the same $\delta = \delta h$ with $0 < \delta < 1$. Introduce *welfare weights* $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_H) \geq 0$ and $\sum_{h=1}^{H} \lambda_h = 1$. Given a weight vector λ, the Pareto optimal growth problem is to solve:

$$\sup \sum_{t=1}^{\infty} \sum_{h=1}^{H} \lambda_h \left[\delta^{t-1} u_h\left(c_t^h\right)\right] \tag{9}$$

$$\text{subject to } \left(\sum_{h=1}^{H} c_t^h\right) + k_t \leq f(k_{t-1}), t = 1, 2, \ldots,$$

$$c_t^h, k_{t-1} \geq 0, k_0 \leq k, h = 1, 2, \ldots$$

The planner seeks a path of consumption for each person and an aggregate capital path satisfying the constraints with the maximum weighted discounted future utility. This problem can be rewritten in an interesting manner.

Given a weight vector λ, define on $\mathbb{R}_+$ the real-valued function u_λ^* as the following program's optimal value function:

$$u_\lambda^*(c) = \sup\left\{\sum_{h=1}^{H} \lambda_h u_h\left(c^h\right) : \sum_{h=1}^{H} c^h = c, c^h \geq 0\right\}. \tag{10}$$

If u_h is a concave, continuous, increasing function on $[0,\infty)$, and twice continuously differentiable function on $(0,\infty)$, then u_λ^* is concave, increasing in c, and continuously differentiable. Note that the Inada condition $u_h'(0) = +\infty$ and $\lambda_h > 0$ imply $c^h > 0$ in the solution to (10) whenever $c > 0$. This also implies $u_\lambda^{*\prime}(0) = +\infty$ holds. Of course, if $\lambda_h = 0$, then $c^h = 0$ in the solution to (10).

The Pareto optimal growth model is then given by the classic discounted Ramsey model:

$$\sup \sum_{t=1}^{\infty} \delta^{t-1} u_\lambda^*(c_t) \tag{11}$$

subject to $c_t + k_t \leq f(k_{t-1})$, $t = 1, 2, \ldots$, c_t, $k_{t-1} \geq 0$, $k_0 \leq k$.

This problem has a unique solution under our basic assumptions. The neoclassical optimal growth model's properties obtain for this Pareto optimal growth model: the optimal aggregate consumption and capital sequences are monotonic and converge to the modified golden-rule consumption, c^*, and capital, k^*. Notice that the steady state capital stock and aggregate consumption levels are independent of the welfare weights. However, given c^*, the steady state allocations to the various households do depend on those weights by way of the solution to (10) with $c = c^*$. Different weights will distribute the steady state aggregate consumption differently. Consumption is equally distributed in the steady state if and only if the welfare weights are equal

with $\lambda h = 1/H$. Along dynamic equilibrium paths aggregate consumption growth also implies each household's consumption grows provided that agent's welfare weight is positive.

The preservation of the capital monotonicity property in this Pareto optimal growth problem suggests that the orthodox vision applies to its equilibrium counterpart. It turns out that with many agents the form of the equivalence principle is more subtle than with a single, representative, agent. The essential issue is the same problem that arises with the classical welfare theorems in finite dimensional commodity spaces – a Pareto optimum may only be a competitive equilibrium with transfer payments. Once this problem is handled, the basic equivalence principles carry over to the many agent case provided all households discount future utility at the same rate. The orthodox vision prevails.

The orthodox vision's realization in the Pareto optimal growth problem with equal discount factors does not extend to a model with heterogeneous agents and distinct discount factors. In this case, the household with the largest discount factor is the most patient one. The modified golden-rule capital stock, k^*, is still well-defined. However, Le Van and Vailakis (2003) prove the Pareto optimal capital sequence initiated at k^* converges to it in the long-run — but it is not a constant sequence: if the economy starts with the stocks k^*, then it is optimal for the planner to deviate from those stocks and only return to them asymptotically. The resulting optimal capital sequence cannot be monotonic, although the authors show it can be eventually monotonic. In part, this reflects the fact that the households enjoy timevarying consumption along their optimal path. The aggregate consumption levels change over time, but the first household emerges as the dominant consumer in the limit. The heterogeneous agent extension of the neoclassical representative agent theory does not exhibit the orthodox vision.

The Ramsey Equilibrium Model

The Ramsey equilibrium developed in Becker (1980) and reviewed in Becker (2006) interprets Ramsey's original long-run steady state conjecture with heterogeneous agents in a modern fashion. The basic model is developed for the case of agents with time additively separable utility functions with fixed discount factors. Each agent has a different discount factor, so one household is more patient than all the others. The technology is specified by a one-sector model with a single all-purpose consumption–capital good as before.

The general complete market competitive one-sector model treats budget constraints as restricting the present value of an agent's consumption to be smaller than or equal to the agent's initial wealth defined as the capitalized wage income plus the present value of that person's initial capital. This allows us to interpret the choice of a consumption stream as if the agent were allowed to borrow and lend at market-determined present value prices subject to repaying all loans. Markets are complete – any intertemporal trade satisfying the present value budget constraint is admissible at the individual level. The Ramsey equilibrium model changes the budget constraint from a single one reckoned as a present value to a sequence, one for each period. Agents are forbidden to borrow against their future labour income, so they cannot capitalize the future wage stream into a present value. Markets are incomplete. It becomes crucial to track the evolution of each person's capital stock. This is unnecessary in the complete market models when all values entering the budget constraint are present values.

The incomplete market structure shows itself in an individual's budget constraint. At each time, a household's available income is derived from rental returns on its capital stocks, and its wage rate (all labour is alike and inelastically supplied). Expenditure at each time is for consumption goods and for capital goods to be carried over to the next period in order to earn rental income. The borrowing constraint takes the form of a non-negativity constraint on the capital stock holdings in each time period. The formal constraint is analogous to (8) with superscripts attached to individual consumption and capital holdings.

The heterogeneous discount factor, incomplete market economy, differs in another important

respect: the operation of a borrowing constraint in the individual household problems also breaks the possibility of an equilibrium allocation arising as the economy's optimal allocation. The welfare maximization approach favoured in the complete market theory is inapplicable.

The Ramsey model has a unique stationary equilibrium in which only the most patient household has capital. That agent also enjoys a labour income. All other households consume their wages and own no capital. The model's dynamics have some distinctive features when compared with the capital and consumption monotonicity characteristic of the representative agent neoclassical model. The main results for the Ramsey equilibrium model appear in a series of papers beginning with Becker and Foias (1987). The survey article by Becker (2006) reviews those results as well as others in detail. Here, it is enough to note that the Ramsey equilibrium aggregate capital starting from an arbitrary distribution of initial capital stocks *eventually* has the capital monotonicity property in the case where the production function's elasticity of substitution is greater than or equal to 1, a condition satisfied by the Cobb–Douglas production function. In this case, the orthodox vision of capital eventually holds. If that elasticity of substitution condition fails, then Becker and Foias showed it was possible for a two-period equilibrium cycle to exist; the orthodox vision necessarily fails.

Behavioural Economics and Quasi-Geometric Discounting

The discounted Ramsey model where the planner discounts future utilities at a constant rate is the fundamental dynamic model in macrodynamics and economic growth theory. The time consistency of the optimal plan, based on the stationarity of the planner's utility function (even in the general recursive case) has been questioned by behavioural economics researchers on the basis of experiments and empirical evidence. For example, Ainslie (1991, p. 334) states that a majority of adults report they would rather have $50 immediately rather than $100 in two years, but almost no one chooses $50 in four years instead of receiving $100 in six years. If these individuals have stationary preferences, the mere passage of four years calendar time should not change the ranking of $50 in year four to $100 in year six if $50 was preferred in the present to $100 in two years. Thus, Ainslie concludes these individuals are time-inconsistent in their intertemporal preference ranking. Ainslie, as well as many others (notably Laibson, 1997; also see the survey by Frederick et al. (2002), for detailed summaries of the evidence and related references based on works by psychologists and economists) argue a different discounting function that describes real human behaviour better than the constant discounting model. The quasi-geometric discounting model developed below illustrates the simplest form of an alternative discounting function that these researchers argue better describes real human intertemporal choices. The quasi-geometric discounting function is an important example of the *hyperbolic discounting functions* appearing in behavioural discussions of time preference. The time preference reversals reported by Ainslie can be thought of as a criticism of standard discounted utility models in much the same way as the Allais paradox in risky choice experiments provides evidence against the expected utility model.

The standard constant discounting model's discounting function is $D(t) = \delta^{t-1}$, where $0 < \delta < 1$ is the discount factor and $t \geq 1$. The function D is also called the *exponential discount function*. The *quasi-geometric discounting* model posits a discounting function of the form $d(t) = \beta\delta^{t-1}$, where $\beta > 0$ is a parameter. The case $\beta = 1$ corresponds to the exponential discount function. If $\beta < 1$, there is short-run impatience – the decision maker is willing to save in the future, just not in the present. If $\beta > 1$, then there is short-run patience – the decision maker is more willing to consume in the future rather than the present. It is known from the fundamental paper by Strotz (1955) that, if a dynamic optimizing planner's discount factor does not have an exponential form, then the resulting optimal solution found from maximizing utility discounted to the present date will be time inconsistent. Thus, a planner solving the problem of maximizing the quasi-geometric utility function:

$$U(\mathbf{c}) = u(c_1) + \beta\left[\delta u(c_2) + \delta^2 u(c_3) + \cdots\right] \quad (12)$$

subject to (2) will exhibit time inconsistency. The solution $\{\overline{c}_t, \overline{k}_{t-1}\}_{t=1}^{\infty}$ so found will change if the planner is able to re-optimize at time 2. That new solution $\left\{\overline{c}^{\#}, \overline{k}^{\#}{}_{t-1}\right\}_{t=2}^{\infty}$ will have the property that $\overline{k}_2 \neq \overline{k}^{\#}{}_2$ when $\overline{k}_1 = \overline{k}_1{}^{\#}$ expresses the initial condition for the second period's optimization problem. Put differently, unless the planner can credibly commit to implementing the solution found in the first period, the planner will make another choice of optimal plans once period 2 is attained than the one originally found at time 1. The time inconsistent solution found in period 1 is really not an optmium as the planner would not implement it when called on to do so in the absence of a credible commitment to that plan.

Phelps and Pollak (1968) proposed a different way to arrive at a solution to the problem of maximizing (12) subject to (2). Their approach recognizes the planner must correctly anticipate future actions. The choice of c_t at some future date t alters the planner's capital stock and impacts the choices of consumption levels for all times past t. These impacts must be somehow considered by the planner in the present when the optimal plan is determined.

Phelps and Pollak imagined the planner as really infinitely many planners, each a *generation* that lives, saves and consumes over just one period. The discount factor, δ, measures impatience; the parameter β reflects the degree to which the current generation values future generations' utility relative to their own utility. Perfect altruism corresponds to the case $\beta = 1$ whereas imperfect altruism arises whenever $\beta < 1$. Later writers, following Laibson (1997), interpreted the generations as different *selves*, one for each time period. In either interpretation, the planner acts as if there are really infinitely many selves in the infinite-horizon Ramsey-styled optimization problem. Phelps and Pollak go on to argue the Ramsey optimal growth problem should be considered as a game with the many selves as the players. A Nash equilibrium of this game constitutes a solution to the planner's problem in the sense that no self (or generation) can improve its payoff given the actions taken by future selves (generations). Modern game theory research published after Phelps and Pollak's article suggests that such a game might have many equilibrium points. One possibility is the Markov perfect equilibrium concept. A Markov perfect equilibrium is time consistent. At time t, no histories of past choices or measurement of the capital stock are assumed to matter for outcomes beyond the current value of the aggregate capital stock that is presented to the self active at that moment. Other equilibrium notions can be formulated to reflect the game's history as play unfolds over time. Trigger strategies provide one way to do this. Of course, a fundamental equilibrium existence question arises for Markov perfect equilibrium as well as those equilibrium concepts derived from the selves adopting trigger strategies.

A Markov perfect equilibrium is represented by a time independent capital policy function, $g(k)$, that the current self expects to govern all future selves' saving and capital accumulation decisions. In this way, the aggregate capital stock is expected to evolve according to the dynamical system $k_t = g(k_{t-1})$ with $k_0 = k$, the capital stock endowment available at time 0. Note that this function depends only on the currently available capital stock. To solve the planner's quasi-geometric utility optimization problem is to find such a policy function. Recall that a policy function of this type characterized the solution to the canonical version of the discounted Ramsey model and reflected the underlying time consistency property of the planner's stationary utility function. It is also a Markov perfect equilibrium in the quasi-geometric case where $\beta = 1$ and $u(c) = \ln c$ with $f(k) = k^{\alpha}$. Of course, a major technical problem is to show a Markov perfect equilibrium exists in models where $\beta \neq 1$. For the log utility, Cobb–Douglas production model, a Markov perfect equilibrium has been constructed in the quasi-geometric case with $\beta < 1$ by Krusell et al. (2002). They showed that there is a Markov perfect equilibrium with policy function:

$$k' = g(k) = \frac{\beta\delta\alpha}{1-\alpha\delta(1-\beta)}k^{\alpha}, \qquad (13)$$

a functional form that agrees with the canonical example's capital policy function when $\beta = 1$. Iteration of this capital policy function (13) from the given initial capital stock produces a monotonic aggregate capital sequence. The qualitative properties of this particular Markov perfect equilibrium in this parameterized quasi-geometric model is the same as the qualitative properties of the canonical discounted Ramsey model, even though the two models' quantitative properties differ. For example, the two models have different steady states. The similarity was noted in Barro's (1999) continuous time model; he dubbed this similarity an observational equivalence result as the two models could not be distinguished empirically on the basis of their qualitative features alone.

Efficient Programs

Programs which are optimal for the discounted Ramsey model as well as its more general recursive utility formulations have an important efficiency property: there is no other feasible consumption sequence that provides more consumption in at least one period and as much in any other when compared with the optimal consumption path. This efficiency property can be studied in capital accumulation models in its own right as a minimal requirement for any reasonable objective function. Considered on its own, the efficiency criterion does not do much to single out a specific course of action for the planner. However, it can be used to eliminate some candidate optima without further reference to a specific welfare function. Moreover, examining efficient programs of consumption and capital accumulation can be undertaken in models with infinitely lived agents as well as models with finitely lived, overlapping generations where the economy evolves over an infinite horizon.

The interest in intertemporal efficiency stems from Malinvaud's (1953) seminal paper. He presented the first extension of Koopmans' activity analysis of efficient allocations in a static production world to an open-ended economy with a recursive technological structure, such as the aggregative one-sector model. He was also the first to recognize that the analog of Koopmans' profit conditions for characterizing an efficient program had to be supplemented in an infinite framework. This new terminal condition, the *transversality condition* (seen in the above discussion of the optimal growth model) was shown to be sufficient for an efficient program satisfying the profit conditions for an appropriate set of shadow prices.

Efficient programs are discussed below for the aggregative one-sector model. A sequence $\{c_t\}$ satisfying (2) for some capital stock sequence is *inefficient* if there is an alternative consumption program $\{c'_t\}$ satisfying (2) for some capital stock sequence that offers at least as much consumption in every period and more consumption in at least one period. A sequence $\{c_t\}$satisfying (2) for some capital stock sequence is *efficient* if it is not inefficient. The *efficiency criterion* ranks programs as either efficient or inefficient. The planner's objective is to select an efficient program. The efficiency criterion presumes that consumption may never be satiated in any period. An infinite number of efficient programs exists in the discounted Ramsey model – for a fixed, finite, time period T, define a feasible program by consuming nothing for periods $t = 0, 1, \ldots, T-1$, and letting the capital stock accumulate according to the difference equation $k_t = f(k_{t-1})$, with $k_0 = k$. At time T, consume the resulting $f(k_{T-1})$ and set $k_T = 0$. For each time after T, consume zero and accumulate no capital. Such a path is efficient. Since T is arbitrary, there are infinitely many efficient paths.

Efficient programs providing consumption in every period also exist. One important example is the path found by first solving for the combination of consumption and capital stock which maximizes stationary (or, sustainable) consumption. This program solves the problem $\max\{f(x) - x : x \in [0, b]\}$. The solution, denoted k^g, satisfies $f'(k^g) = 1$ and called the *golden-rule capital stock*; the corresponding *golden-rule consumption*, c^g, is defined by the relation $c^g = f(k^g) - k^g$. The interpretation is that if the economy's initial capital stock happens to equal

the golden-rule stock, then it is efficient for the planner to choose this stock for all time and maintain the largest possible stationary consumption.

The golden-rule pair (c^g, k^g) has an important relationship to the problem of characterizing efficient programs. The specific result is called the Phelps theorem (see Phelps, 1966, p. 59). It is a sufficient condition for an attainable path to be inefficient. A $\{c_t, k_t\}$ satisfying (2) also satisfies the *Phelps condition* if there is an $\varepsilon > 0$ and a natural number $T(\varepsilon)$ such that for all $t \geq T(\varepsilon)$, $k_t \geq k^g + \varepsilon$. The Phelps condition is equivalent to $\liminf_{t \to \infty} k_t > k^g$. Phelps' theorem states that a feasible program satisfying the Phelps condition is inefficient. In particular, the path of pure accumulation found by iterating $k_t = f(k_{t-1})$ for all t with $k_0 = k$ is inefficient as this program converges to the maximum sustainable capital stock. Any feasible program for which the capital stocks converge to a stock larger than the golden-rule stock is also inefficient. Note that such a program would have the own rate of return, $f'(k_{t-1}) - 1 < 0$ for all t sufficiently large. In particular, this would imply $\Pi_{t=1}^{T} f'(k_{t-1}) \to 0$as $T \to \infty$. It turns out that this is a general property of inefficient programs, as shown by Cass (1972). Intuitively, these inefficient programs have shadow interest rates, $r_t = f'(k_{t-1}) - 1$ that are negative (no market mechanism is identified in this discussion, so the interpretation of $f'(k_{t-1}) - 1$is provisionally made as a shadow price). It is reasonable then to presume that programs with positive shadow interest rates for all time are efficient. The precise criterion that is necessary and sufficient to characterize inefficient programs was identified by Cass (1972). He proved his result with additional curvature assumptions on the production function (which restrict the rate of change of capital's marginal product as capital accumulates, or decumulates) as well as assumed $f'(0) < \infty$. His theorem states that a feasible path is inefficient if and only if:

$$\sum_{t=1}^{\infty} \left[\prod_{s=1}^{t} f'(k_{s-1}) \right] < \infty.$$

Notice that if a path satisfies this Cass condition, then $\Pi_{s=1}^{t} f'(k_{s-1}) \to 0$ as $t \to \infty$, which is the Phelps sufficient criterion for inefficiency. Cass interpreted his condition as saying that the term $\Pi_{s=1}^{t} f'(k_{s-1})$goes to zero 'sufficiently fast'. The term $\Pi_{s=1}^{t} f'(k_{s-1})$ represents the shadow future value of a marginal unit of capital in period 0. The Cass criterion's necessity then asserts that for an inefficient program, the future value of a marginal unit of capital at time 0 is bounded from above. This implies that the terms of trade from present to future never become very favorable (Cass, 1972, p. 207). General forms of the Cass criterion for one-sector models are discussed in the survey by Becker and Majumdar (1989) as well as additional applications to overlapping generations models and interpretations of these conditions for decentralized planning mechanisms. The survey by Tirole (1990) focuses on the connection between the Cass criterion for inefficient programs and the potential for the shadow prices associated with efficient programs to exhibit a type of bubble whereby the shadow market price of a unit of capital differs from its present discounted value of future shadow rental returns.

Controversies and Critiques

Neoclassical capital theory has long been controversial. The famous *Cambridge Controversies* about whether or not the one-sector neoclassical model's properties were either sensible, or could be generalized, produced a substantial literature. See Birner (2002) for a thorough review of both sides' positions. Earlier references include Harcourt (1972), Bliss (1975), and Burmeister (1980). A few key points are noted here.

The debates centred on whether or not there really is something called aggregate capital, whether or not it could be measured independently of the establishment of an equilibrium interest rate, and whether or not an increase in the steady state interest rate necessarily reduced steady state capital.

Bliss (1975) argued that aggregating capital was not more difficult than aggregating any other collection of commodities. It was enough to place a partial order on a vector of capital goods

defining one vector of capital goods to be at least as much as another vector. Standard utility function existence theorems would imply the existence of a continuous, real-valued, order preserving functional representation that could be interpreted as an aggregate capital good. Burmeister (1980) gave conditions under which a generalized steady state regularity condition applied to a many capital goods model permitted theorists to construct an aggregate capital stock and aggregate production function with the desired neoclassical properties (at least across steady states). It should also be noted that there are models where there is a natural measure of an aggregate capital stock in physical terms. For example, the capital stock in renewable resource theories such as ones arising in fishery models measures the fish population as a *biomass*: the mass of living organisms present in a population at a particular point of time. Biomass can be measured as either a weight or as so many calories. Its measurement does not depend on any prices or other quantities that might be established only in an equilibrium. Of course, this is a special situation.

One practical way of arriving at a measure of aggregate capital is to compute its capital value. This can be done by multiplying the prices of the various underlying capital goods times their respective quantities. Presumably, these prices represent these capital goods' discounted future returns (for example, monetary or cash flows). Capitalization of future payments requires an interest rate (or a term structure of interest rates in case the rate of interest varies over time). It follows that capital value cannot be computed independently of the determination of prices. Critics of neoclassical theory stressed this issue. Modern equilibrium models establish the determination of capital goods prices and interest rates in an equilibrium configuration, for both the short and the long runs (this is one task solved by equivalence principles in many capital goods models, when those results are available).

The comparative steady state result for the one-sector neoclassical model is that the steady state capital stock, $k(\delta)$, viewed as a function of the discount (long-run interest) factor δ^{-1}, has the property $dk/d\delta > 0$. The famous reswitching controversy attacks the generality of this result. In multi-sectoral models (even with aggregate capital) the choice of steady state production techniques can give rise to a particular capital–labour ratio arising from two different long-run interest rates.

The Cambridge controversies highlight the special features of the one-sector neoclassical theory. Those arguments concentrated on comparing steady states and either ignored or downplayed the role for transitions from one steady state to another in response to an exogenous change in an economy's deep taste or technology parameters. The debate also largely ignored the accumulation programs that flowed from the planner's decision when starting with initial capital other than the steady state level. The more dynamic view of modern capital theorists emphasizes the full dynamic possibilities open to the planner.

The orthodox vision applied to an aggregative economy portrays saving and consumption activities undertaken within the private sector as promoting a path of accumulation tending towards a steady state. When the economy's capital stock is initially smaller than its stationary level there is growth, and the rate of return on capital falls over time. This portrait of capital accumulation is consistent with the dynamics of the one-sector Ramsey optimal growth – perfect foresight equilibrium model provided there is a representative household whose preferences are taken as the planner's objective.

Bliss (1975) criticized the orthodox vision for models with many distinct capital goods as a single rate of interest could not be defined, and therefore the idea that growth accompanied a declining rate of interest made no sense. Subsequent research has shown that, even in aggregate capital Ramsey optimal growth models with a well-defined interest rate, the economy might not follow the orthodox vision provided there were at least two sectors producing a consumption good distinct from the capital good. The problem was that optimal cycles or even chaotic trajectories could emerge with a sufficiently impatient planner (see Boldrin and Woodford, 1990). Heterogeneous discount factor models also turn out to

differ fundamentally from the representative agent theory, even in the classical one-sector case. The orthodox vision will only apply to *some* economies when there are heterogeneous discount factors.

The Cambridge controversy focuses on the difficulties of aggregating different types of capital and consumption goods. There are also difficulties inherent in interpreting results obtained for representative agent economies. The failure of the orthodox vision noted above is one such example. There is another, perhaps more fundamental, criticism of representative agent-based capital theories. The conditions under which the many different individuals populating a model economy's preferences might be aggregated so that the economic theorist can study the model as if there is a single, stand-in, representative agent are so restrictive as to make conclusions drawn from single agent models flawed on logical grounds alone. See Hartley (1997) for a detailed discussion of the representative agent controversy.

The idea of a representative agent economy such as the Ramsey model is that the aggregate activity in the economy generated by many different consuming and producing actors can be understood as the activity of a single entity, the representative agent, which acts exactly like each of the consuming and producing actors. By studying the microeconomic behaviour of those individuals we can also find the behaviour of the representative agent, and vice versa. However, the argument is made that, even if the microfoundations of each agent are well understood, it does not follow that their aggregate behaviour is explained by the representative agent that behaves exactly like them. Micro-behaviour need not translate into macro-behaviour of the same type. For example, the representative agent Ramsey model's capital monotonicity property holds up in the welfare optimum version of the many agent theory when agents have the same discount factors, but different one-period utility functions and possibly different initial capital stocks. The planner whose preferences are represented by the welfare function (11) does not give rise to the exact same behaviour as that of each of the individual agents' preferences underlying it – individual consumption sequences differ from the aggregate, although they behave qualitatively the same (for example, they are monotonic). This distinction is even more pronounced in case agents also have different discount factors – the impatient agents' consumption tends to zero while the most patient one's consumption remains positive for all time. The aggregate consumption evolves over time in a very different manner from that of individual consumption streams.

Capital Theory with Many Sectors and Capital Goods

Controversies surrounding the neoclassical capital theory of the one-sector model are partly attenuated by studying models with many sectors and types of capital goods. This general form of the theory emphasizes a disaggregated viewpoint, although it also applies to aggregative models. It should also be noted that specifying a multisector model need not be the same as formulating a many capital good model. There are two-sector models with aggregative capital and single-sector models with joint production of many distinct capital and consumption goods.

Pricing and the Portfolio Equilibrium Condition

The major conceptual difference between the one-sector and multisector perfect foresight equilibrium models lies in the form taken by the no-arbitrage condition. This is readily seen in the two-sector model. Suppose there are two sectors consisting of a consumption goods sector and a capital goods sector. The capital and consumption goods are aggregate commodities, as in the one-sector model, but are conceived as distinct goods in the two-sector framework. Suppose that i_{t+1} is the one-period interest rate measured in units of a numeraire commodity, r_{t+1} is the rental rate on a unit of capital measured in the numeraire's units, and q_{t+1} is the unit purchase price for a unit of capital as measured in the numeraire's units. Suppose that the purchase of a unit of capital at time t entitles its owner to receive the rental flows from the next period on as long as

the unit remains in service. Assume further that capital does not depreciate. One requirement for a perfect foresight equilibrium is that there are no one-period reversed arbitrage opportunities. Let an equilibrium path obtain with the prices $\{i_{t+1}, r_{t+1}, q_{t+1}\}$. Suppose the household decision maker acquires another unit of capital at time t. This costs the household q_t units of the numeraire. The opportunity cost of this action in the numeraire's units is $i_{t+1}q_t$, the interest charge that could have been earned otherwise. To reverse this capital acquisition at time $t+1$ the household will sell that unit of capital for q_{t+1} units of the numeraire. This gives the capital gain (loss) equal to $q_{t+1} - q_t$. The household also gets to keep the one-period rental, r_{t+1}. This one-period reversed arbitrage is unprofitable if the marginal revenue equals the marginal cost reckoned in units of the numeraire. That is,

$$i_{t+1}q_t = r_{t+1} + q_{t+1} - q_t. \tag{14}$$

This equation reflects the absence of arbitrage opportunities in a perfect foresight competitive equilibrium. This *perfect foresight equation* is also called the *portfolio equilibrium condition* because it expresses the absence of arbitrage opportunities in the manner in which the agent's wealth is held. Rearranging this equation yields

$$i_{t+1} = \frac{r_{t+1}}{q_t} + \frac{q_{t+1} - q_t}{q_t}, \tag{15}$$

which says that the one-period interest rate, i_{t+1}, equals the capital good's *own rate of return*, r_{t+1}/q_t, plus the *capital gain yield*, $(q_{t+1} - q_t)/q_t$.

Note that $q_t = 1$ holds in the one-sector model. This is the price of the consumption good in units of the numeraire commodity (chosen to be current consumption) since the capital and consumption goods are identical. Hence, there is no capital gain yield in that case and

$$i_{t+1} = r_{t+1}. \tag{16}$$

The interest rate equals the rental rate for capital goods. Thus, even if there is a single capital good, the portfolio equilibrium condition differs when the one-sector and two-sector models are compared.

Next, consider an aggregate model with an exhaustible resource. Suppose there are neither extraction nor storage costs. The aggregate capital stock at the end of time period t that is available for consumption at time $t+1$ is denoted by k_t and is interpreted as the amount of the resource remaining at the end of time t.

Consumption at time t, ct, represents a withdrawal from the stock k_{t-1}. Then the materials balance condition is $c_t + k_t = k_{t-1}$. The initial size of the resource stock is k. There is no rental return in this model; the resource owner's returns are entirely capital gain yields. The perfect foresight equation takes the form

$$i_{t+1} = \frac{q_{t+1} - q_t}{q_t}. \tag{17}$$

If the rate of interest is a constant: $i_{t+1} = r > 0$, then (17) is a linear difference equation with solution $q_{t+1} = (1+r)^t q_0$, where q_0 is the resource's initial price. This implies *Hotelling's r-per cent rule* (Hotelling, 1931) holds in a perfect foresight equilibrium – the equilibrium (current) price of the resource, q_t, increases over time at rate of interest, r.

In models with several distinct capital goods the portfolio equilibrium condition applies to each capital good separately. If there are m capital goods, then the portfolio equilibrium condition takes the form:

$$i_{t+1} = \frac{r^j_{t+1}}{q^j_t} + \frac{q^j_{t+1} - q^j_t}{q^j_t}, \text{for} j = 1, 2, \ldots, m. \tag{18}$$

Here, the superscript j labels capital good j. With many capital goods households have a variety of options for holding their wealth. The rates of return on any portfolio of capital stocks must be equalized or there will be a one-period reversed arbitrage opportunity. Hence, eq. (18) is the equilibrium condition expressing the absence of such arbitrage opportunities.

The major pricing differences between the one-sector and multisector models concern the form of the portfolio equilibrium condition. It is possible to develop equivalence principles for multisector models along the lines of the one-sector theory by making appropriate adjustments in the pricing of capital goods to reflect their multiplicity in the budget constraints and production sector while also recognizing the portfolio equilibrium form of the no-arbitrage conditions in the PFCE and FCE settings.

Establishing the formal equivalence between optimal accumulation models and their equilibrium counterparts in many capital good models requires the equilibrium economy to impose a transversality condition on itself, just as in the one-sector case. The general question is how is the initial price determined so that the equilibrium price profile satisfies the conditions for achievement of a Ramsey-styled central planning solution. This is the crux of the *Hahn problem*. The modern perfect foresight interpretation is that this problem is solved whenever a transversality condition obtains as necessary for an equilibrium. This requires the household sector to be forward looking over the infinite horizon, and markets to operate on all dates and for all commodities. Some writers on capital theory take a critical view of these conditions and argue that markets cannot be relied on to set the correct initial prices, and so the resulting equilibrium path is inefficient. On the other hand, a comparison of idealized markets with idealized planning, as embodied in the equivalence principles, suggests that at the most theoretical level the Hahn problem is resolved when rational, forward-looking agents conduct their economic activities in a complete market setting over an infinite horizon.

Final Comments

The constraints of the neoclassical one-sector model can be used to substitute for consumption in the felicity function by noting $u(c_t) = u(f(k_{t-1}) - k_t)$, where $c_t \geq 0$ if and only if $f(k_{t-1}) - k_t \geq 0$. The current period's payoff depends only on the stocks of capital at the beginning and end of the period. This observation results in a reformulation of the one-sector model focused on the capital stock sequences. Let $u(0) = 0$ to simplify the exposition. Let $D = \{(x, y) \in \mathbb{R}_+ \times \mathbb{R}_+ : f(x) - y \geq 0\}$. Note that $(0,0) \in D$. The felicity function $v(x, y) \equiv u(f(k_{t-1}) - k_t)$ has domain D and $v(0, 0) = 0$. The properties of u and f imply that v is increasing in its first argument and decreasing in its second argument. The concavity of u and f also imply that v is a concave function defined on the convex set D. The planner continues to discount future utility by the factor δ, $0 < \delta < 1$. This alternative representation of the neoclassical model, called the *reduced form model*, gives rise to an optimal growth problem with the planner choosing the sequence $\{k_t\}_{t=0}^{\infty}$ to achieve

$$\sup_{\{k_t\}_{t=0}^{\infty}} \sum_{t=1}^{\infty} \delta^{t-1} v(k_{t-1}, k_t); (k_{t-1}, k_t) \in D \text{ for each } t, \text{ and } 0 \leq k_0 \leq k. \tag{19}$$

This form of the one-sector model is just one realization of the general reduced form model. A complete exposition of this general structure's properties is found in McKenzie's surveys. The reduced form model can accommodate many varieties of capital theoretic problems including multisector and multi-capital good models, von Neumann's model of economic growth, exhaustible and renewable resource models, as well as individual firm investment theory when there are costs of adjusting the firm's capital stocks. The capital stocks of the one-sector model are replaced by a vector of capital stocks where each component represents a particular capital good; the set D is then contained in a multi-dimensional Euclidean space. Schefold (1997) is a recent treatment of multisector models derived from Sraffa's (1960) perspective on capital accumulation models that also revisits the reswitching controversy in a dynamic equilibrium setting. Also see Burmeister (1980) for a critical exposition of Sraffa's contribution. Burgstaller (1995) reviews models from the Sraffa tradition as well as neoclassical models in continuous time in order to find their common ground and connections to earlier capital theories.

The full scope of capital theoretic problems in deterministic, continuous time can be found in Weitzman (2003). The monograph by Becker and Boyd (1997) addresses the analogous problems in discrete time. Conrad and Clark (1987) covers natural resource models from a dynamic perspective. Stokey et al. (1989) provide an excellent introduction to stochastic dynamic models along with development of the discrete time theory using dynamic programming techniques. Chang (2004) presents basic continuous time stochastic calculus and optimal control theory with economic applications including the classical tree-rotation problem.

Capital Theory (Paradoxes)

Luigi L. Pasinetti and Roberto Scazzieri

Abstract

Capital theory has led economists to discover relationships that look 'paradoxical' or counter-intuitive, as they run counter widely accepted 'parables'. The transformation of microeconomic diminishing returns relations into a macro-social law induced the mistaken belief of an inverse, monotonic relation between the interest rate (and profit rate, taken as the 'price of capital') and the quantity of capital per head. Subsequent work alerted economists to the difficulty of finding aggregate measures of heterogeneous capital goods, and to the possibility that a falling rate of interest (and of profit) may be associated with a decrease not an increase) of the quantity of capital per head.

The idea that capital theory might lead economists to discover forms of 'paradoxical' behaviour emerged in the economic literature of the 1960s largely as an outcome of developments in the field of production theory (linear production models leading to enquiries into discrete and discontinuous relations). What happened in capital theory is in fact a special instance of a more general phenomenon. Economists sometimes tend to examine a large domain of economic phenomena by adapting theoretical concepts that had originally been devised for a much narrower range of special issues. The discoveries of 'paradoxical' relations derive from the fact that their process of generalization often turns out to be ill-conceived and misleading, if not entirely unwarranted.

For a long time, in capital theory it had been taken for granted that there is a unique, unambiguous profitability ranking of production techniques in terms of capital intensity, along the scale of variation of the rate of interest. The discovery that this is not necessarily true has induced many economists to speak of 'paradoxes' in the theory of capital. But the roots of apparently paradoxical behaviour are to be found, not in the economic phenomena themselves, but in the economists' tendency to rely on too simple 'parables' of economic behaviour.

Traditional beliefs about capital are deeply rooted in the history of economic analysis, and may be traced back to pre-classical literature. As will be shown in the next section, a long post-classical tradition was then developed on that basis. The length of ancestry might explain the survival of conventional beliefs.

The Emergence of the Conventional View

The notion of 'capital' was associated for a long time with investible wealth and its income generating power, and was largely independent of detailed consideration of the function of invested wealth in the production process. The earliest development of capital theory took place within the accounting framework of a pre-industrial economy (William Petty, John Locke, Richard Cantillon). Within this perspective, capital was often associated with purely financial transactions (lending and borrowing) and the relationship between capital and rate of interest came quite naturally to be conceived as the relationship between loanable funds and their price (see Cannan 1929, pp. 122–53). The origin of the belief in an inverse monotonic relation between the demand for capital and the rate of interest may be traced back to this phase of the literature. The distinction between capital as a fund of purchasing power and capital as a 'sum of values' embodied in physical assets remained in the background (see Hicks 1977, p. 152), but was bound, in time, to generate tension 'between the physical and financial conceptions of capital' (Cohen and Harcourt 2005, p. xli).

The association of capital with the process of production did not come to the fore until quite late, in spite of certain isolated anticipations. (John Hicks 1973, p. 12, even quotes Boccaccio's

Decameron on the issue.) The description of capital as a stock of means of production became common with the Physiocrats and the classical economists. In this period, Cesare Beccaria (1804, ms 1771–72) presented what Jean-Baptiste Say considered to be the first analysis of 'the true functions of productive capitals' (Say 1817, p. xliii). Soon after him, Adam Smith (1776) built upon the distinction between 'productive' capital and 'unproductive' consumption his theory of structural dynamics and economic growth. Finally, David Ricardo gave a definite shape to classical capital theory by examining the relationship between capital accumulation and diminishing returns and by considering in which way different proportions of capital in different industries might influence the relative exchange values of the corresponding commodities (Ricardo 1817, ch. 1, sections 4 and 5).

Classical capital theory is characterized by lack of interest in the purely financial dimension of investment. As a result, the relation between capital accumulation and the rate of interest recedes into the background and is substituted by the relation between real capital accumulation and the rate of profit. In this way, the foundations of capital theory shifted from the exchange to the production sphere, and the demand-and-supply mechanism was confined to the process by which the rate of interest is maintained equal to the rate of profit in the long run. However, a number of economists (starting with Johann Heinrich von Thünen, Mountifort Longfield and Nassau William Senior) continued to be interested in the income-generating function of capital at the level of the individual investor, and tried to combine this approach with the emphasis on the productive function of capital that had emerged in the classical literature. The marginal productivity theory of capital and interest was developed as an answer to this conceptual problem. The essential features of that theory may be clearly seen in Thünen, who suggested a relationship between the rate of interest (i) and the rate of profit (r) quite different from the one found in Ricardo. The reason for this is that Ricardo had taken r to be fixed for the individual entrepreneur, so that equality between i and r was brought about by adjustment between the supply and demand for loans in the financial markets. Thünen suggested a different adjustment mechanism by taking r to be variable for the individual entrepreneur, so that the attainment of the long-run equality between the rate of profit and the rate of interest came to depend on the change in the physical productivity of capital as much as on adjustment in the financial markets (see Thünen 1857).

This view is founded upon a thorough transformation of the Ricardian theory of diminishing returns and provided the logical starting point for the later marginalist theory of diminishing returns from aggregate capital. The analytical and historical process leading to this outcome is a rather complex one, and it is best understood by distinguishing two separate stages. In the first stage, the law of diminishing returns, which Ricardo considered to hold for the economy as a whole in the long run, was applied to the short-run behaviour of the individual entrepreneur. As result, the change in input proportions within any given productive unit is associated with the change in the physical productivity of capital. Here the variation of the capital stock is unlikely to influence the system of prices, so that the decrease (or increase) in the return from the last 'increment of capital' could be unambiguously associated with an increase (or decrease) in the physical capital stock. The second stage consisted in extending the above result to the variations in the aggregate quantity of capital available in the economic system as a whole.

The process which we have described made it possible to transform the classical conception of diminishing returns from a macro-social law into a microeconomic relation derived from the law of variable proportions. This new type of diminishing returns was then extended to the 'macro-social' sphere once again. As a result, it became possible to think that the rate of interest and the rate of profit (tending to be equal to each other) are associated with the physical marginal productivity of aggregate capital: an increase in the relative quantity of capital with respect to the other inputs would be associated with lower marginal productivity of capital and thus with a lower equilibrium rate of interest and rate of profit. This

inverse monotonic relation between the rate of interest (and the rate of profit) and the quantity of capital per head eventually became an established proposition of capital theory. The relevance of this relation can be seen from the attempts by William Stanley Jevons (1871), Eugen von Böhm-Bawerk (1889) and John Bates Clark (1899) to found on the theory of the marginal productivity of factors the explanation of the distribution of the social product among factors of production under competitive conditions.

Further light on the conceptual roots of the marginalist view of capital is shed by the contributions of Jevons and Böhm-Bawerk. In their theories, profit is considered as the remuneration due to the capitalist as a result of the higher productiveness of 'indirect' or 'roundabout' processes of production than of processes carried out by 'direct' labour only. The generalization of the marginal principles which they carried out is thus associated with the description of the production process as an essentially 'financial' phenomenon in which final output, like interest in financial transactions, could be considered as 'some continuous function of the time elapsing between the expenditure of the labour and the enjoyment of the result' (Jevons 1879, p. 266). The subsequent discovery of 'anomalies' in the field of capital accumulation was possible when economists started to question this extension of capital theory from the financial to the productive sphere, and when the technical structure of production was examined on its own grounds independently of the 'financial' aspect which might be considered to be characteristic of 'the typical business man's viewpoint' (Hicks 1973, p. 12).

Anticipations of Debate

It has just been shown that microeconomic diminishing returns provided the foundations for a theory of the diminishing marginal productivity of social capital, which was extended from the microeconomic sphere by way of logical analogy.

The pitfalls of this approach did not take long to emerge, as economic analysis came to grips with the full complexity of the production process. Knut Wicksell, discovered that, in the case of an economic system using heterogeneous capital goods, it might be impossible to describe diminishing returns from aggregate capital. The reason for this is that a variation in the capital stock might be associated with a change in the price system that would make it impossible to compare the quantities of capital before and after the change (see Wicksell 1901–6, pp. 147 ff. and 180). Wicksell also recognized that this difficulty is characteristic of capital because 'labour and land are measured each in terms of its own *technical* unit … capital, on the other hand, … is reckoned, in common parlance, as a sum of *exchange value'* (1901–6, p. 149).

The special difficulty associated with heterogeneous capital goods is in fact an outcome of a particular procedure by which the fundamental theorems concerning capital and interest had been formulated with reference to the idealized setting of an isolated producer, and then extended by analogy to the case of the 'social economy'. The drawbacks of this methodology were perspicaciously noted by Nicholas Kaldor in the late 1930s, when he complained that capital theory had been developed starting with 'a … specialised set-up, with the picture of Robinson Crusoe engaged in net-making' rather than with the 'general case' of 'a society where *all* resources are produced and the services of all resources co-operate in producing further resources' (Kaldor 1937, p. 228.) Kaldor also noted that, had the analysis started with the 'general case', 'a great deal of the controversies concerning the theory of capital might not have arisen' (Kaldor 1937, p. 228).

It is remarkable that so many 'paradoxical' results of modern capital theory were subsequently discovered precisely as an outcome of the procedure here described by Kaldor.

The stage of modern controversy was set by the consideration of two distinct problems: (*a*) the measurement of 'aggregate capital' in models with heterogeneous capital goods; and (*b*) the discovery that production techniques that had been excluded at lower levels of the rate of profit might 'come back' as the rate of profit is increased (this phenomenon is known as *reswitching of technique*).

Joan Robinson started the discussion by calling attention to the difficulties inherent in any physical measure of aggregate capital (Robinson 1953–4). She also pointed out the 'curiosum' that the degree of mechanization associated with a higher wage rate and a lower rate of profit might be lower than the degree of mechanization associated with a lower wage rate and a higher rate of profit. (She attributed this 'curiosum' to Miss Ruth Cohen, but later on she attributed it to her reading of Sraffa's Introduction to Ricardo's *Principles*.)

Immediately afterwards, David Champernowne discovered that, in general, we must admit 'the possibility of two stationary states each using the same items of equipment and labour force yet being shown as using different quantities of capital, merely on account of having different rates of interest and of food-wages' (Champernowne 1953–4, p. 119). Champernowne also admitted that the inverse monotonic relation between the rate of profit and the quantity of capital per head (as well as the inverse monotonic relation between the rate of profit and capital per unit of output) might not be generally true: 'it is logically possible that over certain ranges of the rate of interest, a fall in interest rates and rise in food-wages will be accompanied by a *fall* in output per head and a *fall* in the quantity of capital per head' (Champernowne 1953–4, p. 118). Champernowne's explanation of what appeared to be perverse behaviour from the point of view of traditional theory was that changes in the interest rate can be associated with changes in the cost of capital equipment even if the physical capital stock is unchanged. As a result, perverse behaviour was attributed to pure 'financial' variations and a physical measure of capital was still thought to be possible. This Champernowne tried to obtain by introducing a chain index method for measuring capital (Champernowne 1953–4, p. 125). A few years later, Joan Robinson again took up the same issue in her *Accumulation of Capital* (1956, pp. 109–10). The reason she gave for the 'Ruth Cohen curiosum' is quite different from the one proposed by Champernowne. She explicitly recognized that 'financial' factors such as a higher wage rate and a lower rate of interest would have 'real' consequences by influencing the actual choice of technique. (In the 'perverse' case a lower rate of interest would be associated with the choice of the less mechanized technique.)

When a few years later Michio Morishima attempted a multi-sectoral generalization of Joan Robinson's simple model he confirmed the possibility of a positive relationship between the rate of interest and the degree of mechanization of a technique (Morishima 1964, p. 126). Finally John Hicks came up with the same problem when examining 'the response of technique to price changes' in the framework of a simple economy consisting of a consumption good 'industry' and a net investment good 'industry', and in which the same capital good is used in both industries (see Hicks 1965, pp. 148–56).

But, in spite of all these anticipations, it must be admitted that the issue of technical reswitching was not given an important place in economic theory before the publication of Piero Sraffa's *Production of Commodities by Means of Commodities* (1960). It is with Sraffa's work that the phenomenon took a prominent place. Sraffa was able to show that heterogeneity of capital goods and of 'capital structures' (different proportions between labour and intermediate inputs in the various processes of production) would normally give rise, with the variation of the rate of profit and of the unit wage, 'to complicated patterns of price-movement with several ups and down' (Sraffa 1960, p. 37). This phenomenon would in turn bring about changes in the 'quantity of capital' that are not generally related to the rate of profit in a monotonic way. Reswitching of technique and reverse capital deepening are thus derived from a general property of production models with heterogeneous capital goods. (See reswitching of technique and reverse capital deepening.)

Neoclassical Parables and the Capital Controversy

Following the publication of Sraffa's book, a lively debate on capital theory suddenly flared up in the 1960s, and the way it did is itself an interesting event.

It has already been pointed out that, when propositions derived from individual behaviour are applied to the more complex case of the 'social economy', the extension is admittedly possible on condition that the social economy has a number of special features making it identical, from the analytical point of view, to the case of the isolated individual. To test these features, the social economy is often described in terms of a 'parable' in which those particular conditions are satisfied. This 'parable', though unrealistic, is taken to be useful, from an heuristic or a persuasive point of view.

In this vein Paul Samuelson attempted to construct a 'surrogate production function' by analogy with microeconomic behaviour (Samuelson 1962). His work can be considered as the first explicit attempt to get rid of the complexities of an economic system with heterogeneous capital goods by constructing a model in which that system is described in terms of an 'aggregate parable' with physically homogeneous capital. After introducing the assumption that 'the same proportion of inputs is used in the consumption-goods and [capital-] goods industries' (Samuelson 1962, pp. 196–7), Samuelson was able to prove that 'the Surrogate (Homogeneous) Capital ... gives exactly the same result as does the shifting collection of diverse capital goods in our more realistic model' (1962, p. 201). In particular, 'the relations among w, r, and Q/L that prevail for [the] quasi-realistic complete system of heterogeneous capital goods' could 'be shown to have the same formal properties as does the parable system' (1962, p. 203). This result was taken to be a justification for using the surrogate production function 'as a useful summarizing device' (1962, p. 203). In fact, Pierangelo Garegnani, who was present at a discussion of a draft of Samuelson's paper, did point out that Samuelson's result is crucially dependent on the assumption of equal proportions of inputs (see Garegnani 1970). Samuelson acknowledged Garegnani's criticism in a footnote to his paper and admitted that it would be a 'false conjecture' to think that the 'extreme assumption of equi-proportional inputs in the consumption and machine trades could be lightened and still leave one with many of the surrogate propositions' (Samuelson 1962, p. 202n). But Samuelson and various other economists continued to look for conditions that would ensure a monotonic relation between the rate of profit and the choice of technique even in presence of a nonlinear relation between w and r.

The outcome appeared a few years later. David Levhari, a Ph.D. student of Samuelson's, in his dissertation and then in a paper for the *Quarterly Journal of Economics,* claimed he had proved that reswitching of the whole production matrix would be impossible if this matrix is of the 'irreducible' or 'indecomposable' type (Levhari 1965). This property – Levhari claimed – would exclude reswitching and thus make it possible to extend the use of a 'surrogate production function' to the nonlinear case with production technologies for basic commodities.

However, Levhari's theorem was disproved by Luigi Pasinetti in a paper at the Rome First World Congress of the Econometric Society in 1965. Pasinetti's final draft of his paper was published in the November 1966 issue of the *Quarterly Journal of Economics* (Pasinetti 1966) together with papers written in the meantime by David Levhari and Paul Samuelson (1966), Paul Samuelson (1966), Michio Morishima (1966), Michael Bruno et al. (1966) and Pierangelo Garegnani (1966). This set of papers was called by the journal editor 'Paradoxes in Capital Theory: A Symposium', thereby originating the term. Paul Samuelson concluded the discussion with a 'Summing up' in which he admitted that 'the simple tale told by Jevons, Böhm-Bawerk, Wicksell, and other neoclassical writers', according to which a falling rate of interest is unambiguously associated with the choice of more capital-intensive techniques, 'cannot be universally valid' (Samuelson 1966, p. 568).

The various contributions to this discussion showed that reswitching might occur both with 'decomposable' and 'indecomposable' technology matrices. This result was proved in different ways by Pasinetti (1965, 1966), Morishima (1966), Bruno et al. (1966) and Garegnani (1966). Samuelson stated in his summing up that 'reswitching is a logical possibility in any technology, indecomposable or decomposable' (1966,

p. 582). He then called attention to the associated phenomenon of reverse capital deepening and concluded that 'there often turns out to be no unambiguous way of characterizing different processes as more "capital-intensive", more "mechanized", more "roundabout"' (1966, p. 582).

Although the logical possibility of reswitching was admitted by all participants in the discussion, Bruno, Burmeister and Sheshinski raised doubts as to its empirical relevance: 'there is an open empirical question as to whether or not reswitching is likely to be observed in an actual economy for reasonable changes in the interest rate' (Bruno et al. 1966, p. 545n). The same doubt was expressed in Samuelson's summing up (Samuelson 1966, p. 582). Bruno, Burmeister and Sheshinski also mentioned a theorem, which they attributed to Martin Weitzman and Robert Solow, according to which reswitching of technique may be excluded, in a model with heterogeneous capital goods, provided at least one capital good is produced by 'a smooth neoclassical production function', if 'labour and each good are inputs in one or more of the goods produced neoclassically' (Bruno et al. 1966, p. 546). This theorem is based on the idea that 'setting the various marginal productivity conditions and supposing that at two different rates of interest the same set of input–output coefficients holds, the proof follows by contradiction' (Bruno et al. 1966, p. 546).

It is worth noting that Weitzman–Solow's theorem is simply a consequence of the idea that, in the case of a commodity produced by a neoclassical production function, each set of input–output coefficients ought to be associated in equilibrium with a one-to-one correspondence between marginal productivity ratios and input price ratios. No ratio between marginal productivities would be associated with more than one set of input prices, and this is taken to exclude the possibility that the same technique be chosen at alternative rates of interest, and thus at different price systems. The Weitzman–Solow theorem is at the origin of a line of arguments that has been followed up by a number of other authors, such as David Starrett (1969) and Joseph Stiglitz (1973). These authors have pursued the idea that 'enough' substitutability, by ensuring the smoothness of the production function, is sufficient to exclude reswitching of technique. However, non-reswitching theorems of this type involve that, for each technique of production, the capital stock may be measured either in physical terms or at given prices. For in a model with heterogeneous capital goods, if we allow prices to vary when the rate of interest or the unit wage are changed, there is no reason why the same physical set of input–output coefficients might not be associated with different price systems: even in the case of a continuously differentiable production function, the marginal product of 'social' capital cannot be a purely real magnitude independent of prices. Once it is admitted that 'in general marginal products are in terms of net value at constant prices, and hence may well depend upon what those prices happen to be' (Bliss 1975, p. 195), it is natural to allow for different marginal productivities of the same capital stock at different price systems. It would thus appear that reswitching of technique does not carry with it any logical contradiction even in the case of a smoothly differentiable production function.

But Pasinetti also pointed out that the concept of neoclassical substitutability is itself a very restrictive concept indeed, as it requires the possibility of infinitesimal variations of each input at a time. In fact, Pasinetti noted that it is possible to have a continuous variation of techniques (that is, continuous substitutability) along the w–r relation and yet wide discontinuities in the variation of many inputs between one technique and another, thus making reswitching a quite normal phenomenon (see Pasinetti 1969). Moreover, and even more significantly, a non-monotonic relation between the rate of profit and capital per man may well be obtained even in the absence of reswitching (Pasinetti 1966; Bruno et al. 1966). This last possibility calls attention to the phenomenon that lies at the root of the various 'paradoxes' in the theory of capital: the fact that, unless special assumptions are made, a change in the rate of profit and in the unit wage at given technical coefficients is associated with a change of relative prices.

This debate continued for a few years in the late 1960s and early 1970s, with a series of journal

articles (see for example Robinson and Naqvi 1967) and books (see for example Harcourt 1972). In particular, John Hicks presented a 'Neo-Austrian' model in *Capital and Time* (1973), concluding that reswitching of technique can be excluded only in the special case in which all the techniques have the same 'duration parameters', which means the same 'construction period' and 'utilization period' (1973, pp. 41–4).

In the end, numerous details were added. Yet the basic essential results remained those that had come out of Sraffa's book and of the symposium on 'Paradoxes in Capital Theory'. It is instructive to see that, in a recent exchange of views that has appeared in the *Journal of Economic Perspectives* (2003, Spring and Winter issues), Franklin Fisher (2003), Geoff Harcourt in Cohen and Harcourt (2003) and Luigi Pasinetti (2003), when asked to succinctly summarize the issues at stake, have essentially restated their original positions.

Aftermath and Ways Ahead

The discovery of paradoxes in capital theory has had a number of important repercussions, mostly beyond its original context. For it stimulated a large amount of analytical and empirical research on some of the issues that had been discussed in the controversy, without pressing the attention towards the fundamentals, as had been the case with the original debates. In many instances, the recent developments have been motivated by the need to face the problem of measuring the stock of capital goods in economic systems subject to advances of technical knowledge and structural change, or some of the associated issues in the theory of economic dynamics. In this section we shall refer to some of these developments without pretending to give a complete picture, but with the purpose of identifying the main lines of inquiry.

A first area of research has been the analysis of the necessary conditions for the empirical measurement of aggregate capital. Franklin Fisher elaborated a research line he had himself started in an earlier contribution (Fisher 1969) and called attention to the fact that the aggregation of outputs, as well as that of productive factors, 'requires separability in each firm's production function' (Fisher 1987, p. 55). He also noted that, under constant returns, the two highly restrictive assumptions of no specialization and generalized capital augmentation are necessary, whereas, in most cases of non-constant returns, aggregation would not be allowed even when assuming the same production function for all firms (Fisher 1987, p. 55). Robert Gordon proposed to measure collections of heterogeneous capital goods, under condition of embodied technical change, by considering the associated 'net revenue at a given set of prices (w) of variable inputs' (Gordon 1993, p. 106; see also Gordon 1990). Edward Denison did find Gordon's proposal objectionable and proposed instead to 'equate' new capital goods with the old ones by 'what their relative costs *would* be if both *were* produced at a common date' (Denison 1993, pp. 89–90). An interesting link between this literature and the capital controversy debate has been suggested by Charles Hulton, who has called attention to the advantages of a 'recursive description of the production possibility set', in which the assumption of capital as an original input is dropped, and 'capital and labour are assumed to produce gross output *and* capital which is one period older' (Hulten 1992, p. S15). Hulten's formulation highlights the central role of knowledge advances embodied in new capital goods and suggests the relevance, for distinct purposes, of gross outputs and net outputs 'as indicators of capacity and economic welfare' (Hulten 1992, p. S11). Alexandra Cas and Thomas Rymes have specifically addressed the issue of whether 'knowledge of the constant-price aggregate stock of capital would, *for the comparison of economies,* permit one to "predict" certain variables' (Cas and Rymes 1991, p. 7; emphasis added). In particular, they investigated capital measurement issues brought about by embodied technical change, and proposed a set of 'new measures' aimed at taking the fact into account that 'the net capital stocks of each industry and at the aggregate are themselves being produced with increased efficiency when the capital goods industries are experiencing advances in technical knowledge' (Cas and Rymes 1991, p. 67). The same authors

relate their measures of changing capital stocks under conditions of structural change to 'Pasinetti's concepts of vertically integrated sectors and productivity aggregated by end use' (Cas and Rymes 1991, pp. 90–1). This point of view highlights the common ground behind recent attempts to measure stocks of heterogeneous capital goods in terms of an aggregate concept of productive capacity, be it Pasinetti's 'unit of vertically integrated productive capacity' (Pasinetti 1973, 1981), Cas and Rymes' 'new measures of multifactor productivity' (Cas and Rymes 1991), or Hulten's 'accounting for capacity' (Hulten 1992). In all these cases, the producibility of capital goods is emphasized, as is the close connection between advances of technical knowledge and the reshuffling of inter-industry relationships (particularly those affecting intermediate goods). Philippe Aghion and Peter Howitt have commented on recent discussions about capital measurement for an economy subject to advances of knowledge by recalling Joan Robinson's view that the real issue is not so much about the measurement of capital as rather about the *meaning* one wishes to assign to any given collection of capital goods (Aghion and Howitt 1998, p. 435).

Another line of investigation has concerned the attempt to assess the empirical (or computational) relevance of capital paradoxes, as distinct from their theoretical possibility. In this connection, Stefano Zambelli has used computer simulations in order to investigate the 'realism' of capital paradoxes in artificial economies (Zambelli 2004). This author has found a significantly higher likelihood that the capital–labour ratio be *positively* related to the rate of profit, contrary to the conventional belief of a negative relationship between these two variables. This result is consistent with the empirical investigation carried out by Zonghie Han and Bertram Schefold (2006). These authors have compared pairs of techniques from the OECD input–output database, and have found that 'observed cases of reswitching and reverse capital deepening are more than flukes' (Han and Schefold 2006, p. 22), even if we are far from observing what has been called an 'avalanche of switchpoints' (Schefold 1997, pp. 278–80).

A third line of research has carried the discussion of capital paradoxes into the field of dynamic economic theory. The literature relevant in this connection is itself quite differentiated. For example, Frank Hahn (1966) called attention to his earlier discovery of zones of instability in economies with heterogeneous capital goods, and pointed out that reswitching should be considered as one amongst the multiple causes of instability in capital markets (Hahn 1982). It is interesting that this line of argument, while maintaining that reswitching is a special case of a larger class of phenomena, at the same time and rather surprisingly also makes reswitching to be *more general* than was the case with earlier treatments of the same phenomenon. For capital paradoxes are no longer mainly associated with an economy with heterogeneous capital goods and a uniform rate of profit, but are ' extended' to the case of multisectoral economies with many different capital goods and a *multiplicity* of rates of interest (and rates of profit). Luigi Pasinetti followed a different approach, and examined the analytical features of a dynamic economy in which market interactions are not explicitly examined (Pasinetti 1981). In this case, too, there are reasons to think that reswitching and reverse capital deepening would not represent exceptional cases, and would not be limited to the institutional framework of a perfectly competitive economy. Other authors have examined the relationship between capital paradoxes and dynamic stability, and have argued that reswitching of technique and reverse capital deepening are neither necessary nor sufficient conditions for the economic system to show *lack* of stability and irregular behaviour (Mandler 2005). It has also been emphasized that 'reswitching' adds an important element of instability, the importance of which depends on the process of adaptation, but also on the utility function' (Schefold 2005, p. 467).

More generally, the discovery of capital paradoxes has stimulated a deeper understanding of the features of continuity and discontinuity in the dynamics of economic systems. This line of research has its point of departure in a phenomenon detected by Luigi Pasinetti shortly after the climax of the controversy (Pasinetti 1969). In

Pasinetti's more recent words, 'the vicinity, even the infinitesimal vicinity, of any two techniques on the scale of variation of the rate of profits does not entail at all vicinity of such techniques ... discontinuities in input use.' (Pasinetti 2000, p. 409). John Barkley Rosser Jr. has picked up such suggestions and has investigated the discontinuities in order to identify the implications of capital paradoxes for the analysis of the optimal dynamic path followed by an economy characterized by 'an infinite, differentiable technology' (Rosser 1983, p. 182). This author acknowledges that it may sometimes be impossible to directly observe reswitching along optimal adjustment path (as maintained, for example in Burmeister and Hammond 1977), but he notes that this would only happen 'at the price of dynamic discontinuities', that is, on the condition that the economic system be able to 'jump over' the zone associated with intermediate techniques. The above result has been interpreted as showing that 'in a world of infinite and smooth technologies, reswitching is to be "observed" by observing discontinuities in optimal dynamic paths' (Rosser 1983, p. 183; see also Rosser 2000, pp. 213–20). This point of view emphasizes the analytical importance of capital paradoxes as characteristic instances of the discontinuities that may be generated by the nonlinearity of certain structural relationships. In this way, the propositions discovered during the capital controversies of the mid-20th century are found to be consilient with much later developments in the economic analysis of nonlinear dynamic systems.

Synthesis

The source of most of the difficulties that have emerged in capital theory may be traced back to the fact that 'capital' may be conceived in two fundamentally different ways: (a) as a 'free' fund of resources, which can be switched from one use to another, without any significant difficulty: this is what may be called the 'financial' conception of capital; (b) as a set of productive factors that are embodied in the production process as it is carried out in a particular productive establishment: this is what may be called the 'technical' conception of capital.

The idea that there exists an inverse monotonic relation between the rate of interest and the demand for capital was born in the financial sphere. The parallel idea of an inverse monotonic relation between the rate of profit and the 'quantity of capital' employed in the production process is the outcome of a long intellectual process of extensions and generalizations reviewed earlier in this essay. But the recent debate on capital theory has conclusively proved that such extensions and generalizations are devoid of any foundation. It is logically impossible to make the 'financial' and the 'technical' conceptions of capital coincide, except under very restrictive conditions indeed. More precisely, there is no unambiguous way in which a decreasing rate of profit may be related to the choice of alternative techniques, in terms of monotonically increasing capital intensity, be this considered in terms of capital per unit of output or of capital per unit of labour.

These analytical results are hardly in dispute by now. But their ultimate significance and relevance for economic theory have been, and remain, controversial.

A group of economists have been so impressed by the new discoveries in capital theory, concerning the relations between rate of profit, capital per head, capital per output, and technical progress, as to become convinced that these discoveries are calling for a reconstruction of economic theory from its very foundations. It is stressed that the traditional beliefs are due to mistaken generalizations from the theory of short-run microeconomic behaviour, and it is argued that the economic theory ('marginal economic theory') that led to mistakes and inconsistencies should be abandoned. It is also pointed out that the obvious alternative is a resumption and development of the more comprehensive approach to value, distribution and growth of the classical economists (see Garegnani 1970, 2005, and, in a different context, Pasinetti 1981).

A second line of interpretation maintains that economic theorists should be prepared to give up the analytical tools of equilibrium analysis and

concentrate much more on the actual historical dynamics of economic systems. In this vein, reswitching of technique is acknowledged as a logical possibility but doubts are expressed on its importance in actual economic history (see Robinson 1975, pp. 38–9; Hicks 1979, p. 57).

A third line of interpretation is taken by more traditionally minded theoretical economists. It is argued that the discovery of 'anomalies' in the field of capital theory does point to an important deficiency in 'marginal' economic theory, which leads to the inevitable abandonment of the concept of 'aggregate capital'. However, it is also argued that there is a way of overcoming this deficiency without giving up the basic premises of traditional theory, and in particular without rejecting the application of the demand-and-supply framework to the study of production. This way induces to concentrating the analysis either on the study of 'short-run' ('temporary') equilibria, in which the physical stocks of capital are given, or on the equilibrium of an intertemporal economy, in which goods are described by taking their dates of delivery into account. In either case, the logical possibility (or 'existence') of an equilibrium price vector is studied without explicitly considering the movement of 'free' capital from one use to another. In this approach, the importance of 'capital paradoxes' is explicitly recognized, but the associated difficulties are transferred either to the field of stability analysis or to the theory of the long-period supply of saving as financial capital (see, respectively, Hahn 1982; Bliss 2005).

A fourth line of interpretation has been pursued by many empirically oriented economists. It is acknowledged that the notion of 'aggregate' technical capital is untenable in terms of theory, but it is also argued that the utilization of aggregate production functions may be justified on pragmatic terms, due to supposedly satisfactory econometric fit (see, for example, Fisher 1971; Fisher et al. 1977). This view however, is by no means widely accepted. It has in fact been vigorously challenged by Paolo Sylos Labini (1995), who has reviewed the estimates that have emerged from using the Cobb–Douglas production function and has shown that such a 'production function, when estimated econometrically, tends to yield, in general, poor results' (Felipe and Fisher 2003, p. 251; see also McCombie 1998; and Felipe and Adams 2005). In a recent evaluative essay on aggregation in production functions, Jesus Felipe and Franklin Fisher have sharply criticized the continued use of aggregate parables. In particular, they maintain that 'the revival of growth theory during the last two decades no doubt has produced important discussions, and seemingly interesting empirical results' but ' authors do not realize that they are using a tool whose lack of legitimacy was demonstrated decades ago' (Felipe and Fisher 2003, pp. 250–1). The same economists emphasize that 'the impossibility of testing empirically the aggregate production function' is 'substantially more serious than a mere anomaly', and that 'macroeconomists should pause before continuing to do applied work with no sound foundation and dedicate some time to studying other approaches to value, distribution, employment, growth, technical progress etc., in order to understand which questions can legitimately be posed to the empirical aggregate data' (Felipe and Fisher 2003, pp. 256–7). It is interesting that the theoretical and empirical researches that have taken up this challenge have devoted attention to the construction of a 'capacity measure' of the stock of technical capital that would allow comparisons across different states of technology without having recourse to the traditional 'parables' (see, for example, Pasinetti 1973, 1981; Cas and Rymes 1991; Hulten 1992).

Finally, let us note how the discovery of 'paradoxes' in capital theory has contributed to stimulating research into the dynamic properties of economic systems outside the world of steady state comparisons. In particular, some economists have attempted the theoretical investigation of regularities in the long-run dynamics of economic systems by suggesting a reformulation of the classical theory of structural change in a disaggregated framework (see Pasinetti 1981, 1993; Hagemann et al. 2003). Others have investigated the complex interaction of behavioural patterns along a dynamic trajectory, and have called attention to increasing returns and other

nonlinear phenomena in structurally adaptive economic systems (see Anderson et al. 1988; Arthur et al. 1997).

Whatever the view that is taken, the major victim of the debate has been the Böhm-Bawerk–Clark–Wicksell theory of capital that was so patiently constructed towards the end of the 19th century. This theory relied on a conception of 'aggregate capital' that was taken as measurable independently of the rate of profit and of income distribution. Such a conception of 'capital' has had to be jettisoned, which has stimulated reformulations of the pure theory of capital. There has been on the one hand a return to the Walrasian general equilibrium theory in its intertemporal formulation, and on the other hand a remarkable revival of classical political economy. The controversy had also a number of less striking but perhaps longer-term consequences. The consideration of paradoxes has alerted economists to the richness and complexity of economic relationships, and to the need to avoid a process of generalization from the consideration of special cases. In any case the debate seems to have compelled theoretical economists to be more rigorous about the nature and limits of their assumptions. In many important cases, it has also brought about a change in the main focus of their analysis.

All this leads one reasonably to expect as unlikely that the next generation of economists will leave the issue of capital theory at rest.

Capital Theory: Debates

Heinz D. Kurz

Capital theory is notorious for being perhaps the most controversial area in economics. This has been so ever since the very inception of systematic economic analysis. Much of the interest in the theory of capital lies in the fact that it holds the key to the explanation of profits. Since the notion of 'capital' is at the centre of an inquiry into the laws of production and distribution in a capitalist economy, controversies in the theory of capital are reflected in virtually all other parts of economic analysis.

We can distinguish between debates *within* different traditions of economic analysis and debates *between* them. In what follows our concern will be mainly with the latter. At the cost of severe simplification, the various traditions in the theory of capital and distribution may be divided into two principal groups, one rooted in the surplus approach of the classical economists from Adam Smith to Ricardo and the other in the demand and supply approach of the early marginalist economists. The so-called 'Cambridge controversies' (cf. Harcourt 1969), triggered off by a seminal paper by Joan Robinson (1953), consisted essentially in a confrontation of these two radically different traditions. The debate is still continuing. Currently, the discussion focuses on some of the neoclassical authors' claim that the classical theory, as it was reformulated by Sraffa (1960), is a 'special case' of modern general equilibrium theory. We shall come back to this questionable proposition towards the end of the entry.

The Surplus Approach

The general method underlying the classical economists' approach to the theory of capital and distribution was that of 'normal' or 'long-period' positions. These were conceived as centres around which the economy is assumed to gravitate, given the competitive tendency towards a uniform rate of profit. Because of the assumed gravitation of 'market values' to the 'normal' levels of the distributive and price variables, the former were given little attention only, being governed by temporary and accidental causes, a proper scientific analysis of which was considered neither necessary nor possible. Emphasis was on the persistent or non-temporary causes shaping the economy. Accordingly, the investigation of the permanent effects of changes in the dominant causes was carried out by means of comparisons between 'normal' positions of the economic system.

The development of a satisfactory theory to determine the general rate of profit was thus the

main concern of the classical economists. As regards the content of this theory, profits were explained in terms of the *surplus product* left after making allowance for the requirements of reproduction, which were conceived inclusive of the wages of labour (Ricardo 1817, vol. 1, p. 95). As Sraffa (1951, 1960) emphasized, the determination of the social surplus implied taking as data (i) the system of production in use, characterized, as it is, by the dominant technical conditions of production of the various commodities and the size and composition of the social product; and (ii) the ruling real wage rate(s). In accordance with the underlying 'normal' position the capital stock was assumed to be so adjusted to 'effectual demand' (Adam Smith) that a normal rate of utilization of its component parts would be realized and a uniform rate of return on its supply price obtained. Thus the classical authors separated the determination of profits and prices from that of quantities. The latter were considered as determined in another part of the theory i.e. the analysis of accumulation and economic and social development.

The rate of profit was defined by the ratio between social surplus and social capital, i.e. two aggregates of heterogeneous commodities. Thus the classical theory had to face the problem of value. Ricardo's ingenious device to solve this problem consisted in relating the exchange values of the commodities to the quantities of labour directly and indirectly necessary to produce them. This led to the first formulation of one of the key concepts in the theory of capital ever since – the inverse relationship between the real wage and the rate of profit (Ricardo, vol. 8, p. 194).

It was not until Marx that additional important steps in the development of the surplus approach were taken. In particular, in Marx the analytical role of the 'labour theory of value' in the determination of the general rate of profit was brought into sharp relief. According to him the explanation of profits in terms of the surplus approach would have been trapped in circular reasoning if the value expression of either aggregate (surplus and capital) were to depend on the rate of profit. The measurement of both aggregates in terms of labour values, which themselves were seen to be independent of distribution, was considered a device to circumvent this danger and provide a non-circular determination of the rate of profit, $r = s/(c + v)$, where r is the general rate of profit, s the 'surplus value', c the value of the means of production or 'constant capital', and v the wages advanced or 'variable capital'. A central message of Marx's *Capital* reads that the rate of profit is positive if and only if there is 'exploitation of workers', i.e. there is a positive 'surplus value'.

In Marx's opinion it was only after the rate of profit had been determined that the problem of normal prices, or 'prices of production' as he called them, could be tackled. Marx dealt with it in terms of a multisectoral analysis of the production of commodities by means of commodities; the deviations of relative prices from labour values are systematically traced back to sectoral differences in the 'organic composition of capital', i.e. the proportion of 'constant' to 'variable' capital (cf. the so-called 'transformation' of values into prices of production; Marx 1959, Part II).

Yet Marx did not fully succeed in overcoming the analytical difficulties encountered by the classical economists in the theory of capital and distribution. He was particularly wrong in assuming that the determination of the rate of profit is logically prior to that of normal prices. Given the system of production and the real wage the rate of profit and prices can be determined only simultaneously. This was first demonstrated by Bortkiewicz (1907). For a rigorous and comprehensive formulation of the classical surplus approach see Sraffa (1960), whose contribution will be dealt with in more detail below.

The Neoclassical Approach

The abandonment of the classical approach and the development of a radically different theory, which came to predominance in the wake of the so-called 'marginalist revolution' in the latter part of the 19th century, was motivated (apart from ideological reasons ever present in debates in capital theory) by the deficiencies of the received (labour) theory of value. Since the new theory was to be an alternative to the classical theory, it

had to be an alternative theory about the same thing, in particular the normal rate of profit. Consequently, the early neoclassical economists, including, for example, Jevons (1871), Walras (1874), Böhm-Bawerk (1889), Wicksell (1893, 1901), and Clark (1899), adopted fundamentally the same method of analysis: the concept of 'long-period equilibrium' is the neoclassical adaptation of the classical concept of normal positions.

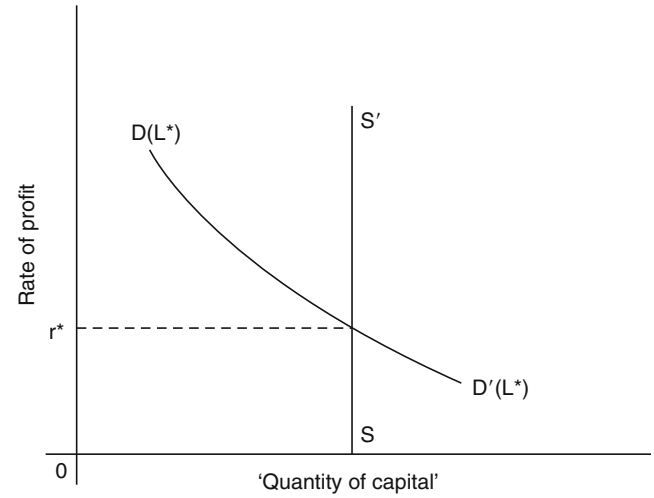
The basic novelty of the new theory consisted in the following. While the surplus approach conceived the real wage as determined *prior* to profits (and rent), in the neoclassical approach all kinds of incomes were explained simultaneously and *symmetrically* in terms of the 'opposing forces' of supply and demand in regard to the services of the respective 'factors of production', labour and 'capital' (and land). It was the seemingly coherent foundation of these notions in terms of *functional* relationships between the price of a service (or good) and the quantity supplied or demanded elaborated by the neoclassical theory that greatly contributed to the latter's success.

As regards the supply side of the neoclassical treatment of capital, careful scrutiny shows that its advocates, with the notable exception of Walras (at least until the fourth edition of the *Eléments*), were well aware of the fact that in order to be consistent with the concept of a long-period equilibrium the capital equipment of the economy could not be conceived as a set of given physical amounts of produced means of production. The 'quantity of capital' in given supply rather had to be expressed in *value* terms, allowing it to assume the physical 'form' best suited to the other data of the theory, i.e. the technical conditions of production and the preferences of agents. For, if the capital endowment is given in kind only a short-period equilibrium, characterized by differential rates of return on the supply prices of the various capital goods, could be established by the forces constituting demand and supply. However, under conditions of free competition, which would enforce a tendency towards a uniform rate of profit, such an equilibrium could not be considered a 'full equilibrium' (Hicks 1932, p. 20).

Thus the formidable problem for the neoclassical approach in attempting the determination of the general rate of profit consisted in the necessity of establishing the notion of a market for 'capital', the quantity of which could be expressed *independently* of the 'price of its service', i.e. the rate of profit. If such a market could be shown to exist, profits could be explained analogously to wages (and other distributive variables) and a theoretical edifice erected on the universal applicability of the principle of demand and supply.

Now, the plausibility of the supply and demand approach to the problem of distribution was felt to hinge upon the demonstration of the existence of a unique and stable equilibrium in the market for 'capital'. (On the importance of uniqueness and stability see, for example, Marshall, 8th edn, 1920, p. 665n.) With the 'quantity of capital' in given supply, this, in turn, implied that a monotonically *decreasing* demand function for capital in terms of the rate of profit had to be established (see Fig. 1). This inverse relationship was arrived at by the neoclassical theorists through the introduction of two kinds of substitutability between 'capital' and labour: substitutability in consumption and in production. According to the former concept a rise in the rate of profit relatively to the wage rate would increase the price of those commodities, whose production is relatively 'capital intensive', compared to those in which relatively little 'capital' per worker is employed. This would generally prompt consumers to shift their demand in favour of a higher proportion of the cheapened commodities, i.e. the 'labour intensive' ones. According to the latter concept a rise in the rate of interest (and thus profits) relatively to wages would make cost-minimizing entrepreneurs in the different industries of the economy employ more of the relatively cheapened factor of production, i.e. labour. Hence, through both routes 'capital' would become substitutable for labour and for any given quantity of labour employed a decreasing demand schedule for capital would obtain. In Fig. 1 the demand schedule DD' corresponding to the *full employment* level of labour L^* (determined simultaneously in the labour market) together with the supply schedule SS' would then ensure a unique and stable equilibrium E with an equilibrium rate of profit r^*. Accordingly, the division of the product between wages and profits

Capital Theory: Debates, Fig. 1



is expressed in terms of the 'scarcity of factors of production', including 'capital' conceived as a value magnitude that is considered independent of the rate of profit.

Let us now briefly look more closely at some of the characteristic features of neoclassical capital theory and point out differences between the main versions in which it was presented.

To define 'capital' as an amount of value requires the specification of the standard of value in which it was to be measured. A rather common procedure was to express capital in terms of consumption goods or, more precisely, to conceive of it as a 'subsistence fund' in support of the 'original' factors of production, labour and land, during the period of production extending from the initial expenditure of the services of these factors to the completion of consumption goods. This notion corresponded to the view that capital resulted from the investment of past savings, which, in turn, implied 'abstention' from consumption. Thus it appeared to be natural to measure 'capital' in terms of some composite unit of consumption goods. However, there was a second dimension of capital contemplated by these authors: the *time* for which capital is invested in a process of production. The idea was that capital can be increased either by using more of it or by lengthening the period of time for which it is invested.

The first author to use time as a single measure of capital was Jevons (1871). The gist of his argument consisted in the concept of a 'production function' $y = f(T)$, where output per unit of labour, y, is 'some continuous function of the time elapsing between the expenditure of labour and the enjoyment of results, T; this function is assumed to exhibit diminishing returns (1871, pp. 240–41). Jevons showed that in equilibrium $r = f'(T)/f(T)$.

Jevons's contribution was the starting point of the Austrian theory of capital and interest with Böhm-Bawerk and Wicksell as its main representatives. Böhm-Bawerk's concern was with establishing a temporal version of the demand and supply approach. This involved the appropriate reformulation of the data of the theory. The central elements of his analysis were the concepts of 'time preference' and the 'average period of production', used in describing consumer preferences and technical alternatives, respectively. As in Jevons social capital was conceived as a subsistence fund and was seen to permit the adoption of more productive but also more 'roundabout', i.e. time-consuming, methods of production. It was to the concept of the 'average period of production' that the marginal productivity condition was applied in the determination of the rate of interest.

Among the older neoclassical economists it was perhaps Wicksell who understood best the difficulties related to the problem of a unified treatment of capital in terms of the demand and supply approach. In particular, Wicksell was

critical of attempts to work with the value of capital as a factor of production alongside the physically specified factors of labour and land in the production function of single commodities. This implied 'arguing in a circle' ([1901] 1934, p. 149), since capital and the rate of interest enter as a cost in the production of capital goods themselves. Hence the value of the capital goods inserted in the production function depends on the rate of interest and will change with it. Moreover, Wicksell expressed doubts as to the possibility of providing a sufficiently general definition of the 'average period of production' that could be used to represent capital in a way that is not threatened by this kind of circularity. In the *Lectures* he tried to overcome these difficulties by introducing production functions in terms of *dated* services of the 'original' factors labour and land.

While Wicksell shared Böhm-Bawerk's procedure of conceiving the 'capital endowment' of the economy as a value magnitude, he become increasingly sceptical whether it was admissible to identify it with some unspecified stock of subsistence goods, which, in turn, was seen to provide some measure of 'real' capital. With capital as a value magnitude Wicksell showed that the rate of interest is generally not equal to the marginal productivity of 'capital'. This discrepancy is due to the revaluation of the capital stock entailed by a change in distribution. The phenomenon is known as the 'Wicksell effect' and was regarded by Joan Robinson as the key to a criticism of the marginal productivity theory of income distribution.

Authors like J.B. Clark and Marshall appear to have been less aware of the fact that the conditions of production of single commodities cannot be defined in terms of production functions that include 'capital' among the factors of production. Obviously, the criticism levelled against these versions applies also to the concept of the 'aggregate production function', which boomed in the late 1950s and throughout the 1960s in conjunction with neoclassical growth theory.

Alternative views of the fundamentals of capital theory were expressed in a controversy between Böhm-Bawerk and J.B. Clark around the turn of this century (cf. in particular Böhm-Bawerk 1906–7; Clark 1907). Böhm-Bawerk criticized Clark's attempt to differentiate between 'true capital', a permanent abiding fund of productive wealth, and 'concrete capital goods', each of which is destructible and has to be destroyed in order to serve its productive purpose; in Böhm-Bawerk's view this is 'dark, mystical rhetoric'. Furthermore, Böhm-Bawerk refuted Clark's claim that no concept of 'waiting' or 'abstinence' is needed to explain interest in stationary equilibrium. Without some concept of time preference, and thus a theory of saving, the determination of the rate of interest is left hanging in the air.

Irving Fisher (1930) extended general equilibrium theory to intertemporal choices. However, he proceeded as if there were a single composite commodity to be produced and consumed at different dates. In his discussion of the theory of interest all prices, wages and rents are assumed to be fixed. Hence the interrelationship between the rate of interest, prices and the remaining distribution variables is set aside. The 'investment opportunities' available to an individual and to society as a whole are summarized in intertemporal production possibility frontiers. Due to the assumption of diminishing returns Fisher arrived at a decreasing demand function for saving with respect to the rate of interest. As Keynes noted, this is equivalent to his 'marginal efficiency of capital' schedule (Keynes 1936, p. 140). Because of 'impatience' the supply of saving is considered to be positively related to the rate of interest. The market equilibrium between the supply of, and the demand for, saving gives the rate of interest, which is equal to the marginal rate of return over the cost of the marginal increase in the capital stock. (For an attempt to generalize Fisher's rate of return approach see Solow 1967. For a critique of Fisher and Solow see Pasinetti 1969; Eatwell 1976).

The 1930s brought a further controversy on the theory of capital (cf. Kaldor 1937). This was triggered off by a series of articles by F.H. Knight (e.g. Knight 1934), in which he launched an attack on the concept of the 'period of production' revived a few years earlier by Hayek, among others. In particular, Knight argued that there is no need to refer to a 'quantity of capital' and that therefore the

'vicious circle' disappears. The rate of interest could be ascertained with reference to the instantaneous rate of investment and the present value of the additional stream of future income generated by it, However, Knight's proposed solution to the problem of circularity in terms of a 'theory of capital without capital' is illusory, since if the accusation of circularity applies at all (because the value of capital goods cannot be ascertained independently of the rate of interest), it applies both to the stock variable 'capital' and the corresponding flow variable 'investment'.

Finally, some recent attempts to revive and reformulate basic elements of the doctrines of the older neoclassical and Austrian authors should be noted, in particular: Weizsäcker (1971), Hicks (1973), and Faber (1979) on the Austrian theory, Morishima (1977) on Walras, and Hirshleifer (1970) and Dougherty (1980) on Fisher. (For a critical assessmenty of the older theories see especially Garegnani 1960).

The Recent Critique of Neoclassical Theory

Sraffa (1960) deserves the credit for having elaborated a consistent formulation of the classical surplus approach to the problem of capital and distribution. His analysis provided the fundamental basis for a critique of the prevalent neoclassical theory during the so-called 'Cambridge controversies in the theory of capital' (see Harcourt 1969; Kurz 1985).

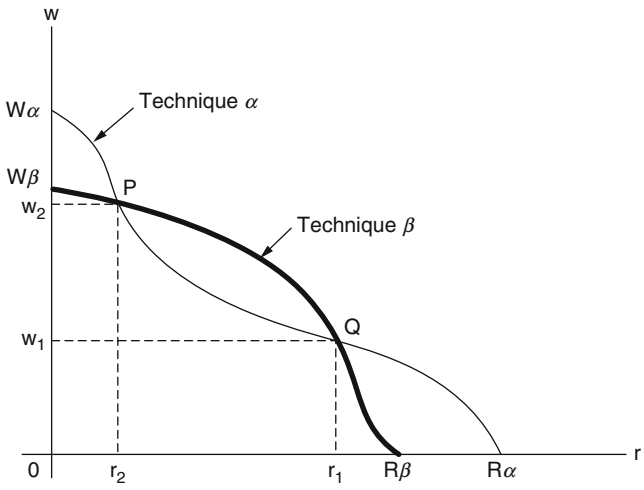
Sraffa starts from a given system of production in use in which commodities are produced by means of commodities. If wages are assumed to be paid at the end of the uniform production period, then, in the case of single-product industries (i.e. circulating capital only) and with gross outputs of the different products all measured in physical terms and made equal to unity by choice of units, we have the price system

$$p = (1 + r)Ap + wl,$$

where p is the column vector of normal prices, A is the square matrix of material inputs, l is the vector of direct labour inputs and w is the wage rate. Under certain economically meaningful conditions, for any given feasible wage rate in terms of a given standard the above equation yields a unique and strictly positive price vector in terms of the standard and a unique and non-negative value of the rate of profit. The investigation of the 'effects' of variations in one of the distribution variables on the other one and on the prices of commodities, assuming that the methods of production remain unchanged, yields the following results. First, the system possesses a finite maximum rate of profits $R > 0$ corresponding to a zero wage rate. Second, the vector of prices in terms of the wage rate p/w (prices in terms of quantities of *labour commanded*) is positive and rises monotonically for $0 \leq r < R$, tending to infinity as r approaches R. Third, at the maximum level of wages corresponding to $r = 0$ relative prices are in proportion to their labour costs, while at $r > 0$ relative prices generally deviate from relative labour costs and vary with changes in r (or w); it is only in the special case of uniform 'proportions' of labour to means of production in all industries that prices are proportional to 'labour values' for all levels of r (w). (For a discussion of joint production, fixed capital and land, see Pasinetti 1980.)

While earlier authors were of the opinion that the capital-labour or capital-output ratios of the different industries could be brought into a ranking that is independent of distribution, this is generally not possible: 'the price of a product. . .may rise or it may fall, or it may even alternate in rising and falling, relative to its means of production' (Sraffa 1960, p. 15). This result destroys the foundation of those versions of the traditional theory that attempted to define the conditions of production in terms of production functions with 'capital' as a factor. Moreover, as regards the concept of the 'capital endowment' of the economy conceived as a value magnitude, the same 'real' capital may assume different values depending on the level of r. Sraffa concludes that these findings 'cannot be reconciled with *any* notion of capital as a measurable quantity independent of distribution and prices' (1960, p. 38).

Capital Theory: Debates, Fig. 2

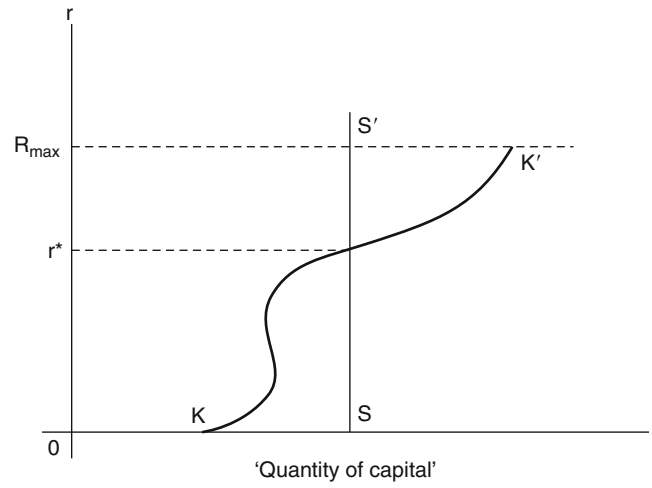


Samuelson (1962), in an attempt to counter Joan Robinson's (1953) attack on the aggregate production function, claimed that even in cases with heterogeneous capital goods some rationalization can be provided for the validity of simple neoclassical 'parables' which assume there is a single homogeneous factor called 'capital', the marginal product of which equals the rate of interest. But, alas, Samuelson based his defence of traditional theory in terms of the construction of a 'surrogate production function' on the assumption of equal input proportions (cf. 1962, pp. 196–7). By this token the 'real' economy with heterogeneous goods was turned into the 'imaginary' economy with a homogeneous output, i.e. the 'surrogate production function' was nothing more than the infamous aggregate production function. (For a critique of Samuelson's approach see particularly Garegnani 1970).

Implicit in the above system of price equations is the inverse relationship between the wage and the rate of profit, or *wage curve*, of the given system of production, $w = w(r)$. We may now turn to the hypothesis that for one or several industries alternative technical methods are available for the production of the corresponding commodity. The technology of the economic system as a whole will then be represented by a series of alternative techniques obtained from all the possible combinations of methods of production for the various commodities. Expressing w and p in terms of a commodity produced in all the alternative systems, we obtain as many different wage curves as there are alternative techniques. In Fig. 2 it is assumed that only two techniques, α and β exist. Clearly, at any level of the wage rate (or rate of profit), enterpreneurs will choose the *cost-minimizing* system of production. It can be shown that, whichever the system initially in use, the tendency of producers to switch to the cheaper system will bring them to the one giving the highest rate of profit (wage rate), whereas systems giving the same r for the same w will be indifferent and can coexist. Thus, in the example of Fig. 2, in the two intervals $0 < w < w_1$ and $w_2 < w \leq W_\alpha$ technique α will be chosen, while in the interval $w_1 < w \leq W_2$ technique β turns out to be superior; at the two switch points P and Q both techniques are equiprofitable. It follows that with a choice of technique the relationship between w and r, or *wage frontier*, will be represented by the outermost segments or envelope of the intersecting wage curves.

Figure 2 shows that the same technique (α) may be the most profitable of a number of techniques at more than one level of the wage rate even though other techniques (here β) are more profitable at wage rates in between. The implication of this possibility of the *reswitching* of techniques is that the direction of change of the input proportions cannot be related unambiguously to

Capital Theory: Debates, Fig. 3



changes of the so-called 'factor prices'. The central element of the neoclassical explanation of distribution in terms of supply and demand is thus revealed as defective. This element consisted in the proposition that a rise of r must decrease the 'quantity of capital' relative to labour in the production of a commodity because of the assumed substitutability in production and consumption. The demonstration that a rise in r may lead to the adoption of the more 'capital intensive' of two techniques clearly destroys the neoclassical concept of substitution in production. Moreover, since a rise in r may cheapen some of the commodities, the production of which at a lower level of r was characterized by a relatively high 'capital intensity', the substitution among consumption goods contemplated by the traditional theory of consumer demand may result in a higher, as well as in a lower, 'capital intensity'. It follows that the principle of substitution in consumption cannot offset the breakdown of the principle of substitution in production. Finally, it is worth mentioning that reswitching is not necessary for *capital-reversing* cf. Symposium 1966, p. 516).

The negative implication of reverse capital deepening for traditional theory can be illustrated by means of the example of Fig. 3, in which the value of capital corresponding to the full employment level of labour is plotted against the rate of profit. Obviously, if with traditional analysis we conceived the curve KK' as the 'demand curve' for capital, which, together with the corresponding 'supply curve' SS', is taken to determine the 'equilibrium' level of r, we would have to conclude that this equilibrium, although unique, is unstable. With free competition and perfectly flexible distributive variables a deviation of r from r^* would lead to the complete extinction of one of the two income categories. According to the critics of traditional theory, the finding that the quantity of a factor demanded need not be related to the price of the factor service in the conventional, inverse manner demonstrates the failure of the supply and demand approach to the explanation of normal distribution, prices and quantities.

Neoclassical Responses

Neoclassical economists tried to counter the attack in various ways. At first it was claimed that reswitching is impossible. When this claim was shown conclusively to be false (cf. Symposium 1966), doubts were raised as to its empirical importance (see, for example, Ferguson 1969), thereby insinuating that neoclassical theory was a simplified picture of reality, the basic correctness of which would not be endangered by 'exceptions' of the kind analysed in the capital debate. Other

advocates of the neoclassical approach were conscious of how defective the attempt was to play down the importance of reswitching and capital-reversing using the 'empirical' route. Since the phenomenon was irrefutable it had to be absorbed and shown to be compatible with the more sophisticated versions of the dominant theory.

Perhaps the first move in this direction was made by Bruno et al. (1966), who drew an analogy between reswitching and the long-known possibility of the existence of multiple internal rates of return. However, whereas the latter phenomenon is a discovery within the partial, 'fixed-price' framework of microeconomic theory of investment, reswitching presupposes a total, general framework. Moreover, we are not told how traditional theory was both able to cope with reswitching and yet preserve its basic structure.

A more interesting challenge came from authors such as Bliss (1975) and Hahn (1982). They contended that because of its concern with a uniform rate of profit Sraffa's analysis can be considered a 'special case' of general equilibrium theory. According to these authors the criticism of traditional neoclassical capital theory implicit in Sraffa is correct but has no bearing upon modern general equilibrium theory. Since in the latter the distribution of income is explained in terms of given *physical* endowments of agents, there is no need to find a scalar representation of the capital stock. The uniformity of profit rates is taken to be 'a very special state of the economy' (Hahn 1982, p. 363) which, for given preferences and production sets, presupposes a particular composition of initial endowments. In general, there will be as many own rates of return as there are different assets in the endowment set.

The first thing to be noticed is that the preservation of the basic supply and demand approach to the explanation of prices, distribution and quantities in modern general equilibrium theory is effectuated at the cost of the abandonment of the traditional long-period method. As we have seen, this method was shared by all 'forerunners' of this theory, including, most notably, Walras and von Neumann (1936). Indeed, the change in the notion of equilibrium involved expresses a fundamental break with the analytical method used by all economic theory up to the 1930s, when partly because of a growing perception among neoclassical economists that the whole approach was threatened by the difficulties concerning the notion of capital a drastic methodological reorientation was advocated (cf. Garegnani 1976; Milgate 1979). Most influential in this move away from the traditional method was apparently Hicks's *Value and Capital* (1939; second edition 1946). Interestingly enough, Hicks himself appears to have become increasingly sceptical as to the usefulness of the 'temporary equilibrium method' then suggested by him (see, for example, Hicks 1965, pp. 73–4).

The second observation concerns Hahn's attempt to interpret Sraffa's analysis as a special case of general equilibrium theory. Since the latter takes as data (i) the preferences of consumers, (ii) the technical conditions of production, and (iii) the physical endowments, Hahn's view necessarily leads to the question of which constellation of these data is compatible with a uniform rate of profit. Clearly, to superimpose the latter specification on an ordinary general equilibrium system would render it over-determined, as some of the older neoclassical authors were well aware of. Hence, following the interpretation under consideration, (i), (ii) or (iii) cannot be taken as independent variables. Now it is Hahn's contention that at the basis of Sraffa's price equations there must be a special proportion between the initial endowments; i.e. (iii) is tacitly assumed to be specified accordingly. However, as we have seen there is no evidence in support of this presupposition. The surplus approach does not require given endowments of produced means of production in order to determine distribution and normal prices. In fact, looking at classical analysis as a whole the quantities of the capital goods available may be considered as dependent rather than independent variables. In analysing the problem of value, capital and distribution the classical economists took the capital stocks installed in the different industries as exactly adjusted to *given outputs*, such that the latter could be produced at minimum costs. The tendency towards normal capital utilization and a uniform rate of profit was seen to be the outcome of the working of

the persistent forces of the system reflected in the competitive decisions of producers.

Since the opinion entertained by Hahn that Sraffa's analysis can be subsumed as a 'special case' under modern neoclassical theory has to be rejected, the question remains, which of the two is the more powerful instrument of analysis. There does not seem to exist a ready-made answer at present. The following remarks on the dominant neoclassical theory must suffice.

Obviously, to take the capital endowment as given in kind implies that only 'short-period' equilibria can be determined. Because firms 'prefer more profit to less' (Hahn 1982, p. 354) the size and composition of the capital stock will rapidly change. Thus, major factors which general equilibrium theory envisages as determining prices and quantities are themselves subject to quick changes. This, in turn, makes it difficult to distinguish them from those accidental and temporary factors, which, at any given moment of time, prevent the economy from settling in the position of equilibrium. More important, the fast variation in relative prices necessitates the consideration of the influence of future states of the world on the present situation.

This can be approached in two different ways. First, if there were complete futures markets the analysis could be carried out in terms of the concept of *intertemporal equilibrium*. However, the assumption that all intertemporal and all contingent markets exist, which has the effect of collapsing the future into the present, can be rejected on grounds of realism and economic reasoning (see, for example, Bliss 1975, pp. 48 and 61). Moreover, there is the following conceptual problem (see Schefold 1985). If in equilibrium some of the capital stocks turn out to be in excess supply these stocks assume zero prices. This possibility appears to indicate that the expectations entrepreneurs held in the past when deciding to build up the present capital stocks are not realized. Hence, strictly speaking we are faced with a disequilibrium situation because otherwise the wrong stocks could not have accumulated. Therefore, the problem arises how the past or, more exactly, possible discrepancies between expectations and facts influence the future.

Since the notion of intertemporal equilibrium cannot be sustained the theory is ultimately referred back to the introduction of individual price expectations concerning future deliveries of commodities for which no present markets exist. This leads to the *temporary equilibrium* version of modern neoclassical theory. The basic weakness of the theories of temporary equilibrium concerns the necessarily arbitrary choice of hypotheses about individual price expectations. Indeed, as Burmeister stresses, 'all too often "nearly anything can happen" is the only possible unaqualified conclusion' (Burmeister 1980, p. 215). Moreover, the stability properties of this kind of equilibrium are unclear, since small perturbations caused by accidental factors may entail changes in expectations, which define that very equilibrium.

The danger of lapsing into empty formalism and of depriving the theory of clear-cut results was of course recognized by several supply and demand theorists and considered a fundamental weakness. In view of it some of them were prepared to dispence with the alleged generality of general equilibrium theory and return to some version of traditional neoclassical analysis. After the recent debate in capital theory this involved ruling out reswitching and other 'perverse', i.e. non-conventional, phenomena in terms of sufficiently bold assumptions about available techniques. It comes as no surprise that given these assumptions the central neoclassical postulate of the inverse relation between the capital-labour ratio and the rate of profit should re-emerge as 'one of the most powerful theorems in economic theory' (Sato 1974, p. 355). However, in order to be clear about this move it deserves to be stressed that it was motivated, as one author expressly admits, by the fact that 'regular economies' have 'desirable properties' (Burmeister 1980, p. 124).

Capital Utilization

Roger Betancourt

Abstract

Utilization of capital can take place through variations in the duration of working time, given intensity, or through variations in the intensity of working time, given duration, or both. This article focuses on the economic factors determining duration and discusses the issues affecting and affected by variations in intensity. The latter can take the form of variations in speed or in the use of inputs that are complements to capital relative to some maximum or optimum. We provide a historical perspective, discuss modern theory, its main applications and links to the issues of speed and capacity, and identify important implications.

Capital utilization is given different interpretations in the economic literature. If a machine is available for use during, say, a day, then various levels of utilization can be obtained by varying the duration of operations within the day. For any fixed duration within the day, however, it is also possible to vary the machine's rate of utilization by varying its speed. In each case there is variation in capital utilization, but both physical and economic characteristics differ widely in the two cases. Moreover, even with duration and speed constant within the day, some writers define variations in capacity utilization via variations in the variable inputs employed with a given machine per day relative to some maximum or optimum daily output. Unfortunately, these as well as other writers frequently use the terms 'capital utilization' and 'capacity utilization' interchangeably.

The discussion here will focus on the analysis of variations in the duration of operations. A brief historical perspective sets the stage for a presentation of modern theory and applications, including links to the issues of speed and capacity. A succinct conclusion provides implications for closely related economic issues.

Historical Perspective

Concern with the duration of operations dates to the late 18th century and the spread of the factory system in England. Early writing emphasized the appropriate length of the working day relative to its social consequence for workers and its economic

consequence for capitalists. Positions on these issues were developed in the context of debates over the various Factory Acts in England. These discussions usually assumed the length of the working day to be the same for capital and labour.

Marx provides a most interesting example of the development of economic thinking on duration up to his time. The length of the working day is given substantial attention in his work (1867, ch. 10); indeed, it provides the cornerstone for his theory of exploitation (see, for example, Morishima 1973, ch. 5); yet Marx pays only minor attention to the separation of capital's work day from labour's work day which is at the centre of modern analysis.

Marshall, like his predecessors, was interested in duration because of its implications for the well-being of workers and the viability of the economic system. But he saw the separation of the work day of labour from the work day of capital inherent in shift-work systems as an opportunity for resolving the conflicting interests of workers and capitalists with respect to the length of the work day. Thus he becomes an advocate of the adoption of multiple shifts early in his professional career (1873) and maintained his interest in the topic throughout his career (see, for example, 1923, p. 650).

Marshall's emphasis became the basis for the work of Robin Marris (1964), who treats capital utilization as a synonym for shift-work. Interestingly enough, the other modern pioneer, Georgescu-Roegen (for example, 1972), stresses the choice of the daily duration of operations, acknowledges Marx's emphasis on the topic, but overlooks Marshall as well as Marris. Both view the choice of duration at the plant level, either directly or through the selection of a shift-work system, as a long-run or *ex ante* decision, that is, before the plant is built. Moreover, both assume the *ex post* elasticity of substitution to be zero, that is, within the day no variations in choice of technique are allowed once the factory is built. However, while Marris uses discrete techniques of production and discrete systems of utilization to describe the structure of the firm's optimization problem, Georgescu-Roegen uses a continuous production function and a continuous index of the daily duration of operations; these differences of method do not generate substantial differences in results.

Both economists use their analyses to argue against anachronistic social legislation and draw implications from their work for an important contemporary economic problem, namely, the improvement of economic conditions in developing countries.

Before presenting the modern theory and its applications it is useful to note a few salient facts. Thanks to Foss's efforts (1981) there are reliable estimates of the average workweek of capital (plant hours) in US manufacturing for 1929 and 1976–67 and 82 hours, respectively. These estimates can be compared to an average workweek for labour of 50 hours in 1929 and 40 hours in 1976. Furthermore, Foss views the rise in capital's workweek between 1929 and 1976 as an underestimate of the increase in shift-work, because of the decrease in the number of days worked per week during this same period. The most thorough update of this data work is Beaulieu and Mattey (1998). It generates an average workweek of capital for manufacturing during the period 1974–92 of 97 hours per week. These 'facts' underlie interest in the topic and the frequent identification of capital utilization with shift-work.

Modern Theory and Applications

A number of contributions have incorporated the choice of duration into the neoclassical theory of the firm. This work is most concisely exposited using a model which relies on duality theory to generate the main results available in this literature (see Betancourt 1986).

The firm's optimization problem is viewed as a two-stage procedure. In the first stage the decision-maker generates a cost function for each given level of duration; in the second stage the decision-maker selects from these cost functions that one which leads to least total cost. The end result in the two-input case is:

$$C^* = dC\left(w^*, r^*, x^*\right). \tag{1}$$

For a given reference unit of duration, w^* represents the average wage rate, r^* the price of

capital services, x^* the level of output, while d represents an index of duration of operations, C is a classical cost function, and C^* represents the total cost of operations at the optimal level of duration.

For example, if an eight-hour shift starting during normal hours is the reference unit of duration, as duration increases beyond this reference period: the average wage rate (w^*) increases because of shift differentials due to workers' preferences for normal hours or social legislation; and the price of capital services per eight-hour shift decreases, although there will be two opposite tendencies in this case. The daily price of a unit of capital increases due to the additional wear and tear created by the longer duration, but this price is now spread over a greater number of hours, and the price of capital services per eight-hour shift (r^*) decreases. Betancourt and Clague (1981, ch. 2, sect. 2) provide a detailed discussion of why the second effect predominates. Finally, as duration increases, the same daily output is spread over a greater number of hours, and the level of output per eight-hour shift (x^*) decreases.

The formulation in (1) yields the main insights about capital utilization or shiftwork at the plant level offered by the early literature that followed Georgescu- Roegen and Marris. A brief listing of these results is as follows: (i) high shift differentials or overtime rates discourage capital utilization by increasing w^*; (ii) technologies with high degrees of returns to scale discourage utilization by raising the costs of operating at low levels of output (x^*); (iii) technologies with high degrees of capital intensity encourage capital utilization because the consequent fall in the relevant cost of capital (r^*) affects a higher percentage of costs; and (iv) technologies with abundant *ex ante* substitution possibilities encourage utilization because they lower the costs of taking advantage of the consequent fall in the cost of capital (r^*) through the building of a more capital intensive factory. These four factors are the main long-run determinants of optimal duration on the cost side.

In addition, two other characteristics of the utilization decision are worth stating. First, factories built to operate at high levels of utilization will be designed to use capital-intensive techniques. Second, how exogenous changes in input costs affect duration depends critically on the *ex ante* elasticity of substitution. For instance, if this elasticity is greater than unity, under constant returns to scale an exogenous fall in the price of capital lowers the costs of building the plant to operate longer hours.

One application of the model is as the theoretical basis for empirical studies of the choice of duration at the plant level. The model's implications were consistent with several different bodies of plant level data (see Betancourt and Clague 1981, chs 4–8) across non-continuous process industries. Recent work using more detailed plant level data for specific industries, for example automobiles, confirms the role of the number of shifts as a long-run margin of adjustment and it stresses the importance of changes in duration through overtime and daily closings as short-run margins of adjustment in the United States (Bresnahan and Ramey 1994). Detailed studies of the auto industry for Europe and Japan (Anxo et al. 1995, chs 12 and 13, respectively) are also consistent with this long-run role for the number of shifts. Mayshar and Halevy (1997) develop a model that allows for *ex post* substitution possibilities as a short-run margin of adjustment. The above studies imply that there is a choice of duration, even in the short run, but in some industries continuous processes dominate and the choice is really to operate or not operate the process. A major extension of the model that captures this feature is provided by Das (1992), who develops and estimates a discrete dynamic programming model for the cement industry at the kiln level. In this context a plant is basically an additive collection of kilns and Das allows for three decisions, namely, operate, retire or keep idle a kiln in any plant.

Alternative approaches to the non-convexities that arise at the plant level have been developed by looking at the industry as the unit of analysis. Prucha and Nadiri (1996) provide an insightful and sophisticated example of this option applied to the US electrical machinery industry by making endogenous the capital utilization decision in the

context of dynamic factor demand models. In a similar industry setting, Cardellichio (1990) uses the assumption of Leontief production functions at the mill level to analyse utilization for the lumber industry as a whole.

From a theoretical perspective an application of the model in (1) has been as the basis for the choice of duration in standard two-sector general equilibrium models. In the context of the international trade literature, Betancourt et al. (1985), for example, use the specific-factors model with variable utilization to reconcile the dual scarcity explanation of Anglo-American trade in the 19th century with the empirical evidence on observed utilization levels. In the context of the public finance literature Coates (1991) generalizes the standard analysis of the incidence of the corporate profits tax by allowing for variable utilization. He concludes that overestimates of the burden of the tax in the order of 10–60 per cent are most probable as a result of ignoring this long-run margin of adjustment in a general equilibrium context. A more abstract general equilibrium approach allowing for firm's decisions over duration and starting times as well as for worker's preferences over these work schedules has been developed recently by Garcia Sanchez and Vazquez Mendez (2005). Its main substantive result replicates one partial equilibrium result noted above, namely, that high capital intensity in the form of a high capital-labour ratio leads to an increase in utilization.

A short-run perspective has played an important role in dramatizing the policy implications of high levels of utilization for employment and output, since in this perspective a doubling of utilization implies a doubling of employment and output. Nevertheless a long-run perspective (see Betancourt and Clague 1981, chs 9–11) provides a far less optimistic view about the likelihood of these outcomes. Ironically the evaluation of a shorter workweek for labour in Europe, which is analytically similar, has been carried out primarily from a short-run perspective (for example, Anxo et al. 1995, ch. 14). Garcia Sanchez and Vazquez Mendez (2005), however, suggest this topic as one for potential application of their long-run model.

Related Issues: Speed and Capacity

The relations between duration, speed and capacity are difficult to analyse and provide an opportunity for confusion. To start, consider a dual representation of the cost function in (1). Namely,

$$x = dF(K, L) \tag{2}$$

where x is the level of daily output, that is, $x = \mathrm{d}x^* = \mathrm{d}F$; F is a neoclassical production function defined over the reference period of duration; K represents both the level of the capital stock employed and the rate of capital services, which implies that the speed of operations (v) is constant and set at unity; and L represents labour services per reference period of duration. Alternatively, those who analyse variations in utilization through choice of speed represent the productive process as follows:

$$x = F(vK, L) \tag{3}$$

where all variables have been previously defined. In (3) duration is set at unity.

Writers who employ (3) assume that the price of the capital stock is an increasing function of speed or utilization (for example, Smith 1970). Since costs are defined as

$C = r(v)K + wL$, where $r'(v) > 0$, the cost of a unit of capital services obtained by increasing speed is an increasing function of v. While in the duration model the price of the capital stock $r(d)$ is an increasing function of duration ($r'(d) > 0$), the cost of a unit of capital services obtained by increasing duration is a decreasing function of duration, that is, $r^* = r(d)/d$ and $r^{*\prime}(d) < 0$. This difference implies that models with one utilization variable to describe the productive process can generate nonsensical economic results if this variable is interpreted as representing either duration or speed, because the behaviour of costs can represent only one of the two interpretations. To illustrate, a recent body of literature relates capital utilization, economic growth and the speed of convergence (for example, Chatterjee 2005), by assuming depreciation to increase with utilization at an increasing rate. This makes sense if one

justifies increases in utilization as a result of increases in speed. Yet this literature justifies increases in utilization as a result of increases in duration through increases in the average workweek of capital.

Another interesting feature of the 'speed' model stems from the first-order conditions for cost minimization, which can be used to show that, if v, K and L are treated as choice variables, at the optimum, $r(v) = r'(v)v$. When duration and speed are endogenous this characteristic generalizes to $r(v, d) = r_v(v, d)\ v$ and optimal speed is determined by optimal duration (Madan 1987). This is consistent with the finding by Bresnahan and Ramey (1994) for the auto industry that line speed and the number of shifts are long-run margins of adjustment.

Consider now the representation of the productive process underlying the typical definitions of capacity utilization. Namely,

$$x = F(K, L) \tag{4}$$

where all variables are defined as before and speed and duration set at unity. Using (4), Panzar's (1976) definition of capacity becomes:

$$h(K) = \max_L F(K, L) \tag{5}$$

where $h(K)$ is an increasing function of K. This definition leads to an output-based definition of short-run capacity utilization; that is:

$$CU = x/x\ \max \tag{6}$$

where x max is given by (5).

When capital equipment is capacity-rated in terms of output units, as in electricity generation, one can measure directly the denominator of (6) and short-run capital and capacity utilization coincide (cf. Winston 1982, ch. 5). In general, however, the denominator in (6) is not well defined. An alternative procedure is to define the denominator in (6) as the optimal level of output, x^0. For instance, in the literature on dynamic factor demand models x^0 is defined as the optimal level of output when the capital stock is endogenous (for example, Morrison 1985; also see Prucha and Nadiri 1996, for a generalization). Since 'optimal' output varies with the specification of the optimization problem, one can generate a variety of reasonable definitions of capacity utilization which measure different concepts. Not surprisingly, the corresponding empirical definitions fail to move together (de Leeuw 1979) or with the average workweek of capital (Beaulieu and Mattey 1998).

Implications

Perhaps the most important economic implication of the analysis of capital utilization above is for our understanding of technical change at the aggregate level. Ignoring increases in duration understates the contribution of capital services to output growth and, thus, overstates the estimates of technical change or the Solow residual in standard sources of growth analysis. Beaulieu and Mattey's estimate of the annual rate of growth in the average workweek of capital for manufacturing over the 1974–91 period is 0.17. They use employment per shift as weights, which are the appropriate ones, and find that only 25 per cent of the variation in growth can be accounted for by overtime.

Macroeconomists have pursued this issue but emphasized its business cycle implications. That is, when the Solow residual is adjusted for the workweek of capital it ceases to be pro-cyclical. For instance, Shapiro (1993) made this point in a widely cited paper. His results continued to hold in Beaulieu and Mattey's more recent data and they have given rise to a substantial literature that we will not explore here. One implication of this finding noted by Shapiro is that it casts doubts on alternative explanations of the behaviour of the residual stressing market power when there are substantial costs to adjusting the workweek of capital, for example through the shift differential.

There is an early literature on the human costs of shift-work which may be captured through the shift differential. Betancourt and Clague (1981, ch. 12) conclude from their review of this literature that observed shift differentials of four to five

per cent in the United States substantially underestimate the human costs of shift-work. This conclusion is consistent with estimates in an unpublished paper by Shapiro (1995) that the marginal shift premium is 25 per cent. A strand of literature in labour economics on compensating differentials has considered shift-work.

Kostiuk (1990) obtains estimates of the shift differential of well above ten per cent in the unionized sector for both 1979 and 1985. He relies on Census of Population Survey data for his analysis.

An issue neglected in the recent literature is the role of obsolescence in capital utilization. Marris (1964) argued that an increase in the rate of obsolescence should strengthen the economic incentive for shift-work, since it ameliorated disincentive effects of wear and tear depreciation. In the last few decades we have observed systematic shifts from mechanical technologies to electronic technologies, which diminish wear and tear costs and increase the rate of obsolescence. This shift should, thus, have provided an incentive for increased capital utilization. Yet, to my knowledge, the economic literature has not addressed this issue explicitly.

Finally, an important reason for interest in capital utilization as an economic variable is the existence of transaction costs and market imperfections. These frictions make ownership of capital equipment and structures attractive relative to rentals for instantaneous capital services. Of course these rental markets do not exist in most cases. A substantial recent literature in industrial organization investigates the effect of transaction costs, including incompleteness of contracts and agency costs, on incentives and the evolution of institutions. With one exception, it has not addressed the impact of changes in transaction costs and market imperfections on capital utilization. The exception is the work of Hubbard (2003) on the trucking industry. He shows that improvements in monitoring technology in the form of on board computers increase capacity utilization, which in this industry coincides with short-run capital utilization just as in the electricity generation industry. Issues of long-run capital utilization and relevance for other industries, however, remain unexplored in this context.

Capital, Credit and Money Markets

Benjamin M. Friedman

The markets for money, credit and capital represent a fundamental dimension of economic activity, in that the many and varied functions of the modern economy's financial markets both reflect and help shape the course of the economic system at large. Financial markets facilitate such central economic actions as producing and trading, earning and spending, saving and investing, accumulating and retiring, transferring and bequeathing. Development of the financial system is a recognized hallmark of economic development in the broadest sense.

Neither the important role played by the financial side of economic activity nor economists' awareness of it is a recent phenomenon. Economic analysis of the roles of money, credit and capital constitutes a tradition as old as the discipline itself. Nevertheless, in comparison with other equally central objects of economic analysis this tradition is as remarkable for its continuing diversity as for the richness of the insights it has generated. A century after Marshall and Wicksell and Bagehot, a half-century after Keynes and Robertson and Hicks, and a quarter-century after the initial path-breaking work of Tobin and Modigliani and Milton Friedman, there is still no firm consensus on many of the more compelling questions in the field: What are the most important determinants of an economy's overall level of capital intensity? How does risk affect the allocation of that capital? Do leverage and intermediation of debt matter for aggregate economic outcomes? Does money matter – and, if so, what is it?

The absence of universally accepted answers to these and other fundamental questions does not signify a failure to develop conceptual understanding of how the markets for money, credit and capital function, or of the basic elements of these markets' interactions with non-financial economic activity. The persistent diversity of thought on these unresolved questions has instead reflected the inability of empirical analysis, hindered by the continual and at times rapid evolution of actual financial systems, to provide persuasive evidence on issues characterized both by a multiplicity of plausibly relevant determining factors and by the inherent unobservability of some of the most important among them – for example, ex ante perceptions of risks as well as rewards.

The Market for Capital

The essential reason for having a capital market in any economy stems from the nature of the productive process. In all economies anyone has ever observed, and the more so in the more developed

among them, production of goods and services to satisfy human wants relies on capital as well as labour. If capital is to exist to use in production, someone must own it; and in economies in which this ownership function lies with individuals or other private entities, the primary initial role of the capital market is to establish the terms on which capital is held. In market-oriented economies the terms on which capital is (or may be) held provide incentives affecting the further accumulation of new capital, so that over time the capital market plays an additional, logically consequent role in determining the economy's existing amount of capital and hence its potential ability to produce goods and services.

In conceptualizing how the market mechanism sets the terms on which an economy's capital is held, economists have traditionally paired the role of capital as an input to the production process with the role of capital as a vehicle for conveying wealth – that is, ultimate command over goods and services – forward in time. The capital market is therefore the economic meeting place between the theory of production, often in the derivative form of the theory of investment, and the theory of consumption and saving. Different assumptions forming the underlying theory on either side in general lead to differing characterizations of how the capital market establishes the terms on which capital is held, and consequently differing characterizations of how the market affects the economy's accumulation of capital over time and hence its capital intensity at any point in time. Among the critical features of production theory and consumption-saving theory that have featured prominently in this analysis of their intersection are the substitutability of capital for other production inputs, the source and nature of technological progress, and the interest elasticity of saving. In most modern treatments, these specifics in turn depend on more basic assumptions like the respective specifications of the production function constraining producers and the intertemporal utility function maximized by wealth-holders.

Notwithstanding the central importance of this basic economic role of the capital market, as well as the insight and ingenuity with which economists over many years have elaborated their understanding of it, what gives the modern study of capital markets much of its particular richness is the focus on one particular factor that could, in principle, be entirely absent from this economic setting, but that is ever present in reality: uncertainty.

The essential feature of capital from this perspective is its durability. Because capital is durable – that is, its use in production does not instantly consume or destroy it – it provides those who hold it with not just the ability but the necessity to convey purchasing power forward in time in a specific form. Precisely because of this durability, capital necessarily exposes those who hold it to whatever uncertainties characterize both the production process and the demand for wealth-holding in the future.

Not just reward but risk too, therefore, are inherent features of capital that must accrue to some holders, somewhere in the economy, if the economy is to enjoy the advantages of production based in part on durable capital inputs. The introduction of risk has profound implications for consumption-saving behaviour. In addition, when the absence of perfect rental markets leads producers who use capital to be also among the holders of capital, the introduction of risk in this way affects production-investment behaviour too. Hence via at least one side of the capital market nexus, and via both sides under plausibly realistic assumptions, the risk consequent upon the durability of capital alters the determination of the terms on which capital is held, and thereby alters the determination of the economy's capital accumulation. Increasingly in recent years, the study of capital markets by economists has focused on the market pricing of this risk. The context in which this risk pricing of function matters, however, remains the consequences, for wealth-holding and for investment and production, of the terms on which capital is held.

The implications of the risk inherent in durable capital depend, of course, on many aspects of the capital market environment. Two prominent features of existing capital markets in particular have importantly shaped the explosive development of the capital markets risk-pricing literature during the past quarter-century. First, durable capital is

not the only available form of wealth holding. Other assets may be risky too, but at least some assets exist which do not expose holders to the risks, involving unknown outcomes far in the future, that are consequent on the durability of typical capital assets. Second, even capital assets are not all identical. Heterogenous capital assets expose their holders to risks that not only are not identical but also, in general, are not independent.

Following Markowitz (1952) and Tobin (1958), the investigation of the allocation of wealth-holding between a single risk-free asset and a single risky asset readily establishes the terms on which (risky) capital is held, in the form of the excess of its expected return over the known return on the alternative (presumed risk-free) asset. In the simplest case of a single-period-at-a-time decision horizon, for example, the maximization of utility exhibiting constant relative risk aversion in the sense of Pratt (1964) and Arrow (1965), subject to the assumption that the uncertain return to capital is normally distributed, leads to the result that an investor's demand for capital, expressed in proportion to the investor's total wealth, depends linearly on the expected excess return:

$$\frac{1}{w} \cdot A_K^D = \frac{1}{\rho \cdot \sigma_K^2} \cdot [E(r_K) - \overline{r}] \qquad (1)$$

where W is the investor's total wealth, A_K^D is the quantity demanded of the risky asset, ρ is the coefficient of relative risk aversion, $E(r_K)$ and σ_K^2 are respectively the mean and variance of the ex ante distribution describing assessments of the uncertain asset return, and $\overline{r}$ is the known return on the alternative asset. (This simple result is both convenient and standard, but it can be only an approximation because normally distributed asset returns are strictly incompatible with utility functions exhibiting constant relative risk aversion.) If it is possible to represent the economy's aggregate asset demands in a form corresponding to Eq. 1 for individual investors, then the requirement that the existing amount of each asset must equal to the amount demanded leads to the result that the expected excess return on capital depends linearly on the composition of the existing wealth:

$$E(r_K) = \overline{r} + \rho\sigma_K^2 \cdot \frac{A_K}{W} \qquad (2)$$

where A_K is the actual existing quantity of the risky asset. If the market equilibration process works via changes in the price of the risky asset, rather than its stated per-unit return, then both A_K and W are jointly determined with $E(r_K)$ and the resulting relationship is analogous though no longer linear:

$$E(r_K) = \overline{r} + \rho\sigma_K^2 \cdot \frac{P[E(r_K)] \cdot \overline{A}_K}{A_F + P[E(r_K)] \cdot \overline{A}_K} \qquad (3)$$

where A_F is the existing quantity of the risk-free asset (taken to have unit price), $\bar{A}_K$ is the quantity of the risky asset in physical units, and P is the price of the risky asset with $[\mathrm{d}P/\mathrm{d}E(r_K)] < 0$. (If capital is infinitely lived, $P = 1/E(r_K)$.) The addition of this element of the theory of risk pricing thus allows the capital market, in the context of a general economic equilibrium, to establish the terms on which durable capital is held – and hence the incentive to capital accumulation – when other, non-durable assets are also present.

The second major aspect of actual capital assets motivating the development of the economic analysis of capital markets is heterogeneity. Capital assets differ from one another not only because of actual physical differences but also because, with imperfect rental markets, the application of identical capital items to different uses in production has some permanence, so that ownership of a particular capital asset typically implies ongoing participation in a specific production activity. In general, each kind of capital asset, categorized not only by physical characteristics but also by production application, exposes those who hold it to a unique set of uncertainties. Moreover, in general the different risks associated in this way with different capital assets are not independent.

The elaboration of the single-risky-asset model in Eqs. 1, 2, and 3 due to Sharpe (1964) and Lintner (1965) readily represents the determination of relative returns in the capital market, in this

context of heterogeneous capital assets with interdependent risks, and hence enables the outcomes determined in the capital market to affect not just the aggregate quantity but also the allocation of the company's capital accumulation. The multivariate analogues of Eqs. 1 and 2 are simply

$$\frac{1}{W}\cdot A_K^D = \frac{1}{\rho}\Omega^{-1}[E(r_k) - \overline{r}\cdot 1] \tag{4}$$

$$E(r_K) = \overline{r}\cdot 1 + \rho\Omega\cdot\frac{1}{W}\cdot A_K \tag{5}$$

where A_K^D, $\boldsymbol{A}_K$ and $\boldsymbol{r}_K$ are vectors with individual elements respectively corresponding to A_K^D, $\boldsymbol{A}_K$ and r_K, $\boldsymbol{\Omega}$ is the variance-covariance structure associated with expectations $E(\mathbf{r}_K)$, and $\mathbf{1}$ is a vector of units. In Eq. 4 the demand for each specific capital asset depends linearly on the expected excess return over the risk-free rate not only of that asset but of all other capital assets as well, with the substitutability between any two assets – that is, the response of the demand for one asset to the expected return on another – determined by the investor's risk aversion as well as by the interdependence among the respective returns on all of the risky assets. In Eq. 5 the equilibrium expected excess return on each capital asset at any time therefore depends (linearly) on the existing quantities of all assets expressed as shares of the economy's total wealth. Under conventional models of investment behaviour, the accumulation of each specific kind of capital over time depends in turn on the entire set of equilibrium returns determined in this way.

Moreover, this role of the capital market in guiding the allocation of capital does not depend in any fundamental way on the presence of an alternative asset with risk-free return. If all assets bear uncertain returns, either because capital assets are the only existing assets, or because even the returns on other assets are uncertain (because of uncertain price inflation, for example), the analogue of Eq. 4 is

$$\frac{1}{W}\cdot A_K^D = \frac{1}{\rho}\left[\Omega^{-1} - \left(1'\Omega^{-1}1\right)^{-1}\Omega^{-1}1'\Omega^{-1}\right]\cdot E(r_K) + \left(1'\Omega^{-1}1\right)^{-1}\Omega^{-1}1. \tag{6}$$

The second term in Eq. 6 represents the composition of the minimum-variance portfolio, which in the absence of a risk-free asset is a unique combination of risky assets, expressed as a vector of asset shares adding to unity. The first term in Eq. 6 expresses the investor's willingness to hold a portfolio different from this minimum-variance combination. The transformation of $\boldsymbol{\Omega}$ contained in the first term maps what is in general a variance-covariance matrix of full rank into a matrix of rank reduced by one, as is implied by the balance sheet constraint emphasized by Brainard and Tobin (1968). Because the resulting matrix is of less than full rank, however, no exact analog of Eq. 5 then exists.

Combining the description of asset demands in Eq. 6 with the requirement of market clearing therefore determines the relative expected returns among all assets – in other words, determines the absolute expected returns on all assets but one, given the expected return on that one – but cannot determine absolute expected returns without at least some reference point fixed outside the risk pricing mechanism. This result is in fact analogous to the implication of Eq. 5 (or Eq. 3), in that Eq. 5 determines the expected return on each risky asset only in relation to the fixed benchmark of the known return on the alternative risk-free asset. In either case the analysis of risk pricing alone is insufficient to determine absolute returns without something else, presumably grounded in the fundamental interrelation between the respective roles of capital in production and in wealth-holding, to anchor the overall return structure.

Actual capital markets perform these functions of pricing risk and thereby guiding the accumulation and allocation of new capital, in essentially all advanced economies with well developed financial systems. In most such economies, the most immediately visible focus of the risk pricing mechanism is the trading on stock exchange of existing claims to capital in the form of equity ownership shares in ongoing business enterprises. Equity shares are composite capital assets not only in the sense that each business firm typically owns a variety of different kinds of physical capital but also because the value of most firms consists in part of intangible capital in the form of

existing knowledge, organization and reputation. In the context of what are often very large costs of establishing new enterprises, together with highly imperfect secondary markets for physical capital assets, even in principle the prices of equity securities need not correspond in any direct way to the liquidation value of a firm's separate items of plant and equipment. Given transactions costs and imperfect secondary markets, the existing enterprise itself is just as much an aspect of an advanced economy's long-lived production technology as is the sheer physical durability of capital.

Markets in which existing equity shares are traded also present the opportunity for the initial sale to investors of new equity shares issued by business enterprises in order to augment their available financial resources. In addition to guiding capital accumulation and allocation by establishing the relevant risk pricing, therefore, capital markets also play a direct role in facilitating capital accumulation by offering firms the opportunity to raise new equity funds directly. Even so, given firms' ability to increase their equity base by retaining their earnings rather than distributing them fully to shareholders – and also given the availability of debt financing (see the discussion of credit markets immediately below) – the extent to which firms actually rely on new issues of equity varies widely from one economy to another. In the United States, for example, well established firms typically do not issue new equity shares in significant volume, and the market for new issues is primarily a resource for new enterprises of a more speculative character. (The aggregate net addition to equity in the US market each year is typically negative, in that equity retirements and repurchases exceed gross new issues.) In most other economies, too, new issues of equity shares provide only small amounts of net funds for business.

Even when new equity additions via new shares issues are small, however, the risk pricing function of the capital market still guides an economy's capital accumulation and allocation process. Internal additions to equity from retained earnings are by far the major source of equity funds for the typical business in most economies, and – at least in theory – the retention or distribution of earnings by firms reflects in part considerations of expected return and associated risk as priced in the capital markets. Firms in lines of business in which new investment is less profitable (after allowance for risk) than the economy's norm not only cannot issue new equity shares on attractive terms but also must either distribute their earnings or face undervaluation of their outstanding shares by market investors. Conversely, firms with unusually profitable prospects at the margin of new investment can favourably issue new shares or can retain their earnings to fund their expansion.

Finally, two further features of actual modern capital markets bear explicit notice. Each, appropriately considered, is consistent with the notion of capital markets serving the basic function of pricing risk, and thereby guiding an economy's capital accumulation and allocation.

First, highly developed capital markets are characterized by enormous volumes of trading. In principle, the risk-pricing mechanism could function with little trading of existing securities, and under the right conditions it could function with none at all. If investors all agreed on the appropriate set of price relationships, there would be neither the incentive nor the need to effect actual transactions. The agreed-upon set of prices might fluctuate widely or narrowly, depending upon changes in assessments of risk and return, but as long as the assessments were universally shared there would be little if any trading.

The huge trading volumes typical of actual modern capital markets therefore suggest that, in fact, investors do not share identical risk and return assessments. Annual trading volume on the New York Stock Exchange, for example, is normally near one-half the total value of listed existing shares. Although the continually changing circumstances of both individual and institutional investors no doubt play some role, it is difficult to explain this phenomenon except in the context of substantial heterogeneity in the response of investors' risk and return assessments to the flow of new information.

The possibility that investors' opinions differ is only a minor complication for the theory of risk

pricing as sketched above. Lintner (1969) showed that competitive capital markets with heterogeneous investors determine outcomes for the pricing of risky assets that just reflect an appropriately constructed aggregation over all individual investors' differing assessments (as well as their differing preferences), weighted by their respective wealth positions. The question remains, however, why investors' assessments differ. One line of analysis, initiated by Grossman (1976), has emphasized systematic differences in assessments due to underlying differences in information available to different investors. By contrast, Shiller (1984) suggested the importance of unsystematic differences not readily explainable within the conventional analytic framework based on rational maximization. The question remains unsettled but important nonetheless.

The second additional feature of actual modern capital markets that bears explicit attention is the proliferation of increasingly complex securities, including options, warrants, futures, and so forth. Given heterogeneity among investors, this development fits naturally in the context of the capital markets' basic economic role of establishing the terms on which the risks inherent in a capital-intensive production technology are to be borne. When investors differ among themselves in age, or wealth, or preferences, or risk and return assessments, in general the most efficient allocation of those risks does not consist of all investors' holding portfolios embodying identical risks and prospective returns. Instead, different investors will hold differing portfolios, and a further role of an economy's capital markets is to allocate the bearing of specific risks across different investors.

Heterogeneity among different kinds of physical assets would itself facilitate such specialization, and heterogeneity among the business enterprises whose equity shares constitute the asset units in actual capital markets typically does so to an even greater extent. Still, even this resulting degree of feasible specialization in risk bearing apparently falls well short of what would be fully consistent with the existing extent of investor heterogeneity.

Complex securities enable the capital markets to achieve a more efficient allocation of risk across heterogeneous investors by more finely dividing the risk inherent in an economy's production technology. Options, for example, permit an investor not merely to hold a (positive or negative) position in the equity of a specific firm but to hold positions corresponding only to designated parts of the distribution describing the possible outcomes for that firm's performance as reflected in the price of its equity shares. While the existing array of complex securities presumably does not approach the set of contingent claims necessary to span the space of possible outcomes in the sense of Arrow (1964) and Debreu (1959), developments along these lines in recent years have presumably rendered risk bearing more efficient. Moreover, following Merton (1973a) and Black and Scholes (1973), the analysis of the market pricing of risk has extended to explicitly contingent claims the central features of market equilibrium. The analysis is richer, therefore, and the outcome more efficient, but the end result of the economic process remains the pricing of the risk associated at any time with the existing stock of capital, with consequent effects on the total accumulation and allocation of capital over time.

The Market for Credit

The presence of heterogeneity among different participants in a market economy also provides an economic rationale for credit markets. The primary initial role of the credit market is to facilitate borrowing and lending – that is, the transfer of purchasing power by the issuing and acquiring (and trading) of money-denominated debts. In establishing the terms on which such transfers take place, the credit market plays a role in guiding the allocation of the economy's resources that is parallel to that played by the capital market.

If all market participants were identical, such a market could establish terms on which the representative agents would be willing to borrow or lend, but no actual borrowing or lending would take place. Under those circumstances the credit market would be of little economic importance. By contrast, actual economies consist of an almost infinite variety of differently positioned

participants. Individuals differ from business enterprises, and private-sector entities differ from governments. Even just among individuals, there are old and young, rich and poor, highly and weakly risk-averse, favourably and unfavourably taxed, home-owners and renters, and so on in ever more dimensions and ever greater detail. As a result, the credit market does not just establish a putative price for strictly hypothetical trades. It facilitates transfers that in turn make possible resource allocations which could not otherwise come about.

At the most basic level, economists since Fisher (1930) have emphasized the role of borrowing and lending in achieving a separation between production and consumption decisions. Here the function of the credit market is to enable individuals to shift purchasing power forward or backward in time, so as to free the timing pattern of consumption streams from the corresponding timing pattern of earnings from production (while still preserving, of course, the relevant constraint connecting the appropriately discounted totals). The overall result of this intertemporal separation is, in general, to achieve more efficient resource allocations in the sense both of greater production from given available inputs as well as higher utility from given available consumption. Without such a separation it would be impossible to construe the intertemporal theory of consumption and saving as in any way distinct from the theory of production and investment. Even the limited heterogeneity between firms and households is sufficient to give rise to borrowing and lending along these lines.

Nevertheless, the question of why money-dominated debts should serve this intertemporal transfer function – rather than having all obligations take the form of direct ownership claims to capital, for example – opens up a whole series of further important issues. Following the analysis of capital markets immediately above, the most readily apparent answer is that debt obligations isolate the specific risks associated with the purchasing power of the unit of denomination (in other words, inflation risk) and risks associated with the borrower's ability to meet the stated obligation (default risk), and that this conventional compartmentalization is evidently convenient for a variety of reasons. Inflation risk and default risk are in general not independent, however. In addition, it is just as easy to imagine alternative conventions that might be just as convenient, like the predominant use of debts denominated in purchasing-power units.

Given the conventional monetary denomination of debt obligations, the function of the credit market in most modern economies is to redistribute immediate claims to purchasing power, in exchange for future claims, along three major dimensions of heterogeneity: between individuals and firms, between the private sector and the government, and between domestic and foreign entities. In addition, redistributions among individuals (and, to a lesser extent, among firms) are often a further important credit market function.

Business firms typically apply to investment not only their equity additions from retained earnings and any new share issues but also funds raised by borrowing. Modigliani and Miller (1958) set forth conditions under which the firm's reliance on debt versus equity financing would be a matter of indifference, in that it would not affect the firm's total value, but conditions prevailing in actual economies and their capital and credit markets do not meet these conditions closely. Business reliance on debt financing is typically large, and it varies systematically across countries and across industries within a given country. Prominent aspects of the divergence of actual economies from the Modigliani-Miller irrelevance conditions which the ensuing voluminous literature has emphasized, include tax structures, risks and costs of bankruptcy by the firm, differential borrowing rates for firms and individuals (due to, for example, risks and costs of bankruptcy by individuals), monitoring costs required to minimize risks, and restrictive features of debt contracts intended to reduce risks due to moral-hazard effects of imperfectly compatible incentive structures.

The resulting substantial reliance on debt financing by business means that credit markets, like capital markets, play a major economic role in guiding an economy's accumulation and allocation of capital over time. When any or all of the

factors cited above lead business enterprises to finance a new investment with some combination of additional equity (from retained earnings or new share issues) and additional debt, the appropriate calculation of investment incentives involves the cost to the firm in both the capital market and the credit market. In circumstances in which the financing margin corresponding to marginal new investment is a debt margin – as is often the case in the United States, for example, where firms' reliance on external funds is typically synonymous with issuance of debt – the relevant cost at the margin is the cost in the credit market.

Use of the credit market to finance government spending is among the oldest and most prevalent forms of financial transactions, and it has, understandably, generated an entire literature unto itself. In practical terms, government reliance on the credit markets in most modern economies is important not only in that governments often issue debt to finance large portions of their total spending but also because government borrowing often absorbs a large mount of the total funds advanced in the market by lenders. As is the case for private borrowers, government debt issues separate in time the ability to spend from the need to raise revenue. In addition, however, because under some circumstances governments need not repay debt obligations at all (they may refinance them forward indefinitely), and also because of uncertainty over the identity of the responsible taxpayers even in the case of future repayment, government debt is in part net wealth to the aggregate of private holders in a way that private debts are not.

The distinguishing feature of government debt in many economies is its essential freedom from default risk. In addition, in most economies the market for government debt is among the most efficiently functioning of all financial markets. Hence the existence of government debt enables the credit market to establish a base, with risk factors limited to inflation and real discounting values, from which it can then price privately issued debts subject to risks associated with default as well. The practice of giving government guarantees to the payment of interest and principal on selected private debts, which has greatly proliferated in recent years, has further increased the variety of forms of default-free debt securities. Yet another important implication of the default-free nature of government debt is that, to the extent that government borrowing takes the place of borrowing that individuals could do on their own account only at higher cost or not at all, government debt is in part net wealth to the private sector even if it is necessarily repaid and even if the identity of the responsible taxpayers is fully known.

International borrowing and lending has also greatly increased in recent years, as technological advances in communications have brought the world's financial markets closer together in the relevant physical sense, while individual countries' governments have progressively relaxed legal and regulatory barriers that impede international capital flows. From the perspective of any one country, the possibility of international borrowing and lending serves a separation function analogous to the fundamental Fisherian separation of production and consumption decisions in a closed economy. An economy that can borrow or lend abroad need not balance its imports and exports at each moment of time. Moreover, once an economy builds up a positive net international creditor position, it can indefinitely finance an excess of imports over exports from the associated interest income. (Conversely, once an economy builds up a net international debtor position, it must indefinitely export in excess of its imports so as to finance the debt service.) From the perspective of the world economy as a whole, international borrowing and lending is even more closely analogous to the closed economy model, in that it facilitates a more efficient allocation of resources across national boundaries.

Apart from these categorical heterogeneities, credit markets also reallocate immediate purchasing power among individuals and among business firms. The need for individuals in differing circumstances to make a complementary arrangements for divergences among their respective income and spending streams is basic to any life-cycle or overlapping-generations model of consumer behaviour. On the borrowing side, practical market limitations on individuals' issuance of

equity-type claims contingent on their future earnings means that the only effective way for most individuals to shift command over purchasing power from the future to the present is through ordinary money-denominated debts. In fact, in most economies individuals' ability to borrow against no security other than future earnings is severely limited in any form, so that most borrowing by individuals occurs in conjunction with the purchase of homes, automobiles or other specific durable goods. On the lending side, individuals choosing to carry purchasing power into the future can hold wealth in any of its available forms, and in fact most individuals hold by far the greater part of their wealth in forms other than credit market instruments. Hence the great bulk of the borrowing done by individuals represents funds advanced by financial intermediary institutions rather than directly by other individuals.

Direct borrowing and lending among business firms is also a significant part of credit market activity especially in highly developed financial systems. On the borrowing side, firms' reliance on debt finance is readily understandable for reasons sketched above, irrespective of whether the funds raised come from individuals, from financial intermediaries or from other businesses. On the lending side, debt held by business firms usually takes the form of very shortterm liquid instruments intended to provide maximum flexibility in the future disposition of the purchasing power thus deferred.

In sum, the credit markets play the fundamental role of enabling an economy populated by heterogeneous agents to achieve superior resource allocations by redistributing immediate purchasing power in exchange for money-denominated claims on the future. Because of the intensive use of debt to finance both business and residential investment, in establishing the terms on which such transfers take place also play a consequent role in guiding the economy's capital accumulation and capital allocation over time that is analogous to – and, in some economies, as important as – the parallel incentives provided by the capital markets. In addition, in part because those elements of total spending that are typically debt-financed bulk large in aggregate demand, in many economies fluctuations of overall economic activity are as closely related to the movement of total credit as to the movements of any other financial aggregates (like any measure of money, for example).

Finally, as in the case for capital markets, several other features of actual credit markets that in principle need not be so, but in fact are so, have exerted a strong influence on the way in which economists have studied these markets over many years. One of the most important in this regard is the fact, noted above, that individuals directly hold relatively few credit market instruments. Instead, the great bulk of the borrowing and lending in any even moderately advanced economy takes place through specialized financial intermediaries, including commercial banks, non-bank thrift institutions, insurance companies, pension funds, mutual funds, and so on.

Standard rationales underlying financial intermediation include the minimization of information and transactions costs, and the diversification of risks, in a world in which assets are imperfectly divisible and both asset returns and wealth-holders' cash-flow positions are imperfectly correlated. In principle, these rationales apply to capital markets as well as credit markets, and in many countries institutions like mutual funds and pension funds do play an important role in holding equity shares. In practice, however, in many countries the bulk of the existing equity securities is still held directly by individuals rather than through financial intermediaries, while the opposite is true for debt instruments. As a result, the study of financial intermediation in general, and of specific kinds of intermediary institutions in particular, has been a major focus of the economic analysis of credit markets.

Another feature of actual credit markets that has likewise attracted a voluminous economic literature has been the simultaneous existence of a great variety of different debt instruments, especially including debts that differ according to their respective stated maturities. Although in principle only a single form of debt instrument, with a unique maturity, would enable the credit market to serve much of its economic functions, in fact almost all known credit markets are characterized

by the simultaneous existence of many debt instruments with differing terms to maturity. The need for the market to price these debts – that is, to establish a term structure of interest rates – not only raises issues of risk analogous to those discussed above in relation to capital markets but also makes explicit the need for a more general intertemporal framework of analysis.

At least since Hicks (1939), economists have been aware at some level that short-term and long-term debts are both risky assets, each from a particular time perspective. Apart from risks associated with default and inflation, short-term debt provides a certain return to holders over a short-time horizon, so that short-term government debt could plausibly constitute the risk-free asset in a no-inflation version of the standard capital asset pricing model represented by Eqs. 1 and 2 above. Over a longer horizon, however, short-term debt preserves capital value only by exposing both borrowers and lenders to an income risk if interest rates fluctuate. Conversely, long-term debt maintains income streams only by exposing borrowers and lenders to the risk of fluctuating capital value over any time horizon shorter than the stated term to maturity. At an a priori level, there is no way to establish which form of risk is more important, and hence no way to establish even the sign of the expected return premium that risk-averse borrowers and lenders would establish in pricing short-term and long-term debts relative to one another.

Following both Hicks and Keynes (1936), most economists have assumed as an empirical matter that typically prevailing preferences are such that lenders require, and borrowers are willing to pay, a positive expected return premium for the capital risk inherent in long-term debt. Hence the subsequent development of the term structure literature has taken a form at least in principle compatible with the single-period capital asset pricing model. More recently, however, following Stiglitz's (1970) explicit demonstration of the connection between the risk pricing of receipt streams and preferences with respect to consumption streams, the economic literature of asset pricing has tended to return to the position that there is no general answer to the question of whether short-term or long-term debts are more risky. Instead, the preferred form of analysis has increasingly become an explicitly intertemporal model, like Merton's (1973b) intertemporal capital asset pricing model or, more recently, Ross's (1976) arbitrage pricing model as generalized by Cox et al. (1985).

Money Markets

The economic role played by the money market is more difficult to establish than that of the markets for capital and credit, in part because 'money' is not straightforward to define. The standard practice among non-economists, which often creates unexpected confusion for economists, is to refer to 'money' indistinguishably from short-term forms of credit, so that 'the money market' is just that segment of the credit market devoted to issuing and trading short-term debts, and 'money rates' are correspondingly the stated nominal interest rates on money market instruments thus defined. By contrast, economists have traditionally viewed, money as distinct from credit, and have given money a central place in macroeconomic analysis which typically appeals to some form of aggregation argument to assume away the existence of credit altogether.

Two lines of thinking, neither necessarily easy to convert into an operational definition of 'money', have traditionally dominated economists' thinking on the subject. One has emphasized the role of money as a form of wealth (in traditional language, a store of value). The problem then is to define which forms of wealth constitute money and which do not. The emphasis in drawing such distinctions has typically rested on the safety and liquidity of the asset, in the sense of its relative freedom from default risk and its ease of conversion, at a predetermined rate of exchange, into whatever is the economy's means of payment. Although the general idea behind such thinking is clear enough, in actually existing economies it has proved impossible to draw the requisite line between money and non-money assets without imposing arbitrary distinctions. Typically, the more highly developed an

economy's financial system, the greater is the need for such arbitrary judgements.

The alternative line of traditional thinking has been to emphasize the role of money in effecting transactions, and hence to define as money just those assets that are acceptable as means of payment. One problem here is that both legalities and common business practice sometimes make ambiguous what constitutes an acceptable means of payment. Indeed, in highly developed financial systems an increasing volume of transactions is effected without requiring the actual holding of any specific asset identifiable as money. Moreover, this approach leads to further difficulties, even apart from definitional problems. If money is used as one side of every transaction in the respective markets for all goods and services and all other assets, then the meaning of 'the money market' is unclear except in the sense that there exists a demand for money equal to the net supply of all other tradeables, and, correspondingly, a supply of money equal to the net demand for all other tradeables.

Under either the store-of-value approach or the means-of-payment approach, the central role conventionally attached to the money market in modern macroeconomic analysis primarily reflects the standard institutional structure within which monetary policy consists in the first instance of actions by the central bank that, either directly or through the financial intermediary system, affect the supply of money however it is defined. Market equilibrium then requires a corresponding change in the demand for money – that is, in the demand for highly liquid assets or for the means of payment, depending on the definitional approach assumed. In either case, the required shift in the public's aggregate portfolio demands presumably requires, in turn, a shift in the structure of expected asset returns, with consequent implications for non-financial economic activity under any of a variety of familiar theories of consumption, investment and production behaviour.

The specifics of this process, however, depend crucially on the definition of 'money'. Under the approach that identifies money with assets meeting sufficient criteria of safety and liquidity, the demand for money is merely a by-product of the theory of risk-averse portfolio selection under uncertainty. Under this approach, what is more difficult is to specify the process connecting the supply of money, so defined, to the central bank's actions. To the extent that the supply of assets defined as money consists largely of the liabilities of depository intermediaries, and to the extent that the relevant institutional arrangements require intermediaries to hold reserves against their liabilities, the connection between money supply and central bank actions that provide or withdraw intermediary reserves is apparent enough. When there is no reserve requirement, however – because either specific kinds of intermediary institutions or specific kinds of intermediary liabilities face no reserve requirement – the connection between monetary policy actions and money supply is more problematic.

The situation under the approach that identifies money with the means of payment is roughly the opposite. Because most economies' means of payment consist largely of the direct liabilities of the central bank and the reservable liabilities of specific intermediaries, connecting the supply of money to central bank reserve actions is relatively straightforward. What is more difficult under this approach is establishing the link to the demand for money thus defined, and hence ultimately the effect on non-financial economic activity. When assets other than the means of payment also provide safety and liquidity, the standard theory of portfolio selection no longer suffices to determine the demand for the means of payment itself. Economic analysis of this problem has largely developed along the inventory-theoretic lines laid out initially by Baumol (1952) and Tobin (1956) and by Miller and Orr (1966). Especially in modern circumstances that readily permit transactions on a credit basis, however, the relevance of such 'cash in advance' models is unclear.

Regardless of the specific conceptual approach taken to define money, it is clear that the deposit liabilities of financial intermediaries bulk large in individuals' direct wealth holding in most actual economies, so that economists' study of money markets has heavily focused on the role of

intermediaries and intermediation. The reasons for the prominent position of intermediary liabilities in individuals' direct wealth-holdings are not difficult to understand. The deposits of banks and similar intermediaries typically provide the most convenient means of settling most transactions, and the asset transformation provided by financial intermediations makes it attractive for most individuals to participate in the market for many kinds of assets via intermediaries rather than directly.

As a result, 'the money market' in most actual economies consists largely of financial intermediaries on one side and both individuals and business firms on the other. Here, as elsewhere in modern economies, the profusion of differentiated financial products is vast. Money market assets in this sense consist of checkable and non-checkable deposits, demand deposits and deposits for stated terms ranging from a few days to many months, deposits with fixed (nominal) returns and variable returns, and so on. Moreover, in the eyes of most market participants, short-term credit market claims that are close portfolio substitutes for intermediary deposits (commercial paper) are money market instruments too.

Capitalism

Robert L. Heilbroner

Abstract

Capitalism is a unique historical formation with core institutions and distinct movements. It involves the rise of a mercantile class, the separation of production from the state, and a mentality of rational calculation. Its characteristic logic revolving around the accumulation of capital reflects the omnipresence of competition. It displays broad tendencies to unprecedented wealth creation, skewed size distributions of enterprise, large public sectors, and cycles of activity. Whereas students of capitalism traditionally envisaged an end to the capitalist period of history, modern economists show little interest in historical projection.

Capitalism is often called *market society* by economists, and the *free enterprise system* by business and government spokesmen. But these terms, which emphasize certain economic or political characteristics, do not suffice to describe either the complexity or the crucial identificatory elements of the system. Capitalism is better viewed as a historical 'formation', distinguishable from formations that have preceded it, or that today parallel it, both by a core of central institutions and by the motion these institutions impart to the whole. Although capitalism assumes a wide variety of appearances from period to period and place to place – one need only compare Dickensian England and 20th-century Sweden or Japan – these core institutions and distinctive movements are discoverable in all of them, and allow us to speak of capitalism as a historical entity, comparable to ancient imperial kingdoms or to the feudal system.

The most widely acknowledged achievement of capitalist societies is their capacity to amass wealth on an unprecedented scale, a capacity to which Marx and Engels paid unstinting tribute in *The Communist Manifesto*. It is important to understand, however, that the wealth amassed by capitalism differs in quality as well as quantity from that accumulated in precapitalist societies. Many ancient kingdoms, such as Egypt, displayed remarkable capacities to gather a surplus of production above that needed for the maintenance of the existing level of material life, applying the surplus to the creation of massive religious or public monuments, military works or luxury consumption. What is characteristic of these forms of wealth is that their desirable attributes lay in the specific use-values – war, worship, adornment – to which their physical embodiments directly gave rise. By way of decisive contrast, the wealth amassed under capitalism is valued not for its specific use-values but for its generalized exchange-value. Wealth under capitalism is therefore typically accumulated as *commodities* – objects produced for sale rather than for direct use or enjoyment by their owners; and the extraordinary success of capitalism in amassing wealth means that the production of commodities makes possible a far greater expansion of wealth than its accumulation as use-values for the rulers of earlier historical formations.

Both Smith and Marx stressed the importance of the expansion of the commodity form of

wealth. For example, Smith considered labour to be 'productive' only if it created goods whose sale could replenish and enlarge the national fund of capital, not when its product was intrinsically useful or meritorious. In the same fashion, Marx described the accumulation of wealth under capitalism as a circuit in which money capital (M) was exchanged for commodities (C), to be sold for a larger money sum (M′), in a never-ending metamorphosis of M–C–M′.

Although the dynamics of the M–C–M′ process vary greatly depending on whether the commodities are trading goods or labour power and fixed capital equipment, the presence of this imperious internal circuit of capital constitutes a prime identificatory element for capitalism as a historical genus. As such, it focuses attention on two important aspects of capitalism. One of these concerns the motives that impel capitalists on their insatiable pursuit. For modern economists the answer to this question lies in 'utility maximization', an answer that generally refers to the same presumed attribute of human nature as that which Smith called the 'desire of bettering our condition'. The unappeasable character of the expansive drive for capital suggests, however, that its roots lie not so much in these conscious motivations as in the gratification of unconscious drives, specifically the universal infantile need for affect and experience of frustrated aggression. Such needs and drives surface in all societies as the desires for prestige and for personal domination. From this point of view, capitalism appears not merely as an 'economic system' knit by the appeals of mutually advantageous exchange, but as a larger cultural setting in which the pursuit of wealth fulfils the same unconscious purposes as did the pursuit of military glory or the celebration of personal majesty in earlier epochs. Such a description conveys the force of the 'animal spirits' (as Keynes referred to them) that both set into motion, and are appeased by, the M–C–M′ circuit. (Heilbroner 1985, ch. 2; Sagan 1985, chs 5, 6).

A second general question raised by the centrality of the M–C–M′ circuit concerns the manner in which the process of capital accumulation organizes and disciplines the social activity that surrounds it. Here analysis focuses on the institutions necessary for the circuit to be maintained. The crucial capitalist institution is generally agreed to be private property in the means of production (not in personal chattels, which is found in all societies). The ability of private property to organize and discipline social activity does not however lie, as is often supposed, in the right of its owners to do with their property whatever they want. Such a dangerous social licence has never existed. It inheres, rather, in the right accorded its owners to withhold their property from the use of society if they so wish.

This negative form of power contrasts sharply with that of the privileged elites in precapitalist social formations. In these imperial kingdoms or feudal holdings, disciplinary power is exercised by the direct use or display of coercive force, so that the bailiff or the seneschal are the agencies through which economic order is directly obtained. The social power of capital is of a different kind – a power of refusal, not of assertion. The capitalist may deny others access to his resources, but he may not force them to work with them. Clearly, such power requires circumstances that make the withholding of access an act of critical consequence. These circumstances can only arise if the general populace is unable to secure a living unless it can gain access to privately owned resources or wealth. Capital thus becomes an instrument of power because its owners can establish claims on output as their *quid pro quo* for permitting access to their property.

Access to property is normally attained by the relationship of 'employment' under which a labourer enters into a contract with an owner of capital, usually selling a fixed number of working hours in exchange for a fixed wage payment. At the conclusion of this 'wage-labour' contract both parties are quit of further obligation to one another, *and the product of the contractual labour becomes* the property of the employer. From this product the employer will pay out his wage obligations and compensate his other suppliers, retaining as a profit any residual that remains.

In detail, forms of profit vary widely, and not all forms are specific to capitalism – trading gains,

for example, long predate its rise. Explanations of profit vary as a consequence, but as a general case it can be said that all profits depend ultimately on inequality of economic position. When the inequality arises from wide disparities of knowledge or access to alternative supplies, profits typically emerge as the mercantile gains that were so important in the eyes of medieval commentators, or as the depredations of monopolistic companies against which Adam Smith inveighed. When the inequality stems from differentials in the productivity of resources or productive capability we have the quasi-rents to which such otherwise different observers as Marshall and Schumpeter attribute the source of capitalist gain. And when the inequality is located in the market relationship between employer and worker it appears as the surplus value central to Marxian and, under a different vocabulary, to classical political economy. As Smith put it, 'Many a workman could not subsist a week, few could subsist a month, and scarce any a year without employment. In the long-run the workman may be as necessary to his master as his master is to him; but the need is not so immediate' (Smith [1776] 1976, p. 84).

This is not the place to enter into a discussion of these forms of profit, all which can be discerned in modern capitalist society. What is of the essence under capitalism is that gains from whatever origin are assigned to the owners of capital, not to workers, managers or government officials. This is a clear indication both of the difference of capitalism from, and its resemblance to earlier social formations. The difference is that product itself now flows to owners of property who have already remunerated its producers, not to its producers – usually peasants in precapitalist societies – who must then 'remunerate' their lords. The resemblance is that both arrangements channel a social surplus into the hands of a superior class, a fact that again reveals the nature of capitalism as a system of social domination, not merely of rational exchange.

Thus we can see that the successful completion of the circuit of accumulation represents a political as well as an economic challenge. The attainment of profit is necessary for the continuance of capitalism not alone because it replenishes the wherewithal of each individual capitalist (or firm) but because it also demonstrates the continuing validity and vitality of the principle of M–C–M′ as the basis on which the formation can be structured. Profit is for capitalism what victory is for a regime organized on military principles, or an increase in the number of adherents for one built on a proselytizing religion.

The Evolution of Capitalism

Capitalism as a 'regime' whose organizing principle is the ceaseless accumulation of capital cannot be understood without some appreciation of the historic changes that bring about its appearance. In this complicated narrative it is useful to distinguish three major themes. The first concerns the transfer of the organization and control of production from the imperial and aristocratic strata of precapitalist states into the hands of mercantile elements. This momentous change originates in the political rubble that followed the fall of the Roman empire. There merchant traders established trading niches that gradually became loci of strategic influence, so that a merchantdom very much at the mercy of feudal lords in the 9th and 10th centuries became by the 12th and 13th centuries an estate with a considerable measure of political influence and social status. The feudal lord continued to oversee the production of the peasantry on his manorial estate, but the merchant, and his descendant the guild master, were organizers of production in the towns, of trade between the towns and of finance for the feudal aristocracy itself.

The transformation of a merchant estate into a capitalist class capable of imagining itself as a political and not just an economic force required centuries to complete and was not, in fact legitimated until the English revolution of the 17th and the French revolution of the 18th centuries. The elements making for this revolutionary transformation can only be alluded to here in passing. A central factor was the gradual remonetization of medieval European life that accompanied its political reconstitution. The replacement of feudal social relationships, mediated through custom and

tradition, by market relationships knit by exchange worked steadily to improve the wealth and social importance of the merchant against the aristocrat. This enhancement was accelerated by many related developments – the inflationary consequence of the importation of Spanish gold in the 16th century, which further undermined the rentier position of feudal lords; the steady stream of runaway serfs who left the land for the precarious freedom of the towns and cities, placing further economic pressure on their former masters; the growth of national power that encouraged alliances between monarchs and merchants for their mutual advantage; and yet other social changes (see Pirenne 1936; Hilton 1978).

The overall transfer of power from aristocratic to bourgeois auspices is often subsumed under the theme of the rise of market society; that is, as the increasingly *economic* organization of production and distribution through purchase and sale rather than by command or tradition. This economic revolution, from which emerge the 'factors of production' that characterize market society, must however be understood as the end product of a *political* convulsion in which one social order is destroyed to make way for a new one. Thus the creation of a propertyless waged labour force – the prerequisite for the appearance of labour-power as a commodity that would become enmeshed in the M–C–M′ circuit – is a disruptive social change that begins in England in the late 16th century with the dispossession of peasant occupants from communal land and does not run its course until well into the 19th century. In similar fashion, the transformation of feudal manors from centres of social and juridical life into real estate, or the destruction of the protected guilds before the unconstrained expansion of nascent capitalist enterprises, embody wrenching socio-political dislocations, not merely the smooth diffusion of preexisting economic relations throughout society. It is such painful rearrangements of power and status that underlay the 'great transformation' out of which capitalist market relationships finally arise (Polanyi 1957, Part II).

A second theme in the historical evolution of capital emphasizes a related but distinct aspect of political change. Here the main emphasis lies not so much in the functional organization of production as in the separation of a traditionally seamless web of rulership, extending over all activities within the historical formation, into two realms, each concerned with a differentiated part of the whole. One of these realms involved the exercise of the traditional political tasks of rulership – mainly the formation and enforcement of law and the declaration and conduct of war. These undertakings continued to be entrusted to the existing state apparatus which retained (or regained) the monopoly of legal violence and remained the centre of authority and ceremony. The other realm was limited to the production and distribution of goods and services; that is, to the direction of the material affairs of society, from the marshalling of the workforce to the amassing and use of the social surplus. In the fulfilment of this task, the second realm also extended its reach beyond the boundaries of the territorial state, insofar as commodities were sold to and procured from outlying regions and countries that became enmeshed in the circuit of capital.

The formation of these two realms was of epoch-making importance for the constitution of capitalism. The creation of a broad sphere of social activity from which the exercise of traditional command was excluded bestowed on capitalism another unmistakable badge of historic specificity; namely, the creation of an 'economy', a semi-independent state within a state and also extending beyond its borders.

This in turn brought two remarkable consequences. One of these was the establishment of a political agenda unique to capitalism, in which the relationship of the two realms became a central question around which political discussion revolved, and indeed continues to revolve. In this discussion the overarching unity and mutual dependency of the two realms tends to be overlooked. The organization of production is generally regarded as a wholly 'economic' activity, ignoring the political function performed by the wage–labour relationship in disciplining the workforce in lieu of bailiffs and seneschals. In like fashion, the discharge of political authority is regarded as essentially separable from the operation of the economic realm, ignoring the provision

of the legal, military and material contributions without which the private sphere could not function properly or even exist. In this way, the presence of two realms, each responsible for part of the activities necessary for the maintenance of the social formation, not only gives to capitalism a structure entirely different from that of any pre-capitalist society but also establishes the basis for a problem that uniquely preoccupies capitalism; namely, the appropriate role of the state vis-à-vis the sphere of production and distribution.

More widely recognized is the second major effect of the division of realms in encouraging economic and political freedom. Here the capitalist institution of private property again takes centre stage, this time not as a means of arranging production or allocating surplus, but as the shield behind which designated personal rights can be protected. Originally conceived as a means for securing the accumulations of merchants from the seizures of kings, the rights of property were generalized through the market into a general protection accorded to all property, including not least the right of the worker to the ownership of his or her own labour-power.

Now the wage–labour relationship appears not as means for the subordination of labour but for its emancipation, for the crucial advance of wage-labour over enslaved or enserfed labour lies in the right of the working person to deny the capitalist access to labour-power on exactly the same legal basis as that which enables the capitalist to deny the worker access to property. There is, therefore, an institutional basis for the claim that the two realms of capitalism are conducive to certain important kinds of freedom, and that a sphere of market ties may be necessary for the prevention of excessive state power. This is surely an important part of Smith's celebration of the society of 'natural liberty', and has been the basis of the general conservative endorsement of capitalism. Unquestionably, the greatest achievements of human liberty thus far attained in organized society have been achieved in certain advanced capitalist societies. One cannot, however, make the wider claim that capitalism is a sufficient condition for freedom, as the most cursory survey of modern history will confirm.

A third theme in the evolution of capitalism calls attention to the cultural changes that have accompanied and shaped its institutional framework. Much emphasis has been given to this theme in the work of Weber and Schumpeter, both of whom stress the historic distinctions between the essentially rational – that is, means-ends calculating – culture of capitalist civilization compared with the 'irrational' cultures of previous social formations. Here it is important to recognize that rationality does not refer to the *principle* of capitalism, for we have seen that the impetus to amass wealth is only a sublimation of deeper-lying non-rational drives and needs, but to the behavioural paths followed in the pursuit of that principle. The drive to amass capital can be analysed in terms of a calculus that is less readily apparent, if indeed present at all, in the search for other forms of prestige and power. This pervasive calculating mind-set is itself the outcome both of the abstract nature of exchange-value, which makes possible commensurations that cannot be carried out in terms of glory or sheer display, and of the pressures exerted by the marketplace, which penalize economic actors who fail to follow the arrow of economic advantage. Capitalism is therefore distinguishable in history by the predominance of a prudent, accountant-like comparison of costs and benefits, a perspective discoverable in the mercantile pockets of earlier formations but highly uncharacteristic of the tempers of their ruling elites (see Weber 1930; Schumpeter 1942, ch. XI).

The cultural change associated with capitalism goes further, however, than the rationalization of its general outlook. Indeed, when we examine the general culture of capitalist life we are most forcibly struck by an aspect that precedes and underlies that highlighted above. This is the presence of an ideological framework that contrasts sharply with that of pre-capitalist formations. I do not use the word *ideology* in a pejorative sense, as denoting a set of ideas foisted on the populace by a ruling order in order to manipulate it, but rather as a set of belief systems to which the ruling elements of the society themselves turn for self-clarification and explanation. In this sense, ideology expresses what the dominant class in a society

sincerely believes to be the true explanations of the questions it faces.

That which is characteristic of the ideologies of earlier formations is their unified and monolithic character. In the ancient civilizations of which we know, an all-embracing world view, usually religious in nature, explicates every aspect of life, from the workings of the physical universe, through the justification of rulership, down to the smallest details of social routines and attitudes. By way of contrast, the ideology that emerges within capitalism is made up of diverse strands, more of them secular than religious and many of them in some degree of conflict with other strands. By the end of the 18th century, and to some degree before, the explanation system to which capitalist societies turn with respect to the workings of the universe is science, not religious cosmology. In the same manner, rulership is no longer regarded as the natural prerogative of a divinely chosen elite but perceived as 'government'; that is, as the manner in which 'individuals' create an organization for their mutual protection and advancement. Not least, the panorama of work and the patterns of material life are perceived not as the natural order of things but as a complex web of interactions that can be made comprehensible through the teachings of political economy, later economics. The individual threads of these separate scientific, political-individualist and economic belief systems originate in many cases before the unmistakable emergence of capitalism in the 18th century, but their incorporation into a skein of culture provides yet another identifying theme of the history of capitalist development.

Within this skein, the ideology of economics is obviously of central interest for economists. A crucial element of this belief system involves changes in the attitude towards acquisitiveness itself, above all the disappearance of the ancient concern with good and evil as the most immediate and inescapable consequence of wealth-gathering. As Hirschman has shown, this change was accomplished in part by the gradual reinterpretation of the dangerous 'passion' of avarice as a benign 'interest', capable of steadying and domesticating social intercourse rather than disrupting and demoralizing it (Hirschman 1977). Other crucial elements of understanding were provided by Locke's brilliant demonstration in *The Second Treatise on Government* (1690) that unlimited acquisition did not contravene the dictates of reason or Scripture, and by the full pardon granted to wealth-seeking by Bentham, who demonstrated that the happiness of all was the natural outcome of the self-regarding pursuit of the happiness of each.

The problem of good and evil was thus removed from the concerns of political economy and relegated to those of morality; and economics as an inquiry into the workings of daily life was thereby differentiated from earlier inquiries, such as the reflections of Aristotle or Aquinas, by its explicit disregard of their central search for moral understanding. Perhaps more accurately, the constitution of a 'science' of economics as the most important form of social self-scrutiny of capitalist societies could not be attempted until moral issues, which defied the calculus of the market, were effectively excluded from the field of its investigations.

The Logic of the System

This conception of capitalism as a historical formation with distinctive political and cultural as well as economic properties derives from the work of those relatively few economists interested in capitalism as a 'stage' of social evolution. In addition to the seminal work of Marx and the literature that his work has inspired, the conception draws on the writings of Smith, Mill, Veblen, Schumpeter and a number of sociologists and historians, notable among them Weber and Braudel. The majority of present-day economists do not use so broad a canvas, concentrating on capitalism as a market system, with the consequence of emphasizing its functional rather than its institutional or constitutive aspects.

In addition to the characteristic features of its institutional 'nature', capitalism can also be identified by its changing configurations and profiles as it moves through time. Insofar as these movements are rooted in the behaviour-shaping properties of its nature, we can speak of them as

expressing the logic of the system, much as conquest or dynastic alliance express the logic of systems built on the principle of imperial rule, or the relatively changeless selfvreproduction of primitive societies expresses the logic of societies ordered on the basis on kinship, reciprocity and adaptation to the givens of the physical environment.

The logic of capitalism ultimately derives from the pressure exerted by the expansive M–C–M′ process, but it is useful to divide this overall force into two categories. The first of these concerns the 'internal' changes impressed upon the formation by virtue of its necessity to accumulate capital – its metabolic processes, so to speak. The second deals with its larger 'external' motions – changes in its institutional structure or in important indicia of performance as the system evolves through history.

The internal dynamics of capitalism spring from the continuous exposure of individual capitals to capture by other capitalists. This is the consequence of the disbursement of capital-as-money into the hands of the public in the form of wages and other costs. Each capitalist must then seek to win back his expended capital by selling commodities to the public, against the efforts of other capitalists to do the same. This process of the enforced dissolution and uncertain recapture of money capital in the circuit of accumulation is, of course, the pressure of competition that is the social outcome of generalized profit-seeking. We can see, however, that competition cannot be adequately described merely as the vying of suppliers in the marketplace. As both Marx and Schumpeter recognized, competition is at bottom a consequence of the mutual encroachments bred by the capitalist drive for expansion, not of the numbers of firms contending in a given market.

The process of the inescapable dissolution and problematical recapture of individual capitals now gives rise to the activities designed to protect these capitals from seizure. The most readily available means of self-defence is the search for new processes or products that will yield a competitive advantage – the same search that also serves to facilitate the expansion of capital through the development of new markets. Competition thus reinforces the introduction of technological and organizational change into the heart of the accumulation process, usually in two forms: attempts to cheapen the cost of production by displacements of labour by machinery (or of one form of fixed capital by another); or attempts to gain the public's purchasing power by the design of wholly new forms of commodities. As a consequence, one of the most recognizable attributes of capitalist 'internal' dynamics has been its constant revolutionizing of the techniques of production and its continuous commodification of material life, the sources of its vaunted capacity to change and elevate living standards.

A further internal change also arises from the expansive pressures of the core process of capital accumulation. This is a threat to the capacity as a whole to extract a profit from the production of commodities. This tendency arises from the long-run effect of rising living standards in strengthening the bargaining power of labour versus capital. There is no way in which individual enterprises can ward off this threat by cutting wages, for in a competitive market system they would thereupon lose their ability to marshall a workforce. Their only protection against a rising tendency of the wage level is to substitute capital for labour where that is possible. For the system as a whole, the need to hold down the bargaining power of labour must therefore hinge on a generalization of individual cost-reducing efforts, through the system-wide displacement of labour by machinery, or by the direct use of government policies to maintain a profit-yielding balance between labour and capital, or by systemic failures – 'crises' – that create generalized unemployment. Whether attempted by deliberate policy or brought about by the outcome of spontaneous market forces, the pressure to secure a profit-compatible level of wages thus becomes a key aspect in the internal dynamics of the system.

A final attribute of the internal logic of capitalism must also be traced to its core process of accumulation. This is the achievement of a highly adaptive method of matching supplies against demands without the necessity of political intervention. This cybernetic capacity is

surely one of the historical hallmarks of capitalism, and is regularly emphasized in the 'comparative systems approach' in which the responsive capacities of the market mechanism are compared with the inertias and rigidities of systems in which tradition or command (planning) must fulfil the allocational task. A critique of the successes and failures of the market system cannot be attempted here. Let us only emphasize that the workings of the system itself derive from institutional attributes whose genesis we have already observed – namely, the establishment of free contractual relations as the means for social coordination; the establishment of a social realm of production and distribution from which government intervention is largely excluded; the legitimation of acquisitive behaviour as the social norm; and activating the whole, the imperious search for the enlargement of exchange-value as the active principle of the historical formation itself.

Large-Scale Tendencies

From the metabolism of capitalism also emerges its larger 'external' motions – the overall trajectory often described as its macroeconomic movement, and the configurational changes that are the main concern of institutional economics. It may be possible to convey some sense of these general movements if we note three general aspects characteristic of them.

We have already paid heed to the first of these, the tendency of the capitalist system to accumulate wealth on an unparalleled scale. Some indication of the magnitude of this process emerges in the contrast between the increase in per capital GNP of developed (capitalist) and less-developed (noncapitalist) countries (Table 1):

Capitalism, Table 1 GNP per capita (1960 dollars and prices)

	Presently developed countries	Presently less-developed countries
Around 1750	$180	$180–90
Around 1930	780	190
Around 1980	3000	410

Source: Paul Bairoch in Faaland (1982), p. 162

After our lengthy discussion of the central role of accumulation within capitalism it does not seem necessary to relate this historic trend to its institutional base. Two somewhat neglected aspects of the overall increase in wealth seem worth mentioning, however. The first is that the increase in per capita GNP includes both augmentations in the volume of output and an extension of the M–C–M′ process itself within the social world. This is manifested in a continuous implosion of the accumulation process within capitalist societies – the process of the commodification of material life to which we earlier referred – and its explosion into neighbouring noncapitalist societies.

This explosive thrust calls attention to the second attribute of the overall expansion of wealth. It is that capital, as such, knows no national limits. From its earliest historic appearance, capital has been driven to link its 'domestic' base with foreign regions or countries, using the latter as suppliers of cheap labour-power or cheap raw materials or as markets for the output of the domestic economy. The consequence has been the emergence of self-reinforcing and cumulative tendencies towards strength at the centre, to which surplus is siphoned, and weakness in the periphery, from which it is extracted. The economic dimensions of this global drift are immediately visible in the previous table. This is the basis for what has been called the 'development of underdevelopment' as the manner in which ancient patterns of international hegemony are expressed in the context of capitalist relationships (Myrdal 1957, Part I: Baran 1957, chs V–VII).

We turn next to a different overall manifestation of the larger logic of capitalist development – its changes in institutional texture. There have been, of course, many such changes in the long span of Western capitalist experience – indeed, it is the very diversity of the faces of capitalism that prompted our search for its deep-lying identifying elements. Nonetheless, two changes deserve to be singled out, not only because of their sweeping magnitude and transnational occurrence, but because they have deeply altered the evolutionary

logic of the system itself. These have been the emergence within all modern capitalisms of highly skewed size distributions of enterprise, and of very large and powerful public sectors.

The general extent of these transformations is sufficiently well known not to require detailed exposition here. Suffice it to illustrate the trend by contrasting the largely atomistic composition of manufacturing enterprise in the United States at the middle of the 19th century with the situation in the 1980s, when seven-eighths of all industrial sales were produced by 0.1 per cent of the population of industrial firms. The enlargement of the public sector is not so dramatic but is equally unmistakable. During the present century in the United States, its size (measured by all government purchases of output plus transfer payments) has increased from perhaps 7.5 per cent of GNP to over 35 per cent, a trend that is considerably outpaced by a number of European capitalisms.

The first of these two large-scale shifts in the configuration can be directly traced to the pressures generated by the M–C–M′ circuit. The change from a relatively homogeneous texture of enterprise to one of extreme disparities of size is the consequence not only of differential rates of growth of different units of capital, but of defensive business strategies of trustification and merger, and the winnowing effect of economic disruptions on smaller and weaker units of capital. There is little disagreement as to the endemic source of this transformation in the dynamics of the marketplace and the imperative of business expansion.

The growth of large public sectors is not so immediately attributable to the accumulation process proper but rather results from changes in the logic of capitalist movements after the concentration of industry has taken place. Here the crucial change lies in the increasing instability of the market mechanism, as its constituent parts cease to resemble a honeycomb of small units, individually weak but collectively resilient, and take on the character of a structure of beams and girders, each very strong but collectively rigid and interlocked. It seems plausible that this rigidification was the underlying cause of the increasingly disruptive nature of the crises that appeared first in the late 19th century and climaxed in the great depression of the 1930s; and it is widely accepted that the growth of the public sector mainly owes its origins to efforts to mitigate the effects of that instability or to prevent its recurrence.

This brings us to the last general aspect of capitalist development; namely, the tendency for interruptions and failures to break the general momentum of capital accumulation. Perhaps no aspect of the logic of capitalism has been more intensively studied than these recurrent failures in the accumulation process. In the name of stagnation, gluts, panics, cycles, crises and long waves a vast literature has emerged to explain the causes and effects of intermittent systematic difficulties in successfully negotiating the passage from M to M'. The variables chosen to play strategic roles in the explanation of the phenomenon are also widely diverse: the saturation of markets; the undertow of insufficient consumption; the technological displacement of labour; the pressure of wages against profit margins; various monetary disorders; the general 'anarchy' of production; the effect of ill-considered government policy, and still others.

Despite the variety of elements to which various theorists have turned, a common thread unites most of their investigations. This is the premise that the instabilities of capitalist growth originate in the process of accumulation itself. Even theorists who have the greatest confidence in the inherent tendency of the system to seek a steady growth path, or who look to government intervention (in modern capitalism) as the main instability-generating force, recognize that economic expansion tends to generate fluctuations in the rate of growth, whether from the 'lumpy' character of investment, volatile expectations, or other causes. In similar fashion, economists who stress instability rather than stability as the intrinsic tendency of the system do not deny the possibility of renewed accumulation once the decline has performed its surgical work; indeed, Marx, the most powerful proponent of the inherently unstable character of the M–C–M′ process, was the first to assert that the function of crisis was to prepare the way for a renewal of accumulation.

In a sense, then, the point at issue is not whether economic growth is inherently unstable,

but the speed and efficacy of the unaided market mechanism in correcting its instability. This ongoing debate mainly takes the form of sharp disagreements with respect to the effects of government policy in supplementing or undermining the corrective powers of the market. The failure to reach accord on this issue reflects more than differences of informed opinion with regard to the consequences of sticky wages or prices, or ill-timed government interventions, and the like. It should not be forgotten that, from the viewpoint of capitalism as a regime, interruptions pose the same threats as did hiatuses in dynastic succession or breakdowns of imperial hegemony in earlier formations. It is not surprising, then, that the philosophic predilections of theorists play a significant role in their diagnoses of the problem, inclining economists to one side or the other of the debate on the basis of their general political sympathies with the regime, rather than on the basis of purely analytic considerations.

Periodization and Prospects

All the foregoing aspects of the system can be traced to its inner metabolism, the money–commodity–money circuit. This is much less the case when we now consider the overarching pattern of change described by the configuration of the social formation as a whole as it moves from one historic 'period' to another.

Traditionally these periods have been identified as early and late mercantilism; pre-industrial, and early and late industrial capitalism; and modern (or late, or state) capitalism. These designations can be made more specific by adumbrating the kinds of institutional change that separate one period from another. These include the size and character of firms (trading companies, putting-out establishments, manufactories, industrial enterprises of increasing complexity); methods of engaging and supervising labour (cottage industry through mass production); the appearance and consolidation of labour unions within various sectors of the economy; technological progress (tools, machines, concatenations of equipment, scientific apparatus); organizational evolution (proprietorships, family corporations, managerial bureaucracies, state participation). David Gordon has coined the term 'social structure of accumulation' to call attention to the changing framework of technical, organizational and ideological conditions within which the accumulation process must take place. Gordon's concept, applied to the general problem of periodization, emphasizes the manner in which the accumulation process first exploits the possibilities of a 'stage' of capitalism, only to confront in time the limitations of that stage which must be transcended by more or less radical institutional alterations (Gordon 1980).

The idea of an accumulation process alternately stimulated and blocked by its institutional constraints provides an illumining heuristic on the intraperiod dynamics of the system, but not a theory of its long-run evolutionary path. This is because not all national capitalisms make the transitions with equal ease or speed from one social structure to another, and because it is not apparent that the pressures of the M–C–M′ process push the overall structure in any clearly defined direction. Thus Holland at the end of the 17th century failed to make the leap beyond mercantilism, and England in turn in the second half of the 19th century failed to create a successful late industrial capitalism. In this regard it is interesting that the explanatory narratives of the great economists apply with far greater cogency to the evolutionary trends within periods than across them – Smith's scenario of growth in *The Wealth of Nations,* for instance, containing no suggestion that the system would move into an industrial phase with quite different dynamics, or Marx's depiction of the laws of motion of the industrialized system containing no hint of its worldwide evolution towards a state-underwritten structure. Although the inner characteristics of the M–C–M′ process enable us to apply the same generic designation of capitalism to its successive species-forms, it does not seem to be possible to demonstrate, even after the fact, that the transition from one stage to another had to be made, or to predict before the fact what the direction of institutional adjustment will be.

These cautions apply to the prospectus confronting capitalism in our day. Its long post World War II boom seems to have been based on three attributes of the social structure of accumulation of that time. One of these was the increasing interconnection between the political and the economic realms, not merely to provide a public base for mass consumption but to utilize the state's power of finance and international leadership to promote foreign private trade and production. Japanese capitalism has been the much cited case in point for the latter development. A second characteristic of the boom was the extraordinary development of technology, based on the close integration of scientific research and technical application. A third was the pronounced bourgeoisification of working-class life, especially in Europe and Japan, greatly reducing the spectre of class conflict in capitalist politics.

On the basis of these developments capitalism enjoyed the longest uninterrupted period of accumulation in its history, from the early 1950s to the mid-1970s. Not only was the boom uninterrupted save for minor and shortlived recessions, but on the wings of its new technological breakthroughs, and under the auspices of its active state cooperation, capitalism made extraordinary advances in introducing its core institutions into many areas of the underdeveloped world.

This halcyon period came to a sharp end in 1980 when growth rates in the United States and Europe fell precipitously. Some, although not all of the causes of this depression can be ascribed to an exhaustion of the expansionary possibilities within the postwar social structure of accumulation. The effect of enlarged and sustained public expenditure gradually shifted from the encouragement of production to the inducement of inflation, thus setting the stage for the adoption of the tight money policies that finally broke the back of the boom. As markets became saturated, the advances in technology lost their capacity to stimulate capital expansion and attention was increasingly directed to their system-threatening aspects – ecologically dangerous products, employment-eroding processes and sovereignty- defying enhancements of the international mobility of money capital and commodities. The international character of capital acquired extraordinary importance, as multinational corporations transplanted fixed capital into underdeveloped regions, from which it launched artillery barrages of commodities back on its domestic territory. And not least, the bourgeoisification of labour may have removed a traditional source of adaptational pressure from capitalism.

It is not possible to foretell how these challenges will be met, or what institutional changes will be forced upon the capitalist world as their consequence, or which capitalist nations will find the institutional and organizational means best suited to continue the accumulation process in this newly emerging milieu. Thus there is no basis for predicting the longevity of the social formation, either in its national instantiations or as a formational whole.

But while history forces on us a salutary agnosticism with regard to the longterm prospects for capitalism, it is interesting to note that all the great economists have envisaged an eventual end to the capitalist period of history. Smith describes the accumulation process as ultimately reaching a plateau when the attainment of riches will be 'complete', followed by a lengthy and deep decline. Ricardo and Mill anticipate the arrival of a 'stationary state', which Mill foresees as the staging ground for a kind of associationist socialism. Marx anticipates a series of worsening crisis, each crises serving a temporary rejuvenating function but bringing closer the day when the system will no longer be able to manage its internal contradictions. Keynes foresees ' a somewhat comprehensive socialization of investment'; Schumpeter, an evolution into a kind of bureaucratic socialism. By way of contrast, contemporary mainstream economists are largely uninterested in questions of historic projection, regarding capitalism as a system whose formal properties can be modelled, whether along general equilibrium or more dynamic lines, without any need to attribute to these models the properties that would enable them to be perceived as historic regimes and without pronouncements as to the likely structural or political destinations towards which they incline. At a time when the need for institutional adaptation seems pressing, such an

historical indifference to the fate of capitalism, on the part of those who are professionally charged with its self-clarification, does not augur well for the future.

Capitalistic and a Capitalistic Production

Lionello F. Punzo

If 'capital' is the set of produced means of production, (almost) all production is capitalistic. Thus, the presence of capital in this sense can at most be (and in the history of economic doctrines was taken to represent) a necessary condition for defining capitalistic production. Differences arose as to the relative emphasis put on the social or techno-economic aspects of such transformation processes.

In Marx's analysis, capitalistic production is the organization of social production specific to a society characterized by private ownership of the means of production and by its separation from 'labour'. This historically given Mode of Production is contrasted with pre- and post-capitalistic forms, where power relationships are regulated according to different principles. By contrast, the distinction between production with and without capital focuses upon the relationship between means and objectives (consumption goods) of production activity. It played a role in the era of the full articulation of neoclassical thought. Its analytical use obviously depended upon the specific conception (and representation) of capital.

According to perhaps the most common theory, Capital is a factor of production, a member of a triad with Labour and Land. This view emphasizes the aspect of capital as a stock of man-produced goods which are at any point of time available in fixed quantities. (A)capitalistic production entails the application of (un)aided labour to natural resources. On the other hand, according to the Austrian (Böhm-Bawerk) definition, capital is the set of intermediate goods (or 'maturing consumption goods') emerging in the transformation of labour services into final goods when indirect methods of production are employed. This conception emphasizes the functional relationship whereby capital is the mode of realization of advanced production activity. Accordingly, acapitalistic production is direct production of consumption goods through application of bare labour to natural resources. Finally, in Wicksell's theoretical compromise, capital is a stock of used-up services of both labour and land. Production without capital is carried on by means of labour and natural resources in a state where capital goods either do not exist or are free goods relative to the available technology. (See Part II of the first volume of Wicksell's Lectures,

1934.) This definition obviously overlooks the fact that capital goods are themselves a byproduct of the advancement of technological knowledge, an idea implicit in Böhm-Bawerk and hinted at by Schumpeter.

At any rate, in all its various interpretations, acapitalistic production was a logical abstraction meant to illustrate, in a simpler analytical context, some basic principles holding for capitalistic production. In Böhm-Bawerk, this is the principle of the higher productivity of indirect (i.e. capitalistic) methods of production. In Wicksell, the distinction is meant to illustrate the marginalistic approach to the distribution of income and to show how it can be extended from the simpler production with labour and land only to production involving capital goods. In the former case, wage rate and rent are regulated by the marginal productivities of the two factors, in a state of full employment of labour and zero entrepreneurial profits. However, the extension of the marginal productivity principle to the theory of interest meets a crucial conceptual difficulty due to the fact that capital, being an aggregate of produced goods, has to be measured in value and the latter depends itself on income distribution. It is to avoid a circular argument that Wicksell proposes to regard capital as 'a single coherent mass of saved up resources'. Hence, interest would be (equal to) the difference between the marginal productivity of saved up labour and land and the marginal productivity of current labour and land. According to Wicksell, 'experience' shows that capital has a higher productivity and this is the reason why its share in the national product is normally positive.

It has been proved, in the debate on capital theory in the 1960s, that Wicksell's attempt at finding a way out of the difficulties of the marginalistic approach to income distribution is unsatisfactory. However, the recurrence of the theme of the distinction between acapitalistic and capitalistic production is interesting for it indicates the neoclassical authors' awareness of the theoretical difficulties they met in the treatment of capital and distribution.

Carey, Henry Charles (1793–1879)

Henry W. Spiegel

American social scientist. Born in Philadelphia, the son of Mathew Carey, he was a prolific author, and his influence, though short-lived, spread from Pennsylvania throughout the nation and to Europe.

Carey's economic views were sharply at variance with those of Ricardo and Malthus, and reflect the optimism characteristic of American conditions favourable to economic expansion, conditions from which Carey himself benefited as a successful entrepreneur and promoter. The two leading themes of his writings were protectionism and harmony of interests. In his first book, *Essay on the Rate of Wages* (1835), he opposed trade restrictions as running counter to the providential order. But in *The Past*, *the Present*, *and the Future* (1848) and in later writings, he vigorously appealed for tariff protection as fulfilling his law of association, a law that called for diversified and balanced regional development. Narrow specialization and foreign trade would violate this law. In *The Slave Trade* (1853) Carey suggested protectionism for the South, where it would foster industrial development.

The scope of Carey's optimistic belief in a harmonious order gradually widened. In his first book he postulated harmony between capitalists and workers, the former benefiting from rising profits and the latter from wages that rose as a result of the accumulation of capital. In his *Principles of Political Economy* (1837–1840) the landowner becomes part of the harmonious order, with his earnings depicted as a return on his capital rather than a gift of nature. Population growth does not disturb the harmony as it is restrained by social conditioning. There are further attacks against the Ricardian rent theory in *The Past*, *the Present*, *and the Future*, where cultivation is said to move from inferior to superior land, not vice versa as Ricardo had taught, and with returns increasing rather than decreasing. In the *Principles of Social Science* (1858–1859) Carey expands his vision of a harmonious order to apply to the universe, and in *The Unity of Law* (1872) he maintains that cosmic and social laws are identical. Carey has been characterized as 'easily the most perverse and the most original American political economist before Veblen' (Conkin 1980, p. 261).

Carey, Mathew (1760–1839)

Henry W. Spiegel

American publicist. Carey came to America as a poor immigrant from Ireland. He settled in Philadelphia, where in 1785 he founded a publishing, printing and bookselling business that eventually became the largest of its kind in the United States; a successor firm is still in the publishing business. Carey became a leading citizen of Philadelphia, got involved in politics, and participated in many local and regional controversies. When, after the end of the War of 1812, the Pennsylvania manufacturers were threatened by a flood of imports, Carey became a leader of the protectionist movement. A prolific writer, he supported its cause by a flood of publications that reached a wide public and helped to establish Hamilton's 'American System'.

In his *Olive Branch* (1814), Carey attempted to reconcile the Federalists and Democrats. A statement promoting protectionism was inserted in later editions of the work, which embodied Carey's message in over 10,000 copies – according to Carey himself, a record for a book not religious in nature.

Among the many pamphlets that Carey wrote in support of various causes, some thirty contain philanthropic appeals aiming to improve the wages and working conditions of the poor. An example of these is his *Address to the Wealthy of the Land* (1831). The free-trade economists with whom he had battled for so long he now takes to task for allegedly discouraging aid to the poor. People, he argues, may be unemployed or casually employed against their wishes, and some work in employments where their supply is large relative to the demand for their labour. He proposes to arouse public opinion against employers who fail to pay a living wage, and points to education and increased mobility of labour as means to improve the position of the poor. Ideas such as these are now commonplaces, but when Carey wrote about them, his was a lonely voice.

The eldest of nine children of Margaret Aitkin and James Carlyle, Thomas Carlyle was born at Ecclefechan in Scotland on 4 December 1795. While Carlyle's contributions ranged over many fields (including history, literary and social criticism, biography, translation and political commentary), in economics he is remembered chiefly as the originator of the epithet 'the dismal science' ('The Nigger Question', 1849; in *Miscellaneous Essays*, vol. 7, p. 84). Among 'the professors of the dismal science', one M'Croudy (J.R. McCulloch) is a principal target of Carlyle's criticism. Yet Carlyle's writings on economics are more extensive than this small measure of recognition might suggest, and his key criticisms of the economic and political tendencies of the 'present times' (as he called them) are contained essentially in three works: *Chartism,* (1840), *Past and Present* (1843) and *Latter-Day Pamphlets* (1850). Almost inevitably, Carlyle's characteristically romantic reaction to the decline of authority and the rise of utilitarian individualism led him into head-on collision with the prevailing economic doctrines of the day. Since, for Carlyle, the challenge of democracy to the *ancien régime* had been carried forward under the mistaken banner 'Abolish it, let there henceforth be no relation at all' (1850, p. 21), it was natural for him to hold that laissez-faire, free competition, the law of supply and demand, and the 'cash nexus' were no more than 'superficial speculations . . . to persuade ourselves . . . to dispense with governing' (1850, p. 20). Although Carlyle's account of the 'cash-nexus' was adopted verbatim by Marx and Engels in the opening pages of *The Communist Manifesto*, in the latter sections of that document his overall position is roundly attacked (see there the reference to the 'Young England', of which Carlyle was a prominent member).

There is also a thinly veiled attack on Carlyle's 'dissatisfaction with the Present . . . and affection and regret towards the Past' in John Stuart Mill's *Political Economy* (1848, pp. 753–4). However, at Carlyle's hands the utilitarian calculus of pleasure and pain fared little better. It was charged

with ignoring all those sentiments, aspirations and interests which distinguished the human from other animals and was dubbed by Carlyle 'the Pig Philosophy' (1850, p. 268). Though Carlyle had few if any followers among economists, he exerted a profound impact upon the thinking of John Ruskin, and he may correctly be regarded as a principal exemplar in England of that reactionary or feudal brand of 'socialism' criticized by Marx and Engels in the *Communist Manifesto.* Carlyle died in Chelsea on 5 February 1881 and was buried in Ecclefechan.

Carroll, Lewis (Charles Lutwidge Dodgson) (1832–1898)

Bernard Grofman

Born on 27 January 1832, he was Student at Christ Church, Oxford, 1852–98, and Lecturer in Mathematics 1856–81. He died on 14 January 1898.

Lewis Carroll was the author of *Alice's Adventures in Wonderland* (1865), *Through the Looking Glass and What Alice Found There* (1872), and a large number of humorous poems of which 'The Hunting of the Snark' (1876) is the best known. In his real identity, that of Charles L. Dodgson, he was a mathematician of modest repute in the areas of geometry, recreational mathematics, and logic: author of *Euclid and his Modern Rivals* (1879), *Curiosa Mathematica* (1888, 1893), and *Symbolic Logic*, *Vol. I* (1896). Under either identity, however, he may appear to be a rather unlikely candidate for inclusion in an encyclopedia of economics. Yet his work on mechanisms for political representation anticipates important ideas in game theory and that branch of public choice theory having to do with committees and elections. The earliest work appeared in three privately printed pamphlets on *The Theory of the Committee* (1873, 1874, 1876) and dealt with a number of topics in majority rule procedures including a discussion of what is known today as the Borda count. Only recently has it been rediscovered and the significance of its contributions realized – almost entirely because of the historical scholarship of Duncan Black (1958, 1967, 1969, 1970).

The Principles of Parliamentary Representation (1st edn, Nov. 1884, 2nd edn, Jan. 1885), applies techniques which we now associate with two-person zero-sum games to solve the problem of the optimal strategy for a two-party competition in a class of voting games in which each party must decide how many candidates it wishes to nominate in a constituency in which each voter may cast v votes (no more than one to each candidate) and there are m seats to be filled. If $v < m$-1 we have what is called the limited vote. If $v = m$ we have plurality or the bloc vote. To make the problem tractable, Dodgson supposes that each of the parties knows the number of its own supporters and those of the opposing party and that each party is able to direct the voting of each of its supporters exactly as it chooses. While not, of course, referring to it as such, he makes use of the idea of a maximin strategy in which each party chooses under the assumption that the opposing party will be optimally distributing its voting strength among an optimal number of candidates.

In this same work, Dodgson considers the question of what voting rule of the type specified above will be optimal in the sense of minimizing the expected proportion of voters whose votes are 'wasted'. By a 'wasted' vote Dodgson here means that the voter's ballot played no part in effecting the outcome; e.g. if a party with s per cent of the

electorate elects h candidates but would have elected that same number of candidates even if it had received support from only s' percent of the electorate ($s' < s$), then ($s - s'$) per cent of the electorate has had its votes wasted. In Dodgson's view, the existence of wasted votes implies that some voters are not having their preferences fully represented. He finds $v = 1$, a special form of the limited vote, commonly called the single non-transferable vote (used in post-World War II Japan) to be optimal under this standard. Under the assumption of a rectangular distribution of party voting support, he finds that the reduction in the magnitude of the expected wasted vote drops off rapidly with increasing m, for $m > 4$.

In related work, Dodgson uses a game-theoretic style of argument to consider optimal party candidate strategies under a cumulative voting system (a semi-proportional system in which each voter may cumulate up to v votes on a single candidate) and under the Hare system (the single transferable vote, a proportional system in which voters indicate their relative orderings of the candidate). For the latter election system, Dodgson looks at the problem of rational coalition forming and provides some examples to show that the results of the Hare system need not be consistent with the expected outcome of a coalitional bargaining game between political parties. However, Dodgson's results are at best suggestive. Indeed the problem he posed has only just been solved (Sugden 1983).

Dodgson's work on proportional representation was guided by his familiarity with research done by a number of Cambridge mathematicians (most involved to some degree with the Proportional Representation Society), a group whom Black (1970) identifies as the Cambridge School of Mathematical Politics. While Dodgson's treatment of proportional representation takes some essential ingredients from these earlier writers, his systematic treatment of the limited vote is a new creation. 'Where there had been only scattered fragments, he leaves a completed edifice' (Black 1970). In making use of the maximin strategy to obtain an equilibrium solution to a particular two-person zero sum game and in examining optimal coalitional strategies in the context of election politics, Dodgson's long-neglected work deserves recognition as a step on the road toward the development of the modern theory of political economy.

Cartel

Leonard W. Weiss

A cartel, according to Webster, can be either 'a written agreement between belligerent nations' such as a prisoner exchange arrangement, or 'a voluntary, often international combination of independent private enterprises supplying like commodities or services' (Webster's 1967). The second concept is our concern here. The majority of cartels have dealt with national or smaller markets, but many of the best known have been international in coverage. Economists often distinguish private cartels and public cartels. In the latter, the government theoretically makes the rules, typically under strong influence from the affected industry and enforces them. Private cartels involve private agreements. They may or may not be publicly enforced depending on the nation, the period and the agreement. Some international cartels are private, but the best known have resulted from agreements among national governments.

Cartels may involve price fixing, output controls, bid-rigging, allocation of customers, allocation of sales by product or territory, establishment of trade practices, common sales agencies or combinations of these. Many medieval cities and mercantilist nations were tightly bound by such restraints of trade, but the cartel movement is usually pictured as arising with the large private firm in the late nineteenth century. Cartels were carried farthest in Germany in the half-century ending with World War II, but they were also important in Austria, Switzerland, Italy, France, Scandinavia and Japan in the same period. They reached their peak during the great depression of the 1930s. Cartelization was slower to develop in Britain and other nations with a common law tradition such as the United States. A prohibition of contracts in restraint of trade (largely a refusal of the courts to enforce) goes back at least to the early fifteenth century in English common law. The prohibition was written into the American Sherman Anti-Trust Act when it was passed in 1890. Even in the United States, however, the National Industrial Recovery Act, passed at the bottom of the great depression in 1933, permitted industries to formulate enforceable 'codes of fair competition'. The Act was ruled unconstitutional by the Supreme Court in 1935, but the United States continued public cartels in such fields as coal-mining, oil production, interstate transportation, and agriculture for many years.

In the years since World War II most private and public industrial cartels have weakened. America's prohibition of private cartels was strengthened and many of its public cartels ended. The Western occupation forces in Japan and Germany imposed cartel prohibitions there. The subsequent national governments revised these rules to permit certain cartels, but they are far removed from the prewar, pro-cartel policies of the same countries. Most other industrial non-communist countries have adopted anti-cartel laws since the war, but few have gone as far as the United States. On the other hand, some international commodity agreements established extremely high prices in the 1970s. In a number of cases such as bauxite and copper the agreements failed within a few years. But the Organization of Petroleum Exporting Countries (OPEC) was able to keep world oil prices far above their costs for more than a decade. This was possible because Saudi Arabia, with more than a quarter of world capacity, was willing to reduce output greatly as smaller producers inside and outside OPEC expanded.

A 'perfect cartel' is one that maximizes the sum of the profits of its members. This requires that output be allocated among participants so that cost is minimized. That, in turn, implies that different producers operate their capacities at different rates. In the long run, some participants' plants would be closed. The traditional solution for private cartels is side payments from the expanding to the contracting producers. In fact, although such payments have been made, perfect cartels have generally been beyond the reach of private cartels short of merger. A perfect cartel would be difficult to distinguish from a well-run firm. The classic example was the prewar German chemical

firm, I.G. Farben (Interessen Gemeinschaft Farbenindustrie meaning 'Community of Interests in the Dye Industry'). It did begin as an eight-firm cartel, but by 1925 they had all merged (Michels 1928).

Enforcement is a crucial aspect of cartels. This requires (a) detection of violations and (b) sanctions on violators. Detection is easy in oral auctions. Violations are immediately obvious when they occur. In the more common cases where firms must bid for customers in sealed-bid auctions or through salesmen, detection is much more difficult, unless winning bids are publicly announced. Cumulative changes in market shares seem to be the most credible evidence of whether 'cheating' is going on or not, but the usefulness of such evidence rapidly declines as the numbers of competing firms increase (Stigler 1964). The implication is that purely private cartels with many members are weak. If they have serious social cost it is most likely to work via changes in institutions such as the establishment of a basing point system or political pressure for oral auctions. Public enforcement seems essential for cartels to raise price for any length of time on unconcentrated markets.

Private enforcement also requires privately imposed sanctions. Oral auctions help here also. Only one conspirator per bid need incur any risk in punishing a violator, and even he need not always 'win'. Punishment in these cases is not severe. Since the violator is usually free to withdraw from the bidding, he need not pay a price that involves a loss. He can be deprived of the gain from collusion and, perhaps, access to the objects being bid for. With sealed bids or where the rivals solicit customers through salesmen, punishment is apt to mean general price wars – the temporary suspension of the cartel. As the numbers in a cartel grow, the gain from violating it generally increases faster than the loss from such punishment when detected (Lambson 1984). Here is another reason to expect purely private cartels to be weak unless the market is concentrated.

In private cartels prices are unlikely to be set at joint maximizing levels. The bargaining power of major participants is apt to reflect their potential profitability without the cartel. Usually the low-cost firms have the best prospects without the cartel. If they determine cartel price, it is likely to be lower than that of a monopolist with the same plants. Small firms may also have a special influence on cartel price. A firm that is too small to be worth disciplining will probably sell at a discount from cartel price. Such a small firm as a cartel member is apt to favour high cartel prices from which it then discounts. If the numbers of such small firms become large, the majors may try to discipline the fringe as a whole to limit their discounts. In fact, however, the growth of a large fringe commonly leads to the collapse of the cartel.

Public cartels are also unlikely to be perfect cartels, but they often differ from private cartels. Many American public cartels (such as those in agriculture, oil prorationing, import quotas for oil refiners, and airlines under the Civil Aeronautics Board) allocated output, access to cheap imports of oil or to profitable markets in favour of small and high-cost firms, just the opposite of what would have occurred under successful private cartels.

Effective cartels are likely to result in excess capacity for several reasons. High-profit prospects attract entrants – as in American oil prorationing in the 1940s, 1950s and early 1960s or the famous oil glut that grew up in the 1980s after the huge price increases imposed by OPEC in the 1970s. High prices permit continued excess capacity that would be driven from the field in a competitive market – as in much of American agriculture. Existing firms will often build excess capacity if it increases sales because with prices far above marginal cost, additional sales are worth the additional cost to the firm (Posner 1975) – as occurred on competitive airline routes in 1945–1977 even though entry was prohibited (Douglas and Miller 1974). An equilibrium at high cartel prices is reached when excess capacity has forced cost up to the point where profits are reduced to normal levels and entry and expansion is no longer attractive. Excess capacity can be avoided if members' output does not depend on current capacity. For instance, American flue-cured tobacco production depends on acreage allotments set in the late 1930s. As a result, the government was able over

many years to prevent the development of excess capacity which presented such problems in other crop programmes.

Excess capacity may arise in private cartels also. In addition to entry and expansion attracted by high prices, excess capacity may be intentionally built or maintained so that the threat of retaliation against violators of the cartel can be credible (Brock and Scheinkman 1985).

Many nations have permitted and enforced cartels of certain sorts which were seen to be in the public interest. Most of the industrial non-communist countries of the world including the United States permit export cartels. From a narrow national point of view this makes some sense at least for large countries. Their national incomes are enhanced by exploitation of any powerful positions they occupy abroad. With all major countries following such strategies, however, the overall effect must be some net loss for most of them. Another reason for export cartels arises when a major importing country negotiates a restriction on exports from foreign sources. The Americans negotiated many such quotas with major foreign exporters to the United States in the 1960s and 1970s.

Import quotas almost always involve public cartels in form. Import licences are distributed among importers by the government and are kept valuable by the trade restriction itself. In the 1930s Germany used import restrictions along with complex foreign-exchange policies to exploit its special position with respect to many of its trading partners. The main purposes of import quotas today are protectionism and/or the allocation of scarce foreign exchange. Exploitative import cartels seem to be few. The large countries employ import quotas very little today, and small nations have little monopsony power. Because of international specialization, small countries can often be large in their main export markets, but specialization in consumption and imports is rare.

A number of countries use cartels to aid temporarily depressed industries. The Japanese 'depression cartels' are an example (Hadley 1970). Depressed industries can form cartels for 1 year or less if approved by a specified government agency. The state of the industry need not derive from a general depression, but the case for such cartels seems strongest in such a setting. No long-term adjustment by the industry is called for, and a temporary cartel may be one of the less costly ways of assisting industries seriously hurt by general economic decline. In normal times occasional bankruptcies may serve to weed out badly managed firms, and economic pressure on a declining industry serves to transfer resources to more productive uses, but widespread financial disasters during a depression seem of little social value. The crucial thing is that the depression cartel be truly temporary and that the problems that made the industry 'depressed' do not call for long-term adjustments.

Japanese cartel law also provides for 'rationalization cartels' (Hadley 1970), which are not so limited in duration as the depression cartels. They require the approval of the appropriate public agency, once more. A number of European nations also provide for rationalization cartels. Rationalization refers to long-term adjustments by an industry such as the replacement of suboptimal or obsolete capacity or the elimination of excess capacity. It is conceivable that joint action by the firms in an industry could offer a better solution to excess capacity than a fight to the finish on the open market might yield. At least the transition would be less painful if a joint decision were made about which plants should be closed and the survivors bought out the firms which were to go out of business. In practice, rationalization cartels have done little of this. Rather, they set price and/or output that reduced the pressure on their members to adjust. They accomplished little or no rationalization as a result.

Where rationalization means replacing suboptimal or obsolete capacity, the cartel approach seems even less promising. It would call upon efficient producers to help their high-cost rivals to become more competitive. A theoretically appealing exception is the specialization cartel. The firms in such a cartel agree to assign products to particular members, thus permitting optimal-scale capacity for each subproduct. Governments that permit such cartels often try to reduce their competitive effects by limiting the combined

shares of the market of the cartel. For instance, in the European Coal and Steel Community such cartels may not have more than 15% of industry sales. However, four such groups permitted in Germany, each with a common sales agency, accounted for most of German steel and half of ECSC steel in the 1960s. Most of the specialization involved output quotas which permitted economies of long production runs. Little specialization of plant and equipment was accomplished, so few economies of scale were realized (Stegemann 1979).

In general, most rationalization cartels have turned out in fact to be oriented primarily toward short-term restraint of trade.

Cartels

Margaret C. Levenstein and Valerie Y. Suslow

Abstract

Cartels are associations of firms that restrict output or set prices. They may divide markets geographically, allocate customers, rig bids at auctions, or restrict non-price terms. They have often been formed with the participation or support of state actors. In contrast to the pre-Second World War period, today most cartels are illegal in most jurisdictions. The average duration of cartels is between five and 7 years, but the distribution of duration is skewed: a large number of cartels break down within a year but a sizable proportion last for over a decade.

Producers form cartels with the goal of limiting competition to increase profits.

Cartels are associations of independent firms that restrict output or set prices. They may divide markets geographically, allocate customers to specific producers, rig bids at auctions, or restrict non-price terms offered to customers. They have often been formed with the active participation or support of state actors. In contrast to the pre-Second World War period, today most cartels are illegal in most jurisdictions.

Upon its creation a cartel immediately faces three key problems: coordination, cheating and entry. In a dynamic economy, the solution to these problems will change over time, so successful cartels must develop an organizational structure that allows them to re-solve these problems continuously.

Stigler's (1964) classic article highlights the incentive to cheat as the most important source of instability undermining cartels. In a repeated setting, a firm weighs the expected gain from cheating today (the benefit from cheating) with the expected reduction in future discounted profits that follows cheating (the cost of cheating). In order for firms to be willing to refrain from cheating, the following must hold:

$$\sum_{t=0}^{T} \delta^t \frac{\prod^m}{n} \succ \Pi^m$$

where Π^m is the one-period cartel profit, n is the number of firms in the industry, and δ^t is the discount rate. Thus, collusion is easier to achieve the larger the difference between cartel and non-cartel profits, the smaller the number of firms, and the more patient these firms are (Tirole 1988).

Friedman (1971) demonstrates that firms may use 'off the equilibrium path' threats of price wars in retaliation for cheating to provide firms with the incentive not to cheat. However, because in his model any cheating would be observed immediately and therefore subject to swift retaliation, firms do not cheat and price wars are not observed. In the Green and Porter class of models (Green and Porter 1984; Abreu et al. 1986), firms cannot observe one another's output (or pricing) actions nor infer them with certainty from public information. Economic fluctuations require that firms revert to equilibrium 'punishment' or 'price war' behaviour at times in order to maintain the incentives necessary to achieve collusion. Thus, the appearance of on-and-off collusion does not represent inherent cartel instability, but rather a mechanism that cartels use to stabilize themselves.

This theoretical perspective also implies a second mechanism for increasing cartel stability: a cartel may invest in information collection in order to better monitor individual firm activities. Improved monitoring both deters cheating and allows cartels to avoid costly price wars that arise from the inability to distinguish cheating from external shocks.

The most successful cartels actively work to create barriers to entry. Sometimes this is done through collective predation, as in Scott Morton (1997) in which incumbent cartel members successfully deterred entry by financially weaker and smaller firms. In other cases, cartels have turned to the state to create regulations, tariffs, or provide anti-dumping protection with the goal of excluding outsiders. Cartels sometimes use vertical exclusion (for example, a joint sales agency) or restrict access to technology (for example, via a patent pool) to limit entry.

Cartels use direct and repeated communication to overcome obstacles to coordination. Cartel negotiations often begin with discussions of prices and market shares, but expand over time to restrict cheating in non-price dimensions, such as terms of sale, advertising, transport costs, and production capacities. Firm asymmetries and changes in firms' costs can make these negotiations challenging. Slade (1989) suggests that price wars arise from changes in firm or industry characteristics. These price wars then facilitate the learning necessary for firms to re-establish collusion. Cartels also learn how to structure incentives so that collusion is more profitable in the long run than cheating. For example, successful cartels often fashion self-imposed penalties or other compensation schemes for firms that exceed cartel quotas. Cartels sometimes develop elaborate

internal hierarchies allowing for communication at various levels of management. A hierarchical cartel structure allows for high-level information exchange and bargaining activities to be separated from regional or local information exchange and monitoring efforts. When trust is particularly difficult to establish and firms doubt the accuracy of communication or data exchanges, cartels often turn to a third party – such as a trade association – to facilitate information sharing.

The average duration of cartels measured over a range of countries and time periods is between five and seven years (Levenstein and Suslow 2006). There is considerable dispersion in cartel duration: the standard deviation of duration is almost as high as the average. Observed cartel duration is very skewed, with a large number of cartels lasting less than a year or two and a long tail of cartels that endure for a decade or more.

Predictable fluctuations in product or industry demand do not generally undermine effective cartels, but rapid industry growth and unexpected shocks do. Macroeconomic fluctuations, which are close to common knowledge, have little impact on cartel stability. Many successful cartels develop an organizational structure that allows them to weather cyclical fluctuations. Cartels that are disrupted by observable cyclical fluctuations may be inherently fragile.

Large customers can undermine cartel stability by increasing the incentive to cheat, as posited by Stigler (1964) and tested by Dick (1996). On the other hand, large customers sometimes benefit from the existence of a cartel if they receive preferential pricing compared with that received by their smaller competitors, and can even contribute to its stability.

Although posited by theory, there is no simple empirical relationship between industry concentration and the likelihood of collusion. This may reflect sampling bias in studies that focus on prosecuted cartels, since cartels with many firms or with the involvement of an industry association may be easier to detect. Or it may be that industries with a small number of firms are able to collude tacitly without resorting to explicit cartels. Finally, it may reflect the endogeneity of concentration: collusion may allow more firms to survive and remain in the market (Sutton 1991; Symeonidis 2002).

Analyses of the impact of cartels on prices and profits generally use one of three approaches: changes in price following cartel formation, comparison between 'good times' and 'price war' periods, and, comparison between the cartel price and a counterfactual or 'but-for' price that would have prevailed in the absence of collusion. Connor and Lande (2005) provide an exhaustive survey of studies of cartel price effects. They conclude that the median overcharge resulting from cartels is approximately 25 per cent.

Cartels can also affect investment and productivity. Cartel participants have often argued that cartels increase investment and productivity growth by allowing firms to smooth production over time. Others have argued that, by removing the pressure of competition, cartels reduce innovation and productivity growth. Theoretical models have suggested that cartels lead to increased investment in capacity either because excess capacity can deter entry and provide enforcement (Dixit 1980) or because, when price competition is suppressed, firms compete in other dimensions (Feuerstein and Gersbach 2003). In some cases, cartels explicitly restrict investment in new capacity. Where there are not such explicit restrictions, empirical studies have found cartels are associated with increases in investment. On the other hand, no consistent relationship between cartels and productivity growth or innovation has been established empirically (Symeonidis 2002).

As firms have become increasingly global, international antitrust law and policy has faced new challenges. Competition authorities have increased enforcement, attempted to harmonize practices and procedures, and increased cooperation across jurisdictions. The United States is the country with the longest history of prosecuting explicit collusion, with state laws antedating the national ban on price fixing enacted with the passage of the Sherman Act of 1890. Many Western European countries adopted laws against price fixing following the Second World War, but also allowed a large number of exemptions. Since the mid-1990s these exemptions have been sharply reduced, and dozens of other countries have

banned price fixing for the first time. Enforcement activities against cartels, and international cartels in particular, rose sharply in the United States in the late 1990s. European countries, including the newest members of the European Union, have also increased their enforcement activities against cartels, as have countries in Asia, Africa and Latin America. Price fixing – long a criminal offence in the United States – has now been criminalized in several other countries, including the United Kingdom and Ireland. This increased enforcement has demonstrated that cartels continue to be active in a wide range of industries in the 21st century.

Carver, Thomas Nixon (1865–1961)

A. W. Coats

Carver's career exemplifies the blend of scientific economics and popular social science so characteristic of his period. He was born on 25 March 1865 in Kirkville, Iowa. After a disrupted undergraduate education at Iowa Wesleyan and the University of Southern California (AB, 1891), he studied at Johns Hopkins under Richard T. Ely and John Bates Clark, eventually obtaining his PhD at Cornell in 1894. A joint appointment in economics and sociology at Oberlin led to a professorship in political economy at Harvard (1900–32), where for a time he taught the only course in sociology. His principal theoretical work in economics was an extension of Clark's marginalism to a synthesis of abstinence and productivity theories of interest. He also made pioneering contributions to the economics of agriculture and rural sociology, and published several textbooks and numerous magazine articles. Carver's attacks on radicalism and socialism, his forthright advocacy of individualism, thrift and free enterprise, and his insistence on the crucial value of natural resources conservation and social balance, made him a cult figure among Harvard students. Acceptance of Malthusian population theory and recognition of the dangers of corporation power did not quench his optimism, although

he favoured public works and credit expansion as a corrective to the 1930s depression. Carver served as adviser to the Department of Agriculture and Director of its rural organization service in 1913–14. An energetic and successful Secretary-Treasurer of the American Economic Association from 1909 to 1913, he was elected President in 1916. He died in Santa Monica, California, on 8 March 1961.

Case-Based Decision Theory

Ani Guerdjikova

Abstract

Case-based decision theory was developed by Gilboa and Schmeidler. This article describes the framework and lays out the axiomatic foundations of the theory. An illustration based on a model of repeated choice is provided and the applications of the theory to economic problems are listed. Finally, the relationship between the case-based decision theory and expected utility theory is discussed.

Keywords

Aspiration levels; Case-based decision theory; Consumer choice theory; Decision making; Expected utility theory

Case-based decision theory (CBDT), developed by Gilboa and Schmeidler (1995, 1997a, 2001a; Gilboa et al. 2002), models decision situations in which neither states of the world nor their probabilities can naturally be inferred from the description of the problem. Instead, the decision maker (DM) has a memory of cases, recording the outcomes of acts in problems encountered in the past. For a specific problem, the evaluation of an act is given by a weighted sum of the utilities of outcomes observed in the memory. The weights represent the similarity of the problem-act pairs in those cases in which the outcomes occurred to the problem-act pair under consideration.

An Example

Consider a CEO who seeks to hire an administrative assistant. The available acts are the various candidates for the job. The CEO does not know how well each of the candidates would perform if actually hired. Each candidate might turn out to be unreliable, dishonest or incompetent. Some candidates might be very efficient at administrative tasks, but unable to deal with customers. Others might be perfect on the job, but unwilling to travel.

In this example, neither the possible outcomes nor the states of the world are naturally implied by the description of the problem. Any attempt to specify these would require imagining every

possible situation in which different characteristics of the candidate might be relevant and assigning to each such situation and each candidate an outcome. A much more realistic approach to the problem is to ask each candidate for references: that is, for records of past cases in which they have been employed and specific outcomes have been observed. To determine the utility assigned to each candidate, the outcomes observed in these past cases are weighted by their relevance (similarity) to the decision at hand.

The Framework

The set of decision situations is P with $p \in P$ being referred to as a *problem.* The decision maker chooses an *act a* out of a set of *available acts, A*. The set of *outcomes* is R with a representative element *r.* The DM does not know the states of the world, the state-contingent outcomes or their distributions. Instead, she uses her *memory, M*, in which information about *past cases* is stored. A case, c, is a triple consisting of a problem encountered, p, an act chosen in this problem, a, and an experienced outcome, r : $c = (p,a,r)$. The set of all possible cases is $C = P \times A \times R$. The memory M is represented by a function: $M : C \rightarrow \mathbb{Z}_0^+$, which lists the number of occurrences of each case in the memory. The order of occurrence of different cases is not specified. This can reflect the belief that the order of outcome realizations does not matter for the evaluation of acts. Alternatively, the time component might be incorporated in the description of the problem. (This invariance property appears as an axiom in Billot et al. 2005. In this formulation of CBDT, which follows Gilboa et al. 2002, it is implicit in the description of the memory.)

Let M be the set of all possible memories: $\mathbb{M} = \{M : C \rightarrow \mathbb{Z}_0^+\}$. The DM has preferences over acts given the problem she faces and given her memory, $\succsim_{p,M}$.

The *similarity function* quantifies the DM's similarity judgment between the choice of act a' in problem p' observed in the memory and the choice of act a in the problem at hand, p. It captures the idea expressed by Hume (1748) that 'from causes which appear similar we expect similar effects'. The similarity function can be formulated as: $s : (P \times A) \times (P \times A) \rightarrow \mathbb{R}$. For instance, a candidate a applying for a position as an administrative assistant at a magazine (problem p) may present references from her previous occupation with a radio station (problem p'). While the two problems are not identical, they might be considered similar, and hence the case (p', a) would be used to evaluate the candidate for the current position. Distinct candidates can also be considered similar, for example if they have similar qualifications, or have graduated from the same school. Finally, similarity might refer to comparisons between problem-act pairs as opposed to comparisons between individual problems or acts. For instance, hiring a candidate who is proficient in Japanese to report on cultural issues from Japan might be considered similar to hiring a candidate with a degree in economics to manage the finance column.

The Representation

For a given problem p and memory M, act a is preferred to act $a', a \succsim_{p,M} a'$, if and only if $U_{p,M}(a) \geq U_{p,M}(a')$ with:

$$U_{p,M}(a) = \sum_{c \in C} M(c)u(r_c)s((p,a),(p_c,a_c)). \quad (1)$$

Here p_c, a_c and r_c are respectively the problem encountered, the action chosen and the outcome observed in case c, and $u(\cdot) : R \rightarrow \mathbb{R}$ is a utility function over outcomes.

Intuitively, for each case, the DM determines the similarity of the problem-act pair (p_c, a_c) to the current decision (p, a). The utility of r_c is then weighted by the similarity $s((p, a), (p_c, a_c))$ and by the number of occurrences of c in the memory, $M(c)$.

In general, the sums of the similarity values related to two distinct acts a and a' are different: that is, $\Sigma_{c \in C} M(c)s((p,a),(p_c,a_c)) \neq \Sigma_{c \in C} M(c)$

$s((p,a'),(p_c,a_c))$. Hence, the utility function is unique only up to a multiplication by a positive constant, while adding a constant to $u(\cdot)$ will in general change the representation. (This distinguishes the concept of utility used here from the notion of utility in classic consumption theory, where the utility function is unique up to arbitrary monotone transformations, as well as from the von-Neumann-Morgenstern (Bernoulli) utility index, which is unique up to positive affine transformations.)

We can therefore distinguish between positive outcomes, for which $u(r) > 0$, and negative outcomes, with $u(r) < 0$. The former correspond to experiences that the DM would like to repeat, while the latter represent experiences she would rather avoid. $\overline{r} \in R$ is a *neutral outcome* if $u(\overline{r}) = 0$. If all outcomes observed in the memory are neutral, all acts are considered indifferent. The neutral outcomes determine the DM's *aspiration level*, $\overline{u} = u(\overline{r}) = 0$, the minimal level of utility she must obtain in order to be satisfied with her choice. Then (1) can be written as: $U_{p,M}(a) = \sum_{c \in C} M(c)[u(r_c) - \overline{u}]s((p,a),(p_c,a_c))$. The representation is preserved if a positive affine transformation is applied to both $u(\cdot)$ and $\bar{u}$.

In the representation above, the aspiration level is constant and does not depend on the memory. (The axiomatization of Gilboa and Schmeidler (1997a) can accommodate some forms of adaptation of the aspiration level, but this requires the similarity function to be memory-dependent.) Various studies (Jucknat 1937; Festinger 1942; Lewin et al. 1944; McClelland 1958; Atkinson and Litwin 1960; Frey et al. 1993; Easterlin 2003) have demonstrated that aspiration levels vary over time depending on the observed outcomes. Hence, in applications, a process of aspiration adaptation is often introduced and studied (see Section 7).

The representation is preserved under positive affine transformations of the similarity function $s((p, a), \cdot)$, which can be normalized to take on values in the interval [0,1]. The similarity values have therefore a cardinal meaning: for instance, if similarity is derived from some metric on $P \times A$, then equivalent metrics can give rise to distinct similarity functions and to distinct preference relations.

Repeated Choice

The role of the main concepts can be understood by considering the special case of repeated choice, i.e. $P = \{P\}$ (from now on, we omit reference to the problem). Let $A = \{a_1 \ldots a_n\}$. u_i denote the utility realization of a_i if chosen. Let $x \in A^\infty$ denote a sequence of choices. We write $x(t)$ for the act chosen at time t. The memory at time t is given by: $M_t((a_i,u_i),x) = |\{\tau \le t | x(t) = a_i\}|$.

The case-based decision rule implies:

$$x(t+1) \in \arg\max_{a \in A} \sum_{a_i \in A} M_t((a_i,u_i),x)s(a_i,a)u_i.$$

The set of paths consistent with this rule is:

$$X =: \{x \in A^\infty | \text{for all } t \in \mathbb{Z}^+, x(t) \in \arg\max_{a \in A} \sum_{a_i \in A} M_{t-1}((a_i,u_i),x)s(a_i,a)u_i\}$$

Of interest are the limit choice frequencies, $f(a,x) =: \lim_{t\to\infty} \frac{|\{\tau \le t | x(t) = a_i\}|}{t}$.

Assume first that:

$$s(a,a') = \begin{cases} 1 & \text{if } a = a' \\ 0 & \text{else} \end{cases} \qquad (2)$$

The choice of aspiration level influences qualitatively the individual's behaviour. Let $A^+ =: \{a_i \in A | u_i > 0\}$ be the set of acts with positive outcomes. If $A^+ \neq \varnothing$, then, for all $x \in X$, $f(a_i,x) = 1$ for some $a_i \in A^+$. Hence, low aspiration levels lead to satisficing behaviour, or habit formation: an act with a positive (but not necessarily maximal) outcome is chosen forever. In contrast, if $u_i < 0$ for all $i \in \{1 \ldots n\}$, then for all $x \in X$, $x \in X$, $\frac{f(a_i,x)}{f(a_j,x)} = \frac{u_i}{u_i}$; see Gilboa and Schmeidler (2001b). (Analogous results can be derived if the utility realization of a_i is a random variable with mean μ_i and finite variance. In this case, u_i has to be replaced by μ_i: see Gilboa and

Pazgal 2001.) A high aspiration level thus implies switching, or change-seeking behaviour. Acts with higher utility realizations are chosen with higher frequency.

Now consider the impact of similarity. Let $u_i < 0$ for all $i \in \{1 \ldots n\}$, so that change-seeking behaviour is implied. A positive/negative $s(a, a')$ makes the choice of a less or more desirable if a' has been chosen before. If acts are consumption goods, positive/negative similarity can be taken to mean that a and a' are substitutes/complements: see Gilboa and Schmeidler (1997b).

To illustrate how similarity perceptions affect the frequencies of choices, consider $n = 3$ and let $s(a_i, a_i) = 1$ for all $i \in \{1,2,3\}$, $s(a_1, a_2) = s(a_2, a_3) = \overline{s} \in (0, 1), s(a_1, a_3) = 0$. Satisficing occurs if $u_i > 0$ for $i \in \{1,2,3\}$. Let $\overline{s} < \frac{1}{2}$ and $u_i < 0$ for $i \in \{1,2,3\}$. In the limit, all three acts are chosen with positive frequencies: $\frac{f(a_1,x)}{f(a_2,x)} = (1-\overline{s})\frac{u_2}{u_1}, \frac{f(a_3,x)}{f(a_2,x)} = (1-\overline{s})\frac{u_2}{u_3}$ and $\frac{f(a_1,x)}{f(a_3,x)} = \frac{u_3}{u_1}$. Hence, similarity affects the frequencies with which various acts are chosen. The form of the similarity function can also affect the set of acts which are chosen in the limit. For $\overline{s} > \frac{1}{2}, f(a_2, x) = 0, \frac{f(a_1,x)}{f(a_3,x)} = \frac{u_3}{u_1}$ obtains for all x with $x(1) \neq a_2$, independently of the value of u_2, in particular, even if $u_2 > 0$. Although a_2 is never chosen, and *has a positive utility realization*, its evaluation is negative, because of its similarity to other acts with negative utility realizations. (Guerdjikova 2007 generalizes this intuition to a continuum of acts with random utility realizations, and identifies properties of the similarity function which lead to satisficing or switching behaviour.)

Applications

Several applications of the CBDT are related to consumer choice theory: Gilboa and Schmeidler (2001b) relate similarity perceptions to substitutability/complementarity between goods; Gilboa and Schmeidler (1997b) use the CBDT to explain 'brand switching' behaviour, while Gilboa and Pazgal (2001) model the consumer's reaction to price increases.

Aragones (1997) uses CBDT to explain the presence of swing voters in a model of political party competition. Jahnke et al. (2005) analyse a production choice problem. Blonski (1999) models social learning, using different similarity functions to capture differences in social structures. Pazgal (1997) shows that case-based learning can lead to Pareto-optimal outcomes in coordination games. Krause (2009) studies herding behaviour. Gayer (2007) analyses a process of probability perception formation using a similarity function which changes with experience. Guerdjikova (2004, 2006) applies the CBDT to financial markets.

Gilboa et al. (2006, 2009) propose a method for estimating the similarity function from data. Gayer et al. (2007) use this method to test whether housing market data in Tel-Aviv are consistent with case-based optimization, and find that this is indeed the case for the renting segment. Grosskopf et al. (2008) test the CBDT in a laboratory setting and find some evidence supporting the theory.

Axiomatization

Gilboa et al. (2002) provide an axiomatization of (1). For a fixed problem $p \in P$, consider a family of preference relations over acts $\left(\succsim_{p,M}\right)_{M \in \mathbb{M}}$. Hence, the DM has preferences over acts not only for the actually observed memory, but also for any hypothetical memory in $\mathbb{M}$. The *combination* of two memories, M and M' is another memory $M'' \in \mathbb{M}$ defined as $M''(c) = M(c) + M'(c)$ for all $c \in C$

Axiom 1 (Order) For every $M \in \mathbb{M}, \succsim_{p,M}$ is complete and transitive.

Axiom 2 (Combination) If $a \succsim_{p,M} a'$ and $a \succsim_{p,M'} a'$, then $a \succsim_{p,M+M'} a'$.

Axiom 3 (Archimedian) If $a \succsim_{p,M} a'$, then for every $M' \in \mathbb{M}$, there exists $a k \in \mathbb{N}$ such that $a \succsim_{p,kM+M'} a'$.

Axiom 1 is standard and without it a real-valued representation is impossible. Axiom 2 states that if two separate pieces of evidence support the choice of act a more than that of a',

then so should their combination. If a CEO received independent recommendations from two past employers to hire a candidate, he would not need to bring the two employers together for a consultation. Combining the two 'memories' would not change the recommendation. Axiom 2 is less compelling in the context of hypothesis testing: two memories might both be too short in order to reject a given null hypothesis, but the combination of them might contain a sufficient number of observations for the hypothesis to be rejected. Axiom 2 is also violated if similarity perceptions depend on the experience: see Gilboa and Schmeidler (1993, 2003) for examples. Axiom 3 states that every evidence that supports a' more than a can be outweighed by a sufficient number of repetitions of cases that support a more than a'. Axiom 3 is violated if an outcome observed from a given act renders it inferior regardless of any further evidence. For instance, an administrative assistant who has been dishonest once might never be able to find an employment, regardless of how many additional good recommendations she presents.

Axioms 1–3 are consistent with a representation of the following type: $a \succsim_{p,M} a'$ if and only if $\Sigma_{c \in C} M(c) v((p,a),c) \geq \Sigma_{c \in C} M(c) v((p,a),c)$. Here, $u(r_c)s((p, a)(p_c, a_c))$ is substituted with the less informative $v((p, a), c)$. (The axiomatization of this rule is provided in Gilboa and Schmeidler 2001a; 2003).

Let $L : P \times A \to \mathbb{N}$. For $r \in R$, let $L_r \in \mathbb{M}$ denote the memory in which $M(p,a,r) = L_r(p,a)$ and $M(p,a,r') = 0$, for all $r' \neq r$. Hence, each L_r represents a memory in which the only outcome observed is r. The next definition identifies the neutral outcomes in R, i.e. those outcomes for which $u(r) = 0$.

Definition 1 *An outcome $\overline{r}$ is neutral if for every $L : P \times A \to \mathbb{N}$ and every two acts $a, a' \in A, a \succsim_{L_r} a'$.*

Axiom 4 (Diversity) For any four distinct acts, a_1, a_2, a_3 and $a_4 \in A$, and for every non-neutral r $\in R$, there exists an $L : P \times A \to \mathbb{N}$ such that $a_1 \succsim_{p,L_r} a_2 \succsim_{p,L_r} a_3 \succsim_{p,L_r} a_4$. If $|A < 4$, then the same condition holds for any list of length $|A|$.

Axiom 5 (Case-Independence of Desirability) For any r and r' that are non-neutral, either

(i) for every $L : P \times A \to \mathbb{N}$ and all $a, a' \in A, a \succsim_{p,L_r} a'$ holds iff $a \succsim_{p,L_r} a'$, or
(ii) for every $L : P \times A \to \mathbb{N}$ and all $a, a' \in A, a \succsim_{p,L_r} a'$ holds iff $a' \succsim_{p,L_r} a$.

Axiom 4 rules out the case that an act a is dominated by act a' for all possible memories. It precludes, for example, lexicographic preferences of the following type: a CEO working with Japanese clients might feel that it is always better to hire an assistant who speaks fluent Japanese than an assistant who does not, regardless of their letters of recommendation. Finally, Axiom 5 states that the relevance of a case depends only on the problem and the act, but not on the observed outcome. Intuitively, if $a \succsim_{p,L_r} b$, then either outcome r is desirable and the cases in L_r are more similar to (p, a) than to (p, b), or r is undesirable and (p, a) is less similar to the cases in L_r than (p, b). Of course, if cases in the memory are assigned different similarity weights depending on the outcomes observed, this property will not hold.

Axioms 1–5 are sufficient for the existence of the representation and imply its uniqueness in the following sense: if the utility function u and the similarity function s represent $\left(\succsim_{p,M}\right)_{M \in \mathbb{M}}$, then so do αu and $\beta s((p,a),(p',a')) + w_{p',a'}$, where α and $\beta \in \mathbb{R}$ satisfy $\alpha\beta > 0$ and $w_{P',a'} \in \mathbb{R}$ for all $(p', a') \in P \times A$. While Axioms 1–3 and 5 are necessary for the representation, Axiom 4 is not: it imposes an additional linear independence condition on the similarity values for any four distinct acts. However, Gilboa and Schmeidler (2001a) show that Axioms 1–3 and 5 alone are not sufficient, and hence without Axiom 4, a representation of preferences by a real function might not exist.

Case-Based Decision Theory and Expected Utility Theory

We first identify situations in which case-based learning leads to choices that maximize expected

utility with respect to the true distribution of outcomes. In the framework of Section 4, let the utility realization of a_i be a random variable with mean μ_i and finite variance. Denote the aspiration level at time t by $\bar{u}_t$. A path $x = (x_1 = (\overline{u}_1, a_1, u_1) \ldots x_t = (\overline{u}_t, a_t, u_t) \ldots) \in (\mathbb{R} \times A \times \mathbb{R})^{\mathbb{N}}$ describes the aspiration level, the act chosen and the outcomes observed in each period. Let $x^t =: (x_1 \ldots x_t)$.

The case-based rule becomes: $a_{t+1}(x_t) \in \arg\max_{a \in A} \Sigma_{\tau=1}^{t} s(a_\tau, a)[u_\tau - \overline{u}_t]$.

Gilboa and Schmeidler (1996) show that if $s(a, a')$ is defined as in (2) and if for some infinite sparse set $T \subset \mathbb{N}$ and a constant $h \in \mathbb{R}^+$:

$$\overline{u}_t = \begin{cases} \alpha \overline{u}_{t-1} + (1-\alpha) \max\limits_{a \in \{\overline{a} \in A \, s.t. \ |\{\tau | a_r(x) = \overline{a}\}| > 0} \dfrac{\Sigma_{\{\tau | a\tau(x) = a)} u_\tau}{|\{\tau | a_\tau(x) = a\}|} & \text{for } t \notin T \\ \overline{u}_{t-1} + h & \text{for } t \in T \end{cases}$$

then $f\left(x, \text{argmax}_{i \in \{1 \ldots n\}} \mu_i\right) = 1$ obtains almost certainly. The aspiration adaptation process has the property that the DM is realistic, updating his aspirations towards the highest obtained average utility, but also optimistic, increasing her aspirations by $h > 0$ in certain periods. This combination guarantees that her limit behaviour coincides with that of an expected utility maximizer who is informed of the probability distributions over outcomes. (Guerdjikova 2008 extends this result to a more general class of similarity functions. Pazgal 1997 applies the same adaptation rule to strategic interaction and shows that it selects for the Pareto-optimal equilibrium in coordination games.)

In the context of learning from data, Billot et al. (2005) provide a connection between the notion of similarity and the formation of probabilistic beliefs. (Billot et al. 2005 work with a finite set of outcomes containing at least three elements, $|R| \geq 3$. Gilboa et al. 2006 provide an axiomatization for $|R| = 2$, while Gilboa et al. 2009 extend the analysis to the case of a continuously distributed random variable.) Billot et al. (2005) assume that the order in which data arrives is irrelevant. Hence, each data set can be represented by a function $M \in \mathbb{M}$. For a given act a, they consider a mapping $h_a : \mathbb{M} \to \Delta^{|R|-1}$, which associates with each potential memory $M \in \mathbb{M}$ a probability distribution over the possible outcomes of a. The concatenation axiom requires that for all M and $M' \in \mathbb{M}$, there exists an α A (0,1) such that $h_a(M + M') = \alpha h_a\ (M) + (1 - \alpha)\ h_a(M')$. This axiom, together with the requirement that at least three of the vectors $h_a(M)$ are linearly independent, ensures that $h_a(M)$ can be written as $ha(M)(r) = \dfrac{\Sigma_{c \in C^{s(a,c)}} \hat{p}_a^c(r) M(c)}{\Sigma_{c \in C^{s(a,c)M(c)}}}$, where $s(a, c)$ is the perceived similarity between case c and action a, and $\hat{p}_a^c(r)$ is the probability that would have been assigned to outcome r if the memory consisted of only one case c. Hence, probabilities can be represented as similarity-weighted frequencies.

Gilboa and Schmeidler (2001a) emphasize that case-based decision making and expected utility maximization are not rival theories. The linear additive structure of both models implies that we cannot hope to distinguish between the two theories based on their empirical predictions. Matsui (2000) shows the formal equivalence between the two by using a more general formulation of the CBDT, in which similarity also depends on the observed outcomes. His construction shows that embedding CBDT into expected utility theory requires the use of a very large state space, and vice versa, embedding expected utility into CBDT requires a very large set of problems. Hence, the two theories should be viewed as complementary: the language and the concepts of one of the theories will in general appear more suitable for the description of a specific problem than those of the other.

Along with Knut Wicksell and David Davidson, Gustaf Cassel was the founder of modern economics in Sweden. He started as a mathematician and began his career as an economist by treating problems of railway rates and progressive taxation from a mathematical point of view. In order to deepen his understanding of economics he went to Germany, where he attended the seminars of Schönberg, Cohn and other traditional representatives of the economic profession. After visits to England, where he made the acquaintance of Marshall and of Sidney and Beatrice Webb, and a short period of lecturing at the university of Copenhagen, in 1902 Cassel took up a position as associate professor in economics at the university of Stockholm. In 1904 he was appointed a professor in economics and public finance. As holder of the chair he acquired a series of gifted pupils, Gunnar Myrdal and Bertil Ohlin among others, who, although they developed the theoretical heritage of Wicksell rather than that of Cassel, became the founders of the Stockholm School of economics. Before the First World War Cassel frequently served as a government expert on problems of railway rates, taxation, state budgets and banking and his involvement in problems of economic policy increased with the post-war economic problems. During the 1920s he became an adviser to the League of Nations on monetary problems and was commonly regarded as a leading international authority in this field, lecturing and publishing widely. All his life he worked also as a columnist for the Swedish daily paper *Svenska Dagbladet*. Although Cassel was originally liberal, he progressively turned more and more conservative denouncing the labour movement, the welfare state and Keynesianism in the name of 'Modern Scientific Principles'.

It is no easy task to evaluate the contributions of Gustav Cassel to economics. He never cared much about paying homage to his predecessors, from whom he sometimes took over fruitful ideas, while at the same time being unjustifiably critical towards other theorists. His expositions are not seldom marred by contradictions and a vagueness in expression, only scantily veiled by his mastery in round and polished sentences. At the same time Cassel took a keen interest in very many fields of economic theory and practice, he had a firm grip on empirical economics and his gifts in tracking down the relevant and essential aspects of economic problems were unusual. These qualities, in combination with a forceful and pedagogical exposition and, on the top of this, an imperturbable conviction of being the chosen spokesman for progress and the principles of science, made him influential not only among men of practical matters but also among fellow economists.

Cassel's main work is his *Theoretische Sozialökonomie* (1918) but his most important theoretical ideas were in fact conceived already around the turn of the century. In his essay 'Grundsätze für die Bildung der Personentarife auf den Eisenbahnen' (1900b), he criticized the idea of calculating railway rates on the basis of average costs and instead advocated marginal cost pricing. For a railway enterprise as a monopolistic business unit, rates which equalized marginal costs and marginal revenues were the optimal ones, though this might imply that some rates were lower than average costs. Even if the principle had been advocated already in 1885 by the American railway economist A.T. Hadley, it was succinctly formulated by Cassel.

Venturing into general economic theory, Cassel in these years also criticized Ricardo's labour theory of value in the essay 'Die Produktionskostentheorie Ricardos und die ersten Aufgaben der theoretischen Volkswirtschaftslehre' (1901), presented an outline of his own theory of price, 'Grundriss einer elementaren Preislehre' (1899) and developed a theory of interest in *The Nature and Necessity of Interest* (1903). The Ricardian labour theory of value was, according to Cassel, untenable because it

assumed that the labour–capital ratio was equal in different enterprises and industries, that labour was homogeneous and that the marginal land did not pay any rent. He did not care to take issue with the Marxian development of the labour theory of value. The labour theory of value belonged to the so-called one-sided value theories. But so did the marginal utility theory of value, which was deficient primarily because it lacked a clearly conceptualized unit of measurement for utility but also because goods, according to Cassel, are not generally divisible and the valuations of goods are not continuous functions of the supply. Therefore, Cassel suggested that one should do away with all conceptions of value and rest content with money prices and not bother with what might lie behind money prices. Thus Cassel did not consider the fact that money itself may vary in value, nor that the marginal utility of money certainly varies between individuals. Following Marshall, Cassel explained prices by reference to supply and demand and, following Walras, he devised a general equilibrium model for market prices in the form of a system of simultaneous equations. In fact, Cassel's price theory is a simplified version of the theory of Walras, who was characterized as 'in a sense one of my precursors'. However, by popularizing Walras, Cassel contributed much towards the understanding of the mutual interdependencies in a market economy. It was quite logical that the theory of interest that Cassel devised also should be based upon supply and demand, viz. supply of waiting and demand for the use of capital, as a special case of the general theory of price, and he boldly asserted that waiting and use denoted the same thing. Although his theory of interest, showing a close resemblance to that of Senior, was not original, it still merits our attention because of its vivid illustrations and some striking applications. This is particularly the case for Cassel's argument against the idea of a continually falling rate of interest. Given that most saving is made in order to safeguard a permanent future level of income, the shortness of life puts a ceiling under the rate of interest. This was the necessary and sufficient condition for the necessity of interest.

The year after the publication of *The Nature and Necessity of Interest*, Cassel also published his theory of the business cycle and his theory of the secular development of the general level of prices in two articles in the Swedish journal *Ekonomisk tidskrift*, 'Om kriser och däliga tider' (1904a) and 'Om förändringar i den allmänna prisnivän' (1904b). Both these theories were later incorporated and somewhat elaborated in his *Theoretische Sozialökonomie* (1918). In his theory of the business cycle Cassel was evidently influenced by Spiethoff and Tugan-Baranowsky, who recently had made public their theories explaining the business cycle with reference to the variations in investment of fixed capital and of loanable funds. What is really new in Cassel's treatment is his precise formulation of the accelerator principle, which he expounds with reference to the relationship between the demand for freights and the output of ships. The treatment of growth theory had to await the publication of his *Theoretische Sozialökonomie* and also on this point Cassel was wholly original, in fact foreshadowing the Harrod growth formula by his own formula for 'the uniformly progressing economy', the only difference being that Cassel worked with an average instead of a marginal capital coefficient.

Cassel's theory of the secular development of the general level of prices also demands our attention as a piece of brilliant imagination and was as late as 1930, after Kitchin's refinements, accepted as the theoretical basis for the first interim report of the gold delegation of the League of Nations. Cassel's theory was a straightforward quantity theory of money. By calculating the relative variations of gold output in relationship to a calculated normal need of gold for preserving a constant general level of prices, Cassel showed that there was a very good correlation between the relative variations of gold output and the corresponding variations in the general level of prices. Cassel's theory met with all the objections the quantity theory of money usually meets and in addition a series of more specific criticism: that it presupposes a constant ratio between velocity (V) and transactions (T), which is difficult to believe; that it overlooks the important role of silver in the 19th century as well as the varying proportions of the more relevant variable monetary gold; and that a case as good as Cassel's could be made, and in fact was made by Warren and Pearson, by making

the gold price rather than gold output the effective cause of price changes. But since Kitchin's (and Woytinski's) calculations, taking only monetary gold in regard, showed a still better fit between the variations of gold output and prices, Cassel's theory is still a serious candidate.

After this first period of theoretical activity around the turn of the century, Cassel mainly devoted his energy to synthesizing and propagating his ideas on the national and the international scene. The only really new element in his theoretical set-up was the famous purchasing power parity theory of the exchange rates, according to which the international rates of exchanges are determined by the purchasing power of the national currencies. It is easy to show that this is a rather poor general theory for the explanation of the exchange rates. But it contained a pragmatic truth during and after the First World War, when trade balances and, hence, the supply and demand of currencies, to a great extent, were determined by the course of rapid inflation in different countries. It is precisely this instinct for pragmatic truths that explains Cassel's success and influence in the international community of bankers and politicians during the 1920s. In his memoranda to the international conferences of the League of Nations Cassel first and foremost advocated stability of monetary affairs by means of control of the quantity of money, increased interest rates and cut-downs of state expenditures. But he was also critical towards the subsequent ruthless policy of deflation creating widespread unemployment and new disequilibria in world trade as well as intolerable debt burdens. Together with Keynes he criticized the unwillingness of the claimants to the German war debt to receive German goods as payment. When confronted by the permanent unemployment of the 1920s, Cassel concentrated his attacks on trade unions and the level of wages and untiringly explained the gospel contained in Say's Law. During the course of the 1930s it became all too clear that Gustav Cassel had been left behind by the march of events and of economic theory. It was his tragedy that he himself, who once waved his magic wand over international economic affairs, could not bear the truth. After some years of protracted rearguard skirmishes he devoted himself to more philosophical problems and wrote up a voluminous autobiography characteristically entitled 'In the Service of Reason' (*I förnuftets tjänst*, 1940–41). His last words on his death-bed were 'A world currency!'

Caste System

Susan Wolcott

Abstract

India's caste system performed two fundamental functions: insurance through transfers between caste members and, in villages, insurance through protected job assignments across castes. In most of India the landlord had a social responsibility to maintain his lower caste workers in lean periods. This division of labour has been viewed as coercive and exploitative. Yet many groups changed their caste occupation, both upward and downward in ritual ranking. During industrialization, traditional occupational categories did not restrict occupational choices in new industries, but caste continued to play a role in recruitment and support during work stoppages.

The caste system in India is a division of society into ranked, hereditary, endogamous occupational groups. It is loosely based on the four *varnas* of Brahmanas (priests), Kshatriyas (warriors and aristocracy), Vaishyas (merchants) and Shudras (the servants of the others). Castes either belonged to one of these four, or were below them in the

hierarchy; these latter are the so-called untouchables. In practice, the *varnas* are less important than were the relationships among and between the numerous sub-castes, or *jatis*. The sub-castes were specific to each region and were the true functional unit of the caste system. They were, for example, the endogamous unit. And obligations of *jati* members to each other were much stronger than were obligations of caste members more generally. Below the terms '*jati*' and 'caste' are used interchangeably.

Caste was not a monolithic institution. Reviewing the historical literature on caste, Rudner (1994, p. 25) notes that it is impossible for any one description to capture the 'on-the-ground diversity of India's caste systems'. He suggests as a definition: 'complex, multilayered, multifunctional corporate kin groups with enduring identities, a variety of rights over property, and crucial economic roles, often within large regions'.

Because of this diversity, caste's role in the Indian economy varied across regions and across groups. But two functions were fundamental: insurance through transfers between caste members and, in village India, insurance through protected job assignments across castes. On the first of these, Srinivas (1962, p. 70) writes, 'joint family and caste provide for an individual in our society some of the benefits which a welfare state provides for him in the industrially advanced countries of the West'. Economists have completely ignored this aspect of caste. But in the modern period it seems to be economically significant: financial transfers among rural villagers are common in developing countries. However, this practice is much more common in India than in any other country yet studied (Cox and Jimenez 1990, Table 1). As caste ties are weakening over time and as income rises, it is likely that such transfers were even more prevalent historically.

And across castes, because each *jati* was, at least in theory, occupationally segregated in the villages of colonial India, it played a protected role in the economic order and had a claim on the wealth produced by the village. This relationship is called the *jajmani* system in much of India, and the *baluta* system in Maharashtra (Kolenda 1978).

A particular division of responsibilities is that between landlords and agricultural labourers. Especially in north, south and east India, the landlord had a social responsibility to maintain his workers in lean periods. Platteau (1995) reviews the literature on this topic and presents a mathematical formalization of this relationship. Greenough (1982) gives an account of the strains on this system and its ultimate collapse in an extreme crisis.

This division of labour has also been viewed as coercive and exploitative. Akerlof (1976) models a situation in which groups can be confined to inferior occupations by social opprobrium. Maddison (1971, p. 28) argues that these occupational divisions were not only coercive but also foolish: 'One might think that some of the lowest productivity occupations were invented simply to provide everyone with a job in a surplus labor situation, but there was no shortage of land and the productivity of the economy would have been higher if there had been greater job mobility.'

But these authors exaggerate the rigidity of the caste system in regard to occupational segregation. Mukerjee (1937) provides a long list of groups which had changed their caste occupation, both upward and downward in ritual ranking, as well as lists of splitting and merging sub-castes. He argues that, although there was rigid social control within the caste, the system revealed 'plasticity' in regard to economic incentives. As an example of this, Commander (1983) notes that historical sources imply that the Chamars of the United Provinces – hereditarily leather workers – were for much of the 19th century largely agricultural labourers. He argues cogently that, although ritual and custom were important in determining economic rewards and relative position in the *jajmani* system, so were land availability and labour scarcity.

Did caste have a role in modern industrialization? The best survey on this subject remains that of Morris (1960). One point is obvious. Traditional occupational categories did not restrict occupational choices in new industries. Whether or not caste affected the economic lives of the workforce in other ways is less clear. Morris (1960, p. 128) writes that he 'is inclined to the

view that *jati* relationships ultimately are irrelevant in the factory'. Most analysts argue, however, that, because of the economically supportive links between *jati* members, caste did have a role in recruitment and support during work stoppages (Chandavarker 1994; Klass 1978). The differentiated and fluid nature of caste makes a general statement impossible.

The term, meaning 'the science of exchanges', was proposed as a replacement for the name 'political economy' by the Rev. Richard Whately in his 1831 Drummond Lectures at Oxford on political economy (Whately 1831). As the leader of the group of embattled religious and economic liberals at Oriel College, Oxford, during the 1820s, Whately, a distinguished logician, had become tutor and lifelong friend of the economist Nassau W. Senior. In his Drummond Lectures, Whately was concerned to refute the dominant Oxford view that political economy, being concerned with wealth, was materialistic and opposed to Christianity. In focusing on exchanges, Whately denounced Adam Smith's definition of the scope of political economy as the science of wealth.

Whately defined man as 'an animal that makes exchanges', pointing out that even the animals nearest to rationality have not 'to all appearance, the least notion of bartering, or in any way exchanging one thing for another' (Whately 1831, p. 7). Focusing on human acts of exchange rather than on the *things* being exchanged, Whately was led almost immediately to a subjective theory of value, since he saw that 'the same thing is different to different persons' (p. 8) and that differences in subjective value are the foundation of all exchanges.

In 1831 Whately was named Archbishop of Dublin, where he promptly used his influence to

create and financially support a permanent five-year Whately Chair of Political Economy at Trinity College. For the rest of his life Whately personally selected the holders of the chair; as a result, the Whately professors carried on their mentor's tradition of catallactics and subjective utility theory. In contrast to John Stuart Mill's development of economics as a science of the abstraction 'economic man', man engaged only in avaricious pursuit of wealth, the third holder of the Whately Chair, James Anthony Lawson (1817–87), developed the idea of economics as catallactics, as studying exchanging man. Lawson, holder of the chair in his twenties (1841–6), and later to become an MP and Attorney-General for Ireland, stated in his first lecture that economics views man 'in connection with his fellow-man, having reference solely to those relations which are the consequences of a particular act, to which his nature leads him, namely, the act of making exchange' (Lawson 1844, pp. 12–13). Yet, Lawson himself fell back on discussions of wealth in his second lecture, demonstrating that, in their specific exposition, the catallacticians had not yet fully emancipated themselves from the older definitions of the scope and nature of political economy (Kirzner 1960).

One pseudonymous English writer who adopted catallactics in this period was Patrick Plough, who included and explained the term in the title of his tract, *Letters on the Rudiments of a Science, called, formerly, improperly, Political Economy, recently more pertinently, Catallactics* (London, 1842).

Catallactics reached the status of a self-conscious school of thought in the writings of the zealous and indefatigable Scottish lawyer and economist Henry Dunning Macleod. Stressing value as the result of a subjective desire of the mind, Macleod furthered the emancipation of economics from material wealth by showing that immaterial goods or services are also subjects of exchange. Macleod insisted that catallactics was the only correct school of economic thought and traced back the origins of the school beyond Whately to the late 18th-century French philosopher Etienne Bonnot de Condillac. While Condillac, in his *Le commerce et le gouvernement* (1776), did not actually use the term catallactics, he defined economics as the philosophy of commerce, or the science of exchanges. Condillac also noted that value stems only from mental desires, and hence demand, for exchangeable goods, and proclaimed that men engage in exchange precisely because each man values what he gains in exchange more than what he gives up. Hence both parties to an exchange gain in value (Macleod 1863, pp. 530–5).

The catallactic school found its culmination in the United States, in Arthur Latham Perry (1830–1905), for half a century a highly influential professor of political economy at Williams College. Perry endorsed the Macleod view of the history of economic thought, the sound catallactic school descending from Condillac through Whately and Macleod. He went beyond the inconsistencies of his forerunners, however, by purging the word 'wealth' from economics altogether, and proposing the 'property' – that which can be bought and sold – be used as a term denoting valuable things not yet sold and therefore in need of an estimate of their value (Perry 1865).

While interest in the catallactic approach faded after the work of Perry, a variant appeared in the early work of Schumpeter (1908). In this manifesto for the reconstruction of economic theory, Schumpeter wished to purge economics of all concern about purposeful human motives or actions and replace it with exclusive concentration on mechanistic alterations of economic quantities. Exchanges then become 'purely formal' variations in economic quantities of goods (Schumpeter 1908, pp. 49–55, 86, 582; Machlup 1951; Kirzner 1960).

Schumpeter did, however, manage to contribute positively to the catallactic approach. Whately and his followers had strongly rejected any element of Crusoe economics, since for them economic analysis had to be confined to interpersonal exchange. In Schumpeter's formalistic approach, actions of Crusoe could alter the placement of quantities of economic goods and therefore could be considered 'exchanges'.

It remained for Ludwig von Mises (1949) to bring back the term catallactics in his treatise on economics, and to broaden it by embedding its analysis of the market, or the science of

exchanges, in the wider discipline of 'praxeology', the science of human action. Crusoe economics then becomes vindicated in the broader sense of analysing Crusoe's actions and his use of resources to achieve his values and goals, as well as in the sense of exchanging his present state for a more satisfying one.

Catastrophe Theory

Y. Balasko

The theory of general equilibrium defines equilibrium prices p as the solutions in the commodity space of the vector equation defined by equality of supply and demand, namely $z(p) = 0$, where z denotes aggregate excess demand. This formulation leads to a purely mathematical problem, namely the study of the properties of the solutions of the equation $z(p) = 0$. The first problem to come into the picture is that of existence. Its positive solution leads to new issues such as the determinateness of the solutions or their number. The fact that these problems cannot be solved uniformly with exactly the same answer for every economy necessitates the introduction of suitable parameters in terms of which the properties of the solutions of the equilibrium equation can be properly described. Let ω denote this parameter chosen in some suitable vector space Ω. This means that the aggregate demand function z can be viewed as depending on ω 0 Ω which we now denote by $z(., \omega)$ and the goal of equilibrium theory becomes one of relating the properties of the solutions to $z(p, \omega) = 0$ with the parameter ω. In practice, one chooses for ω the initial endowments of every consumer, the equilibrium model simply describing a pure exchange economy.

This way of handling problems by parameterizing them had been introduced by Poincaré, who called it the continuation method. It has also been extensively used by engineers dealing with applied issues involving solving equations dependent on parameters. The topic popularized by Thom under the name catastrophe theory consists simply in combining Poincaré's continuity method with the tools of singularity theory. As a first approximation, a singularity is just another word for a multiple root of the equation $z(p, \omega) = 0$ where the unknown is the vector p. One easily sees, at least intuitively, that multiple roots, and especially double roots, correspond to borderline cases associated with changes in the number of solutions, the standard picture being that solutions appear or disappear in pairs at these double roots. Clearly enough, this may entail discontinuous behaviour of the equilibrium solution despite the fact every other feature of the model is continuous or even smooth. Catastrophe theory has often been unduly identified to this discontinuity property.

In a pure exchange economy consisting of l commodities and m consumers, the parameter

space Ω, namely the set of initial endowments, can be identified to $(R^1)^m$. Prices can conveniently be normalized, for example, with the help of the numeraire convention, so that the price space can be identified to $S = \mathbb{R}^{l-1}_{++}$ Then, the problem is to describe the set E of solutions (p, ω) to $z(p, \omega) = 0$, i.e., $E = \{(p, \omega) \in S \times \boldsymbol{\Omega} / z(p, \omega) = 0\}$ (global approach), and the solutions $(p, \omega) \in E$ when ω varies (local approach). The main results are the following ones:

1. Under smoothness assumptions for preferences, E is a smooth submanifold of $S \times \boldsymbol{\Omega}$ diffeomorphic to $\boldsymbol{\Omega}$. Furthermore, the natural projection $\pi : E \to \boldsymbol{\Omega}$ defined by the formula $(p, \omega) \to \omega$ is proper (and smooth).
2. The set Σ consisting of $\omega \in \boldsymbol{\Omega}$ for which the equilibrium equation possesses a multiple root is closed with Lebesgue measure zero.
3. Let P be the set of Pareto optima. This subset does not intersect Σ. Furthermore, there is uniqueness of equilibrium when ω describes the connected component containing the set of Pareto optima P in the complement of the set Σ in $\boldsymbol{\Omega}$.

This latter result implies that, for an economy where the trade vector remains small to some extent, equilibrium is unique and depends smoothly on the parameters defining the economy. On the other hand, when this trade vector is large, the economy is likely to have multiple equilibria so that, when the parameter vector ω varies, 'catastrophic' changes of the equilibrium prices and allocations are susceptible of being observed.

These relationships between the properties of equilibria and their number are special cases of a far more general property of the general equilibrium model. We state it as follows. Let $N(\omega)$ denotes the number of solutions of the equilibrium equation $z(p, \omega) = 0$, with $p \in S$. Then, assume that N is given (i.e., the number of solutions of the equilibrium equation is known for every $\omega \in \boldsymbol{\Omega}$). Furthermore, assume there exists an economy ω with at least two equilibria, i.e., $N(\omega) \geq 2$. Then, there is enough information to determine all the equilibrium prices associated with every economy $\omega \in \boldsymbol{\Omega}$. In other words, the economic model possesses the quite remarkable property that knowing the number of solutions suffices to determine the precise value of these solutions (provided there is an economy with multiple equilibria). If there is uniqueness of equilibrium, the above statement does not hold true any more. In that case, one finds that this unique equilibrium price vector is constant, i.e., does not depend on the economy $\omega \in \boldsymbol{\Omega}$.

Catastrophic Risk

Richard A. Posner

Abstract

Catastrophic risks are defined here as events of low or unknown probability that if they occur inflict enormous losses often having a large non-monetary component. The Indian Ocean tsunami of 2004 is at the lower level of the catastrophic-risk scale of destruction; examples from higher levels including large asteroid strikes, pandemics and global warming. The challenge is to modify the principles of cost–benefit analysis to deal with serious problems caused by uncertainty (as distinct from risk), nonlinearity in value-of-life estimates, the need to project social discount rates into the distant future, and the difficulty of devising suitable policy instruments.

The Indian Ocean tsunami of December 2004 and, less than a year later, the flooding of New Orleans as a result of Hurricane Katrina focused attention on a type of disaster to which policymakers pay too little attention – a disaster that has a low or unknown probability of occurring but that, if it does occur, creates enormous losses. Great as were the death toll, the physical and emotional suffering of survivors, and property damage caused by the tsunami, and the even greater property damage caused by the flooding of New Orleans, even greater losses could be inflicted by other disasters of low (but not negligible) or unknown probability. The asteroid that exploded above Siberia in 1908 with the force of a hydrogen bomb might have killed millions of people had it exploded above a major city. Yet that asteroid was only about 200 feet in diameter, and a much larger one (among the thousands of dangerously large asteroids in orbits that intersect the earth's orbit) could strike the earth and, wherever it struck, cause the total extinction of the human race through a combination of shock waves, fire, tsunamis, and blockage of sunlight. Other catastrophic risks include, besides earthquakes such as the one that caused the 2004 tsunami, natural epidemics (the 1918–19 Spanish influenza epidemic killed between 20 million and 40 million people), nuclear or biological attacks by terrorists, certain types of lab accident (one discussed later in this article), and abrupt global warming. The probability of catastrophes resulting, whether or not intentionally, from human activity appears to be increasing because of the rapidity and direction of technological advances.

The Economic Approach to Catastrophe

It is generally believed that the prediction, assessment, prevention, and mitigation of catastrophes is the province of science. However, economic analysis has an important role to play, as well. Able scientists can commit analytical errors when discussing policy that economists would easily avoid. Thus, Barry Bloom, dean of the Harvard School of Public Health, has criticized the editors of leading scientific journals for having taken the position that 'an editor may conclude that the potential harm of publication outweighs the potential societal benefits' (Bloom 2003, pp. 48, 51). (The specific reference is to publications from which terrorists could learn how to create lethal bioweapons.) Bloom calls this 'a chilling example of the impact of terrorism on the freedom of inquiry and dissemination of knowledge that today challenges every research university' (Bloom 2003, p. 51). The implication – that freedom of scientific research should enjoy absolute priority over every other social value – neglects the need to weigh costs and benefits in order to determine the best balance between public safety and scientific progress.

To illustrate the economic approach to catastrophe, suppose that a tsunami as destructive as the Indian Ocean tsunami occurs on average once a century and kills 250,000 people. That is an average of 2500 deaths per year. Even without attempting a sophisticated estimate of the value of life to the people exposed to the risk, one can say with some confidence that, if an annual death toll of 2500 could be substantially reduced at moderate cost, the investment would be worthwhile. A combination of educating the residents of low-lying coastal areas about the warning signs of a tsunami (tremors and a sudden recession in the ocean), establishing a warning system involving emergency broadcasts, telephoned warnings, and air-raid- type sirens, and improving emergency response systems would have saved many of the people killed by the Indian Ocean tsunami, probably at a total cost below any reasonable estimate of the average losses that can be expected from tsunamis. Relocating people away from coasts would be even more efficacious, but, except in the most vulnerable areas or in areas in which residential or commercial uses have only marginal value, the costs would probably exceed the benefits. For annual costs of protection must be matched with annual, not total, expected costs of tsunamis.

As another example, consider the question of optimal precautions against the type of flood that

inundated New Orleans. In 1998 it was estimated that it would cost $14 billion to prevent such a flood; the estimated 'economic' cost (which ignores the loss of life and physical and emotional suffering) of the recent flood is $100 billion to $200 billion; and the Corps of Engineers estimated the annual probability of such a flood at 1 in 300. If we take the lower cost and assume that the $14 billion investment would eliminate the probability of a flood within 30 years, a period in which the probability of a flood if the measures were not taken would be a shade under ten per cent, yielding an expected benefit from the flood-control measures of $10 billion, the measures would flunk a cost–benefit test. Note that the calculation does not include discounting future benefits to present value; the reason is that the benefits are likely to grow – a flood that occurred 30 years hence would be likely to do more damage because property values would increase.

Value of Life Estimates

What might tip the balance in favour of the flood-control measures would be monetizing the expected loss of life and other human suffering. There is now a substantial economic literature inferring the value of life from the costs people are willing to incur to avoid small risks of death; if from behaviour toward risk one infers that a person would pay $70 to avoid a 1 in 100,000 risk of death, his value of life would be estimated at $7 million ($70/.00001), which is in fact the median estimate of the value of life of an American (Viscusi and Aldy 2003, pp. 5, 18, 63). The value of this transformation is simply that, once a risk is calculated, its expected cost is instantly derived simply by multiplying the risk by the value of life.

But there is significant nonlinearity to be considered at both ends of the risk spectrum. At the high end, if one is asked what he would demand to play one round of Russian roulette, the typical answer will be a good deal more than 1/6 of $7 million. At the low-probability end of the risk spectrum, there is a tendency to write the cost of the risk down to or near zero (see, for example, Kunreuther and Pauly 2004; Viscusi 1997). In other words, the studies from which the $7 million figure is derived may not be robust with respect to risks of death either much larger or much smaller than the 1 in 10,000 to 1 in 100,000 range of most of the studies – and we do not know what the risk of death from a tsunami was to the people killed, though it was probably towards the low end of the range.

Even if we disregard this issue, because value of life is positively correlated with income, the $7 million figure cannot be used to estimate the value of life of the people killed by the Indian Ocean tsunami, or at least most of them (and perhaps likewise the people killed in the New Orleans flood, most of whom were poor). Additional complications arise from the fact that the deaths were only a part of the cost inflicted by the disaster – the injuries, the suffering, and the property damage that also resulted from the tsunami have to be estimated along with the efficacy and expense of precautionary measures that would have been feasible. The risks of smaller but still destructive tsunamis that such measures might protect against must also be factored in; nor is the 'once a century' risk estimate much better than a guess. Nevertheless, it seems apparent that the total cost of the tsunami was high enough to indicate that precautionary measures would have been cost-justified.

The tsunami, unlike the New Orleans flood, could not have been prevented. The only possible precautionary measures would have been either a warning system to enable prompt evacuation or permanently relocating population away from the coastline. Similar measures would have been possible alternatives to preventive measures for New Orleans as well, especially a system for prompt evacuation; but such a system would not have prevented either property damage or massive if temporary population relocation, both of which were huge costs of the flood.

The Political Economy of Catastrophe Prevention and Response

Since precautionary measures of some kind taken in anticipation of a tsunami on the scale that

occurred would clearly have been cost-justified, why were they not taken? Tsunamis are a common consequence of earthquakes, which themselves are common; and tsunamis can have other causes besides earthquakes – a major asteroid strike in an ocean would create a tsunami that would dwarf the Indian Ocean one. The answer, or answers, may be economic in character.

First, although a once-in-a-century event is as likely to occur at the beginning of the century as at any other time, it is much less likely to occur some time in the first decade of the century than some time in the last nine decades of the century. (The point is simply that the probability is greater the longer the interval being considered: one is more likely to catch a cold in the next year than in the next 48 hours.) Politicians with limited terms of office and thus foreshortened political horizons are likely to discount low-risk disaster possibilities steeply because the risk of damage to their careers from failing to take precautionary measures is truncated.

Second, to the extent that effective precautions require governmental action, the fact that government is a centralized system of control makes it difficult for officials to respond to the full spectrum of possible risks against which cost-justified measures might be taken. Given the variety of matters to which they must attend, officials are likely to have a high threshold of attention below which risks are simply ignored. The US government, preoccupied with terrorist threats, paid insufficient attention to the risk of a disastrous flood of New Orleans, though the risk was understood to be significant.

Third, where risks are regional or global rather than local, many national governments, especially in the poorer and smaller countries, may drag their heels in the hope of taking a free ride on the larger and richer countries. Knowing this, the latter countries may be reluctant to take precautionary measures and by doing so reward and thus encourage free riding. Again, there is a US parallel: state and local government may stint on devoting resources to emergency response, expecting aid from other state and local governments and the federal government.

Fourth, countries are poor often because of weak, inefficient, or corrupt government, characteristics that may disable poor nations from taking cost-justified precautions. Again there is a US parallel: Louisiana is a poor state and New Orleans, which has a very large poor population, has a reputation for having an inefficient and even corrupt government.

And fifth, the positive correlation of per capita income with value of life suggests that it is quite rational for even a well-governed poor country to devote proportionately fewer resources to averting calamities than rich countries do. This would also be true of a poor state or city of the United States.

The failure to act in accordance with cost–benefit principles is dominant characteristic of public policy towards catastrophic risk. An example is the asteroid menace, which is analytically similar to the menace of tsunamis. The National Aeronautics and Space Administration, with an annual budget of more than $10 billion, spends only $4 million a year on mapping dangerously close large asteroids, and at that rate may not complete the task for another decade, even though such mapping is the key to an asteroid defence because it may provide many years of advance warning. Deflecting an asteroid from its orbit when it is still hundreds of millions of miles away from hitting the earth appears to be a feasible undertaking. Although asteroid strikes are less frequent than tsunamis, there have been enough of them to enable the annual probabilities of various magnitudes of such strikes to be estimated, and from these estimates an expected cost of asteroid damage can be calculated. As in the case of tsunamis, if there are measures, beyond those being taken already, that can reduce the expected cost of asteroid damage at a lower cost, thus yielding a net benefit, the measures should be taken, or at least seriously considered.

Cost–Benefit Analysis Under Uncertainty

Often it is not possible to estimate the probability or magnitude of a possible catastrophe; the situation is one of uncertainty rather than of risk; how

then can cost–benefit analysis, or other techniques of economic analysis, help us in devising responses to such a possibility? The probability of bioterrorism or nuclear terrorism, for example, cannot be quantified; nevertheless, there is rough sense of the range of possible losses that such terrorism would inflict – a range that has no upper limit short of the extinction of the human race – and from this it can be inferred that, even if the probability of such a terrorist attack is small, the expected cost – the product of the probability of the attack and of the consequences if the attack occurs – probably is quite high.

An example of how economic analysis can produce insights even when catastrophic risks are non-quantifiable involves the Relativistic Heavy Ion Collider (RHIC) that went into operation at Brookhaven National Laboratory in Long Island in 2000. As explained by the distinguished English physicist Sir Martin Rees, the collisions in RHIC might conceivably produce a shower of quarks that would 'reassemble themselves into a very compressed object called a strangelet. . . . A strangelet could, by contagion, convert anything else it encountered into a strange new form of matter. . .. A hypothetical strangelet disaster could transform the entire planet Earth into an inert hyperdense sphere about one hundred metres across' (Rees 2003, pp. 120–1). Rees considers this 'hypothetical scenario' exceedingly unlikely, yet points out that even an annual probability of 1 in 500 million is not wholly negligible when the result, should the improbable materialize, would be so total a disaster.

Concern with such a possibility led John Marburger, the director of the Brookhaven National Laboratory, to commission a risk assessment by a committee of distinguished physicists before authorizing RHIC to begin operating. The committee concluded that the risk of a strangelet disaster was negligible. No cost–benefit analysis of RHIC was conducted, with or without including the risk of a strangelet disaster on the cost side. RHIC cost $600 million to build, and its annual operating costs were expected to be $130 million. No attempt was made to monetize the benefits that the experiments conducted in it were expected to yield; because the experiments are designed to satisfy scientific curiosity rather than to create knowledge that is likely to lead to the invention of useful products, estimation of the benefits is impossible. They may be slight.

The probability of a strangelet disaster in the course of RHIC's planned ten-year life cannot actually be quantified, though there have been attempts. One team of physicists estimated the probability of a strangelet disaster as no more than 1 in 50 million. The official risk-assessment team offered a series of upper-bound estimates, including a 1 in 500,000 probability of a strangelet disaster over the ten-year period, which is 100 times greater than the other's team's estimate. These really are wild, as well as wildly divergent, guesses. Still another uncertainty is what dollar figure to place on the destruction of the earth and all its human and other inhabitants, given the nonlinearity of value of life estimates. Yet, given these uncertainties, the fact that the benefits of RHIC may be quite small suggests that the possibility, remote as it may seem, of a strangelet disaster would weigh heavily, in an economic analysis, against the project. There are more than six billion people on Earth – not to mention unborn future generations – and if their average value of life is estimated at a modest $1 million, the cost of extinction would be $6 quadrillion, and a 1 in 100 million annual risk of a strangelet disaster would yield an annual expected extinction cost of $60 million for ten years to add to the $130 million in annual operating costs and the initial investment of $600 million – roughly a one-third increase in total cost. This could well be decisive against the project, given its entirely conjectural benefits.

Global Warming: Risk And Response

Another, more familiar, example of the difficulty of quantifying catastrophic risk is the problem of global warming. The Kyoto Protocol, which came into effect by its terms when Russia signed it although the United States has not done so, requires the signatory nations to reduce their carbon dioxide emissions to a level seven to ten per cent below what they were in the late 1990s, but

exempts developing countries, such as China, a large and growing emitter, and Brazil, which is destroying large reaches of the Amazon rainforest, much of it by burning. The effect of carbon dioxide emissions on the atmospheric concentration of the gas is cumulative, because carbon dioxide leaves the atmosphere (by being absorbed into the oceans) at a much lower rate than it enters it, and therefore the concentration will continue to grow even if the annual rate of emission is cut down substantially. Between this phenomenon and the exemptions, there is a widespread belief that the Kyoto Protocol will have only a slight effect in arresting global warming; yet the tax or other regulatory measures required to reduce emissions below their level of six years ago will be very costly.

The Protocol's supporters generally are content to slow the rate of global warming by encouraging – by means of heavy taxes (for example, on gasoline or coal) or other measures (such as quotas) that will make fossil fuels more expensive to consumers –conservation measures such as driving less or driving more fuel- efficient cars that will reduce the consumption of these fuels. But from an economic standpoint that is probably either too much or too little. It is too much if, as most scientists believe, global warming will continue to be a gradual process, producing really serious effects – the destruction of tropical agriculture, the spread of tropical diseases such as malaria to currently temperate zones, dramatic increases in violent storm activity (increased atmospheric temperatures, by increasing the amount of water vapour in the atmosphere, increase precipitation), and a rise in sea levels (eventually to the point of inundating most coastal cities) – only toward the end of the 21st century. By that time science, without prodding by governments, is likely to have developed economical 'clean' substitutes for fossil fuels (there already is a clean substitute – nuclear power) and even economical technologies for either preventing carbon dioxide from being emitted into the atmosphere by the burning of fossil fuels, or removing it from the atmosphere.

But the Protocol is too little and too late, as a response to the costs of global warming, if the focus is changed from gradual to abrupt global warming. At various times in the Earth's history, drastic temperature changes have occurred in the course of just a few years. During the Younger Dryas epoch of about 11,000 years ago, shortly after the end of the last ice age, global temperatures soared by about 14 degrees Fahrenheit in the course of a decade. Because the earth was still cool from the ice age, the effect of the increased warmth on the human population was positive. But a similar increase in a modern decade would have devastating effects on agriculture and on coastal cities, and might even cause a shift in the Gulf Stream that would result in giving all of Europe a Siberian climate.

Because of the enormous complexity of the forces that determine climate, and the historically unprecedented magnitude of human effects on the concentration of greenhouse gases, the possibility that continued growth in that concentration could precipitate – and within the near rather than the distant future – a sudden warming similar to that of the Younger Dryas cannot be excluded. Indeed, no probability, high or low, can be assigned to such a catastrophe. But it may be significant that, while dissent continues, many climate scientists are now predicting dramatic effects from global warming within the next 20 to 40 years, rather than just by the end of the century (Lempinen 2005). It may be prudent, therefore, to try to stimulate an increase in the rate at which economical substitutes for fossil fuels, and technology both for limiting the emission of carbon dioxide by those fuels when they are burned in internal-combustion engines or electrical generating plants, and for removing carbon dioxide from the atmosphere, are developed. This can be done by stiff taxes on carbon dioxide emissions. Such taxes give the energy industries, along with customers of theirs such as airlines and manufacturers of motor vehicles, a strong incentive to finance R&D designed to create economical clean substitutes for such fuels and devices to 'trap' emissions at the source before they enter the atmosphere. Given the technological predominance of the United States, it is important that these taxes be imposed on US firms, which they would be if the United States ratified the Kyoto Protocol.

One advantage of the technology-forcing tax approach over public subsidies for R&D is that the government would not be in the business of picking winners – the affected industries would decide what R&D to support – and another is that the brunt of the taxes could be partly offset by reducing other taxes, since emission taxes would raise revenue as well as inducing greater R&D expenditures.

It might seem that subsidies would be necessary for technologies that would have no market, such as technologies for removing carbon dioxide from the atmosphere. There would be no private demand for such technologies because, in contrast to ones that reduce emissions, technologies that remove already emitted carbon dioxide from the atmosphere would not reduce any emitter's tax burden. But this problem is easily solved by making the tax a tax on *net* emissions. Then an electrical generating plant or other emitter could reduce its tax burden by removing carbon dioxide from the atmosphere as well as by reducing its own emissions of carbon dioxide into the atmosphere.

It might seem that, because the demand for conventional fuel sources is inelastic in the short run, the imposition of stiff taxes or quotas required by the Kyoto Protocol would have little effect on the level of emissions. But the significance of the taxes, which actually depends on the inelasticity of demand, is that it would create both pressures and resources for finding a technological fix that would counter the cumulative effect of emissions on the atmospheric concentration of carbon dioxide by driving annual emissions to zero or even below.

Global Warming: the Discounting Problem

A further advantage of focusing on the risk of abrupt rather than gradual global warming is that it allows the vexing problem of discount rate to be elided. The problem is acute when concern focuses on gradual global warming. Suppose that a $10 billion expenditure on capping emissions today would have no effect on human welfare during this century but, by slowing global warming, would produce a savings in social costs of $100 billion in 2100. At a discount rate of three per cent, the present value of $100 billion a century from now is only $5 billion. That would make the expenditure of $10 billion today seem a very poor investment. (For the sake of simplicity, benefits that are expected to accrue after 2100 are ignored in this analysis.) The same amount of money invested in financial instruments could be expected to grow to $192 billion by 2100, on the assumption of a three per cent real interest rate for the next 100 years (though in fact interest rates cannot be forecast over such a long period). If the fund were then disbursed to the victims of global warming, they would be better off than if the $100 billion cost of global warming assumed to be incurred in that year had been averted. Less conservative investments, moreover, would yield larger expected returns – ten per cent or more rather than three per cent.

But it is not a real alternative to spending $10 billion now to invest it in a fund for future victims of global warming. No such fund will be created, and so they will not be compensated. In circumstances such as this, discounting future to present values is not a method of helping people to decide how to manage their affairs in the way most conducive to maximizing their welfare. Rather, it is a method of maximizing global wealth without regard to its distribution among persons. In the case of gradual global warming, the victims are likely to be concentrated in poor countries, so that basing policy on the discounted costs of global warming would further immiserate the future inhabitants of those countries by increasing the authorized level of emissions harmful to them.

A discount rate based on market interest rates tends to obliterate the interests of remote future generations. The implications are drastic. 'At a discount rate of five per cent, one death next year counts for more than a billion deaths in 500 years. On this view, catastrophes in the further future can now be regarded as morally trivial' (Parfit 1984, p. 357). (What right would the Romans have had to regard our lives as worthless in deciding whether to conduct dangerous experiments?) The trade-off is only slightly less extreme if one substitutes 100 years for 500. At a five per cent discount rate, the present value of one dollar to be received in 100 years is only three-quarters of a cent – and if

for money we substitute lives, then to save one life this year we should be willing to sacrifice almost 150 lives a century hence.

And yet not to discount future costs at all would be absurd, certainly as a practical political matter. For then the present value of benefits conferred on our remote descendants would approach infinity. Measures taken today to arrest global warming would confer benefits not only in 2100 but in every subsequent year, perhaps for millions of years. The present value of $100 billion received every year for a million years at a discount rate of zero per cent is $100 quadrillion.

But the vexing problem of how much weight to give to the welfare of remote future generations can be finessed, at least to some extent, if not solved. A discounted present value can be equated to an undiscounted present value simply by shortening the time horizon for the consideration of costs and benefits. For example, the present value of an infinite stream of costs discounted at four per cent a year is equal to the undiscounted sum of those costs for 25 years, while the present value of an infinite stream of costs discounted at one per cent a year is equal to the undiscounted sum of those costs for 100 years. The formula for the present value of one dollar per year forever is $1/r, where r is the discount rate. So if r is four per cent, the present value is $25, and this is equal to an undiscounted stream of one dollar per year for 25 years. If r is one per cent, the undiscounted equivalent is 100 years.

One way to argue for the four per cent rate (that is, for truncating our concern for future welfare at 25 years) is to say that we're willing to weight the welfare of the next generation as heavily as our own welfare but that's the extent of our regard for the future. One way to argue for the one per cent rate is to say that we are willing to give equal weight to the welfare of everyone living in this century, which will include us, our children, and our grandchildren, but beyond that we don't care. Looking at future welfare in this way, we may be inclined towards the lower rate, which would have dramatic implications for willingness to invest today in limiting global warming. The lower rate could even be regarded as a ceiling. Most people have some regard for human welfare, or at least the survival of some human civilization, in future centuries. We are grateful that the Romans didn't exterminate the human race in chagrin at the impending collapse of their empire.

Another way to bring future consequences into focus without conventional discounting is by aggregating risks over time rather than expressing them in annualized terms. If we are concerned about what may happen over the next century, then instead of asking what the annual probability of a collision with a ten-kilometre- wide asteroid is, we might ask what the probability is that such a collision will occur within the next 100 years. An annual probability of 1 in 75 million translates into a century probability of roughly 1 in 750,000. That may be high enough – in view of the consequences if the risk materializes – to justify spending several hundred million, perhaps even several billion, dollars to avert it.

Inverse Cost–Benefit Analysis

A helpful approach to cost–benefit analysis under conditions of extreme uncertainty is what can be called 'inverse cost–benefit analysis' (Posner 2004, pp. 176–84). Analogous to extracting probability estimates from insurance premiums, it involves dividing what the government is spending to prevent a particular catastrophic risk from materializing by what the social cost of the catastrophe would be if it did materialize. The result is an approximation to the implied probability of the catastrophe. Expected cost is the product of probability and consequence (loss): $C = PL$. If P and L are known, C can be calculated. If instead C and L are known, P can be calculated: if $1 billion ($C$) is being spent to avert a disaster that if it occurs will impose a loss (L) of $100 billion, then $P = C/L = .01$.

If P so calculated diverges sharply from independent estimates of it, this is a clue that society may be spending too much or too little on avoiding L. It is just a clue, because of the distinction between marginal and total costs and benefits. The optimal expenditure on a measure is the expenditure that equates marginal cost to marginal benefit. Suppose we happen to know that P is not .01 but .1, so that the expected cost of the

catastrophe is not $1 billion but $10 billion. It doesn't follow that we should be spending $10 billion, or indeed anything more than $1 billion, to avert the catastrophe. Perhaps spending just $1 billion would reduce the expected cost of catastrophe from $10 billion all the way down to $500 million and no further expenditure would bring about a further reduction, or at least a cost-justified reduction. For example, if spending another $1 billion would reduce the expected cost from $500 million to zero, that would be a bad investment, at least if risk aversion is ignored.

The federal government is spending about $2 billion a year to prevent a bioterrorist attack (increased to $2.5 billion for 2005 under the rubric of 'Project BioShield') (Office of Management and Budget 2003, pp. 37–8; US Department of Homeland Security 2004). The goal is to protect Americans, so in assessing the benefits of this expenditure casualties in other countries can be ignored. Suppose the most destructive biological attack that seems reasonably possible on the basis of what little we now know about terrorist intentions and capabilities would kill 100 million Americans. We know that value-of-life estimates may have to be radically discounted when the probability of death is exceedingly slight. But there is no convincing reason for supposing the probability of such an attack less than, say, 1 in 100,000; and the value of life that is derived by dividing the cost that Americans will incur to avoid a risk of death of that magnitude by the risk is about $7 million. Then, if the attack occurred, the total costs would be $700 trillion – and that is actually too low an estimate because the death of a third of the population would have all sorts of collateral consequences, mainly negative. Let us, still conservatively however, refigure the total costs as $1 quadrillion. The result of dividing the money being spent to prevent such an attack, $2 billion, by $1 quadrillion is 1/500,000. Is there only a 1 in 500,000 probability of a bioterrorist attack of that magnitude in the next year? One doesn't know, but the figure seems too low.

It doesn't follow that $2 billion a year is too little to be spending to prevent a bioterrorist attack; one must not forget the distinction between total and marginal costs. Suppose that the $2 billion expenditure reduces the probability of such an attack from .01 to .0001. The expected cost of the attack would still be very high – $1 quadrillion multiplied by .0001 is $100 billion – but spending more than $2 billion might not reduce the residual probability of .0001 at all. For there might be no feasible further measures to take to combat bioterrorism, especially when we remember that increasing the number of people involved in defending against bioterrorism, including not only scientific and technical personnel but also security guards in laboratories where lethal pathogens are stored, also increases the number of people capable, alone or in conjunction with others, of mounting biological attacks. But there *are* other response measures that should be considered seriously. And one must also bear in mind that expenditures on combating bioterrorism do more than prevent mega-attacks; the lesser attacks, which would still be very costly both singly and cumulatively, would also be prevented.

Costs, moreover, tend to be inverse to time. It would cost a great deal more to build an asteroid defence in one year than in ten years because of the extra costs that would be required for a hasty reallocation of the required labour and capital from the current projects in which they are employed. And so would other crash efforts to prevent catastrophes. Placing a lid on current expenditures would have the incidental benefit of enabling additional expenditures to be deferred to a time when, because more will be known about both the catastrophic risks and the optimal responses to them, considerable cost savings may be possible. The case for such a ceiling derives from comparing marginal benefits to marginal costs; the latter may be sharply increasing in the short run.

An investment banker and heterodox monetary economist, Waddill Catchings was born in Sewanee, Tennessee, on 6 September 1879, and died in Pompano Beach, Florida, on 31 December 1967. He graduated from Harvard College in 1901 and Harvard Law School in 1904. Joining the New York City law firm Sullivan & Cromwell on a salary of ten dollars a week, Catchings proved skilful in managing the affairs of companies that went into receivership during the financial panic of 1907, and became president of three ironworks. During the First World War, Catchings worked in the export department of J. P. Morgan & Company, then the US purchasing agent for the British and French governments. A Harvard classmate of Arthur Sachs, Catchings joined Goldman, Sachs & Company in 1918 as partner in charge of underwriting, helping to organize General Foods and National Dairy Products (later Kraft).

Catchings complained that his Harvard professors 'casually explained that their theories would hold true in the long run. But what people are interested in is the short, not the long, run. So I made up my mind that as soon as I had enough money I would set about reconciling these two phases of business – theory and practice' (quoted in his obituary in the *New York Times,* 1 January 1968). In 1920, Catchings and his Harvard classmate William Trufant Foster (a rhetoric professor and college administrator) established the Pollak Foundation for Economic Research, directed by Foster, funded by Catchings, and dedicated to promoting their belief that, in Catchings's words, 'If business is to continue zooming, production must be kept at high speed, whatever the circumstances' (*New York Times* obituary). High and growing levels of production could be maintained by high and growing levels of consumer spending, and the business cycle could be eliminated by appropriate Federal Reserve policy and by keeping public works projects in reserve for economic downturns. In addition to a syndicated newspaper column, Foster and Catchings wrote *Money* (1923), *Profits* (1925), *Business without a Buyer*

(1927), *The Road to Plenty* (1928), and *Progress and Plenty* (1930), all Pollak Foundation Studies. Gleason (1959) and Carlson (1962) consider Foster and Catchings as possible precursors of Keynesian macroeconomics and Harrod–Domar growth theory. The four per cent annual increase in currency and credit endorsed by Foster and Catchings is a possible forerunner of monetarism, but they opposed any mandating of a price level rule, preferring a goal of maintaining prosperity (Tavlas, 1976).

In December 1928, Catchings launched the Goldman Sachs Trading Corporation (GSTC), a closed-end investment trust (ten per cent owned by Goldman, Sachs & Company) which in July 1929 launched the Shenandoah Corporation, another closed-end investment trust, 40% owned by GSTC, followed in August by the Blue Ridge Corporation, with Shenandoah owning a majority of Blue Ridge's common shares. At their peak, this highly leveraged pyramid controlled $500 million of investments, but it was swept away in the stock market crash. GSTC shares, which were initially sold to the public at $104, reached $326 (thanks in part to $57 million that GSTC spent buying its own shares by March 1929, and more purchases later) before falling to $1.75. Catchings had launched Shenandoah and Blue Ridge without consulting the Sachs brothers (who were in Europe in the summer of 1929), and in May 1930 his partners forced his resignation, paying him $250,000 despite his capital account's deficit.

Catchings withdrew from the Pollak Foundation (whose endowment disappeared in the crash) to concentrate on his own finances, and moved to California. In the 1950s Catchings was a director of Chrysler, Standard Packaging, and Warner Brothers. After Foster died in 1950, Catchings collaborated with Charles F. Roos (a co-founder of the Econometric Society) on *Money, Men and Machines* (1953). Denouncing Keynesian economics, Catchings and Roos accused the Federal Reserve System of interfering with economic freedom and destabilizing the economy through roller-coaster monetary policies in futile attempts to keep higher wages from causing higher prices. Their book won the Freedoms Foundation's George Washington Honor Medal. Catchings's last books were *Do Economists Understand Business?* (1955), *Bias Against Business* (1956), and *Are We Mismanaging Money?* (1960).

Catching-Up

Stanislaw Gomulka

The search for a pattern in the observed wide variation in the cross-country growth rate of output per man hour has led to the observation that the latecomers in industrialization should, and in fact do, tend to innovate faster than does the world's 'technology frontier area' (TFA), the latter defined as the regions in which the world's best technology is employed. The reason behind this observation is the commonsense notion that in technology or organization, as well as in science, learning and imitating is typically cheaper and faster than is the original discovery and testing. The distance between the level of development of the TFA and that of a less developed country (LDC) may be taken as a measure of the backlog of technological opportunities to exploit. The larger the greater may be expected to be the economic incentive to take advantage of some of these opportunities and, other things being equal, the greater the rate of international technology transfer. The idea that there might be 'advantages of backwardness' in this sense is usually associated with the names of Thorstein Veblen and Alexander Gerschenkron. Veblen (1915) applied it to Germany vis-à-vis England; Gerschenkron (1962) updated it and extended the work to include Russia, France and Italy. A formalization of this idea by Nelson and Phelps (1966) assumed that an increase in the level of technology of an LDC is proportional to the technology gap between it and the TFA. This assumption implies that the relationship between the rate of innovation and the relative technology gap is, for any LDC and in the course of time, positive and linear. Moreover, the LDCs' innovation rate would always exceed that of the TFA but fall toward it asymptotically, the relative gap falling as a result toward a country-specific positive constant, called the 'equilibrium technology gap'. This falling of the relative technology gap between an LDC and the TFA is what is meant by (international and/or technological) catching-up.

Studies of the world pattern of productivity growth rates in the period 1950–85 have led to the important qualification of the original Veblen–Gerschenkron hypothesis, namely that for the group of highly backward LDCs, the rate of innovation tends to be lower the greater the relative technology gap. The relationship across all countries is thus of the 'hat-shaped type' (Gomulka 1971; Horvat 1974). The usual interpretation of the negative part of the Hat-shape Relationship rests on the notion of 'absorptive capacity' being the severely limiting factor in the initial phase of the catching-up. As educational standards and physical infrastructure are improved and export capabilities developed, a larger amount of foreign technology becomes profitable. Technology imports themselves also help upgrade skills and increase exports, attracting still larger technology imports, and so forth. It is this causality sequence which gives rise to the relationship's negative part. However, before absorptive capacity is developed to reach a level at which an LDC's rate of innovation is the same as that of the TFA, an LDC's relative backwardness would be increasing.

The Hat-shape Relationship may be interpreted as an international, macroeconomic equivalent of logistic or S-shaped diffusion curves observed often for individual inventions. Theoretical research has been centred on modelling the dynamics of catching-up under different channels of technology transfer, such as direct foreign investment Findlay (1976), a cost-free diffusion (Gomulka 1971), or trading conventional goods for embodied technology (Gomulka 1970). The most recent development of the theory also takes into account economic dualism and technology transfer costs. This particular theory combines international technology transfer with internal diffusion from the modern to the traditional sector, and interprets 'appropriate technology' in a dynamic context. Empirical studies indicate that embodied technology transfer is an important, perhaps the main, channel for most LDCs (Gomulka and Sylvestrowicz 1976). However, in

the postwar catching-up of the US by countries with large R and D sectors, such as Japan, West Germany and the USSR, the import of capital goods from the US has apparently played a small role, indicating that disembodied diffusion, both (virtually) cost-free and commercial, have probably played the main role. The post-1975 labour productivity slowdown in countries of the latter character may be interpreted as evidence of these highly developed countries approaching their specific equilibrium technology gaps. These equilibrium gaps, as well as innovation rates in the course of the catching-up itself, appear to be strongly influenced by cultural and systemic factors. Consequently, the process of catching-up is bringing about a state of international growth equilibrium in which the innovation rate would be common to all countries, but in which productivity and technology levels would continue to vary significantly among the world's countries.

Categorical Data

A. Colin Cameron

Abstract

Categorical outcome (or discrete outcome or qualitative response) regression models are models for a discrete dependent variable recording in which of two or more categories an outcome of interest lies. For binary data (two categories) probit and logit models or semiparametric methods are used. For multinomial data (more than two categories) that are unordered, common models are multinomial and conditional logit, nested logit, multinomial probit, and random parameters logit. The last two models are estimated using simulation or Bayesian methods. For ordered data, standard multinomial models are ordered logit and probit, or count models are used if ordered discrete data are actually a count.

Categorical outcome models are regression models for a dependent variable that is a discrete variable recording in which of two or more categories, usually mutually exclusive, an outcome of interest lies.

Categorical outcome models are also called discrete outcome models or qualitative response models, and are examples of a limited dependent variable model. Different models specify different functional forms for the probabilities of each category. These models are binomial or multinomial models, usually estimated by maximum likelihood.

Key early econometrics references include McFadden (1974), Amemiya (1981), Manski and McFadden (1981) and Maddala (1983). For textbook treatments see Amemiya (1985), Wooldridge (2002), Greene (2003) and Cameron and Trivedi (2005). The recent econometrics literature has focused on semiparametric estimation (see Pagan and Ullah 1999) and on simulation-based estimation of multinomial models (see Train 2003).

Binary Outcomes: Logit and Probit Models

Binary outcomes provide the simplest case of categorical data, with just two possible outcomes. An example is whether or not an individual is employed and whether or not a consumer makes a purchase.

For binary outcomes the dependent variable y takes one of two values, for simplicity coded as 0 or 1. If $y_i = 1$ with probability p_i, then necessarily $y_i = 0$ with probability $1 - p_i$, where i denotes the i^{th} of N observations. Regressors $\mathbf{x}_i$ are introduced by parameterizing the probability p_i, with

$$p_i = \Pr[y_i = 1 | \mathbf{x}_i] = F(\mathbf{x}_i'\beta),$$

where $F(\cdot)$ is a specified function and a single-index form is assumed.

The obvious choice of $F(\cdot)$ is a cumulative distribution function (CDF) since this ensures that $0 < p_i < 1$. The two standard models are the logit model with $p_i = \Lambda(\mathbf{x}_i'\beta) = e^{\mathbf{x}_i'\beta}/(1 + e^{\mathbf{x}_i'\beta})$, where $\Lambda(z) = e^z/(1 + e^z)$ is the logistic CDF, and the probit model with $p_i = \Phi(\mathbf{x}_i'\beta)$, where $\Phi(\cdot)$ is the standard normal CDF.

Interest usually lies in the marginal effect of a change in regressor on the probability that $y = 1$. For the r^{th} regressor, $\partial p_i/\partial x_{ir} = F'(\mathbf{x}_i'\beta)\beta_r$ where F' denotes the derivative of F. The sign of β_r gives the sign of the marginal effect, if F is a continuous CDF since then $F' > 0$, though the magnitude depends on the point of evaluation $\mathbf{x}_i$. Common methods are to report the average marginal effect over all observations or to report the marginal effect evaluated at $\bar{\mathbf{x}}$.

Parameter estimates are usually obtained by maximum likelihood (ML) estimation. Given p_i, the density can be conveniently expressed as $f(y_i) = p_i^{y_i}(1 - p_i)^{1-y_i}$. On the assumption of independence over i, the resulting log-likelihood function is

$$\ln L(\beta) = \sum_{i=1}^{N} \{y_i \ln F(\mathbf{x}_i'\beta) + (1 - y_i)\ln(1 - F(\mathbf{x}_i'\beta))\}.$$

It can be shown that consistency of the ML estimator requires only that $p_i = F(\mathbf{x}_i'\beta)$, that is, that the functional form for the conditional probability is correctly specified.

There is usually little difference between the predicted probabilities obtained by probit or logit, except for very low and high probability events. For the logit model $\ln[p_i/(1 - p_i)] = \mathbf{x}_i'\beta$, so that β_r gives the marginal effect of a change in x_{ir} on the log-odds ratio, a popular interpretation in the biostatistics literature.

A simpler method for binary data is OLS regression of y_i on $\mathbf{x}_i$, with White heteroskedastic robust standard errors used to control for the intrinsic heteroskedasticity in binary data. A serious defect is that OLS permits predicted probabilities to lie outside the (0,1) interval. But it can be useful for exploratory analysis, as OLS coefficients can be directly interpreted as marginal

effects and standard methods then exist for complications such as endogenous regressors.

When one of the outcomes is uncommon, surveys may over-sample that outcome. For example, a survey of transit use may be taken at bus stops to over-sample bus riders. This is a leading example of choice-based sampling. Standard ML estimators are inconsistent and instead one must use alternative estimators such as appropriately weighted ML.

The preceding discussion presumes knowledge of F. A considerable number of semiparametric estimators that provide consistent estimates of β given unknown F have been proposed. Manski's (1975) smooth maximum score estimator was a very early example of semiparametric estimation.

Index Models

Define a latent (or unobserved) variable y_i^* that measures the propensity for the event of interest to occur. If y_i^* crosses a threshold, normalized to be zero, then the event occurs and we observe $y_i = 1$ if $y_i^* > 0$ and $y_i = 0$ if $y_i^* \leq 0$. If $y_i^* = \mathbf{x}_i'\beta + u_i$, then

$$p_i = \Pr\left[y_i^* > 0\right] = \Pr\left[-u_i < \mathbf{x}_i'\beta\right] = F\left(\mathbf{x}_i'\beta\right),$$

where $F(\cdot)$ is the CDF of $-u_i$.

The logit model arises if u_i has the logistic distribution. The probit model arises if u_i has the more obvious standard normal distribution, where imposing a unit error variance ensures model identification. The probit model ties in nicely with the Tobit model, where more data are available and we actually observe $y_i = y_i^*$ when $y_i^* > 0$. And it extends naturally to ordered multinomial data.

Random Utility Models

In many economics applications the binary outcome is determined by individual choice, such as whether or not to work. Then the outcome should be the alternative with highest utility. The additive random utility model (ARUM) specifies the utility for individual i of alternative j to be $U_{ij} = \mathbf{x}_{ij}'\beta_j + \varepsilon_{ij}, j = 0, 1$, where the error term captures factors known by the decision-maker but not the econometrician. Then

$$\begin{aligned} p_i &= \Pr[U_{i1} > U_{i0}] \\ &= \Pr\left[(\varepsilon_{i0} - \varepsilon_{i1}) \leq \mathbf{x}_{i1}'\beta_1 - \mathbf{x}_{i0}'\beta_0\right] \\ &= F\left(\mathbf{x}_{i1}'\beta_1 - \mathbf{x}_{i0}'\beta_0\right) \end{aligned}$$

where F is the CDF of $(\varepsilon_{i0} - \varepsilon_{i1})$. For components x_{ir} of $\mathbf{x}_i$ that vary across alternatives (so $x_{i0r} \neq x_{i1r}$) it is common to restrict $\beta_{0r} = \beta_{1r} = \beta_r$. For components x_{ir} of $\mathbf{x}_i$ that are invariant across alternatives (so $x_{i0r} = x_{i1r}$) only the difference $\beta_{1r} - \beta_{0r}$ is identified.

The probit model arises, after rescaling, if ε_{i0} and ε_{i1} are i.i.d. standard normal. The logit model arises if ε_{i0} and ε_{i1} are i.i.d. type 1 extreme value distributed with density $f(\varepsilon) = e^{-\varepsilon}\exp(-e^{-\varepsilon})$. The latter less familiar distribution provides more tractable results when extended to multinomial models.

Multinomial Outcomes

Multinomial outcomes occur when there are more than two categorical outcomes. With m outcomes the dependent variable y takes one of m mutually exclusive values, for simplicity coded as $1, \ldots, m$. Let p_j denote the probability that the j^{th} outcome occurs. The multinomial density for y can be written as $f(y) = \prod_{j=1}^{m} p_j^{y_j}$ where $y_j, j = 1, \ldots, m$, are m indicator variables equal to 1 if $y = j$ and equal to 0 if $y \neq j$. Introducing a further subscript for the i^{th} individual and assuming independence over i yields log-likelihood

$$\ln L(\beta) = \sum_{i=1}^{N}\sum_{j=1}^{m} y_{ij} \ln p_{ij},$$

where the probabilities p_{ij} are modelled to depend on regressors and unknown parameters β.

There are many different multinomial models, corresponding to different parameterizations of p_{ij}.

Unordered Multinomial Models

Usually the outcomes are unordered, such as in choice of transit mode to work. The benchmark model for unordered outcomes is the multinomial logit model. When regressors vary across alternatives (such as prices), the conditional logit (CL) model specifies $p_{ij} = e^{\mathbf{x}_{ij}'\beta} / \sum_{k=1}^{m} e^{\mathbf{x}_{ij}'\beta}$. If regressors are invariant across alternatives (such as gender), the multinomial logit (MNL) model specifies $p_{ij} = e^{\mathbf{x}_i'/\beta_j} / \sum_{k=1}^{m} e^{\mathbf{x}_i'\beta_k}$, with a normalization such as $\beta_1 = 0$ to ensure identification. In practice some regressors may be a mix of invariant and varying across alternatives; such cases can be reexpressed as either a CL or MNL model.

The CL and MNL models reduce to a series of pairwise choices that do not depend on the other choices available. For example, the choice between use of car or red bus is not affected by whether another alternative is a blue bus (essentially the same as the red bus). This restriction, called the assumption of independence of irrelevant alternatives, has led to a number of alternative models.

These models are based on the ARUM. Suppose the j^{th} alternative has utility $U_{ij} = \mathbf{x}_{ij}'\beta + \varepsilon_{ij}, j = 1, \ldots, m$. Then

$$\begin{aligned} p_{ij} &= \Pr\left[U_{ij} \geq U_{ik} \text{ for all } k\right] \\ &= \Pr\left[\left(\varepsilon_{ik} - \varepsilon_{ij}\right) \leq \left(\mathbf{x}_{ij}'\beta - \mathbf{x}_{ik}'\beta\right) \forall\, k\right]. \end{aligned}$$

The CL and MNL models arise if the errors ε_{ij} are i.i.d. type 1 extreme value distributed. More general models permit correlation across alternatives j in the errors ε_{ij}.

The most tractable model with error correlation is a nested logit model. This arises if the errors are generalized extreme value distributed. This model is simple to estimate but suffers from the need to specify a particular nesting structure.

The richer multinomial probit model specifies the errors to be m–dimensional multivariate normal with $(m + 1)$ restrictions on the covariances to ensure identification. In practice it has proved difficult to jointly estimate both β and the covariance parameters in this model. A recent popular model is the random parameters logit model. This begins with a multinomial logit model but permits the parameters β to be normally distributed. For these two models there is no closed form expression for the probabilities and estimation is usually by simulation methods or Bayesian methods.

Ordered Multinomial Models

In some cases the outcomes can be ordered, such as health status being excellent, good, fair or poor.

The starting point is an index model, with single latent variable, $y_i^* = \mathbf{x}_i'\beta + u_i$. As y^* crosses a series of increasing unknown thresholds we move up the ordering of alternatives. For example, for $y^* > \alpha_1$ health status improves from poor to fair, for $y^* > \alpha_2$ it improves further to good, and so on. For the ordered logit (probit) model the error u is logistic (standard normal) distributed.

An alternative model is a sequential model. For example, one may first decide whether or not to go to college ($y = 1$) and if chose college then choose either two-year college ($y = 2$) or four-year college ($y = 3$). The two decisions may be modelled as separate logit or probit models.

A special case of ordered categorical data is a count, such as number of visits to a doctor taking values 0, 1, 2, …. An ordered model can be applied to these data, but it is better to use count models. The simplest count model is Poisson regression with exponential conditional mean $\mathrm{E}[y_i | \mathbf{x}_i] = \exp\left(\mathbf{x}_i'\beta\right)$. Common procedures are to use the Poisson but obtain standard errors that relax the Poisson restriction of variance-mean equality, to estimate the richer negative binomial model, or to estimate hurdle or two-part models or with-zeroes models that permit the process determining zero counts to differ from that for positive counts.

Multivariate Outcomes and Panel Data

Multivariate discrete data arise when more than one discrete outcome is modelled. The simplest example is bivariate binary outcome data. For example, we may seek to explain both employment status (work or not work) and family status (children or no children). The standard model is a bivariate probit model that specifies an index model for each dependent variable with normal errors that are correlated. Such models can be extended to permit simultaneity.

For panel binary data the standard model is an individual specific effects model with $p_{it} = F\left(\alpha_i + \mathbf{x}_{it}'\beta\right)$ where α_i is an individual specific effect. The random effects model usually specifies $\alpha_i \sim N\left[0, \sigma_\alpha^2\right]$ and is estimated by numerically integrating out α_i using Gaussian quadrature. The fixed effects model treats α_i as a fixed parameter. In short panels with few time periods consistent estimation of β is possible in the fixed effects logit but not the fixed effects probit model. If $\mathbf{x}_{it}$ includes $y_{i,\,t-1}$, a dynamic model, fixed effects logit is again possible but requires four periods of data.

Catholic Economic Thought

Pedro Teixeira and António Almodovar

Abstract

Although Catholic economics' roots date back to the beginnings of Christianity, its emergence as a structured discourse developed later and slowly. The establishment of a distinctive Catholic approach to modern social and economic problems had to await a more extensive development of the market system and the emergence of political economy. The most prolific period for Catholic economic thought began in 1891 and continued until the end of the Second World War. In the second half of the twentieth century the church's interest focused on the analysis of such themes as development, international aid and cooperation.

Catholic economic thought is the outcome of a series of efforts to evaluate the workings of economic life according to a definite set of religious principles. In its more evolved forms, these efforts have inevitably led to include the findings of political economy, and later of economics, in its assessment of economic life, but also to assess the findings of economic analysis itself. According to a strict ecclesiological perspective, only the hierarchy of the Church is authorized to identify the appropriate religious principles that are to be applied to the analysis of the livelihood of man. Therefore, some of the assessments made by Catholics may be considered by the Church's hierarchy as inappropriate.

Catholic economic thought is not to be confused with the social doctrine of the Catholic Church. Since 1891, the most relevant religious principles for the appraisal of social questions from a theological perspective are gathered in the social doctrine of the Church, which is essentially based in the so-called social encyclicals, which are official documents written by several popes, often based on documents prepared by other high-ranking Church officials. These documents emerged as attempts to offer a better moral and philosophical framework for the workings of a modern society, not as in-depth and systematic discussions of man's economic life or as blueprints for a thorough discussion of economic concepts and theories. By being focused on the material aspects of life, Catholic economic thought is prone to give more emphasis to particular problems – such as usury and finance, social and labour questions or, later, the outline of an alternative economic and social system. However, Catholic economic literature has as a rule been less focused than political economy on technical aspects.

Catholic economic thought has an inescapable doctrinal and normative accent. Its '*ought*' sentences are considered as quasi-*positive* ones, in the sense that they were allegedly meant by God to become factual statements in a society functioning in accordance with natural law (see Barrera 2001, pp. 117–31). This normative stance acts as an explicit incentive for social action, in order both to amend the workings of existing institutions and to establish new ones – such as charitable institutions, cooperatives, institutions of mutual assistance, and particular ways of labour–capital association. In certain periods, when Catholics were more openly engaged in the revision of economic life, their thought went as far as to suggest the establishment of a specific economic system, which was a third way between the liberal and the socialist ones. But, even when they were more focused on the implementation of particular social and economic measures, people engaged in these initiatives also left some thoughts that are of more general interest.

Early Attempts to Formulate Catholic Economic Thought

Although the roots of Catholic economics date back to the beginnings of Christianity, the emergence of a structured discourse developed later and slowly. Thus, even if some of the basic Catholic principles for social and ethical teaching were already present in the gospels and in the patristic literature, the systematic theology of Aquinas was instrumental in the move towards a more organized approach to economic problems. The earliest scholarly attempt to produce an explicit and meaningful set of theological principles applied to economic problems was performed in the sixteenth century by authors belonging to the Salamanca School. Under the philosophical umbrella provided by Thomism, Dominicans like Vitoria, Soto, and Mercado, and Jesuits like Molina, Mariana and Lugo addressed the problems of usury, prices, and justice in wages. Although these ideas were not formally adopted by the Church, this literature was widely used by confessors in search of appropriate answers for the moral questions raised by the development of economic activity (on the economic thought of the school of Salamanca, see Grice-Hutchinson 1978, 1993,

and Camacho 1998; these authors are also relevant as examples of a revival of Thomist moral theology, which they applied to international law: see Curran 2002).

The Nineteenth Century

The establishment of a distinctive and clear-cut Catholic approach to modern social and economic problems had nevertheless to wait for a more extensive development of the market system and the emergence of political economy. By the late 1830s, the first Catholic political economists were already trying to infuse some basic Christian values into the teachings of classical political economy. Together with the socialists, they were concerned about the consequences of unbridled competition, the concentration of riches in the hands of the few, the exploitation of the poor and weak, and the existence of pervasive unemployment. However, contrary to socialists, Catholics thought that those evils, together with excessive materialism and burgeoning social and political unrest, were to be curbed by individuals renouncing material goods and by extended charity, not by abolishing private property or an expansion of the state. Their criticism voiced the fundamental Christian values of universal fraternity and respect for human dignity, as expressed in the Gospels and in the Apostolic letters.

It is important to note that in the mid-nineteenth century there was a series of authors who wrote on economic subjects from a Catholic perspective before the *Rerum Novarum*, the encyclical of Pope Leo XIII on capital and labour, promulgated 15 May 1891. Among these we find the names of Charles de Coux, Alban de Villeneuve-Bargemont, Joseph Droz, Charles Périn, and Matteo Liberatore. The first four authors are representative of the Catholic perspectives that emerged gradually in the context of nineteenth-century France and Belgium. Three of them – Coux, Périn and Droz – were openly against any solution for economic problems that would require increased state intervention, and they asked the rich to voluntarily avoid all extreme forms of exploitation and competition; as a rule, they were reasonably sympathetic towards political economy, and may be considered as the forerunners of the conservative tendency that was later organized around the Angers school. Villeneuve-Bargemont had less confidence in voluntary individual action as a remedy for the emerging poor question. Contrary to the Catholic *conservative* approach, Villeneuve-Bargemont thought that the scale of the problem was so serious that the state should intervene in favour of the labouring masses before they fell irrevocably under the spell of socialism. Thus he may be considered as a precursor of the so-called *progressive* tendency, later developed by the Fribourg Union and the Liège school. Matteo Liberatore deserves mention, since he was one of the persons involved in the drafting of Leo XIII's *Rerum Novarum* (1891). His views were closer to Villeneuve-Bargemont than to Charles Périn, since he believed that modern poverty was a phenomenon that could not be solved by traditional means (charity), because its causes were embedded in modern social and economic organization. Modern exploitation and modern social unrest were seen not only as consequences of the acceptance of a social and economic model based on the erroneous philosophical notions underlying political economy, but also because the spread of the latter stimulated people to act in a way that damaged social cohesion. Contrary to materialist and utilitarian views, wealth should considered as a means, not an end, and should be distributed according to justice; and the human person should always be respected – meaning that in no circumstance should labour be considered as a mere commodity to be bought and sold in the market. Once individualism and competition were once again checked by an attention to mutual needs, modern phenomena such as the class struggle (between labour and capital) would vanish and a sense of mutually beneficial collaboration would take its place. Measures such as the re-establishment of updated medieval corporations – which had to be adapted to the new realities and not just re-established, were a possible institutional solution for bringing peace and harmony to the relations between producers, namely because they would help to resume natural

social relations and reduce the moral, social, and professional void in which liberalism had placed the individuals. Efforts to promote the modern resurgence of these institutions were at the origins of what later became corporatism (see below).

The Golden Age, 1891–1940s

The most prolific period for Catholic economic thought began in 1891 and continued up to the end of the Second World War. Stirred by Leo XIII's *Rerum Novarum*, the willingness to address social and economic questions gave rise to extensive debate and to intense publishing activity (see De Rosa 2004; Hobgood 1991, p. 112).

The central issue of *Rerum Novarum* is the condition of workers, especially industrial workers, and the moral and material risks arising from what was seen as their degrading situation. Leo XIII made clear from the outset that he considered the major cause to be the political and economic transformations of the previous hundred years. This had destroyed or seriously damaged valuable traditional social structures such as medieval corporations. It had also launched a process of secularization of the legal and political framework, which had greatly diminished the moral influence of the Church. Liberalism had created a social vacuum in which unregulated competition, greed and usury had prospered, resulting in a substantial concentration of wealth and power. The latter eventually created an unbalanced distribution of privileges that made possible the exploitation of the workers by the all-mighty owners of capital. Leo XIII also asserted that the supposed remedies offered by socialists were inadequate to the task. In addition to the obvious problem of atheism, the crucial issue in the Church's critique of socialism was the former's concern with private property. Although the Church criticized the extreme capitalist/individualist/ utilitarian uses of private property, these criticisms did not question its fundamental existence.

The Church proposed a new relationship between workers and capitalists. Workers should opt for non-violent ways of solving labour disputes, and should perform faithfully and completely the tasks that were allocated to them. In return, paramount among the duties of capitalists was the acknowledgment of and the respect for the human dignity of the workers. This meant respecting the workers' physical and intellectual health, and the payment of a fair family wage that would put a stop to the need for female and youth labour. Capitalists' social responsibility was central to the way Christians should relate to wealth. Leo XIII underlined the ephemeral and secondary nature of earthly wealth and success. If the Church accepted the inequality of property, it also cared for the poorest members of society, knowing that, unless these were actively supported, they would fall into a state of quasi-serfdom, which would lead to social disruption.

One of the outcomes of the *Rerum Novarum* was the development of an array of books, typically bearing the title of *Principles or Courses on Social Economics*. Often written by Jesuits for the use of both clergy and active Catholic laity, this peculiar type of book tried to re-embed the political economy into a social philosophy so as to secure a coherent and global society based on Christian values (Galindo 1996, p. 143). The authors of such works had to perform complex scholarly work if they were to fulfil their aim. First, they had to explain classical political economy to their readers; then they had to introduce and explain the Pope's criticisms of the philosophical tenets underlying economic liberalism; next they had to deal with socialism, in order to make sure that this doctrine would not be seen as a possible alternative to the shortcomings of economic liberalism; and finally, they had to highlight the proper course of Catholic thought and action that was to be followed in order to put right contemporary evils. Authors that engaged in this type of work include Charles Antoine, S.J. (1896), Giuseppe Toniolo (1907–9) and Heinrich Pesch, S.J. (1905–26), the latter being considered by Schumpeter as the best example of neo-scholasticism (1954, p. 765). Another set of books focused on the outlines of a specifically Catholic system – a third, neo-corporative, way between liberalism and socialism. This system had its roots both in France (Mun, La Tour du

Pin) and Germany (Vogelsang, Kettler), and was further developed under the auspices of the Liège School. It was eventually accepted, if not warmly supported, by the encyclical *Quadragesimo Anno*.

Quadragesimo Anno appeared in 1931, when Pius XI took the initiative in clarifying and updating the position of the Catholic Church on the economic and social condition of the contemporary world. His view was that, although capitalism per se was not an evil system, there was a problem with the way it had developed, for it had led to economic despotism, namely, a concentration of wealth which gave to a few members of society huge power, which was often used to influence and subjugate governments and countries. The subjugation of the state to the interests of a wealthy minority, whose power was nurtured by ambition, greed and speculative behaviour, fostered social disorder and could lead to the collapse of essential social bonds.

The Church supported the existence of private property, but it also underlined its dual nature (individual and social) and the difference between property ownership and property usage. Hence, the relations between capitalists and workers in the capitalistic system should be reorganized according to this view. According to Pius XI, labour and capital did have common interests, and this communality of efforts and purposes called for a sharing of both the responsibility for the productive process and of the wealth created, including the profits resulting from the productive activity. Commutative justice would be insufficient, and should be complemented by social justice.

Pius XI also emphasized the principle of subsidiarity. According to this principle, the state should not intervene when intermediate levels of society (associations, local community, and family) could act effectively. Social harmony ought therefore to be built upon the contribution of intermediate communities and groups, these taking multiple forms. However, the reconstruction of the social fabric, which had been ruined by unlimited competition and the concentration of wealth, required the state to regulate competition, subordinating it to the higher values of justice and charity. To accomplish the necessary rebalance of social power in order to promote the common good, Pius XI made explicit references to the advantages and risks of the emerging corporatist organization (in Italy and elsewhere). Overall, he thought that the advantages (pacifying society, curbing the insidious influence of socialist organizations, and bringing together workers and capitalists in the search for the common good) could outweigh the possible risks of bureaucratization and state dirigisme. Pius XI saw the establishment of the corporative system as a step in the right direction, towards a Christian social-economic order, through its contribution to a harmonious society and its emphasis on the pursuit of the common good.

The Post-war Period

At the beginning of the 1960s, the Catholic Church underwent profound institutional and theological changes. With the Second Vatican Council (1962–5), Thomism, the theological and philosophical basis of the earlier social and economic doctrine of the Church, lost its unique status (see Nichols 2002, pp. 139–43). Vatican II also marked a change in the role of the laity, and opened the dialogue between different churches. Although until the early 1960s, socialism and communism stood at the forefront of Church's criticisms, some bridges were later to be established with Marxist sociology (see Curran 2002, pp. 201, 203).

The Catholic Church's approach to economic problems also took a different direction in the second half of the twentieth century, now focusing in the analysis of themes like development and North–South relationships, international aid and cooperation. This is particularly visible in John XXIII's *Mater et Magistra* (1961) and Paul VI's *Populorum Progressio* (1967). In the latter, Paul VI considered that the wealthiest nations had the duties of solidarity, justice and charity towards less developed ones, and that these duties should be addressed through international aid, fair trade and a framework conducive to mutual progress. He was particularly critical of free trade, since he regarded any exchange between unequals as potentially unjust. Hence, he called for fair and just competition between nations.

The social question was nevertheless not forgotten. In the *Mater et Magistra*, John XXIII stated that wages should not be left to market forces alone, for they should be determined by the laws of justice and equity. Private property was not to be considered solely as a right that should be protected, but also as an obligation to practise solidarity among human beings. John XXIII also gave explicit support to the political organization of workers in order to promote their legitimate rights. This text was also the first to address, and largely support, the so-called welfare state and its associated system of social insurance and social security, on the grounds of its contribution to the desirable redistribution of wealth. Although the Church kept its distance vis-à-vis socialism, Paul VI considered that there were some possibilities for cooperation between Catholics and socialist movements insofar as this contributed to a more just society (see his apostolic letter *Octogesima Adveniens* on the occasion of the 80th anniversary of *Rerum Novarum*, 1971).

The dialogue between economic analysis and theology was, if not on hold, at least withdrawn to the backstage. This is likely to have been for several different reasons, ranging from the changing priorities in theology and a new emergence of ecclesiological concerns with the inner life of the Church, to the growing professionalization of economics, which made it ever more difficult to acquire the desirable proficiency in both fields (see Wilson 1997, pp. 88–9 and 113). In the late 1950s, Catholic writers like Achille Dauphin-Meunier and Jean-Yves Calvez had already begun to assert that the Church had no other wish than to present its own social doctrine. To these authors, the Church was not to offer or to support 'an economic theory' but only a 'philosophical and religious clarification of the fundamental aspects of human existence within economic relationships' (Calvez and Perrin 1958, p. 11).

The Contemporary Situation

Catholic social doctrine received a significant stimulus in the 1980s and 1990s with John Paul II. He used the 90th and 100th anniversaries of *Rerum Novarum* to express views on the economic realm. In *Laborem exercens* (1981) he focused on the role of work as a central feature of all human activity and therefore of all economic activity. He considered that contemporary developments in technological, economic and political conditions had reinforced the pastoral care that the Church should associate with all issues related to work, such as unemployment and lifelong learning. He criticized what he considered the error of considering human labour solely according to its economic purpose, and underlined the principle of priority of human labour over capital, which should not be attained through class or social warfare but by peaceful struggle for social justice. Likewise, in *Centesimus Annus* (1991) he focused on the harshness of the modern conditions of the working class and pointed out how erroneous the collectivist and totalitarian solution was. Thus he insisted on the idea of redistribution of wealth in order to fulfil 'the universal destination of material goods'. John Paul II also devoted special attention to economic and social development, with particular attention being paid to issues such as international division of labour, international debt and poverty. In the encyclical *Sollicitudo Rei Socialis* (1987) he criticized both 'liberal capitalism' and 'Marxism collectivism' and proposed a view of 'authentic human development' which was not only economic but also social and spiritual. Thus, underdevelopment had not only social and economic causes, but also moral ones, not the least being the lack of international solidarity that denied human interdependence beyond national or political borders. His position vis–àvis social warfare and any possible analytical or political convergence with Marxism is vividly illustrated by the reaction of the Church's hierarchy to Liberation Theology, whose main proponents were either silenced or led to abandon the Catholic Church because of the restrictions imposed on them regarding teaching, preaching and writing.

Modern Catholic theology has focused on achieving a comprehensive and coherent presentation of social ethics (see Curran 2002). Those who give a certain emphasis to economic aspects (see Barrera 2001; Hobgood 1991), always take

care to reiterate 'the caveat that [the Church's social teachings do] not offer an alternative school of thought between classical laissez-faire capitalism and socialist centralized planning' (Barrera 2001, p. viii). Notwithstanding this change of focus, the modern effort to systematize the teachings of the encyclicals has led in some cases to the identification of six basic principles: universal access, the primacy of labour, subsidiarity, socialization, solidarity, and stewardship (2001, p. 1, and table on p. 258). By means of these principles, the criticisms addressed to economics continue to stress its defective philosophical base and go on emphasizing the collective risks that are incurred by a society unwilling to restrain excessively individualist, materialist, and utilitarian behaviour. The claims of contemporary Catholic economic thought therefore continue to emphasize the need for justice and equity, something that can be achieved only through the establishment of corrective measures to the workings of the market in order to prevent its deleterious action on the social fabric. The basic appeal therefore remains, that economics should not refuse the normative approach provided by the Catholic view of mankind.

Cattaneo, Carlo (1801–1861)

R. P. Bellamy

Cattaneo was a leading spokesman for social and political reform in his native Lombardy. A polymath, he made important contributions to history, geography, linguistics and philosophy and took a prominent role in politics, as well as writing on economics and engaging in various business ventures. However, he preferred the title of economist to all others, and a concern with economic reform runs through his work. An admirer of Charles Bonet, a follower of Condillac, he developed his own theory of human progress from barbarism to civility. At the heart of his thesis was a sensationalist epistemology adapted from Vico, which he called the psychology of associated minds. He argued that if individuals were allowed to experience sufficient contrasting ideas and situations then humankind would gradually improve and both our needs and the means of satisfying them infinitely multiply. He was therefore a staunch advocate of both political liberty and free trade, which he regarded as linked. He criticized the feudal privileges and economic nationalism of the period, calling for the abolition

of the decrees against the Jews and opposing the protectionist doctrines of Friedrich List, but defended private property as an inalienable right essential to individual liberty and vehemently attacked socialist proposals for public ownership, especially Proudhon's.

He regarded the contrast between the highly developed Lombard agriculture, based on irrigation schemes devised by small proprietors, and the backward cultivation of the vast feudal estates in the south as illustrating the links between liberalism and economic development. He believed the collective enterprises of Lombard farmers, based on mutual self-interest, provided a model for republican self-government, but were only feasible within small territories where a relative homogeneity of interest and culture obtained. He therefore attacked the projects of both Cavour and Mazzini for Italian unification under a single government, devising an alternative proposal for a federal republic. He felt federalism provided the best antidote to the centralizing tendencies of the age, and ultimately hoped for a United States of Europe on the North American model.

His ideas, largely disseminated through reviews such as *Politecnico* (which he founded in 1839 and ran from 1839 to 1844 and from 1860 to 1863), were very influential at the time, and he was even asked by Gladstone to devise a scheme for agricultural reform in Ireland. He took a major part in the development of the Italian railway network, arguing that the lines should be constructed according to economic rather than political considerations. Participation in the revolution of 1848 against Austrian rule led to his exile in Switzerland. Although Garibaldi and Cavour separately sought his advice and aid in 1860, his federal republicanism led him to fall out with both of them and he was excluded from academic and political posts in the new Italian kingdom.

Causal Inference

C. W. J. Granger

When a particular event is observed, such as an economic variable taking a value in some region of the set of all possible values, it is natural to ask why that event occurred rather than some other. If, just earlier, some other event was observed to occur, it is also natural to ask if the joint observation of the two events indicates a relationship and possibly one that could be called an influence of one event by another, or even a causation. For a unique, or very rare event, such as the start of a world war, it will be very difficult to present more than sensible and suggestive statistical evidence about causation. However, in economics, values for many variables are observed with great regularity, such as daily stock market prices or monthly production figures and so a generating mechanism can be postulated that produces these values and the investigation and understanding of this mechanism is obviously one of the main tasks for the economist. In such studies, ideas such as theories, laws and causation arise very naturally, and economists in their workings use such words very frequently. It is unfortunately true that not all writers give the same meanings to these words. The understanding of causality is not the same for all economists, but this is hardly surprising as statisticians and philosophers are also not in agreement among themselves.

Economists who have attempted to discuss the meaning of causation in economics include Herbert Simon (1953), Herman Wold (1954), Julian Simon (1970), Sir John Hicks (1979), and Arnold Zellner (1979). Most of the writers emphasize the difference between a mere association and the deeper sub-class of associations that might be called causal relationships. To distinguish these, some statisticians have emphasized the use of experimental studies, but these are rarely available in economics and so this aspect of causation will not be further considered.

One can either discuss causation in very general, abstract terms or the discussion can be focused on the specific question of whether it is possible to test for causation using the data available. The latter requires an operational procedure and definition. There are basically two types of causal testing situations. In the first, a population of economic agents is observed and some variables measured for each, for example, the amount of electricity used by a household. The totality of these measurements gives a distribution. A question can then be asked – why does this household use more electricity than that one? This is a cross-sectional causality question. It is also possible to measure parameters of the distribution, such as the mean or the variance, and to ask why these parameters are changing through time. Thus, the question is asked, why is electricity demand higher this year than last? This could be called a temporal causality question. The definitions of causality and their interpretations may differ between these two cases.

It is convenient to assume the existence of a quantity called the 'degree of belief' held by an individual about the correctness of some causal theory or proposition and to assume further that this quantity can be represented as a probability. The objective of any causal analysis, such as a statistical test, might be to try to influence the degree of belief of oneself or of others. For this purpose, the analysis need not be complete or perfect, but merely to have enough value to make one reconsider one's beliefs.

A mere association between a pair of economic variables, such as a correlation or a non-independent joint distribution, is insufficient to determine a causation, partly because such associations are symmetric between the variables, the extent to which X is correlated to Y, or can be explained by Y, is exactly the same as Y is correlated, or explained, by X. It is generally thought that causation is a non-symmetric relationship, and there are various ways in which asymmetry can be introduced, the most important of which are controllability, a relevant theory, outside knowledge, and temporal priority. Amongst the economic writers, each has its advocates and detractors.

Concerning controllability, Strotz and Wold (1960) write:

> z is a cause of y if, by hypothesis, it is or 'would be possible' by controlling z indirectly to control y, at least stochastically. But it may not be possible by controlling y indirectly to control z this way.

Essentially this idea is from their experimental background and uses hypothetical experiments. By utilizing enough knowledge about lack of controllability in a system, so that some possible causal links are put to zero, tests can be constructed on the remaining links. This would obviously be the case if a system of variables, all measured at the same time, could be displayed recursively, so that the jth equation involved only the first j variables. However, by redefining variables as linear combinations of the original set, such a recursive system can always be achieved and not uniquely, unless there are sufficient identifying qualifications on the system. J. Simon suggests that controllability is required to make causal analysis useful for policy-makers. The equivalence of causation and controllability is not generally accepted, the latter being perhaps a deeper relationship. If a causal link were found and was not previously used for control, the action of attempting to control with it may destroy the causal link.

Hicks, Zellner and J. Simon, in discussing causal links, all emphasize the relevance of a sound economic theory. Hicks (1979) accepts static or equilibrium theory as sufficient for use, while J. Simon (1970) suggests that a statement that is 'logically connected to the general framework of systematic economics is much more

likely to be considered causal than one that stands alone'. Thus, the theory is used to increase the degree of belief, and these writers suggest that a strong degree of belief cannot be achieved without a convincing theory. Zellner (1979) takes a much stronger view, leaning heavily on the work of the philosopher H. Feigl who says that 'the clarified (or purified) concept of causation is defined in terms of *predictability according to a law* (or more adequately, according to a set of laws)'. In his work, Zellner appears to be saying that for him a degree of belief cannot be anything but very small unless the causal analysis is based on some generally acceptable economic theory. He gives no examples of such economic laws and it is interesting to note that Hicks (1979, p. 2) says that 'there are few economic laws that are at all firmly based'.

Concerning temporal priority, it is generally, although not universally, accepted that the cause cannot occur after the effect. It is also frequently assumed that the cause will occur before the effect, providing a convenient asymmetry, but this view is certainly more controversial. Both Zellner and Hicks firmly reject it and Hicks maintains that instantaneous and contemporaneous causality is the 'characteristic form of the causal relation in modern economics'. It is certainly true that much economic theory is written as though causation is instantaneous. However, as Hicks also points out, all economic variables are accumulations of the outcomes of economic decisions and it is difficult to present a sensible decision mechanism in which there is an instantaneous relationship between the observed inputs to the decision (the causes) and the observed outputs (the effects). Thus, for statistical testing purposes, which has to use just observed variables, the temporal priority assumption appears to be more reasonable. It is also clear that if any part of the cause cannot occur later than any part of the variable being effected, instantaneous causation cannot occur between some pairs of stock and flow variables. For example, production of steel in a month could not instantaneously cause production of automobiles in the month, as part of one variable occurs after part of the other. There is always the possibility of apparent instantaneous causation occurring because of temporal aggregation or missing common causes.

Occasionally other outside information is used to break the symmetry of association. One variable may be thought to be generated outside the economic system, such as a weather variable, so that causation can only flow from it to part of the economy. This idea is the classical one of exogeneity. For a discussion of this topic with generalizations concerned with estimation problems, see Engle et al. (1983). A particular case is when a variable is thought to be completely controlled, such as tax rates or possibly money supply, so that controlled money could cause price changes but not vice versa. In all these cases, the outside information may be useful, if it is correct.

Although many important economic questions can be phrased in the cross-sectional causal situation, they have received little causal testing in that context, except under the 'outside information' assumption. However, many tests have been conducted for economic questions that can be stated as temporal causation. These tests have been conducted using the concepts known in the literature as 'Granger-causation'. This approach is based on two axioms – that the cause will occur before the effect (strict temporal priority) and that the cause contains unique information about the effect. The second can be stated more formally as follows. Let A_t represent all the observable information available at time t and $A_t - Y_t$ represent all this information except that contained in the series $Y_{t-j}, j \geq 0$. Then Y_t will be said to cause X_{t+1} if

$$\Pr \text{ob}(X_{t+1} \text{in} C | A_t) \neq \Pr \text{ ob}(X_{t+1} \text{in} C | A_t - Y_t)$$

for any region C. The two axioms have the simple consequence that any well-behaved function $f(X_{t+1})$ will be generally better forecast using any cost function as a criterion. Thus, tests of this type of causation potentially can be based on forecastability but to be operational some simplifications are required. If one has a belief about a temporal causation then it could be called a prima facie causality. If a test is based on the above definition, but with the unuseful universal information-set replaced by a restricted but practical information set I_t, and if the test finds evidence

for causation, then the relationship remains a prima facie cause. The set I_t will consist of a group of time series and the larger and more relevant it is, the more stringent will be the test; it is then more likely that degrees of belief will change. The choice of the causation to investigate and the choice of I_t will probably depend on some theory, but this could be a low-level theory and, if the tests so suggest, may be worth further development. In practice, tests are rarely based on distributions but on parameters of the distributions such as means. This could be stated as 'Y_t is a prima facie cause in mean of X_{t+1} with respect to I_t' if

$$E[X_{t+1}|I_t] \neq E[X_{t+1}|I_t - Y_t].$$

It will follow that X_{t+1} is better forecast, using a least squares criterion, if Y_t is used than if it is not used. Standard time-series modelling techniques will provide models of X_{t+1} based on I_t and on $I_t - Y_t$ and the post-sample forecasting ability of the two models can then be used to test this particular form of causation. Some of these tests are described in Pierce and Haugh (1977) and evaluated in Nelson and Schwert (1982). They are generally linear in data, although do not have to be, and, if misapplied, can of course lead to incorrect results. To correspond strictly to the definition, tests should be based on the post-sample forecasting abilities of the alternative models.

The definition has both some advantages and some problems, and these are discussed in Granger (1980). In theory, the tests are not altered if backward filters are applied to the data, but some kinds of seasonal adjustments or measurement errors can give problems. If Y_t causes X_{t+1} the X_t may, but need not cause Y_{t+1}, so that feedback can occur but need not. Similarly, if Y_t causes X_{t+1} and X_t causes Z_{t+1} then Y_t may, but need not cause, Z_{t+2}. It has to be remembered when interpreting results based on tests that missing common causal variables can always alter the interpretation, that causation may be lost if one variable is controlled so as to reduce the strength of the causal link, and that temporal aggregation or using data measured over intervals much wider than actual causal lags can also destroy causal interpretation.

Causality in Economic Nodels

Herbert A. Simon

Causal notions arise when we seek to understand the workings of a complex system by analysing it into component subsystems and mechanisms. Thus, if we wish to understand the quantities of strawberries that are produced and consumed and

the prices at which they are exchanged, we may consider a number of mechanisms that affect quantity and price. What mechanisms we will include depends on how widely we draw the boundaries of the system to be examined.

For example, we may include (1) a weather mechanism that determines the amount of rainfall; (2) a productivity mechanism that determines the yield of strawberries per acre; (3) a supply mechanism that determines the acreage sowed in strawberries; and (4) a demand mechanism that determines the quantity of strawberries purchased. In this formulation, each mechanism, which might be represented by an equation, determines the value of a particular variable as a function of some other variables (not specified in the account above). The variable whose value is so determined (dependent variable) may be called the *effect* of the working of that particular mechanism, while the values of other variables entering into the mechanism (independent variables) are the *causes* of that effect.

In the example before us, we might write:

$$R = r \tag{1}$$

$$Y = f_1(R,\ F, T) \tag{2}$$

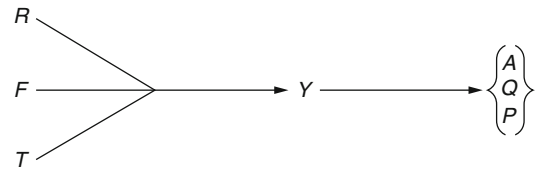
$$A = f_2(p) \tag{3}$$

$$Q = YA \tag{D}$$

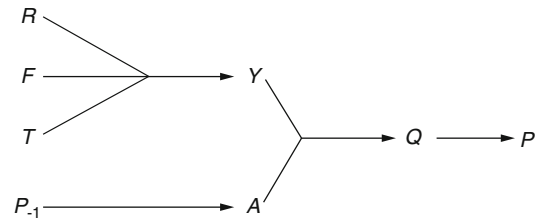
$$p = f_3(Q) \tag{4}$$

Here R is rainfall, and r a positive constant; Y is the yield per acre, F the amount of fertilization, and T the amount of tillage; A is the acreage sowed, and p the market price; and Q is the total yield. Equation D represents a definition, not a separate mechanism. In Eq. 4, p is taken as the dependent variable, since Q is assumed already to be determined by Eqs. 2 and 3 (cobweb assumption) (Fig. 1).

The system of equations defines a *causal ordering* among the variables. The value of R is determined exogenously, as are the values of F and T. That is to say, they are determined in some larger system of which the mechanisms described in the equations are only a subset. The value of Y follows from those of R, F, and T. The values of A, Q, and p are determined simultaneously. Thus, the equations determine a partial ordering:



Causality in Economic Nodels, Fig. 1



Causality in Economic Nodels, Fig. 2

Notice that the asymmetry that underlies this ordering cannot be interpreted as the asymmetry of logical implication, for from 'A implies B' we can infer that 'not-B implies not-A', while from, 'Heavy rainfall causes the yield to be large' we cannot conclude that 'A small yield causes a scanty rainfall.' The most accurate mode of expression is: 'The amount of rainfall determines (causes) the amount of yield' – large or small in both cases. The asymmetry reflects a distinction between exogeneity and endogeneity of variables, based, in turn, upon controllability (in the case of variables that can be manipulated directly), or time precedence. Thus R is exogenous to mechanism Eq. 2 on the assumption that the weather is unaffected by changes in the yield of strawberries. (That this is an empirical assumption is clear from the fact that widespread cultivation *can* cause changes in climate) (Fig. 2).

If we wish to remove the ambiguity from the causal relations among A, Q, and p, we may

assume (as in the classical cobweb theory) a time lag, replacing p in Eq. 3 by the exogenous and predetermined variable, p_{-1}. Then the causal ordering becomes:

Now it is clear why we took p as the dependent variable in Eq. 4. Introducing the time lag requires making an empirical assumption – specifically an assumption about how farmers form expectations about future prices. In a rational expectations model, for example, this lag would not be admissible.

Formalization

To formalize these ideas, consider a system of n simultaneous linear equations in n variables (*linear structure*). We assume that each equation represents a mechanism. In some linear structures, certain subsets of equations can be solved independently of the remaining equations (*self-contained subsets*). Consider the *minimal self-contained subsets* of a system (those that do not themselves contain smaller self-contained subsets). With each such subset, associate the variables that can be evaluated from the subset alone (endogenous variables), and call them *variables of order zero*. Next, substitute the values of these variables in the remaining equations of the system, and repeat the whole process, obtaining the variables of order one, two, and so on, and the corresponding minimal self-contained subsets of equations. If a variable of some order occurs with non-zero coefficient in an equation belonging to a subsystem of higher order, then that variable is one of the causes of the values of the endogenous variables of the latter set.

Thus, in our original example, Eq. 1 is the minimal self-contained subset of zero order, and R is its variable; Eq. 2 is the minimal subset of first order, and Y its variable; while Eqs. 3, D, and 4 constitute the minimal self-contained subset of second order, and A, Q, and p are their variables. The exogenous variables, F and T, can be regarded as parameters of the system, or equations parallel to Eq. 1 can be added for them, so that each belongs to a separate minimal self-contained subset of order zero.

Identifiability of Causal Ordering

The causal ordering among variables in a linear self-contained structure depends on which variables appear with non-zero coefficients in which equations. Consider a set of observations of the variables satisfying the equations of such a structure. Clearly these observations will also satisfy a new structure made up of equations that are arbitrary linear combinations of equations drawn from the original set. But different combinations of variables will generally appear in the equations of the new structure than appeared in the equations of the original structure. Taking these linear combinations 'blends' the separate mechanisms represented by the original equations. Hence, the causal ordering is not preserved under such a transformation, although the same empirical observations are compatible with both sets of equations.

From this consideration it follows that causal ordering cannot be inferred from simultaneous observations, no matter how numerous, of the variables of a structure. Additional assumptions must be made to identify a unique structure from the observations. The *identification problem* of econometrics is the problem of finding a sufficient number of prior assumptions to determine a unique set of equations, each corresponding to a mechanism, that fits the observations. The equations thus determined are usually called *structural equations*, while algebraically equivalent equations derived from them by linear combination are called *reduced form* equations.

The assumptions needed to identify structural equations may be derived from prior knowledge about mechanisms (e.g., our knowledge that the weather affects crops, but crops do not usually affect the weather). Where experimentation is possible, holding particular variables constant while varying others, experimental findings are a powerful source of empirically valid identifying assumptions. Sometimes, there is prior knowledge, also, that particular mechanisms are independent of each other (that farmers make their decisions independently of consumers, and vice versa). Whatever their source, the

identifying assumptions are genuine empirical assertions, and cannot be made arbitrarily or for reasons of statistical convenience if the correct causal inferences are to be drawn. So-called 'spurious' correlation is best interpreted as a relation between variables that does not have causal force because it was estimated from equations that did not correspond to independent mechanisms.

Causality in Economics and Econometrics

Kevin D. Hoover

Abstract

Economics was conceived as early as the classical period as a science of causes. The philosopher–economists David Hume and J. S. Mill developed the conceptions of causality that remain implicit in economics today. This article traces the history of causality in economics and econometrics, showing that different approaches can be classified on two dimensions: process versus structural approaches, and a priori versus inferential approaches. The variety of modern approaches to causal inference is explained and related to this classification. Causality is also examined in relationship to exogeneity and identification.

Philosophers of Economics and Causality

The full title of Adam Smith's great foundational work, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776), illustrates the centrality of causality to economics. The connection between causality and economics predates Smith. Starting with Aristotle, the great economists are frequently also the great philosophers of causality. Aristotle's contributions to economics are found principally in the *Topics*, the *Politics*, and the *Nicomachean Ethics*, while he lays out his famous four causes (material, formal, final and efficient) in the *Physics*. Material and formal causes are among the concerns of economic ontology, a subject addressed by philosophers of economics (see, for example, Mäki 2001) albeit rarely by practicing economists. Sometimes, as for example in Karl Marx's grand theory of capitalist development, economists have appealed to final causes or teleological explanation (for a defence, see Cohen 1978; for a general discussion, see Kincaid 1996). But, for the most part, taking physical sciences as a model, economics deals with efficient causes. What is it that makes things happen? What

explains change? (See Bunge 1963, for a broad account of the history and philosophy of causal analysis.)

The greatest of the philosopher/economists, David Hume, set the tone for much of the later development of causality in economics. On the one hand, economists inherited from Hume the sense that practical economics was essentially a causal science. In 'On Interest', Hume (1742, p. 304) writes:

> it is of consequence to know the principle whence any phenomenon arises, and to distinguish between a cause and a concomitant effect. Besides that the speculation is curious, it may frequently be of use in the conduct of public affairs. At least, it must be owned, that nothing can be of more use than to improve, by practice, the method of reasoning on these subjects, which of all others are the most important; though they are commonly treated in the loosest and most careless manner.

On the other hand, Hume doubted whether we could ever know the essential nature of causation 'in the objects' (Hume 1739, p. 165). Coupled with a formidable critique of inductive inference more generally, Hume's scepticism has contributed to a wariness about causal analysis in many sciences, including economics (1739, 1777). The tension between the epistemological status of causal relations and their role in practical policy runs through the history of economic analysis since Hume.

History

Hume's Foundational Analysis

Although Hume's dominant concerns are moral, historical, political, and social (including economic), physical illustrations serve as his paradigm causal relationships. *A* (say, a billiard ball) strikes *B* (another ball) and causes it to move. Any analysis must address two key features of causality: first, causes are asymmetrical (in general, if *A* causes *B*, *B* does not cause *A*). Hume sees temporal succession (the movement of *A* precedes the movement of *B*) as accounting for asymmetry. Second, causes are effective. A cause must be distinguished from an accidental correlation and must bring about its effect. Hume sees spatial contiguity (the balls touch) and necessary connection (the movement of *B* follows of necessity from the movement of *A*) as distinguishing causes from accidents and establishing their effectiveness.

Hume was famously sceptical of any idea that could not be traced either to logical or mathematical deduction or to direct sense experience. He asks, whence comes the idea of the necessary connection of cause and effect? It cannot be deduced from first principles. So, he argues that our idea of necessary connection, which he concedes is the most characteristic element of causality, can arise only from our experience of the constant conjunction of particular temporal sequences. But this then implies that causality stands on a very weak foundation. For one corollary of Hume's belief that all ideas are based either in logic or sense experience was that we do not have any secure warrant for inductive inference. Neither logic nor experience (unless we beg the question by implicitly assuming the truth of induction) gives us secure grounds from observing instances to inferring a general rule. Therefore, what we regard as necessary connection in causal inference is really more of habit of mind without clear warrant. Causes may be necessarily connected to effects; but, for Hume, we shall never know in what that necessary connection consists.

While later philosophers have differed with Hume on the analysis of causality, his views were instrumental in setting the agenda, not only for philosophical discussions, but for practical causal analysis as well.

The 19th Century: Logic and Statistics

Even more influential than Hume in shaping economics, John Stuart Mill, another philosopher/economist, was less sceptical about causal inference in general, but more sceptical about its application to economics. In his *System of Logic* (1851), Mill advanced his famous canons of induction: the methods of (*a*) agreement, (*b*) difference, (*c*) joint (or double) agreement and difference, (*d*) residues, and (*e*) concomitant variations. For example, according to the method of difference, if we have two sets of

circumstances, one in which a phenomenon occurs and one in which it does not, and the circumstances agree in all but one respect, that respect is the cause of the phenomenon. Mill's canons are essentially abstractions from the manner in which causes are inferred in controlled experiments. As such, Mill doubted that the canons could be easily applied to social or economic situations, in which a wide variety of uncontrolled factors are obviously relevant. Mill argued that economics was what Daniel M. Hausman (1992) has called an 'inexact and separate science', whose general principles were essentially known a priori and which held only subject to *ceteris paribus* clauses. Mill's apriorism proved to be hugely influential in later economics. Lionel Robbins (1935) expressed considerable scepticism about the place of empirical studies within economic science. Some Austrian economists, such as Ludwig von Mises (1966), went so far as to deny that economics could be an empirical discipline at all. Mill's apriorism also influenced those economists who see economic theory as similar to physical theory as a domain of universal laws.

Other 19th-century economists were less sceptical about the application of causal reasoning to economic data. For instance, W. Stanley Jevons (1863) pioneered the construction of index numbers as the core element of an attempt to prove the causal connection between inflation and the increase in worldwide gold stocks after 1849. Jevons's investigation can be interpreted as an application of Mill's method of residues (see Hoover and Dowell 2001). He saw the various idiosyncratic relative price movements, owing to supply and demand for particular commodities, as cancelling out to leave the common factor that could only be the effect of changes in the money stock.

The 19th century witnessed extensive development in the theory and practice of statistics (Stigler 1986). Inference based on statistical distributions and correlation measures was closely connected to causality. Adolphe Quetelet envisaged the inferential problem in statistics as one of distinguishing among constant, variable, and accidental causes (Stigler 1999, p. 52). The economist Francis Ysidro Edgeworth pioneered tests of statistical significance (in fact Edgeworth may have been the first to use this phrase). He glossed the finding of a statistically significant result as one that 'comes by cause' (Edgeworth 1885, pp. 187–8).

The 20th Century: Causality and Identification

Further developments of statistical techniques, such as multiple correlation and regression, in the 20th century were frequently associated with causal inference. It was fairly quickly understood that, unlike correlation, regression has a natural direction: the regression of Y on X does not produce coefficient estimates that are the algebraic inverse of those from the regression of X on Y. The direction of regression should respect the direction of causation.

By the early 20th century, however, the dominant vision of economics was one in which prices and quantities are determined simultaneously. This is as much true for Alfred Marshall (1930), who is often described (not perfectly accurately) as an advocate of partial equilibrium analysis, as it is for Léon Walras (1954), the principal font of modern general equilibrium analysis. Simultaneity does not necessarily rule out causal order, though it does complicate causal inference. Although regressions may have a natural causal direction, there is nothing in the data on their own that reveal which direction is the correct one – each is an equally eligible rescaling of a symmetrical and non-causal correlation. This is a problem of observational equivalence. And it is the obverse side of the now familiar problem of econometric identification: in this case, how can we distinguish a supply curve from a demand curve? The problem of identification was pursued throughout most of the first half of the 20th century until the fairly complete treatment by the Cowles Commission at mid-century (Koopmans 1950; Hood and Koopmans 1953; see Morgan 1990, for a thorough treatment of the history of the identification problem).

The standard solution to the identification problem is to look for additional causal determinants that discriminate between otherwise simultaneous relationships. Both the supply of milk and

demand for milk depend on the price of milk. If, however, the supply also depends on the price of alfalfa used to feed the cows and the demand also on the daily high temperature (which affects the demand for milk to make ice cream), then supply and demand curves can be identified separately. Identification can be viewed through the glasses of simultaneous equations, pushing causality into the background, or it can be viewed as a problem in causal articulation. In the first case, economists frequently use the language of exogenous variables (the price of alfalfa, the temperature) and endogenous variables (the price and quantity of milk). Exogenous variables can also be regarded as the causes of the endogenous variables. From the 1920s to the 1950s, different economists placed different emphasis on the causal aspects of identification (Morgan 1990) and the various papers reprinted in Hendry and Morgan (1995).

Modern econometrics can be dated from the development of structural econometric models following the pioneering work in the 1930s of Jan Tinbergen, the conceptual foundations of probabilistic econometrics in Trgyve Haavelmo's (1944) 'Probability approach to econometrics', and the technical elaboration of the identification problem in the two Cowles Commission volumes. Structural models did not in themselves necessarily favor the language of identification over the language of causality. Indeed, in Tinbergen's (1951) textbook, dynamic, structural models are explicated with a diagram that uses arrows to indicate causal connections among time-dated variables. Nevertheless, after the econometric work of the Cowles Commission, two approaches can be clearly distinguished.

One approach, associated with Hermann Wold and known as *process analysis,* emphasized the asymmetry of causality, typically grounded it in Hume's criterion of temporal precedence (Morgan 1991). Wold's process analysis belongs to the time-series tradition that ultimately produced Granger causality and the vector autoregression (see section "Alternative Approaches to Causality in Economics").

The other approach, associated with the Cowles Commission, related causality to the invariance properties of the structural econometric model. This approach emphasized the distinction between endogenous and exogenous variables and the identification and estimation of structural parameters. Implicitly, structural modellers accepted Mill's a priori approach to economics. While they differed from Mill in their willingness to conduct empirical investigations, the selection of exogenous (or *instrumental*) variables was seen to be the province of a priori economic theory – a maintained assumption rather than something to be learned from data itself.

In his contribution to one of the Cowles Commission volumes, Herbert Simon (1953) showed that causality could be defined in a structural econometric model, not only between exogenous and endogenous variables, but also among the endogenous variables themselves. And he showed that the conditions for a well-defined causal order are equivalent to the well-known conditions for identification. Despite the equivalence, with the demise of process analysis and the ascendancy of structural econometrics – aided indirectly perhaps by a revival of Humean causal scepticism among the logical-positivist philosophers of science – causal language in economics virtually collapsed between 1950 and about 1990 (Hoover 2004).

Alternative Approaches to Causality in Economics

Different approaches to causality can be classified along two lines as shown in Fig. 1. One the one hand, approaches may emphasize structure or process. On the other hand, approaches may rely on a priori identifying assumptions or they may seek to infer causes from data. The upper left cell, the a priori structural approach, represented by the Cowles Commission, dominated economics for most of the postwar period. But since we already discussed it at some length in section "History", and since it was largely responsible for turning the economics profession away from *explicit* causal analysis, we add nothing more about it here and instead turn to the other cells in Fig. 1.

Causality in Economics and Econometrics, Fig. 1 Classification of approaches to causality in economics

	Structural	*Process*
A Priori	Cowles Commission: Koopmans (1953); Hood and Koopmans (1953)	Zellner (1979)
Inferential	Simon (1953) Hoover (1990; 2001) Favero and Hendry (1992) Natural experiments: Angrist and Krueger (1999; 2001)	Granger (1969) Vector autoregressions: Sims (1980)

The Inferential Structural Approach

The most important of the inferential structural approaches is due to Simon (1953). Simon eschews temporal order as a basis for causal asymmetry and, instead, looks to recursive structure. As we observed in section "History", Simon's account is closely related to the Cowles Commission's structural approach. Consider the bivariate system:

$$Y_t = \theta X_t + \varepsilon_{1t}, \tag{1}$$

$$X_t = \varepsilon_{2t}, \tag{2}$$

where the random error terms ε_{it} are independent, identically distributed and θ is a parameter. Simon says that X_t causes Y_t, because X_t is recursively ordered ahead of Y_t. One knows all about X_t without knowing about Y_t, but one must know the value of X_t to determine the value of Y_t. Equations (1) and (2) also appear to show that any intervention in (2), say a change in the variance of ε_{2t}, would transmit to (1); while any intervention in (1), say a change in θ or the variance of ε_{1t}, would not transmit to (2). Apparently, X_t could then be used to control Y_t.

Unfortunately, merely being able to write an accurate description of the two variables in the form of (1) and (2) does not guarantee either the apparent asymmetry of information or control. The same data can be repackaged into a statistically identical form with an apparently different causal order. For example, consider the following related system:

$$Y_t = \omega_{1t}, \tag{3}$$

$$X_t = \delta Y_t + \omega_{2t}, \tag{4}$$

where $\delta = \dfrac{\theta \mathrm{var}(\varepsilon_2)}{\theta^2 \mathrm{var}(\varepsilon_2) + \mathrm{var}(\varepsilon_1)}$, $\omega_{1t} = \varepsilon_{1t} + \theta\varepsilon_{2t}$, and $\omega_{2t} = (1 - \delta\theta)\,\varepsilon_{2t} - \delta\varepsilon_{1t}$.

Equations (3) and (4) are derived from Eqs. (1) and (2). The details of the algebra are not important. Essentially, (3) and (4) are linear combinations of (1) and (2) with multiplicative factors carefully chosen, so that the error terms ω_{1t} and ω_{2t} are uncorrelated. Such linear combinations preserve the values of X_t and Y_t and their statistical likelihood (that is, the two systems of equations have the same reduced form) and, so, describe the data equally well. Equations (3) and (4) have a form analogous to (1) and (2); but, on Simon's criterion, it appears that Y_t causes X_t on Simon's criterion. While it looks like the key parameters for (3) and (4) are derived from those of (1) and (2), we could have taken (3) and (4) as the starting point and derived (1) and (2) symmetrically. What we would like to do is to replace the equal signs with arrows that show that the causal direction runs from the right-hand to the left-hand sides in the regression equations in one of the systems, but not in the other. Unfortunately, there is no way to do this, no choosing between the systems, on the basis of a single set of data by itself. This is the problem of observational equivalence again.

The a priori approach of the Cowles Commission relies on economic theory to provide appropriate identifying assumptions to resolve the observational equivalence. Christopher Sims

(1980) attacked the typical application of the Cowles Commission's approach to structural macroeconometric models as relying on 'incredible' identifying assumptions: economic theory was simply not informative enough to do the job. But Simon, who was otherwise supportive of the conception of causality in the Cowles Commission, took a different tack.

Simon sees the problem as choosing between two alternative sets of parameters: which set contains the structural parameters, $\{\theta$ and the variances of the $\varepsilon_{it}\}$ or $\{\delta$ and the variances of the $\omega_{it}\}$? Simon suggested that experiments – either controlled or natural – could help to decide. If, for example, an experiment could alter the conditional distribution of X_t without altering the marginal distribution of Y_t, then it must be that Y_t causes X_t, because this would be possible only if a structure like (3) and (4) characterized the data. If it did, a change in the conditional distribution would involve either δ or the variance of ω_{2t}, neither of which would affect the variance of ω_{1t}. In contrast, if (1) and (2) truly characterized the causal structure of the data, a change to the conditional distribution of X_t would, in fact, involve a change to the variance of ε_{2t}, which, according to the equivalences above, would alter either δ or the variance of ω_{2t}. Similar relationships of stability and instability in the face of changes to the marginal distribution can also be demonstrated (Hoover 2001, ch. 7). The appeal to experimental evidence is what marks Simon's approach out as inferential rather than a priori.

Hoover (1990, 2001) generalizes Simon's approach to the type of nonlinear systems of equations found in modern rational-expectations models. He shows that Simon's idea of natural experiments can be operationalized by coordinating historical, institutional, or other non-statistical information with information from structural break tests on what, in effect, amounts to the four regressions corresponding to (1), (2), (3), and (4) above generalized to include lagged dynamics. With allowances for complications introduced by rational expectations, the key idea is that, in the true causal order, interventions that alter the parameters governing the true marginal distribution do not transmit forward to the conditional distribution (characterized by (1) or (4)) nor do interventions in the true conditional distribution transmit backward to the marginal distribution (characterized by (2) or (3)). Since the true structural parameters are not known a priori, non-statistical information is important in identifying an intervention as belonging to the process governing one variable or another.

Although avoiding the term 'causality', Favero and Hendry's (1992) analysis of the Lucas critique in terms of 'super-exogeneity' is also a variant on Simon's causal analysis (Ericsson and Irons 1995; Hoover 2001, ch. 7). Super-exogeneity is essentially an invariance concept (Engle et al. 1983). Favero and Hendry find evidence against the Lucas critique (non-invariance in the face of changes in policy regime) in the super-exogeneity of conditional probability distributions in the face of structural breaks in marginal distributions – the same sort of evidence that Hoover cites as helping to identify causal direction.

The recent revival of causal analysis in microeconomics in the guise of 'natural experiments', although apparently developed independently of Simon, nonetheless proceeds in much the same spirit as Hoover's version of Simon's approach (Angrist and Krueger 1999, 2001). This literature typically employs the language of instrumental variables. A natural experiment is a change in a policy or a relevant environmental factor that can be identified non-statistically. Packaged as an econometric instrument, the experiment can be used – in much the same way that variations in alfalfa prices and temperature were used in the example in section "History" – to identify the underlying relationships and to measure the causally relevant parameters.

While the development of structural approaches in econometrics has largely been independent, there is some cross-fertilization between economists and philosophers (for example, Simon and Rescher 1966); and recently philosophers of causality have looked to economics for inspiration and examples (for example, Cartwright 1989; Woodward 2003).

The Inferential Process Approach

Perhaps the most influential explicit approach to causality in economics is due to Clive

C

W. J. Granger (1969). Granger causality is an inferential approach, in that it is data-based without direct reference to background economic theory; and it is a process approach, in that it was developed to apply to dynamic time-series models (see Granger–Sims causality in this dictionary for technical details). Granger–Sims causality is an example of the modern probabilistic approach to causality, which is a natural successor to Hume (for example, Suppes 1970). Where Hume required constant conjunction of cause and effect, probabilistic approaches are content to identify cause with a factor that raises the probability of the effect: A causes B if $\mathrm{P}(B|A) > \mathrm{P}(B)$, where the vertical '|' indicates 'conditional on'. The asymmetry of causality is secured by requiring the cause (A) to occur before the effect (B) (but the probability criterion is not enough on its own to produce asymmetry since $P(B|A) > P(B)$ implies $\mathrm{P}(A|B) > \mathrm{P}(A)$).

Granger's (1980) definition is more explicit about temporal dynamics than is the generic probabilistic account, and it is cast in terms of the incremental predictability of one variable conditional on another:

X_t Granger-causes Y_{t+1} if $\mathrm{P}(Y_{t+1}|$ all information dated t and earlier$) \neq \mathrm{P}(Y_{t+1}|$ all information dated t and earlier omitting information about X).

This definition is conceptual, as it is impracticable to condition on *all* past information.

In practice, Granger causality tests are typically implemented through bivariate regressions. As an illustration, consider the regression equations:

$$Y_t = \Pi_{11} Y_{t-1} + \Pi_{12} X_{t-1} + \upsilon_{1t}, \qquad (5)$$

$$X_t = \Pi_{21} Y_{t-1} + \Pi_{22} X_{t-1} + \upsilon_{2t}, \qquad (6)$$

where the Π_{ij} are parameters, and the υ_{it} are random error terms. In practice, lag lengths may be larger than one, but far less than the infinity implicit in the general definition. X_t Granger-causes Y_{t+1} if $\Pi_{12} \neq 0$, and Y_t Granger-causes X_{t+1} if $\Pi_{21} \neq 0$.

Sims (1972) famously used Granger causality to demonstrate the causal priority of money over nominal income. Later, as part of a generalized critique of structural econometric models, Sims (1980) advocated vector autoregressions (VARs) – atheoretical time-series regressions analogous to Eqs. (1) and (2), but generally including more variables with lagged values of each appearing in each equation. In the VAR context, Granger causality generalizes to the multivariate case.

While Granger causality has something useful to say about incremental predictability, there is no close mapping between Granger causality and structural notions of causality on either the Cowles Commission's or Simon's accounts (Jacobs et al. 1979). Consider a structural model:

$$Y_t = \theta X_t + \beta_{11} Y_{t-1} + \beta_{12} X_{t-1} + \varepsilon_{1t}, \qquad (7)$$

$$X_t = \gamma Y_t + \beta_{21} Y_{t-1} + \beta_{22} X_{t-1} + \varepsilon_{2t}, \qquad (8)$$

where ε_{1t} and ε_{2t} are identically distributed, independent random errors and θ, γ, and the β_{ij}s are structural parameters. The independence of the parameters and the error terms implies that causality runs from the right-hand to the left-hand sides of each equation. Equations (5) and (6) can be seen as the reduced forms of (7) and (8).

We focus on X causing Y. X structurally causes Y if either θ or $\beta_{12} \neq 0$. And X Granger causes Y if $\Pi_{12} = \frac{\beta_{12} + \theta\beta_{22}}{1 - \theta\gamma} \neq 0$. Thus, if X Granger causes Y, then X structurally causes Y. Note, however, that this result is particular to the case in which (7) and (8) represents the universe, so that (5) and (6) represent the complete conditioning on past histories of relevant variables. If the universe is more complex and the estimated VAR does not capture the true reduced forms of the structural system, which in practice they may not, then the strong connection suggested here does not follow.

More interestingly, even if (5), (6), (7), and (8) are complete, structural causality does not necessarily imply Granger causality. Suppose that $\beta_{12} = \beta_{22} = 0$, but $\theta \neq 0$, then X structurally causes Y, but since $\Pi_{12} = 0$, X does not Granger cause Y.

Now suppose that X does not Granger cause Y. It does not necessarily follow that X does not structurally cause Y, since if θ, β_{12}, and $\beta_{22} \neq 0$, and $-\beta_{12}/\beta_{22} = \theta$, then it will still be true that

$\Pi_{12} = 0$. This may appear to be an odd special case, but in fact conditions such as $-\beta_{12}/\beta_{22} = \theta$ arise commonly in optimal control problems in economics.

A simple physical example makes it clear what is happening. Suppose that X measures the direction of the rudder on a ship and Y the direction of the ship. The ship is pummeled by heavy seas. If the helmsman is able to steer on a straight course, effectively moving the rudder to exactly cancel the shocks from the waves, the direction of the rudder (in ignorance of the true values of the shocks) will not predict the course of the ship. The rudder would be structurally effective in causing the ship to turn, but it would not Granger-cause the ship's course.

The a Priori Process Approach

The upper right-hand cell of Fig. 1 is represented by Arnold Zellner's (1979) account of causality (cf. Keuzenkamp 2000, ch. 4, s. 4). Zellner's notion of causality is borrowed from the philosopher Herbert Feigl (1953, p. 408), who defines causation '... in terms of predictability according to law (or more adequately, according to a set of laws)'. On the one hand, Zellner opposes Simon and sides with Granger: predictability is a central feature of causal attribution, which is why his is a process account. On the other hand, he opposes Granger and sides with Simon: an underlying structure (a set of laws) is a crucial presupposition of causal analysis, which is why his is an a priori account.

Much obviously depends on what a law is. Zellner's own view is that a law is a (probabilistic) description of a succession of states of the world that holds for many possible boundary conditions and covers many possible circumstances. He couches his position in an explicitly Bayesian theory of inference. Feigl identifies causality with lawlikeness or predictability. It is the fact that formulae fit previously unexamined cases, as well as examined ones, which constitutes their lawlikeness. This is close to Simon's invariance criterion (the true causal order is the one that is invariant under the right sort of intervention).

The central problem, then, is how to distinguish laws from false generalizations or accidental regularities – that is, how to distinguish conditional relations invariant to interventions from regularities that are either not invariant or are altogether adventitious. Zellner believes that a theory serves as the basis for discriminating between laws and casual generalizations. Although Zellner's approach permits us to learn some things from the data, in keeping with the spirit of Bayesian inference, it does so within a narrowly defined framework (cf. Savage's 1954, pp. 82–91, 'small world' assumption). Economic theory in Zellner's account restricts the scope of an investigation a priori.

Zellner objects to Granger causality for two reasons. First, it is not satisfactory to identify cause with temporal ordering, as temporal ordering is not the ordinary, scientific or philosophical foundation of the causal relationship. Second, Granger's approach is atheoretical. In order to implement it practically, an investigator must impose restrictions – limit the information set to a manageable number of variables, consider only a few moments of the probability distribution (in our exposition, just the mean), and so forth. For Zellner, if these restrictions cannot be explained theoretically, Granger's methods will discover only accidental regularities.

Zellner explicitly criticizes Granger for ignoring the need for theoretical basis for empirical investigation – implicitly focusing on only one side of a process in which theory informs empirics and empirics inform theory. He criticizes Simon for defining cause to be a formal property of a model (recursive order) without making essential reference to empirical reality. Zellner's criticism is, however, more aptly directed at the Cowles Commission's approach, since (as we saw in section "The Inferential Structural Approach") Simon distinguishes himself through tying causal order to empirical inference.

Structural Vector Autoregressions

Not all approaches to causality fall quite neatly into the cells of Fig. 1; or, more to the point, an approach that falls into one cell may morph into one that falls into another cell. The history of Sims's VAR program is an important case.

Sims (1980) advocated VARs as a reaction to the manner in which the Cowles Commission

programme, which identified structural models through a priori theory, had been implemented (see section "The Inferential Process Approach"). From a causal perspective, it was closely related to Granger's analysis. Starting with VAR such as Eqs (5) and (6), Sims wished to work out how various 'shocks' would affect the variables of the system. This is complicated by the fact that the error terms in (5) and (6), which might be taken to represent the shocks, are not in general independent, so that a shock to one is a shock to both, depending on how correlated they are. Sims's initial solution was to impose an arbitrary orthogonalization of the shocks (a Choleski decomposition). In effect, this meant transforming (5) and (6) into a system like (6) and (7) and setting either θ or γ to zero. This amounts to imposing a recursive order on X_t and Y_t, such that the covariance matrix of the error terms is diagonal (that is, ε_{1t} and ε_{2t} are uncorrelated). A shock to X can then be represented by a realization of ε_{1t} and a shock to Y by a realization of ε_{2t}.

Initially, Sims treated the choice of recursive order as a matter of indifference. Criticizing the VAR program from the point of view of structural models, Leamer (1985) and Cooley and LeRoy (1985) pointed out that the substantive results (for instance, impulse-response functions and innovation accounts) depend on which recursive order is chosen. Sims (1982, 1986) accepted the point and henceforth advocated Structural vector autoregressions (SVARs). SVARs can be identified through the contemporaneous causal order only. So, for example, to identify (5) and (6), it is enough to assume that either θ or γ in (7) or (8) is zero; one need not make any assumptions about the β_{ij}s. Ironically, since the initial impulse behind the VAR programme was to avoid theoretically tenuous identifying assumptions, the choice of restrictions on contemporaneous variables used to transform the VAR into the SVAR are typically only weakly supported by economic theory.

Nevertheless, the move from the VAR to the SVAR is a move from an inferential to an a priori approach. It is also a move from a fully non-structural, process approach to a partially structural approach, since the structure of the contemporaneous variables, though not of the lagged variables, is fully specified. The SVAR approach can, therefore, be seen as straddling the cells on the first line of Fig. 1.

The Graph-Theoretic Approach to Causal Inference

A final approach to causality in economics sometimes provides another example of an inferential structural approach, and sometimes straddles the cells on the second line of Table 1. Graph-theoretic approaches to causality were first developed outside of economics by computer scientists (for example, Pearl 2000) and philosophers (for example, Spirtes et al. 2000), but have recently been applied within economics (Swanson and Granger 1997; Akleman et al. 1999; Bessler and Lee 2002; Demiralp and Hoover 2003).

The key ideas of the graph-theoretic approach are simple (see Demiralp and Hoover 2003 or Hoover 2005 for a detailed discussion). Any structural model can be represented by a graph in which arrows indicate the causal order. Equations (1) and (2) are represented by $X \rightarrow Y$ and Eqs. (3) and (4) by $Y \rightarrow X$. More complicated structures can be represented by more complicated graphs. Simultaneity, for instance, can be represented by double-headed arrows. The graphs allow us easily to see the dependence or independence among variables. Pearl (2000) and Sprites et al. (2000) demonstrate the isomorphism between causal graphs and the independence relationships encoded in probability distributions. This isomorphism allows conclusions about probability distributions to be derived from theorems proven using the mathematical techniques of graph theory.

Many of the results of graph-theoretic analysis are straightforward. Suppose that $A \rightarrow B \rightarrow C$ (that is, A causes B causes C). A and C would be probabilistically dependent; but, conditional on B, they would be independent. Similarly for $A \leftarrow B \leftarrow C$. In each case, B is said to *screen* A from C. Suppose that $A \leftarrow B \leftarrow C$. Then, once again A and C would be dependent, but conditional on B, they would be independent. B is said to be the *common cause* of A and C. Now suppose that A and B are independent conditional on sets of variables that exclude C or its descendants, and

$A \rightarrow C \leftarrow B$, and none of the variables that cause A or B directly causes C. Then, conditional on C, A and B are dependent. C is called an *unshielded collider* on the path ACB. (A *shielded* collider would have a direct link between A and B.) These are the simplest relationships of probabilistic dependence and independence. More complex ones may also obtain in which A is independent of B only conditional on more than one other variable (say, C and D).

A number of causal search algorithms have been developed (Sprites et al. 2000). These start with information about correlations (or other tests of unconditional and conditional statistical independence) among variables. The most common of these, the PC algorithm, assumes that graphs are strictly recursive (known in the literature as *acyclical*) and starts with a graph in which all variables are causally connected with an unknown causal direction (represented by the headless arrow, '—'). It then tests for independence among pairs of variables, conditioning on sets of zero variables, then one, then two, and so forth until the set of variables is exhausted. Whenever it finds independence, it removes the causal connection between the variables in the graph. Once the graph is pared down as far as it can be, it considers triples of variables in which two are conditionally independent but are connected through a third. If conditioning on that third variable renders the variables conditionally dependent, then that variable is an unshielded collider and it is connected to the other two variables with causal arrows running toward it. After all the unshielded colliders have been identified, further logical analysis can be used to orient additional causal arrows. For example, we might reason as follows: suppose we have a triple $A \rightarrow C \rightarrow B$; unless the causal arrow runs away from C toward B, C would be identified as an unshielded collider; but C was not identified as an unshielded collider earlier in the search; therefore, the causal arrow must run away from C towards B, so that the graph becomes $A \rightarrow C \rightarrow B$.

Sometimes the data allow the complete orientation of a causal graph, but sometimes some causal connections are left undirected. In this case, the graph marks out an equivalence class, and the algorithm has identified 2! causal graphs consistent with the empirical probability distribution, where $n =$ the number of undirected causal connections.

While most applications of graph-theoretic methods assume that the true causal structures are recursive (that is, strictly acylical), economics frequently treats variables that are cyclical or simultaneously determined. Although the recursiveness assumption is restrictive, it is an assumption that is also frequently made in the SVAR literature. Some progress has been made in developing graph-theoretic search algorithms for cyclical or simultaneous causal systems (Pearl 2000, pp. 95–6, 142–3; Richardson 1996; Richardson and Spirtes 1999).

Swanson and Granger (1997) showed that estimates of the error terms of the VAR (the υ_{it} in Eqs (5) and (6)) can be treated as the original time-series variables purged of their dynamics. A causal order identified on such variables corresponds to the causal order necessary to convert a VAR into an SVAR. Demiralp and Hoover (2003) present Monte Carlo evidence that the PC algorithm is effective at selecting the true causal connections among variables and, when signal strengths are high enough, moderately effective at directing them correctly. Search algorithms can, therefore, reduce or even eliminate the need to appeal to a priori theory when identifying the causal order of an SVAR.

Where Simon's approach looked for relatively important interventions as a basis for causal inference to a structure, the graph-theoretic approach uses relatively routine random variations to identify patterns of conditional independence that map out causal structures. The two approaches are complementary: Simon's approach may be used to resolve the observational equivalence reflected in causal connections that remain undirected after the application of a causal search algorithm.

From Metaphysics to Econometric Practice

The analysis of causation was originally a branch of metaphysics. In moving from the scholastic to the practical, two deep divisions appeared among economists.

The first is the divide between those who believed that causality in economics could be characterized by relatively simple uniformities (the process approaches) and those who believed that it must be characterized by a rich understanding of the underlying mechanisms (the structural approaches). Economists debate the appropriate level at which to characterize either the uniformities or the mechanisms – individual or aggregate. But this debate over the microfoundations of macroeconomics is another story. The second divide is between those who believe that economic logic itself gives privileged insight into economic behaviour (a priori approaches) and those who believe that we must learn about economic behaviour principally through observation and induction (the inferential approaches).

These are old debates – unlikely to be resolved decisively to the satisfaction of all economists in the near future. How one aligns oneself in them largely determines which particular approaches to causality appear to be compelling in practical economic research.

Cazenove, John (1788–1879)

J. M. Pullen

Cazenove wrote nine books and pamphlets on political economy, dealing with a wide variety of theoretical concepts and practical issues. In addition, he made a valuable contribution to political economy as an editor of Richard Jones's *Literary Remains* (1859, p. xl), and T.R. Malthus's *Definitions in Political Economy* (1853). There is also strong evidence to suggest that he was the anonymous editor of the second edition of Malthus's *Principles of Political Economy* (Pullen 1978). He contributed a review to the *British Critic* ('Chalmers – On Political Economy', October 1832, a vigorous criticism of James Mill and Ricardo), and could possibly have contributed others (Gordon 1985, pp. 17–19).

Malthus had a high regard for Cazenove. He recommended to his publisher that the first edition of his *Principles* should be reviewed by Cazenove in the *Quarterly Review* (letter of 26 January 1821, in the archives of John Murray), and he nominated Cazenove for membership of the Political Economy Club, at its second meeting in 1821. J.L. Mallet recorded in his diary that, in the Club debates, 'on most occasions Ricardo and Mill led on one side, and Malthus and Cazenove on the other'. In a letter to Thomas Chalmers of 6 February 1833, Malthus described Cazenove as 'a particular friend' and as 'a very clever man, and good political economist'. When Malthus died in 1834, Cazenove applied (unsuccessfully) for his position as professor of history and political economy at the East India College (James 1969, pp. 355–6). But Cazenove's friendship with Malthus, and his agreement with some of Malthus's main doctrines, did not prevent him from criticizing Malthus on occasions and adopting an independent line (Pullen 1978, pp. 293–4).

Cazenove's omission from the first two editions of *Palgrave's Dictionary* and the absence of any entry under 'Cazenove' in the *Index of Economic Articles* up to 1979, indicate that his writings have so far attracted very little attention. But Gordon (1985) has shown that Cazenove does not deserve this neglect. His writings are a worthwhile contribution to political economy in their own right, and an important part of the anti-Ricardian tradition. In particular, Cazenove opposed Say's Law and recognized the possibility of a general glut. Like Malthus he emphasized the role played by effective demand, and denied that continued economic growth can be achieved merely through saving and capital accumulation. He stressed the idea – also put forward by Malthus, under the name of 'the doctrine of proportions' – that economic progress requires a balance between saving and consumption.

Cazenove's grandfather, David de Cazenove, and his father, James de Cazenove, were merchants of French Huguenot origin who migrated to London from Geneva in 1777 (*Burke's Landed Gentry*). Cazenove was born and died in London. He appears to have worked in his father's firm, Jas. Cazenove & Co., which he described (1861, pp. 42–3) as 'a large commercial firm' with 'some sixty or seventy foreign correspondents'. He retired from the business early – in 1832, at the age of 44, he described himself as 'late a continental merchant' – but his literary output continued until 1861. His father's brother, Phillip Cazenove, founded the present London firm of stockbrokers, Cazenove & Co. His brother, Philip Cazenove, was for many years the senior partner of Cazenove & Co., but there is no evidence that John Cazenove ever worked in that firm (information from Mr H. de L. Cazenove, of Cazenove & Co.) John Cazenove's son, John Gibson Cazenove, MA, DD (1822–96) of Brasenose College, Oxford, was Chancellor of Edinburgh Cathedral and author of theological works.

Censored Data Models

G. S. Maddala

The *censored* normal regression model considered by Tobin (1958), also commonly known as the 'tobit' model, is the following:

$$y_i^* = \beta x_i + u_i \quad u_i \sim \mathrm{IN}(0, \sigma^2)$$

The observed y_i are related to y_i^* according to the relationship

$$\begin{aligned} y_i &= y_i^* \quad \text{if } y_i^* > y_0 \\ &= y_0 \quad \text{otherwise} \end{aligned} \tag{1}$$

where y_0 is a prespecified constant (usually zero). They y_i^* could take values $<y_0$. The only thing is that they are not observed. Thus, y_i is set equal to y_0 because of *non-observability*. The values x_i are observed for all the observations. If *both* y_i and x_i are unobserved for $y_i \leq y_0$ then we have what is known as a *truncated* regression model.

The problem is essentially one of missing data. Data on y are missing for some observations. Hence, we have to ask why data are missing. In some cases this is owing to the design of the experiment, as in the case of the data from the negative income tax experiment. These data have been analysed by Hausman and Wise (1977), who consider a truncated regression model. In almost all other cases y_0 is the outcome of choices of individuals. In this case the model is incomplete unless the determinants of y_0 are studied.

Some Early Developments

The first application of the censored regression model (1) is that of Tobin (1958) who studied the expenditures on durable goods by 735 non-farm households. y_i^* is the ratio of total durable expenditures to disposable income and

$y_0 = 0$. However, y_i is not equal to zero here because of non-observability, but because of individuals' choices. Thus, the censored regression model (1) is inappropriate for this problem. In fact, the tobit model is inappropriate for almost all the applications in which it has been used (including that by Tobin).

The model by Cragg (1971) considers this as a sequential decision problem. For the case of demand for automobiles, the decisions are whether or not to buy a car and how much to spend if the decision to buy a car is made. In this model we have the latent variable:

$$I_i = x_i\delta_1 + \eta_{1i} \quad \eta_{1i} \sim \text{IN}(0,1) \tag{2}$$

The subscript i denotes the ith individual. We observe the dummy variable D_i which is defined as

$$\begin{aligned} D_i &= 1 \, if \, I_1 > 0 \qquad (\text{buyers}) \\ &= 0 \text{ otherwise} \quad (\text{non} - \text{buyers}) \end{aligned} \tag{3}$$

For those who purchased a car, Cragg specifies a log normal model. Thus, denoting expenditures by y_i, we have

$$\log y_i = x_i\delta_2 + \eta_{2i} \quad \eta_{2i} \sim \text{IN}\left(0, \sigma^2\right) \tag{4}$$

The equation is defined only for the individuals for which $D_i = 1$.

In practice, however, it is questionable whether individuals make their decisions this way. The decision of whether or not to buy a car and how much to spend if a car is bought are often joint decisions. One can formulate this model in terms of two latent variables. Though there are several variants of this that one can think of, one formulation is the following.

$y_1 =$ the cost of the car the individual wants to buy.

$y_2 =$ the maximum expenditure the individual can afford.

The actual expenditure y is given by

$$\begin{aligned} y &= y_i \quad \text{if} \quad y_1 \le y_2 \\ &= 0 \quad \text{if} \quad y_1 > y_2 \end{aligned} \tag{5}$$

We can, in fact, consider y_1 and y_2 both to be log normal. This model is discussed in Nelson (1977), though not with reference to the example of automobile expenditures.

It is tempting to use the simple tobit model (1) every time that one has a bunch of zero (or other limit) observations on y. However, this is inappropriate. For instance, if hours worked for a number of individuals in a sample are zero, it does not mean that one can apply the tobit model to explain hours worked. One has to construct a model where hours worked are zero because of some decisions about labour force participation, in terms of reservation and market wages, as done by Heckman (1974). Estimation of this model from censored as well as truncated samples is discussed in Wales and Woodland (1980).

Selection Models

In the estimation of censored regression models we often have to formulate the censoring function that incorporates individual decisions. This function is also called a *selection criterion*. Usually the selection criterion involves the choice variables and other explanatory variables. Thus, the model is formulated as:

$$y_1 = \beta_1 x_1 + u_1 \quad \text{Choice 1} \tag{6}$$

$$y_2 = \beta_2 x_2 + u_2 \quad \text{Choice 2} \tag{7}$$

and

$$I^* = \gamma_1 y_1 + \gamma_2 y_2 + \beta_3 x_3 + u \quad \text{Selection criterion} \tag{8}$$

The observed y is defined as

$$\begin{aligned} y &= y_1 \quad \text{if} \quad \text{I}^* > 0 \\ &= y_2 \quad \text{if} \quad I^* \le 0. \end{aligned}$$

Interest centres on the determinants of γ_1 and γ_2 (see Lee 1978; Willis and Rosen 1979). One can substitute y_1 and y_2 in (8) and get a reduced form for the selection criterion. In this approach interest mainly centres on the so-called 'selectivity bias' in the estimation of (6) and (7) by OLS.

Since both y_1 and y_2 are censored, we have to estimate the parameters in (6) and (7) by the use of ML methods. Heckman (1979) suggests a simple correction to the OLS, which involves the addition of an extra explanatory variable to each of (6) and (7) obtained from the estimation of the criterion function (8) in its reduced form. This criterion is based on the assumption of normality. Goldberger (1983) made some calculations with alternative error distributions and showed that this adjustment for selection bias is quite sensitive to departures from normality.

There have been two solutions to this problem. One is the extension of the analysis of selectivity to general error distributions. This is the approach considered in Lee (1982, 1983), a summary of which is also given in Maddala (1983, pp. 272–275) along with earlier suggestions by Olsen. The other alternative approach is to consider distribution-free estimates (see Cosslett 1984), though this methodology is in early stages of development. Thus, there are computationally feasible alternatives available to explore the selectivity problem without assuming normality and there are procedures available to test the assumption of normality as well (see Lee and Maddala 1985).

The 'Heckman correction' for selectivity bias is very popular, mainly because it is easy to apply. But for this same reason it has also been applied in cases where it is not applicable; such cases are cited in Maddala (1985).

Some Other Problems

Many of the problems connected with the estimation of the censored regression model, assuming parametric distributions, are discussed in Maddala (1983, Chaps. 6 and 9) and Amemiya (1984). For distribution-free methods one can refer to Miller and Halpern (1982), Cosslett (1984) and Powell (1984). It is now well known that the properties of the estimators change with the violation of some basic assumptions. For instance, heteroskedasticity and errors in the dependent variable do not affect the consistency property of OLS estimators in the normal regression model. With the censored regression model, the ML estimators are no longer consistent under these assumptions. Stapleton and Young (1984) suggest that with errors in the dependent variable, the 'correct' ML estimation appears computationally difficult but find some alternative estimators promising.

There has been some progress made in the development of distribution free estimation and estimation when the standard assumptions are violated. For tests of some of the standard assumptions, see Lee and Maddala (1985).

Central Bank Communication

Michael Ehrmann and Marcel Fratzscher

Abstract

Since the early 1990s, communication has become a primary tool for monetary authorities in managing expectations, both of financial markets and of the wider public, and an important ingredient in making the central bank accountable. The rapidly growing literature on central bank communication clearly confirms the importance of communication in managing expectations, thereby enhancing the effectiveness of monetary policy. Yet there is a large degree of heterogeneity in communication practices across monetary authorities in the world, and there continues to be a lively and controversial debate about what constitutes an optimal communication strategy.

Central bank communication refers to the process by which monetary authorities convey information regarding their objectives, strategies and tools, as well as about their current assessment of the economic situation and the monetary stance. Such communication typically serves two purposes: making the central bank accountable, and enhancing the effectiveness of central bank policies.

Whereas only a few decades ago, transparency was usually seen as counterproductive to an effective conduct of monetary policy, it is nowadays considered best practice in central banking. One trigger for this has been the move to grant independence to more and more central banks, which in turn entails an obligation of those central banks to be more accountable.

Central banking laws often specify a number of obligations to ensure a central bank's accountability, which at the same time shape their communication policies. Testimonies to parliament and the requirement to deliver annual reports are examples. In several cases the relevant central banking acts also prescribe the targets for the monetary authority; their communication is therefore automatic, and not at the discretion of the central bank. At the same time, most central banks communicate substantially more often, and in much greater detail, than required by law.

As to the second purpose, it became increasingly clear throughout the 1990s that managing expectations is a central part of monetary policy, and that transparency is vital for that purpose. Given that communication is essential for accountability and transparency, central banks are now putting considerable effort into designing and conducting their communication policies.

Blinder et al. (2008), in their survey of the literature on central bank communication, derive the conditions under which central bank communication may matter for the conduct of monetary policy. A crucial issue in this regard is that a central bank usually has direct control only over a short-term interest rate, yet needs to influence interest rates at all maturities and to affect market expectations not just about current levels but about the future path of interest rates.

If the economic environment were constant, if the central bank was credibly committed to an unchanging policy rule, and if private agents had full information and rational expectations, the path of monetary policy could be inferred correctly from the central bank's observed actions (Woodford 2005). In reality, of course, none of these conditions are likely to hold. In particular, in a changing environment economic agents are subject to a continuous learning process. The central banks' views are also of interest to the public in a world of uncertainty and asymmetric information, especially given the complexity and extent of the information that feeds into monetary policy decisions, which often require judgment and the use of heuristics (Svensson 2003; King 2005).

The revolution in thinking and practice that has taken place over the recent decades can be exemplified with the case of the US Federal Reserve, which over the last 15 years has gone a long way towards greater transparency. For instance, it has started to issue statements instantaneously after each monetary policy decision, where the decision is not only announced, but also briefly explained, and to provide qualitative forward guidance about future monetary policy decisions. It has also expedited the release of the minutes of Federal Open Market Committee (FOMC) meetings, and it has increased the frequency and expanded the content of the publicly released forecasts for several economic variables made by FOMC members.

The Announcement of a Central Bank's Objective

If a central bank is granted independence from its government, it must be given a clearly defined mandate. This is generally done by defining central bank objectives, often in a quantified fashion. But even if a central bank is not given a quantitative objective, it often decides to provide its own quantification, or is required to do so. The potential effects of such a clarification and quantification are substantial. Not only do they make an independent central bank more (easily) accountable, since its actions can be assessed by cross-checking actual economic outcomes with those mandated; furthermore, the announcement of an objective, and in particular its quantification, provides a yardstick for the expectations of economic agents.

The available empirical evidence demonstrates that increased transparency about central banks' strategies, and in particular the announcement of an explicit inflation objective, has fostered central bank credibility as well as the predictability of the path of monetary policy. Moreover, the recent trend towards more transparent central banking practices has certainly played a considerable part in improving the short-term predictability of policy decisions by many central banks over recent decades (BIS 2004, pp. 73–80).

The announcement of central bank objectives may also have a direct bearing on economic outcomes. For instance, Benati (2008) finds that inflation persistence is considerably lower in countries with explicit inflation targets. Levin et al. (2004) furthermore show that in inflation-targeting countries, private sector inflation expectations are not correlated with lagged inflation, indicating that inflation expectations are better anchored. This evidence has been corroborated by Gürkaynak et al. (2009), who show that in some advanced inflation-targeting countries, long-term inflation expectations are less responsive to macroeconomic data releases than in the United States, where no explicit inflation objective has been announced.

However, the fact that the announcement of a central bank's objective has an effect on inflation expectations need not automatically imply that there will be an effect on the ultimate objective. This question needs to be settled empirically. The available evidence is rather inconclusive at this stage, with for example Kuttner and Posen (1999) arguing that inflation is lower in inflation-targeting countries, whereas Ball and Sheridan

(2005) cannot find any such evidence, given that also the countries in their control groups managed to achieve low inflation rates.

In sum, the empirical evidence suggests that the announcement of a central bank's objective is beneficial, since it eases the conduct of monetary policy through its effect on agents' expectations, and because it helps to achieve sound macroeconomic outcomes. At the same time, it does not seem to be the only means to achieve such outcomes.

The Announcement of Policy Decisions

It is common practice nowadays among central banks to inform the public about monetary policy decisions as soon as the decision has been taken. There is substantial evidence that this practice improves the markets' understanding of monetary policy considerably. For example, Lange et al. (2003) observe that the announcement of FOMC policy decisions since 1994 has enabled markets to improve their forecasts of monetary policy decisions. Furthermore, Demiralp and Jorda (2002) provide evidence that, by announcing changes to the intended federal funds rate in real time, it has been possible to move the federal funds rate with a smaller volume of open market operations, which indicates that the announcement of policy decisions can make policy implementation more efficient.

The Communication of the Current Assessment of the Economic Situation and the Monetary Policy Stance

By announcing an objective, and possibly releasing information about its monetary policy strategy, about the models used and about the variables considered in the economic analysis, a central bank aims to help the public better understand its broader framework and the way in which it reacts to different circumstances and contingencies. However, even if the broader framework is generally well understood, it will be impossible to communicate *ex ante* all contingencies in such a way that the public can always deduce perfectly the central bank's assessment, just by interpreting the incoming macroeconomic data. Regular communication of the central bank's assessment of the current economic situation and the monetary policy stance does therefore remain important. Accordingly, central banks often release statements that provide explanations for a given policy decision, publish inflation and growth forecasts, and deliver speeches in the inter-meeting period.

As argued above, central banks have recently achieved a high degree of short-term predictability. Accordingly, markets react predominantly not to the announcement of a decision, but to the communication surrounding it, such as any explanation of the underlying reasons and any forward-looking component. Gürkaynak et al. (2005) find that longer-term maturities in the yield curve react in particular to the forward-looking component of the communication.

In line with this, Reeves and Sawicki (2007) show that the collective forms of Bank of England communication have a rather strong market impact, such as the minutes of the committee meetings and the Inflation Report. Communication by individual committee members, such as speeches or interviews, has nonetheless also been shown to be important. Kohn and Sack (2004) find that the testimonies by the FOMC chairman have substantial effects on financial markets, throughout the entire maturity spectrum. Financial market responsiveness to committee members' speeches have been identified, for example in Ehrmann and Fratzscher (2007) for the Federal Reserve, the Bank of England and the European Central Bank (ECB).

Potential Risks

The evidence suggests that central bank communication is an important policy tool, with substantial effects on financial markets, and the potential to enhance the effectiveness of monetary policy making. However, as any effective tool, it needs to be properly utilized; otherwise, it can lead to undesired outcomes.

Communicating too frequently, or providing too much information, can be damaging if there is a limit to how much information can be digested

effectively (Kahneman 2003). A widespread example where central banks limit their transparency relates to the blackout periods, whereby committee members would typically not make public statements about monetary policy-related issues just before policy meetings. As shown by Ehrmann and Fratzscher (2009), there are good reasons for adhering to such a rule, because communication during the blackout period leads to excessive market volatility.

A debate has also centred around how central banks should communicate if they receive noisy signals themselves. In coordination games in the vein of Morris and Shin (2002), or in learning models like Dale et al. (2008), whether or not a central bank should communicate depends crucially on the relative precision of the central bank's and the private sector's information. However, it has been debated to what extent a case for limiting central bank communication can arise in these models. With regard to the coordination game literature, Svensson (2006) argues that central bank communication would need a much (and implausibly) lower signal-to-noise ratio than that of private information.

Clarity is essential for good communication. A possible risk to clarity can arise because monetary policy is typically set by committees rather than by single individuals. This can give rise to a 'cacophony problem' (Blinder 2004, ch. 2) if too many disparate voices on a topic confuse rather than clarify the message. Central banks take different approaches in that regard. Whereas FOMC members communicate their individual views to the public (Bernanke 2004), this is not so for the ECB, which now adheres to a one-voice policy (Jansen and De Haan 2006). Importantly, however, markets adapt to such differences in communication style, for example by reacting more strongly to statements by the chairperson of committees with dispersed communication, and more equally to statements by all committee members if these communicate in a collegial fashion (Ehrmann and Fratzscher 2007).

Open Issues

The recent research on central bank communication, surveyed in Blinder et al. (2008), has provided a large number of relevant insights. Central bank communication is an important policy tool, with substantial effects on financial markets, and the potential to enhance the efficiency of monetary policy making. However, what constitutes an optimal communication strategy remains an unsettled issue. There is a large diversity in the communication policies of central banks, because the design of communication policies must take into account the cultural and institutional environment in which a central bank operates. Accordingly, it is evident that 'one size does not fit all'.

Other issues and debates remain unresolved at the time of writing. For instance, there are different ways of providing forward guidance. It is difficult to evaluate the recent approach of publishing projected paths for the central bank's policy rate, given that we have gained only very limited experience to date. Another open issue relates to the transmission of central bank communication. The role of the media has barely been studied. Finally, while much of the empirical research has focused on the effects of communication on financial markets, a better understanding of the communication with the general public is required, since it is the general public whose inflation expectations eventually feed into the actual evolution of inflation – for example, through corresponding wage claims and savings, investment and consumption decisions.

Central Bank Independence

Carl E. Walsh

Abstract

Many countries have implemented reforms designed to grant their monetary authorities greater independence from direct political influence. These reforms were justified by research showing central bank independence was negatively correlated with average inflation among developed economies. An important line of research developed measures of central bank independence and studied their relationship with inflation and real economic activity. Different theoretical approaches have been used to model central bank independence. Critics of the reform movements towards central bank independence have expressed concerns that independence can weaken the accountability of central banks.

Central bank independence refers to the freedom of monetary policymakers from direct political or governmental influence in the conduct of policy.

During the 1970s and early 1980s, major industrialized economies experienced sustained periods of high inflation. To explain these periods of inflation, one must account for why central banks allowed them to happen. One influential line of argument pointed to the inflation bias inherent in discretionary monetary policy if the central bank's objective for real output (unemployment) is above (below) the economy's natural equilibrium level or if policymakers simply prefer higher output levels (Barro and Gordon 1983). Under rational expectations, the public anticipates that the central bank will attempt to expand the economy; as a consequence, real output is not systematically affected but average inflation is left inefficiently high.

This explanation for inflation raises the question why central banks might prefer economic expansions or have unrealistic output goals. Economists have frequently pointed to political pressures as the answer. Elected officials may be motivated by short-run electoral considerations, or may value short-run economic expansions highly while discounting the longer-run inflationary consequences of expansionary policies. If the ability of elected officials to distort monetary policy results in excessive inflation, then countries whose central banks are independent of such pressure should experience lower rates of inflation. Beginning with Bade and Parkin (1988), an important line of research focused on the relationship between the central bank and the elected government as a key determinant of inflation.

This empirical research found that average inflation was negatively related to measures of central bank independence. Cukierman (1992) provides an excellent summary of the empirical work; references to the more recent literature can be found in Eijffinger and de Haan (1996) and Walsh (2003, ch. 8). The empirical findings led to a significant body of work addressing the following questions: what do we mean by central bank independence? How should central bank independence be measured? What causal interpretation should be placed on the empirical correlations between central bank independence and macroeconomic outcomes discovered in the data? What is the theoretical explanation for these correlations?

The Meaning of Independence

The historical, legal and de facto relationships between a country's government and its central bank are very complex, involving many difference aspects. These include, but are not limited to, the role of the government in appointing (and dismissing) members of the central bank governing board, the voting power (if any) of the government on the board, the degree to which the central bank is subject to budgetary control by the government, the extent to which the central bank must lend to the government, and whether there are clearly defined policy goals established in the central bank's charter.

Most discussions have focused on two key dimensions of independence. The first dimension encompasses those institutional characteristics that insulate the central bank from political influence in defining its policy objectives. The second dimension encompasses those aspects that allow the central bank to freely implement policy in pursuit of monetary policy goals. Grilli et al. (1991) called these two dimensions 'political independence' and 'economic independence'. The more common terminology, however, is due to Debelle and Fischer (1994), who called these two aspects 'goal independence' and 'instrument independence'. Goal independence refers to the central bank's ability to determine the goals of

policy without the direct influence of the fiscal authority. In the United Kingdom, the Bank of England lacks goal independence since its inflation target is set by the government. In the United States, the Federal Reserve's goals are set in its legal charter, but these goals are described in vague terms (for example, maximum employment), leaving it to the Fed to translate these into operational goals. Thus, the Fed has a high level of goal independence. Price stability is mandated as the goal of the European Central Bank (ECB), but the ECB can choose how to interpret this goal in terms of a specific price index and definition of price stability.

Instrument independence refers only to the central bank's ability to freely adjust its policy tools in pursuit of the goals of monetary policy. The Bank of England, while lacking goal independence, has instrument independence; given the inflation goal mandated by the government, it is able to set its instruments without influence from the government. Similarly, the inflation target range for the Reserve Bank of New Zealand is set in its Policy Targets Agreement (PTA) with the government, but, given the PTA, the Reserve Bank has the authority to sets its instruments without interference. The Federal Reserve and the ECB have complete instrument independence.

Measuring Independence

The most widely employed index of central bank independence is due to Cukierman et al. (1992), although alternative measures were developed by Bade and Parkin (1988) and Alesina et al. (1991), among others.

The Cukierman, Webb and Neyapti index is based on four legal characteristics as described in a central bank's charter. First, a bank is viewed as more independent if the chief executive is appointed by the central bank board rather than by the government, is not subject to dismissal, and has a long term of office. These aspects help insulate the central bank from political pressures. Second, independence is greater the more policy decisions are made independently of government involvement. Third, a central bank is more independent if its charter states that price stability is the sole or primary goal of monetary policy. Fourth, independence is greater if there are limitations on the government's ability to borrow from the central bank.

Cukierman, Webb and Neyapti combine these four aspects into a single measure of legal independence. Based on data from the 1980s, they found Switzerland to have the highest degree of central bank independence at the time, closely followed by Germany. At the other end of the scale, the central banks of Poland and the former Yugoslavia were found to have the least independence.

Legal measures of central bank independence may not reflect the actual relationship between the central bank and the government. In countries where the rule of law is less strongly embedded in the political culture, there can be wide gaps between the formal, legal institutional arrangements and their practical impact. This is particularly likely to be the case in many developing economies. Thus, for developing economies, it is common to supplement or even replace measures of central bank independence based on legal definitions with measures that reflect the degree to which legally established independence is honoured in practice. Based on work by Cukierman, measures of actual central bank governor turnover, or turnover relative to the formally specified term length, are often used to measure independence. High actual turnover is interpreted as indicating political interference in the conduct of monetary policy.

Empirical Evidence

The 1990s saw many countries, both developed and developing, adopt reforms that increased central bank independence. This trend was strongly influenced by empirical analysis of the relationship between central bank independence and macroeconomic performance. Among developed economies, central bank independence was found to be negatively correlated with average inflation. The estimated effect of independence on inflation was statistically and economically

significant. Based on data from the high inflation years of the 1970s, for example, moving from the status of the Bank of England prior to the 1997 reforms that increased its independence to the level of independence then enjoyed by the Bundesbank would be associated with a drop in annual average inflation of four percentage points.

The form of independence may also matter for inflation. Debelle and Fischer (1994) report evidence that it is the combination of goal *dependence* and instrument *independence* that produces low average inflation, although their empirical results were weak.

Even if central bank independence leads to lower inflation, the case for independence would be greatly weakened if it also leads to greater real economic instability. However, little relationship was found between measures of real economic activity and central bank independence (Alesina and Summers 1993). In other words, countries with more independent central banks enjoyed lower average inflation rates yet suffered no cost in terms of more volatile real economic activity. Central bank independence appeared to be a free lunch.

While standard indices of central bank independence were negatively associated with inflation among developed economies, this was not the case among developing economies. Developing countries that experienced rapid turnover among their central bank heads tended to experience high rates of inflation. This is a case, however, in which causality is difficult to establish; is inflation high because of political interference that leads to rapid turnover of central bank officials? Or are central bank officials tossed out because they can't keep inflation down?

The empirical work attributing low inflation to central bank independence has been criticized along two dimensions. First, studies of central bank independence and inflation often failed to control adequately for other factors that might account for cross-country differences in inflation experiences. Countries with independent central banks may differ in ways that are systematically related to average inflation. After controlling for other potential determinants of inflation, Campillo and Miron (1997) found little additional role for central bank independence.

Second, treating a country's level of central bank independence as exogenous may be problematic. Posen (1993) has argued strongly that both low inflation and central bank independence reflect the presence of a strong constituency for low inflation. Average inflation and the degree of central bank independence are jointly determined by the strength of political constituencies opposed to inflation; in the absence of these constituencies, simply increasing a central bank's independence may not cause average inflation to fall.

Theoretical Models of Independence

Central bank independence has often been represented in theoretical models by the weight placed on inflation objectives. When the central bank's weight on inflation exceeds that of the elected government, the central bank is described as a Rogoff-conservative central bank (Rogoff 1985). This type of conservatism accorded with the notion that independent central banks are more concerned than the elected government with maintaining low and stable inflation. Rogoff's formulation reflects a form of both goal independence – the central bank's goals differ from those of the government – and instrument independence – the central bank is assumed to be free to set policy to achieve its own objectives. Because the central bank cares more about achieving its inflation goal, the marginal cost of inflation is higher for the central bank than it would be for the government. As a consequence, equilibrium inflation is lower.

One problem with interpreting independence in terms of Rogoff-conservatism is that Rogoff's model implies that a conservative central bank will allow output to be more volatile in order to keep inflation stable. Yet the empirical research finds no relationship between real fluctuations and measures of central bank independence.

An alternative way to model central bank independence is to view the central bank as having its own objectives, but the central bank must also take into account the government's objectives when deciding on policy. The central bank might

have either a lower desired inflation target than the government or an output target that, unlike the government's target, is consistent with the economy's natural rate of output. If actual policy is set to maximize a weighted average of the central bank's and the government's objectives, the relative weight on the central bank's own objectives provides a measure of central bank independence. With complete independence, no weight is placed on the government's objectives; with no independence, all weight is placed on the government's objectives. If the objectives of the central bank and the government differ only in their desired inflation target, then the degree of central bank independence affects average inflation but not the volatility of either output or inflation. Such a formulation is consistent with the empirical evidence discussed above.

Often, theoretical approaches have not distinguished clearly between goal and instrument independence. Suppose independence is measured by the relative weight on the government's and the central bank's objectives. This can be interpreted as reflecting either goal dependence – the objectives of the central bank must put some weight on the goals of the government – or instrument dependence – the actual instrument setting diverges from what would be optimal from the central bank's perspective in order to reflect the government's concerns.

Independence and Accountability

While many countries have granted their central banks more independence, the idea that central banks should be completely independent has come under criticism. This criticism focuses on the danger that a central bank that is independent will not be accountable. Although maintaining low and stable inflation is an important societal goal, it is not the only macroeconomic goal; monetary policy may have no long-run effect on real economic variables, but it can affect the real economy in the short run. In a democracy, delegating policy to an independent agency requires some mechanism to ensure accountability. For this reason, reforms have often granted central banks instrument independence while preserving a role for the elected government in establishing the goals of policy and in monitoring the central bank's performance in achieving these goals.

Central Banking

Charles Goodhart

When the first government-sponsored banks were founded in Europe, for example the Swedish Riksbank (1668) and the Bank of England (1984), there was no intention that these should undertake the functions of a modern central bank, that is, discretionary monetary management and the regulation and support, for example through the 'lender of last resort' function, of the banking system. Instead, the initial impetus was much more basic, generally relating to the financial advantages a government felt that it could obtain from the support of such a bank, whether a State bank, as in the case of the Prussian State Bank, or a private bank, like the Bank of England. This naturally involved some favouritism, often supported by legislation, by the government for this particular bank in return for its financial assistance. The favoured bank was often granted a monopoly advantage, for example over the note issue in certain areas, or as the sole chartered joint stock bank in the country; and this may have had the effect in some countries, such as England and France, of weakening the early development of other commercial banks, so that, at the outset, the foundation of a government-sponsored bank was a mixed blessing for the development of banking in such countries.

Other government-sponsored central banks, for example the Austrian National Bank founded in 1816 at the end of the Napoleonic wars, were established to restore the value of the national currency, notably after its value had been wrecked by government over-issue in the course of war finance. Others were founded partly in order to unify what had become in some cases (e.g in Germany, Switzerland and Italy) a somewhat chaotic system of note issue; to centralize, manage and protect the metallic reserve of the country, and to facilitate and improve the payments system. While these latter functions were seen as having beneficial economic consequences, the ability to share in the profits of seignorage and greater centralized control over the metallic (gold) reserve had obvious political attractions as well. In any case, prior to 1900, most economic analysis of the role of Central Banks concentrated on the question of whether the note issue, and the gold reserves of the country, should be centralized, and, if and when centralized, how controlled by the Central Bank.

Once such government-sponsored banks had been established, however, their central position within the system, their 'political' power as the government's bank, their command (usually) over the bulk of the nation's specie reserve, and, most important, their ability to provide extra cash, notes, by rediscounting commercial bills made them become the bankers' bank: commercial banks would not only hold a large proportion of their own (cash) reserves as balances with the Central Bank, but also rely on it to provide extra liquidity when in difficulties. In several early cases, such as the Bank of England's, this latter role had not been initially intended; in most cases of Central Banks founded in the 19th century the full ramifications of their role as bankers' bank were only dimly perceived at the time of their founding; these functions developed naturally from the context of relationships within the system.

Initially, indeed, the role of Central Banks in maintaining the convertibility of their notes, into gold or silver, was not different, nor seen as different, from that of any other bank. Their privileged legal position, as banker to the government and in note issue, then led naturally to a degree of centralization of reserves within the banking system in the hands of the Central Bank, so it became a banker's bank. It was the responsibility that this position was found to entail, in the process of historical experience, that led Central Banks to develop their particular art of discretionary monetary management and overall support and responsibility for the health of the banking system at large.

This management has had two (interrelated) aspects: a macro function and responsibility relating to overall monetary conditions in the economy, and a micro function relating to the health and wellbeing of the (individual) members of the

banking system. Until 1914 such management largely consisted of seeking to reconcile the need to maintain the chosen metallic standard, usually the gold standard, on the one hand with concern for the stability and health of the financial system, and beyond that of the economy more widely, on the other. Thereafter, as the various pressures of the 20th century disrupted first the gold standard and thereafter the Bretton Woods' system of pegged exchange rates, the macroeconomic objectives of monetary management have altered and evolved. Yet at all times concern for the health of the banking system has remained a paramount concern for the Central Bank.

This concern for the wellbeing of the banking system as a whole was, at least for those Central Banks founded in the 19th century or before, largely an evolutionary development and not one that they had been programmed to undertake from the start. Indeed in England the legislative framework of the 1844 Bank Charter Act was to prove something of a barrier to the development of the micro-supervisory functions of the Bank: for this Act divided the Bank into two Departments – the Issue Department, whose note issuing function was to be closely constrained by strict rules (to maintain the Gold Standard); and the Banking Department, which was intended to behave simply as an ordinary competitive, profit-maximizing, commercial bank.

Nevertheless the micro-functions of a Central Bank in providing a central (and therefore economical) source of reserves and liquidity to other banks, and hence both a degree of insurance and supervision, cannot be undertaken effectively by a commercial competitor, basically because of competitive conflicts of interest. The advantages of having some institutions providing such micro-Central Banking functions are such that even in those various countries initially without Central Banks there was some natural tendency towards their being provided, after a fashion, from within the private sector – for example by clearing houses in the United States, or by a large commercial bank providing quasi-Central Bank functions. Nevertheless, because of conflicts of interest, such functions were not, and cannot be, adequately provided by competing commercial institutions.

Some Central Banks, mainly those that began their existence under private ownership (e.g. the Bank of England, the Banca d'ltalia, but also some that were subject to political oversight, e.g. the Banque de France, the Commonwealth Bank of Australia), retained for a considerable time a large role in ordinary commercial banking. It was, however, the metamorphosis from their involvement in commercial banking, as a competitive, profit-maximizing bank among many, to a non-competitive, non-profit-maximizing role that marked the true emergence in those countries of proper Central Banking. This metamorphosis occurred naturally, but with considerable difficulty in England, the difficulty arising in part from the existence of property rights in the profits of the Bank, and in part from concern about the moral hazards of the Bank consciously adopting a supervisory role, (as evidenced in the arguments between Bagehot and Hankey, reported in Bagehot's *Lombard Street*).

Indeed, with the Central Bank coming to represent the ultimate source of liquidity and support to the individual commercial banks, this micro-function does bring with it naturally a degree of 'insurance'. Such insurance, in turn, does involve some risk of moral hazard: commercial banks, believing that they will be protected by their Central Bank from the consequences of their own follies, may adopt too risky and careless strategies. That concern has led Central Banks to become involved – to varying extents – in the regulation and supervision of their banking systems. In all countries the Central Bank plays *some* role in the support of its commercial banks, because it alone can provide 'lender of last resort' assistance; but the extent to which it shares the insurance, supervisory, and regulatory function, both for the banking system more narrowly and for the wider financial system, with government and private bodies set up specifically for such purposes, varies from country to country. With structural changes apparently breaking down the barriers between the banking system on the one hand and other financial intermediaries on the other in the course of the 1970s and 1980s, the question of the division of responsibility of the Central Bank on the one hand, and other

supervisory government bodies and insurance agencies on the other, has become topical.

The Central Bank's more glamorous function is the conduct of macro-monetary policy. The main objective of this function in normal times has been to maintain the (internal and external) value, and reputation, of the national currency. At times of national crisis, notably during wars, however, the financial needs of the State have generally overridden the desire for financial stability, with the conduct of monetary policy then being mainly determined by questions of how the necessary finance can most effectively be mobilized to support the urgent needs of the State. Apart from such national emergencies, the desire to achieve financial stability became synonymous, during the 19th and early 20th centuries, with adherence to the Gold Standard.

The break-down of the Gold Standard in the interwar period left many countries with high unemployment, a falling price level, and international trade and capital flows increasingly constrained by direct controls. In this context it became widely felt that monetary policy was relatively powerless: once interest rates were brought down to low levels, there was little more, it was argued, that monetary policy could do. The management of aggregate demand would, therefore, have to be left to fiscal policy, with direct controls of various kinds used to constrain subsequent inflationary pressures (e.g. in World War II) and international disequilibria.

The erosion of direct controls in the late 1940s and 1950s, and the establishment of the Bretton Woods system of pegged, but adjustable, exchange rates, meant that Central Banks generally were able, during the 1950s and 1960s, to return to their accustomed policy of maintaining the value of their national currencies by seeking to hold these pegged to the US dollar and thence, until the late 1960s, to gold. With the US dollar at the centre of the world financial system, the Federal Reserve System had a different and special responsibility, to maintain the internal stability of the $. After many successful years, US monetary policy and the Bretton Woods system were overwhelmed by pressures arising from the Vietnam War, political strains within the Western Alliance, and, finally, the 1973 Oil Shock.

Up till then, most Western governments had sought to maximize employment and growth, along broadly Keynesian lines, subject to trying to maintain the exchange rate peg. With that peg no longer in place after 1972, governments then placed various emphases on supporting full employment on the one hand and monetary constraint on the other. In the event, however, there seemed no evidence that countries with more expansionary monetary policies, and thence more inflation, did achieve notably higher rates of growth of employment. This experience led directly to the adoption of 'pragmatic' monetarist policies by the Central Banks of the main industrialized countries, whereby they sought to achieve publicly announced, steadily declining rates of growth for certain domestic monetary intermediate target aggregates.

This policy shift has, in turn, had a chequered history. Monetarists claim that the commitment to, and technical execution of, monetary targetting has been unsatisfactory. Keynesians claim that it has involved no more than simple deflation, with the policy's success in reducing inflation in the early 1980s tarnished by a dramatic growth in unemployment and a poor rate of growth of real output. Moreover, the conduct of policy has been complicated by a generally growing instability, partly induced by structural change, in the relationship between money and nominal incomes, an unstable velocity of money; and also by serious and persistent volatility in exchange rates and interest rates, often leaving these seemingly way out-of-line with economic fundamentals.

As of 1985, it seems difficult to see how a fully international system of pegged exchange rates could be re-established, though this would provide the traditional, and simplest, milieu for Central Bank policy. (This, though, would still allow regional groupings of countries to seek to maintain a stable exchange rate system between themselves, such as the European Monetary System, generally based on a central key currency within the group.) On the other hand, previous enthusiasm for rules, and for fixed targets for monetary growth, is dissipating, partly as the evolving

structure of the financial system once again brings into question the appropriate definition, role, and essential properties, of money and banks. So for the moment, there seems no valid alternative to a discretionary conduct of monetary policy, with an eye not only both to monetary and exchange rate developments, but also to the broader evolution of the economy.

Central Limit Theorems

Werner Ploberger

Abstract

Central limit theorems describe the behaviour of distributions of sums of random variables. We start with the classical result of distributions of sums of independent random variables converging to the Gaussian (bell-curve) distribution. We describe the most important cases of convergence to Gaussian distributions (sums of martingale differences) as well as convergence to other distributions.

Keywords

Central limit theorems; Convergence; Edgeworth expansions; Feller condition; Laplace, P. S.; Lindeberg condition; Long-term variance; Lyapunov condition; Martingale differences; Maximum likelihood; Monte Carlo simulation

C10

At the end of the 17th century, the mathematician Abraham de Moivre first used the normal distribution as an approximation for the percentage of successes in a large number of experiments. Later on, Laplace generalized his results, but it took 20th century mathematics to give an exact and

complete description of this subject. So let me now describe the modern approach. We assume that for each n we have given a sequence $X_{1,n,}...,$ $X_{n,n}$ of random variables, which we assume to be independent. Then we want to 'approximate' the distribution of

$$S_n = \sum_{i=1}^{n} X_{i,n}$$

by a standard normal distribution, whose density equals

$$\frac{1}{\sqrt{2\pi}} \int_A \exp\left(-\frac{x^2}{2}\right) \mathrm{d}x.$$

Let us denote by $P(B)$ the probability of an event B. If X is a random variable, than let us denote by $E(X)$ its expectation. For $A \subseteq \mathrm{R}$ let $[X \in A]$ be the event that X takes a value into A. Written in formal terms, we want to establish that

$$\lim_{n\to\infty} P([S_n \in A]) = \frac{1}{\sqrt{2\pi}} \int_A \exp\left(-\frac{x^2}{2}\right) \mathrm{d}x \quad (1)$$

or

$$\lim_{n\to\infty} Ef(S_n) = \frac{1}{\sqrt{2\pi}} \int f(x) \exp\left(-\frac{x^2}{2}\right) \mathrm{d}x. \quad (2)$$

The first question we have to ask ourselves is the nature of the approximation. Clearly it is impossible to approximate the distribution of S_n for *all* sets. Consider the binomial distribution discussed above. In this case, each S_n can only take a finite number of values. Therefore the possible values for all S_n lie for all n in a countable set, which has zero probability under the normal distribution.

So we have to aim at a compromise: the smaller the class of sets A or functions f, the more 'convergent' sequences S_n we have. The most successful compromise is the convergence in distribution of the random variables (or the weak convergence of the probability distributions). We postulate that (2) holds for all bounded, continuous functions f. This requirement can be shown to be equivalent to postulating that (1) holds for all sets A so that the boundary of A (that is, the difference between closure of A and inner points of A) has zero probability under the limiting measure. So in our case, where the limiting distribution is normal, (1) holds if A is an interval (a, b): the boundary consists of two points, namely a and b. Equation (1) does not hold if, for example, A is the set of all rational numbers in (0, 1): then the boundary equals [0, 1], which obviously has non-zero probability under the normal distribution (see Billingsley 1999).

It is noteworthy that there are many more equivalent ways to define convergence in distribution for unidimensional random variables; for example, convergence in distribution is equivalent to the convergence of the cumulative distribution functions to the cumulative distribution function of the limiting distribution in all points where the latter is continuous. Another well-known criterion is the convergence of the characteristic functions.

Now we are in a position to formulate our first main theorem, the central limit theorem (CLT) of Lindeberg and Feller (see Billingsley 1995).

Suppose we have given a triangle array of random variables $X_{i,n}$, so that for each n the $X_{i,n}$ are independent, not necessarily identically distributed. We furthermore have

$$EX_{i,n} = 0,$$
$$\sum_{i=1}^{n} \mathrm{Var}(X_{i,n}) = 1.$$

Then the following two propositions are equivalent:

- The 'Lindeberg' condition: For all $\delta > 0$

$$\sum_{i=1}^{n} E\left(X_{i,n}^2 I\left[|X_{i,n}| > \delta\right]\right) \quad (\mathrm{L})$$

converges to zero.

- Our sums

$$S_n = \sum_{i=1}^{n} X_{i,n}$$

converge in distribution to a standard normal and the 'Feller' condition is satisfied:

$$\max_{1\le i\le n} \mathrm{Var}(X_{i,n}) \to 0. \qquad \text{(F)}$$

It seems plausible to assume the Feller condition (F). It simply states that the maximal contribution of an individual $X_{i,n}$ to the variance of the sum gets arbitrarily small. This seems reasonable. The Lindeberg condition (L) which is necessary for our theorem is a little stronger. Not only the maximum, but the *total* contribution of the $X_{i,n}$ taking 'large' values to the variance of the sum, must vanish asymptotically!

It is quite easy to establish that (L) is fulfilled if

$$X_{i,n} = \frac{1}{\sqrt{1}} X_i, \qquad (3)$$

where the X_i are independent and identically distributed. In the general case, a sufficient condition is the 'Lyapunov condition': for some fixed $\varepsilon > 0$ we have

$$\sum_{i=1}^{n} E\left(|X_{i,n}|^{2+\varepsilon}\right) \to 0.$$

So we need a little more than second moments to establish convergence to a standard normal. Practitioners often assume that the requirements of the theorems are fulfilled automatically. This assumption is quite dangerous. We need a little more than lack of outliers; the contribution to the variance of the largest values must be negligible.

This relation between higher moments and goodness of the approximation with a standard normal is extensive. Under the assumption of at least three absolute moments, the theorem of Berry–Esseen shows that in the case (3) of independent, identically distributed X_i the maximal difference between the cumulative distribution functions of S_n and the standard normal is $1/\sqrt{n}$. Related are 'coupling' results. One can show that – possibly on a richer probability space – there exist *exactly* normally distributed random variables U_n. In particular, if the X_i have a Laplace transform, then the 'Hungarian construction' allows one to construct U_n so that the difference to S_n is $\mathrm{O}(\log(n)/\sqrt{n})$. If the X_i 'only' have fourth moments, then it is easy (for the insider: use Skorohod embedding) to construct U_n so that the difference to S_n is of the order of $1/\sqrt[4]{n}$.

All these bounds are very interesting from the theoretical point of view. Playing around with numbers for n with realistic sample sizes, one can easily see that the bounds found that way are unrealistic. Although these bounds cannot be improved, they are a little pessimistic. Nevertheless, they indicate when we venture into dangerous territory: a lack of fourth moments indicates a 'slow' convergence.

So the normal approximation is a useful first-order approximation of the distributions of sums of random variables. To improve this approximation, various techniques are used. Since the 19th century, Edgeworth expansions have proved useful. Nowadays, however, cheap computing makes direct calculation of distributions by Monte Carlo simulation possible.

Independent, Non-normal Limit Theorems

Let us define $\mathrm{X}_{i,n}$ to be independent, identically distributed and taking the value of zero with probability $1 - \lambda/\mathrm{n}$ and one with probability λ/n with some $\lambda > 0$. Now one has an easy example where the Lindeberg condition is not fulfilled. (For $\delta < 1$, $\sum_{i=n}^{n} E\left(X_{1,n}^2 I(|X_{i,1}| > \delta\right) = \lambda$, since $\mathrm{X}_{i,n}$ can take only the values 0 and 1). Nevertheless, it is well known that $\sum_{i=1}^{n} X_{i,n}$ converges in distribution to a Poisson distribution with intensity λ. So the normal distribution is not the only limiting distribution of sums of independent random variables. One can, however, show that the normal and the Poisson distribution and mixtures (with possibly an infinite number of components) of these distributions are the only possible limits of sums S_n of independent, identically distributed random variables $X_{i,n}$. These limiting distributions are called 'infinitely divisible'. A precise formula for the logarithm of the characteristic function is given by the formula of Levy–Khinchin.

We even have some analogon, some generalization of the normal distribution. The properly normalized sum of normally distributed random variables is normal again. Can we generalize this property? Let us assume that

$$X_{i,n} = a_n(X_i - b_n), \tag{4}$$

where the X_i are independent and identically distributed, and the a_n are scale factors, and let us assume that the distribution of the S_n is identical to the distribution of the X_i. These distributions are called the 'stable' distributions. Their density is determined essentially by two parameters, traditionally called α and β. α determines the 'tail behaviour' and varies between 0 and 2, and β determines the symmetry. For $\alpha = 2$, we have the normal distribution, for $\alpha < 2$ the distributions are more heavily tailed: in general, one has only moments of order smaller than α. There is no closed form for their densities in the general case, only the characteristic functions can be expressed by elementary functions. One special case ($\alpha = 1$) is the Cauchy distribution with density

$$\frac{1}{\pi(1+x^2)}.$$

The index α determines the scale factors a_n: in general, one has $a_n = n^{\frac{1}{\alpha}}$.

Convergence of sums to stable distributions can be achieved in more general circumstances. In general, under certain conditions on the 'tail' of the X_i (the probabilities exceeding 'large' values have to obey certain regularity conditions) the sums of the $X_{i,n}$ defined by (4) one can ensure convergence (see Ibragimov and Linnik 1971).

Central Limit Theorems for Dependent Random Variables

Many econometric applications involve sums of dependent random variables. Hence it is important to remove the requirement of independence. Traditionally, one tried to replace independence by some form of 'mixing'.

Independence of two σ-algebras $\mathfrak{A}$ and $\mathfrak{B}$ can be defined in various ways.

Usually one defines $\mathfrak{A}$ and $\mathfrak{B}$ to be independent if for all $A \in \mathfrak{A}$ and $B \in \mathfrak{B}$

$$P(A \cap B) = P(A)P(B).$$

Another usual definition is that for all $A \in \mathfrak{A}$

$$P(A/\mathfrak{B}) = P(A),$$

where $P(\cdot/\cdot)$ should denote the conditional probability. Consequently, one can measure the 'degree of dependence' of σ-algebras $\mathfrak{A}$ and $\mathfrak{B}$ by

$$\alpha(\mathfrak{A}, \mathfrak{B}) = \sup_{A \in \mathfrak{A}, B \in \mathfrak{B}} |P(A \cap B) - P(A)P(B)|$$

or

$$\psi(\mathfrak{A}, \mathfrak{B}) = \sup_{A \in \mathfrak{A}} |P(A/\mathfrak{B}) - P(A)|.$$

Suppose one has give a process X_t. Then one defines the 'mixing coefficients'

$$\alpha_k = \sup_t \alpha\left(\mathfrak{A}_\sigma\left(X_t, X_{t+1,\ldots}\right), \mathfrak{A}_\sigma\left(X_{t-k}, X_{t-1-k,\ldots}\right)\right)$$

or

$$\psi_k = \sup_t \psi\left(\mathfrak{A}_\sigma\left(X_t, X_{t+1,\ldots}\right), \mathfrak{A}_\sigma\left(X_{t-k}, X_{t-1-k,\ldots}\right)\right).$$

Typically, conditions Like

$$\sum \sqrt{\alpha_k} < \infty$$

or

$$\psi_k \to 0$$

are sufficient conditions for a CLT. So the CLT remains valid for stationary processes if the random variables in questions get less and less dependent if the time difference gets larger and larger (Ibragimov and Linnik 1971; Davidson 1994).

CLT for Martingale Differences

One of the most important applications is the CLT for martingale differences. A process X_t is a 'martingale difference' if for all t

$$E(X_t/\mathfrak{F}_{t-1}) = 0,$$

where $\mathfrak{F}_{t-1}$ is an increasing sequence of σ-algebras which contain at least $X_{t-1}, X_{t-2},\ldots$. Then we have a result perfectly analogous to the case of independent random variables.

Suppose we have given a triangle array $X_{t,T}, t = 1,\ldots, T$, of martingale differences with σ-algebras $\mathfrak{F}_{t-1,T}$ and the following two conditions are satisfied:

- the conditional Lindeberg condition

$$\sum_{t=1}^{T} E\left(X_{t,T}^2 I_{\left[|X_{t,T}|\geq\varepsilon\right]}/\mathfrak{F}_{t-1,T}\right) \to 0,$$

- the norming condition

$$\sum_{t=1}^{T} E\left(X_{t,T}^2/\mathfrak{F}_{t-1,T}\right) \to 1,$$

where the convergence should be understood to be in probability. Then

$$S_n = \sum_{i=1}^{n} X_{i,n}$$

converges in distribution to a standard normal distribution (Davidson 1994; Hall and Heyde 1980).

This limit theorem is one of the most important ones for applications in econometrics. It is relatively easily seen that derivatives of log-likelihood functions are martingale differences. Hence this theorem is instrumental in establishing the limit theorems for maximum likelihood estimators.

An easy consequence of the theorem is that for every (strictly) stationary, ergodic martingale difference X with $\sigma^2 = E\left(X_t^2\right) < \infty$ we have an almost classical CLT:

$$\frac{1}{\sigma\sqrt{n}} \sum_{i=1}^{n} X_i$$

which converges in distribution to a standard normal.

Gordin's Theorem

Martingale differences form a large class of processes. Unfortunately, however, this class is not sufficiently large for many important applications (martingale differences must be, for example, uncorrelated). As an alternative, one might use mixing conditions. These conditions are, however, hard to verify. They usually involve inequalities involving *all* events from the σ-algebras involved. Hence a theorem allowing for general, autocorrelated processes with conditions which are easy to verify is an important tool in theoretical econometrics. Such a result was found by Gordin in 1969. Hayashi (2000) demonstrates the versatility of the theorem.

Suppose we have a stationary, ergodic process X_i, $i \in Z$ so that $EX_i^2 < \infty$. Assume that $\mathfrak{F}_i$ are adapted σ-algebras (that is, X_i are $\mathfrak{F}_i$-measurable), and let

$$\varepsilon_i = E(X_i/\mathfrak{F}_1) - E(X_i/\mathfrak{F}_0).$$

Then let us assume that

$$\sum_{i=1}^{\infty} \sqrt{E\varepsilon_i^2} < \infty.$$

Then

$$\frac{1}{\sqrt{n}} \sum_{i=1}^{n} X_i$$

converges in distribution to a normal distribution with zero mean and variance σ_{LT}^2 where

$$\sigma_{LT}^2 = E\left(\sum_{i=1}^{\infty} \varepsilon_i\right)^{2'}.$$

σ_{LT}^2 is usually called the 'long-term variance'.

Conclusion

Almost all theorems about limit distributions of estimators and test statistics depend on central limit theorems. So it should not be surprising that central limit theorems and their generalizations are an active field of research. Especially, generalizations of the concept of convergence in distribution to more general spaces generate theorems, which are important from the theoretical as well as the practical point of view. Billingsley (1999) and Davidson (1994) give an introduction to these 'functional limit theorems'.

Central Place Theory

Marcus Berliant

Abstract

Central place theory is a descriptive theory of market area in a spatial context. Its main assumptions are that consumer population is distributed uniformly while firms locate in cities; the latter form a hierarchy with overlapping market areas. But central place theory runs afoul of Starrett's spatial impossibility theorem. Not grounded in the analytical tools of modern economics, central place theory does not have firm foundations. Thus, it is difficult to build on central place theory, either theoretically or empirically.

Keywords

Central place theory; City hierarchy; Increasing returns to scale; Krugman, P.; Spatial impossibility theorem; Urban agglomeration

Central place theory is a descriptive theory of market area in a spatial context. Its definition, history, and relation to modern microeconomic theory are set out in this article.

Central place theory is a collection of loosely related, informal, descriptive models of city size, city location, and market area based on the trade-off between increasing returns to scale in production and the cost of transport of goods from firm to home. Land markets are often absent. At its core, central place theory is an empirically motivated description of production in southern Germany. It is a remarkable empirical regularity in search of a formal theory; a better name would be 'central place regularity'.

The beginnings of the theory are attributed to Christaller (1933), who first made detailed observations of urban hierarchies and then attempted to model them. The basic ideas put forward are that consumer population is distributed uniformly, while firms locate in cities. Cities form a hierarchy in that cities higher in the hierarchy produce all the goods that cities one level lower in the hierarchy produce, and one more. The ratio of market areas of a commodity produced only at a given level of the hierarchy (and above) to the market area of a commodity produced at the next lower level of the hierarchy (and above) is assumed to be constant, independent of the level in the hierarchy considered. Thus, the cities in a given area form a hierarchy where the size of a city's market area and the variety of commodities it offers are perfectly

correlated. In graphical terms, the result is a collection of hierarchically ordered cities with the market areas of cities not at the same level of the hierarchy overlapping, but market areas of cities at the same level disjoint. Commodities characterized by low transport cost but high returns to scale are provided by a few cities high in the hierarchy. Commodities characterized by high transport cost but low returns to scale are provided by most cities.

Lösch (1944) expanded on this theory. He postulated a homogeneous agricultural plane with farmers. Some turn to beer production, and face linear, downward sloping demand curves with choke prices, that is, prices above which the demand is for beer is zero. For a given price at the brewery, total delivered price increases with distance from the plant due to transport cost. In the plane with a uniform distribution of inebriated consumers or farmers, demand for a firm's beer is given by the volume of a cone centred at the brewery, with height given by the brewery's mill price and the slope of its sides determined by the demand curve and the cost of beer transport. With a marginal cost curve, equilibrium can be found. Unfortunately, the collection of bases of cones, namely, disks, does not partition the plane. So hexagons are used, forming a Teutonic triangulation of hierarchical hexagons. In this theory, the central places are the breweries. (St. Louis is a prime example).

One can view the theory as producing a complex of overlapping, ordered layers of hexagonal partitions of the plane corresponding to the market areas of cities in a hierarchy. Agriculture is the basis for and genesis of this structure.

The theory has developed beyond these basic descriptive models; see McCann (2001, ch. 2.7) for a nice summary and cites. Hartwick (2004) is the culmination of a line of research more in accord with optimizing behaviour, pricing, and trade theory that also relates the models to the rank-size rule.

The reader should be cautious in interpreting this entire literature because equilibrium and efficiency are often confused, while the models tend to be mechanistic in nature as opposed to allowing agents to optimize in equilibrium. To the general economist, the theory will appear to be informal and imprecise. Paul Krugman (1995, pp. 38–41) criticizes central place theory, or 'Germanic geometry', for its lack of formal foundations, particularly regarding market structure and firm behaviour. This criticism applies even to the contemporary literature. (Paul Krugman is also credited with the first alliteration in this literature. This article only builds on the original contribution).

Even if one is willing to overlook these defects, there is one further important flaw. Central place theory generally runs afoul of Starrett's spatial impossibility theorem; see Starrett (1978), Fujita (1986), and Fujita and Thisse (2002, ch. 2.3) for discussion. In essence, the impossibility theorem says that, in a closed economy with perfect and complete markets at all locations, location-independent utility and production functions, and no relocation cost, there is no competitive equilibrium where commodities are transported. Thus, if the assumptions are satisfied, either there is no equilibrium or in equilibrium agents and commodities are distributed uniformly among inhabited locations, and locations are autarkic. Central place theory apparently makes these assumptions, though due to its imprecision perhaps it doesn't. Naturally, although the literature considers consumer migration at times, the assumption of a uniform distribution of consumers could render the theorem inapplicable. *I* conjecture that it simply makes the existence of an (autarkic) equilibrium more likely. But this is probably not worth pursuing, as location models that fix consumer locations in a uniform distribution can generate only cities without people.

So where does this leave us? The modern theory of agglomeration, and thus the modern theory of central places, begins with the impossibility theorem. Its contrapositive tells us that, to generate models with non-trivial agglomeration at equilibrium, at least one of the hypotheses must be violated. Even then, equilibrium might not exist, or in equilibrium cities could collapse to a point or have agents spread uniformly. Models of non-trivial cities involve a very delicate balancing act between forces pulling agents together and forces

pushing them apart. The New Economic Geography has provided one of several possible types of models capable of producing cities and even hierarchies of cities. Fujita and Mori (1997) and Fujita et al. (1999) generate a form of central place theory in a general equilibrium framework by employing imperfect competition and increasing returns at the firm level. Unfortunately, this type of model has many defects, as detailed in Berliant (2006), including a reliance on specific functional forms and indeterminacy: one equilibrium is selected from a continuum.

Central place theory is not grounded in the analytical tools of modern economics, so it does not have firm foundations. Thus, it is difficult to build on central place theory, either theoretically or empirically.

In my view, the future of central place theory is as a stylized fact to be explained by our models, much like the rank-size rule.

Central Planning

Tadeusz Kowalik

Central planning denotes the total body of government actions to determine and coordinate directions of national economic development. The process of central planning is composed of pre-plan studies and forecasts, formulation of aims for given periods of time, establishment of their priorities (order of importance), listing ways and means, and, eventually, the plan's implementation. Central planning is a term usually associated with Centrally Planned Economies (CPE) as opposed to Private Enterprise (or Market) and Mixed Economies (UN official classification), but it is often used in a broader sense to denote any systematic macroeconomic control by the government. For Tinbergen (1964), central planning means planning by governments, or national planning (in the Netherlands as well as in some other countries there are Central Planning Bureaux, even though these economies cannot be classed with the group of CPEs).

In this broader meaning, central planning takes several different names, specifically: 'direct', 'hierarchical' (Bauer 1978) or 'centralistic' as practised in most centrally planned economies; 'financial' as in Hungary; 'indicative' as in France.

The term 'planning' often stirs emotions. For some people, especially for many Communist economists, central planning is good by definition. Others use it to denounce socialism and indeed any kind of government intervention as 'planned chaos' (von Mises 1947). The scope

and meaning of central planning varies along with changing fashion. When Arthur Lewis confessed 'we are all planners now' (Lewis [1949] 1956, p. 74), it was fashionable to described any kind of state interventionism as 'planning'. Robbins (1947, p. 68) termed his proposal for a modest anti-inflationary or anti-deflationary fiscal policy as 'overall financial planning'. Since the 1970s, though, general opinion seems to have been increasingly wary of planning, indeed sceptical about its effectiveness. Accordingly, even some planners in the state administration who staunchly stood by that idea preferred to cover their activity under less emotionally charged terms (such as 'steering').

Initially, central planning used to be generally regarded as an inalienable feature of socialist economy and hence as the exact opposite of market and commodity production typical of capitalism. It was interpreted as planning in physical units, by central command, based upon a hierarchical structure of national economy which had at its disposal ways and means to enforce decisions by administrative order. Precisely this kind of planning system developed in the Soviet Union, less as a product of any definite concept or vision of socialist economy than as an outcome of many different interacting factors – doctrine and ideology, the specific situation of Russia at that time, and the political ends to which the victorious revolutionary authorities subordinated the economy.

Origins

After the Bolshevik victory in Russia Lenin's writings, apart from the above-mentioned view of planning as the exact opposite of market (which was shared by many other Marxists), provided two other theoretical contributions to the formidable task of organization of the economy. Following Rudolf Hilferding, Lenin (like Bukharin) described imperialism as an ante-chamber of socialism on account of the steadily accelerating process of production concentration (trusts) and the centralization of banks which were rapidly expanding their control of domestic industries. The German wartime economy with its large-scale combination of latest technology, planning and efficient organization, was viewed by Lenin as something like an archetype for a future socialist economy.

In the period of 'War Communism' (1918–20) the need for planning was repeatedly proclaimed but no national plan could actually be drawn up. It was only towards the end of the period that Gosplan, a planning commission, was created, although its job was modest and only vaguely defined for years thereafter. No firm way could be found to reconcile planning with the New Economic Policy (NEP) introduced in 1921.

The most important accomplishment of the early 1920s was the plan for electrifying all Russia, which was drawn up at Lenin's personal initiative in 1920 and which came to be referred to as GOELRO. That plan provided for the building, within the following 10–15 years, of power stations and related infrastructure in major industrial regions. At that stage, planning was viewed as primarily an engineering rather than economic activity (as can be seen if only from the composition of the commission, which included mostly engineers and agriculture specialists).

From 1925 onwards, Gosplan began to publish each year what were called economy-wide 'control figures' initially for a year only but later for five-year periods. Those figures were regarded as a non-binding set of estimations and forecasts. Their main contribution to the development of planning was that they eventually led up to the design of what is called the balancing method, which juxtaposes demand for goods with their output. First five-year plans also began to be drafted outside Gosplan.

The Soviet economy became a 'centrally planned' economy only at the time of the First five-Year Plan (1928/9–1932/3). That was a time of tough internal struggle in the party and one of escalating heroic development programmes. Each new draft version of the five-year plan, beginning with the first one after the Party Congress in December 1927 through to its final approval, set up increasingly ambitious tasks. But the balancing of tasks with resources in the plan was based mainly on overly optimistic (and largely unfeasible) forecasts of labour productivity growth. The party and the state authorities soon

began to mobilize the population to over-fulfil the plan, or, more precisely, those targets in the plan which were arbitrarily recognized as the most important ones (priority tasks). Thenceforward, plans became tools for mobilization rather than for balanced allocation of resources. Annual plans often shook up the current five-year plan to accommodate it to these new priorities (or super-priorities).

The First Five-Year Plan (which was officially declared fulfilled in four-and-a-quarter years) generated many bottlenecks and disproportions; this suggested that the pace should perhaps be slowed down – and priorities rearranged, as to some extent was attempted in the final version of the next five-year plan (for 1933–37). At the same time the new plan was even more detailed and its scope expanded significantly (the number of branches comprised by the plan increased to 120 from the original 50). The authors of the first five-year plans apparently did not realize the full institutional and political implications of over-ambitious tasks, the scale of which were in some cases downright unfeasible. In order to rescue those regarded as top priorities (especially those concerning heavy industries and manufacturing), others had to be sacrificed (those relating to standards of living were the first victims). This could only be accomplished by methods typical of wartime economy, that is, highly centralized organization, rigid subordination and discipline, all-embracing rationing, various kinds of coercion, and political mobilization. That was exactly what was attempted during the first two five-year plan periods.

To a considerable extent this amounted to a revival of the methods tried in the period of 'War Communism', including compulsory labour and rationing, however not as formal and lasting institutions like, for example, labour mobilization during the civil war, but either as side-effects of other campaigns (mass deportations during the collectivization drive, purges of the 1930s, etc), or as emergency responses to situations of extreme penury (rationing) which eventually should make room for allocation of labour and consumer goods through some kind of market (for ideological reasons the term was never used in relation to labour). This was combined with abandonment of the original egalitarianism in incomes policy; increased reliance on material incentives geared to plan fulfilment and piece rates became a distinctive mark of the Stalinist period.

C

Main Features (Formal Aspects)

The first two five-year plans set the general shape for a model of Soviet central planning, transplanted after World War II to communist Eastern Europe. That model survived unchanged through to the mid-1950s (except in Yugoslavia), and in most communist countries it functions to this day in its general outline.

In both its design and implementation stages, central planning is based on a hierarchical pattern of national economy, which in turn presupposes obedience and discipline. Freedom of choice (which is lifted only temporarily or partly) applies to purchases of consumer goods within the existing commodity supply and the state-determined purchasing power, as well as to choice of occupation and workplace within the statutory obligation to be in employment.

Using information on the economy's shape and tendencies at any given moment, the central authority formulates a set of general guidelines of the plan, possibly based on prior special studies and forecasts. The plan's guidelines include such aggregates as the distribution of the national income between accumulation and consumption, the shares and main directions of investment by sectors, the desired rate of overall economic growth etc. These guidelines as a rule are pre-defined by the leading bodies of the ruling party, and are then disaggregated by the government into guidelines for particular industrial ministries and local authorities to produce their own draft plans, which are further disaggregated and communicated to industrial associations and individual enterprises. Government guidelines include two kinds of indices; directives, which are mandatory for local planners in drafting their blueprints (whatever alteration may prove necessary can only be made by a superior agency) and information indices. The enterprise draft plans are

then aggregated by industrial associations and branch ministries, and their draft plans are in turn aggregated into a national (or central) economic plan for one or five years which is usually approved by parliament. Only after that are final corrections and adaptations introduced into lower-level plans. This particular procedure of plan construction has been called the 'spindle technique' in reference to textile machines, for guidelines and draft versions first travel from the top downwards, then up, and then again down the hierarchy.

One pivotal point in this procedure is the plan's internal consistency. The idea is to match demand for each particular resource with the level of its supply during the plan period. A whole system of balance sheets (indeed thousands of them) is used for that purpose. Balance sheets set – in physical or equivalent units – available amounts of materials, capacities, energy, labour, as well as financial means (personal income and spending, foreign trade balance, the budget) against anticipated demand in each case.

Plan fulfilment is a fundamental obligation of each economic organization. Managers and, to some extent the workforce as well, are evaluated for their plan performance and rewarded or penalized accordingly. Tasks named in an enterprise plan are both commands by a superior authority and obligations to supply enough resources to safeguard smooth cooperation. Although enterprises are given not only quantitative targets but also qualitative ones (e.g. technological input/output coefficients for materials, power etc, the importance of output–quantity performance is overriding.

Advantages and Failures

This particular model of planning was conceived in a country with abundant resources of labour (open or disguised unemployment) and primary products; it was applied also in several other countries with large unused capacities. Providing able to mobilize idle resources initially produced very high growth rates, although one cannot take official statistical records at their face value. Determination of obligatory priorities on a national scale enabled countries to concentrate resources and efforts on several selected spectacular tasks. The successful bid to transform the Soviet Union into a superpower in a relatively brief time is perhaps the least debatable success of this planning model.

However, from the mid-1950s onwards centrally planned economies have been coming under growing criticism both from professional economists and from the general public. The criticism became particularly sharp as growth indicators declined and started to affect the (slow anyway) improvement of living standards; the system's weakness in generating and absorbing technological innovations became increasingly evident. However, critical voices – even when acknowledged by political authorities – did not lead, as a rule, to consistent and effective changes in the economic system.

The main lines of criticism of deficiencies of the existing system of central planning can be summarized as follows:

The procedure for building plans outlined above cannot guarantee efficient allocation of resources. The tasks and resources for their implementation are not decided by the central planning agency in a truly 'sovereign' way because such an agency is bound to rely on the supply of information from lower-rank agencies. But that information, apart from some natural delays or mistakes made in its transmission upwards, is often deliberately distorted by enterprises, which use it as a weapon in plan bargaining. Enterprises usually want to wrench as large means and as small tasks as possible from the central economic authority for themselves. Industrial association, indeed even branch ministries, often helps them achieve this purpose. At that stage, too, the main battle for investment funds begins. Enterprises and local authorities try to get 'put on' the plan by deliberately underrating estimated costs of their undertakings. Eventually, the plan is apparently brought into balance, but it has built-in significant disproportions right from its start, which leads to a waste of resources.

Even greater waste results from the centralistic bureaucratic method of controlling the execution of plan tasks, which eventually leads to equating planning with management. The over-taut plan,

based as it is on unrealistic assumptions, especially regarding labour productivity growth, can later be 'fulfilled' only by setting up a whole system of ad hoc priorities and superpriorities which makes a reduction of nonpriorities unavoidable. As a rule, the victimized sectors are those related to the sphere of personal incomes or social or municipal services (public transport), the health service, housing, education – treated as residuum.

Once they have been assigned the required resources by the central economic authority, enterprises no longer feel compelled to seek ways of saving materials or energy. Because deliveries of materials and energy are as a rule irregular, enterprises try to provide against such risks by hoarding excessive inventories of materials and reducing employment only reluctantly. Moreover, enterprises are given no effective inducements to seek new technology, indeed even to emulate existing new techniques.

Prices set by the central authority are as a rule rigid and random, reflecting neither costs nor relative scarcities of individual goods. As a consequence, both at the central level and at enterprise level clear criteria of choice are largely absent.

Viewed from the consumer's vantage point, centrally planned economies provide poor-quality goods and a meagre product mix. Their incapability of meeting greater diversification of needs, which inevitably progresses along with increase in income levels, is one of the major reasons for the growth of a 'second economy' (moonlighting, corruption etc).

Over-taut plans, implemented through commands, unavoidably generate an inflated control system and subject the economy to political goals. Subordination of economies to politics is often presented as expression of general (social) interest; in reality this subordination often conceals vested interests of small informal groups. In the process of plan negotiations and rearrangement of priorities in the course of implementation, centralistic administrative planning engenders informal lobbies which exert growing pressure on the central authority. A product of quasi-missionary zeal to develop the production of means of production, the heavy industry lobbies are the strongest of all. Gradually, the central authority is losing its 'sovereignty' to them. Even when the authority begins to appreciate 'harmony' more than 'rush' (Kornai 1972) it is unable to shed that pressure.

This very role of lobbies goes against the widely held belief that in the centrally planned economies the superior position belongs to the preferences of the central planners. Increasingly concrete decisions are made under growing pressures of various informal vested interest groups. In this situation, criteria of choice cannot be clear or unequivocal, which makes public control of the central planning agency's operations even more difficult. For the same reason, and even more because of the secretive style of work of state agencies, as well as absence or limitation of consumer organizations, environmental groups, independent trade unions, and with restricted press freedom, the central authorities cannot play the part of an umpire reconciling different social interests. Protection of public interest becomes fictitious under these conditions. Thus, when official doctrines proclaim unity of interests, this may simply conceal a growing tendency towards a peculiar kind of 're-privatization' of centrally planned economics.

Evolution and Prospects

Since the mid-1950s, in the system of central planning as practised in countries of the so-called 'real socialism' two categories of change have taken place.

The growth and mathematization of economics, in particular the expansion of linear programming, operations research, input–output analysis, cybernetics and systems analysis, the wide extension of computer applications etc., have supplied planners with subtler tools for their work. The development of these tools fuelled hopes, already in the 1960s, that planning would proceed 'from balancing the plan towards the choice of optimal plan' (Lange 1965). 'Planometrics' came into use then, indeed even something like a 'computopia' began to develop.

The second kind of change was more institutional in character. It came along with de-Stalinization, of which economic reform was and still remains a part. Unlike in Yugoslavia,

where the economic system was to correspond to an entirely different model of socialist society compared with the Soviet-type one, in the countries belonging to CMEA institutional changes amounted, generally speaking, to a transfer of some economic decision-making to lower-level units, an expansion of material incentives for managers and workers alike, and an extension of market mechanisms.

As a result of the new techniques and of the partial decentralization, central planning has probably become a slightly more efficient tool of economy-wide control. However, all those improvements were ultimately too negligible and inconsistent to stand up to the growing complexity of economy, in particular to offset the depleting reserves of extensive-type growth factors (excess labour, cheap raw materials) by more intensive methods of growth stimulation. The technology gap between CMEA and advanced Western countries, which became clear in the 1960s and has kept widening since then, has not been bridged; if anything it has continued to widen. Hence, repeated calls for more or less radical economic reform are still the order of the day.

Planning and Freedom

Ever since its inception, the question of economic planning has set off disputes about democracy and individual freedom. In its original purely ideological concept, planning used either to be equated with democracy or presented as democracy's exact opposite: suffice it to mention the New Leftist utopia of a social system based on the belief that production and distribution can somehow be planned by the people with a total absence of market and state. The eternal Kingdom of Freedom was to come simply as soon as market and state alike have been abolished.

More elegant, albeit no less utopian, is the free-marketeers' blueprint for rejecting any governmental planning as a threat to efficiency and freedom. Although quite fashionable (and not only in the West), this mode of thinking is nonetheless outside the mainstream of disputes over planning versus freedom.

In fact, most major currents of social thinking have undergone a process of radical rethinking in the course of recent decades. This holds for liberalism (Mannheim 1940; Galbraith 1973; Lindblom 1977) and for non-Communist socialism (Crosland 1956; Crossman 1965; Nove 1983) as well as for Marxism (Brus 1975; Horvat 1982; Kornai 1985). Whatever differences may divide all these currents of thought, as indeed individual thinkers within each current, all of them are aware of two kinds of threat to freedom – one that comes from allembracing, hierarchical and bureaucratic planning, and another that comes from the failure to plan anything at all. The market mechanism is regarded as something like a barrier to bureaucratic arbitrariness. But its failures in turn may put at hazard not only economic but even political stability, thereby destroying the foundations of the desired social order. Planning, within given limits, thus turns out to be an indispensable condition of freedom. While making a plea for a polycentric model of economy – both in the sense of providing for different forms of ownership and of decision-making – all these currents of thinking believe that society as a whole should have an authentic say (via its representatives) on the main lines of investment and on general rules for national income distribution.

Of course, there is nothing inevitable in the long-run direction this movement will take either in the West or in the East. The chance to create a social order which would be based upon the three main tiers of plan, the market and freedom would be much greater if it were clear that each of these is a necessary condition for high socio-economic efficiency, and that freedom too can be viewed not only as a value in itself but also as a specific kind of production factor. Some authors have questioned this dependence of economic efficiency on political democracy (Gomulka 1977). However, neither studies of this relationship in many Third World countries (Adelman and Taft 1967) nor the record of previous reforms in the Communist world supply any definite answer to this question. On the other hand, the analysis of pressures on, and prospects of, the evolution of Communist systems in Eastern Europe has led to a rather persuasive argument (Brus 1980) that

without democratizing internal political relations these systems will be unable to remove (or at least to reduce substantially) central planning's chronic deficiencies, such as insufficient and distorted information flows, negative selection of managerial personnel, chronic investment failures, labour alienation etc. The stagnation threatening the Communist countries presses the ruling groups to more radical reforms which would combine plan, market and freedom. At the same time, repeated setbacks of neoliberal economic policies in the West may well generate fresh and strong public pressure for changes in a similar direction.

Centre of Gravitation

Luciano Boggio

In the Classical theory concerning the price of commodities there are two notions of price: the *market price*, which is the price actually prevailing, and the *natural price*, which is equal to 'what is sufficient to pay the rent of the land, the wages of the labour, and the profits of the stock. . .according to their natural rates' (Smith 1976, p. 72); and the natural price is a *centre of gravitation* for the actual price, i.e. the latter is continually tending to the former.

In the description of this tendency given by the Classics, one can distinguish two main propositions. According to the first one, the market price depends on the difference between current supply and 'effectual demand' – which is 'the demand of those who are willing to pay the natural price of

the commodity' (Smith 1776, p. 73) – the market price being higher, lower than, or equal to the natural price, if such a difference is, respectively, negative, positive or zero. According to the second proposition, the difference between market price and natural price gives rise to movements of capitals and changes in the structure of production, so that the output of a commodity increases (decreases) if such a difference is positive (negative).

The position of the economy in which market price equals natural price and output equals effectual demand is a 'centre of repose and continuance' (Smith 1776, p. 75), a position which is bound to repeat itself unaltered, until an exogenous change (e.g. in the available techniques of production) takes place.

On the basis of current definitions and methods of dynamical analysis (see, e.g. Lasalle 1976), one can recognise in the above theory the description of a dynamical system, in which the state variables are prices and output (or capital) quantities and for which the vector formed by natural prices and the corresponding output (or capital) quantities is an equilibrium.

The notion of a uniform rate of profit price vector, towards which actual prices tend to move, having been accepted – after Ricardo – by generations of economists, including Marshall and Walras, was then abandoned in the works on general equilibrium of recent decades.

The uniform-rate-of-profit price vector – let us call it *production price vector* – had a central place in Sraffa's book *Production of Commodities by Means of Commodities, Prelude to a Critique of Economic Theory* (1960), but nothing was said in it about the relation between such price vector and actual prices.

As a 'prelude to a critique of economic theory' Sraffa's analysis does not require such a relation; but it does, if it is to be used as a building block for a 'reconstruction' of economic theory. For this reason the Classical theory, according to which 'long period positions' are 'centres of gravitation' for actual prices, has been recently reintroduced (Garegnani 1976).

This reintroduction, however, also requires a critical re-examination today in the light of the contemporary methodology of dynamics. In order to illustrate this point, we shall try to formalise the gravitation theory of the Classics in a simple way.

Let us consider an economy in which there are n sectors, each producing a different commodity. The production of every commodity requires capital advances, which must cover the purchases of material inputs as well as the payment of a subsistence wage rate to each employed worker.

To simplify the discussion further, we also *assume* that for our economy a unique semi-positive price vector exists, such that in each sector the following two conditions hold together:

(a) a uniform rate of profit prevails;
(b) demand and supply are equal.

We call this vector 'the production price vector' of our economy and denote it by $p^* = p_i^*$, $i = 1, 2, 3, \ldots, n$. The existence of such a vector can be *proved* in various kinds of models (see, e.g. Boggio 1985).

Let us now reconsider the two propositions in which we have summarised the description of the gravitation process given by the Classics and call d_{it}, p_{it} and q_{it}, respectively, the effectual demand for, the actual price and the current output of the i-th commodity at time t, $t \in R_+$.

Then a simple way to model the first proposition is the following

$$p_{it} - p_i^* = g_i(d_{it} - q_{it}), \qquad i = 1, 2, \ldots, n \quad (1)$$

where g_i is a continuous sign-preserving function.

As for the second proposition, that is, the relation between output changes (as determined by capital movements across sectors) and profitability (as expressed by the difference between market and natural price), it can be modelled as

$$\dot{q}_i = s_i\left(p_{it} - p_i^*\right), \qquad i = 1, 2, \ldots, n\frac{1}{2} \quad (2)$$

where $\dot{q}_i = dq_{it}/dt$ and s_i is a continuous sign-preserving function.

These two equations, however, are not sufficient to prove the gravitation thesis. They must be

supplemented by some specific assumption about the time-pattern of d_t, the vector of effectual demands. Let us assume that d_t is constant

$$d_t = d^* \tag{3}$$

where d^* is a fixed semi-positive vector. Then from (1), (2) and (3) we get

$$\dot{q}_i = s_i\left[g_i\left(d_i^* - q_{it}\right)\right] \tag{4}$$

Since $d\left(q_{it} - d_i^*\right)$ is always equal to $\dot{q}_i$, one can see that, by equation (4), its sign is always opposite to that of $\left(q_{it} - d_i^*\right)$. Therefore as t grows $\left|q_{it} - d_i^*\right|$ decreases motonically, i.e. q_{it} tends to d_i^*. This implies that as t tends to d_i^*, must also, by equation (1), tend to d_i^*.

Hence the couple (p^*, d^*) is a globally asymptotically stable equilibrium for system (1)–(2)–(3). Notice that the same conclusion could be reached if we assumed that d_{it}, instead of being constant, were growing at a constant proportional rate.

This result means that, according to our model, although exogenous changes may shift the actual price vector and/or the production price vector, the gravitation mechanism will always tend to close the gap between them.

However, our model and the gravitation theory of the Classics are rather crude and, in several points, unsatisfactory. A clear example of this is the assumed equivalence between a positive (negative) value of $\left(p_{it} - p_i^*\right)$ and a capital-attracting (-repelling) sectoral rate of profit. If the higher than average rates of profit are capital-attracting and the lower than average rates are capital-repelling, one can show that such an equivalence does not hold in general (see Steedman 1984). The ratio between a given sectoral profit rate and the average rate depends also on the prices of the commodities required as input in that sector. The Classical description neglects these inter-industry links and any attempt to incorporate them in the analysis requires the simultaneous consideration of all prices, output levels, etc. thereby disrupting the beautiful simplicity of the Classical theory of gravitation.

The study of the stability of production prices by means of the methods of contemporary dynamic analysis has recently begun (for references and more comments, see Boggio 1985). Two main approaches have been followed. In the first approach the process of price formation is based on some kind of mark-up or full-cost rule. Very strong stability results are obtained. But the assumption of exogenous mark-ups or target profit rates is not entirely satisfactory. In the second approach the original description of the Classics is followed more closely: actual price changes depend upon supply and demand and output changes depend upon profit differentials.

We notice that in the latter approach the equilibrium vector is formed by both production (relative) price vector and steady state output proportions. Since no economy grows in a balanced way, the reference to balanced growth is often considered such a weakness as to deprive a theory of any usefulness. Actually, the meaning of balanced growth, as of every equilibrium concept, is not necessarily to offer in itself a description of reality. If the equilibrium is stable, the effects of changes in the data of the system can be approximately studied by means of the displacements of equilibrium positions: in the case under discussion, the effects on prices by the displacements of production prices, the effects on output proportions by the displacements of balanced growth proportions. A condition for the correct use of this method, an outstanding example of which in the field of economics is the above described theory of the Classics, is that the changes in the data should be slower than the movements of the state variables of the (dynamical) system. These remarks suggest the great advantage of studying change by means of comparisons or sequences of equilibria: the more fundamental aspects of change are selected out of the variety of accidental and transitory ones.

As for the results obtained in the latter approach to the study of the stability of production prices, they are mainly against stability, except for the case when strong price substitution effects in consumption are introduced. A more promising approach, in terms both of realism and of stability results, consists, probably, in assuming that price

changes depend *mainly* on cost changes, but some role in determining the former is also played by excess demand.

Much more work in this field, however, seems necessary. Its importance derives not only from the question of 'gravitation' itself, but also from more general issues of economic theory.

By specifying in a rigorous and formal way a dynamical process for which Sraffa prices are (part of) an equilibrium and by showing that such a process is not reducible to a neo-Walrasian disequilibrium process – in which prices react to excess demands, supply *instantaneously* adjusts to prices and expected future prices are replaced by current prices of 'futures' – such a work can establish in the clearest way that Sraffa prices are not simply reducible to a special case of neo-Walrasian general equilibrium theory.

Secondly, if it can show that, to give a stylized description of price-quantity dynamical interrelationships, there are more plausible ways than the neo-Walrasian one, such a work can give a contribution in the direction of replacing the neo-Walrasian paradigm.

Certainty Equivalence

Xavier Freixas

JEL Classifications
D8

In order to take a decision in an uncertainty context, it is necessary, from a theoretical point of view, to build a model and specify all the consequences in every possible state of the world. In applied work this method is much too involved.

Consequently, for applied purposes, it would be interesting to have a model where uncertainty is treated in such a way that the decision problems are as simple as the equivalent ones in a certainty framework. The identification of the conditions under which such an isomorphism between the optimal decisions under uncertainty and the optimal decisions in an equivalent certainty context holds is called the certainty equivalent problem.

Theil (1954) has been the first to point out the problem and to suggest a specific model in which the certainty equivalent property holds.

Theil imposes the following two assumptions: (i) the vector x of instruments and the vectory y of result variables are related by a simple equation

$$y = g(x) + S \tag{1}$$

where S is a vector of random variables, that we can take to have a zero expected value without loss of generality. (ii) The decision-maker's objective function is quadratic and can be written as

$$u(x,y) = A(x) + \sum_{i=1}^{m} A_i(x)y_i + \frac{1}{2}\sum_{i=1}^{m} \times \sum_{y=1}^{m} A_{ij}y_iy_j \qquad (2)$$

Using such a model it is straightforward to show that whenever the optimal solution to the problem of maximizing the expected utility under the constraint (1) exists, it is the same as the optimal solution to the equivalent certain problem:

$$\begin{cases} \text{Max } u(x,y) \\ y = g(x) \end{cases}$$

This result is extended not only to the multi-period problem but also to the case where the decision-maker receives more and more information as time elapses. The resulting stochastic problem is then more involved, but it is simply solved by use of dynamic programming, the optimal strategy in period t being a function of the previously observed signals η_{t-k}

$$X_t^* = x_t^*(\eta_1, \eta_2, ..., \eta_{t-1})$$

Again, the conditions for the first period solution to this problem to be the solution of the equivalent certain problem are very strong. As before, it has to be the case that the objective function is quadratic, but in addition the constraint relating instruments to results is restricted to be of the following type:

$$y = RX + S$$

where R is a matrix with some required specifications (namely, the value of the instrument variables of one period have no effect on the result variables of the preceding periods).

The conditions that guarantee the equivalence between the uncertainty problem and the certainty problem are so restrictive, that an alternative view of the problem has been suggested. Instead of setting restrictions on the parameters of the model, the uncertainty itself is restricted to be 'small'. Formally, this is equivalent to consider an entire class of problems that can be ranked in their uncertainty as measured by a parameter ε and whose limit is the certain problem. The question is then to know under what conditions the solution to the limit of the random problems, that is equal to the one of the certain problem, is independent of ε to the first order, so that

$$\frac{dE\left[x_t^*(\eta_1, ..., \eta_t)\varepsilon\right]}{d\varepsilon} = 0 \qquad \text{for } \varepsilon = 0.$$

This slightly different point of view is called the 'first order certainty equivalence' problem and has been dealt with by Theil (1957) and Malinvaud(1969).

The very general conditions obtained by Malinvaud for the first order certainty equivalent to hold are (i) that the objective function is twice differentiable and (ii) that the optimal strategy is continuous with respect to the degree of uncertainty. If this condition holds, the optimal values of the instruments at time 1 are, to the first order approximation, independent of the degree of uncertainty.

It is clear that this condition cannot be met if there are constraints on the future instrument variables, since this will bring in a kink. A particular and natural example of a framework where the first order certainty equivalence does not hold is when decisions are irreversible. As pointed out in Henry (1974), it is then the case that the value of the decision in the first period will affect the decision set in the following periods, and consequently, the use of the certainty equivalent would generate a systematic error.

CES Production Function

Ryuzo Sato

Abstract

The CES (constant elasticity of substitution) production function, including its special case the Cobb–Douglas form, is perhaps the most frequently employed function in modern economic analysis. Not only is the CES function used for the formal depiction of production technology, it is used as a convenient tool for empirical analysis as well. In addition to production theory, the CES function, more commonly known as the Bergson family of utility functions, is employed in utility theory.

Keywords

Bergson family of utility functions; CES production function; Cobb–Douglas functions; Elasticity of substitution; Jensen inequalities

The CES (constant elasticity of substitution) production function, including its special case the Cobb–Douglas form, is perhaps the most frequently employed function in modern economic analysis. Not only is the CES function used for the formal depiction of production technology, it is used as a convenient tool for empirical analysis as well. In addition to production theory, the CES function, more commonly known as the Bergson family of utility functions, is employed in utility theory.

Ordinary CES Production Functions

The simplest form of CES function utilized in production theory is the constant returns to scale type (Arrow et al. 1961):

$$Y = T[\alpha K^{-\rho} + (1-\alpha)L^{-\rho}]^{-(1/\rho)} \qquad (1)$$

where $Y =$ output, $K =$ capital, $L =$ labour, and the parameters T, α and ρ satisfy the conditions: $T \geq 0$, $0 \leq \alpha \leq 1$ and $\rho \leq -1$. As is implied by its name, the elasticity of factor substitution between capital and labour for production function (1) is expressed as some constant value.

For any neoclassical production function, $Y = f(K, L)$, the elasticity of factor substitution between capital and labour is defined as the proportionate change in the K/L ratio (k) relative to the proportionate change in the marginal rate of factor substitution $r = f_L/f_k$ along a given isoquant curve, where $f_L = \partial Y/\partial L$ and $f_K = \partial Y/\partial K$ are the respective marginal products. That is,

$$\sigma = \frac{\mathrm{d}\log k}{\mathrm{d}\log r} = \frac{f_k f_L (f_k K + f_L L)}{KL\left(2f_{KL}f_K f_L - f_K^2 f_{LL} - f_k^2 f_{KK}\right)}, \qquad (2)$$

where σ represents the elasticity of substitution and f_{KL}, f_{KK} and represent the cross and own derivatives of the respective marginal products.

Applying definition (2) to production function (1) we obtain:

$$\sigma = \frac{1}{1+\rho} \quad \text{or} \quad \rho = \frac{1-\sigma}{\sigma}. \qquad (3)$$

Consequently, it is easy to see why ρ is often referred to as the 'substitution' parameter. The α parameter in production function (1) is the 'distribution' parameter that permits the relative importance of capital and labour to vary in production. In the extreme case where $\rho \to 0$ or $\sigma = 1$ the CES function (1) converges to the Cobb–Douglas form:

$$Y = TK^{\alpha}L^{1-\alpha}. \qquad (4)$$

In this form, it is evident that α and $1-\alpha$ are the production elasticities of capital and labour respectively. Under conditions of perfect competition, α and $1-\alpha$ will also equal the respective relative income shares (or income distribution). The T parameter in both production functions (1) and (4) is the 'efficiency' (or technical progress) parameter.

With the exception of its special case the Cobb–Douglas form, the ordinary CES production function is cumbersome and difficult to manipulate. However, the underlying expression for the marginal rate of factor (technical) substitution has a simple form and this is the primary reason for the popularity and wide use of this production function.

Homothetic and Non-homothetic CES Production Functions

Any monotonic transformation of the ordinary CES production functions (1) belongs to a class of CES production functions called the homothetic class, that is,

$$Y = F(f), F' > 0,$$

where

$$f = T[\beta K^{-\rho} + (1-\beta)L^{-\rho}]^{-(1/\rho)}. \tag{5}$$

In addition to the class of homothetic CES production functions, there is a more general, and perhaps more meaningful, class of non-homothetic CES production functions. One can refer to the class of non-homothetic CES functions as the 'general class' of CES production functions as it contains the homothetic class as a special case.

The class of non-homothetic CES production functions is derived as a solution to the differential equation that defines a constant elasticity of factor substitution. However, unlike the case of the homothetic CES production functions where the marginal rate of factor substitution is (implicitly) assumed to be independent of either the output level and the process of technical change, the family of non-homothetic CES production functions explicitly assumes that output level and technical change will have some kind of impact on the factor input ratio.

The class of non-homothetic CES production functions can be expressed as follows (Sato 1975):

$$C_1(Y)K^{-\rho} + C_2(Y)L^{-\rho} = 1, \quad \rho = \frac{1-\sigma}{\sigma}, \sigma \neq 1, \tag{6a}$$

$$C_1(Y)\log K + C_2(Y)\log L = 1, \sigma = 1, \tag{6b}$$

where C_1 and C_2 are functions of the output level Y. When $C_1 = aC_2$, where a is a constant, we can express (6a) as

$$K^{-\rho} + aL^{-\rho} = \frac{1}{C_1(Y)} = B(Y)$$

or

$$Y = B^{-1}(K^{-\rho} + aL^{-\rho}).$$

Note that with the appropriate choice of B and a, we can always express the above in the form of the ordinary CES production function. In general, the non-homothetic CES production functions are in an implicit form and can never be expressed in an explicit form.

Classification of Non-homothetic CES Production Functions

The general class of non-homothetic CES production functions can be classified in a number of ways, depending on the specific purpose in mind. For example, it is well known that the ordinary CES production function belongs to the explicit and separable class of homothetic CES functions. In a similar fashion, we can derive an explicit and separable class of non-homothetic CES functions (Sato 1974). Another way of

classifying non-homothetic CES production functions is to consider the form of the underlying marginal rate of factor substitution function. However, the most precise way of classifying the family of non-homothetic CES production functions is to utilize Lie group theory.

A Historical Note

It was Arrow et al. (1961) who first utilized the ordinary CES production function expressed in (1) for the estimation of constant returns to scale aggregate production functions using cross-country data. Since then, the ordinary CES function and its variants have been widely applied in both theoretical and empirical work involving production behaviour.

Prior to its application to production analysis, the ordinary CES function, was utilized in the study of demand as the Bergson family of utility functions (Samuelson 1965). Earlier writers in growth economics, such as Dickinson (1955) and Solow (1956), used special cases of the CES function, such as $\sigma = 2$. In the field of mathematics, Courant (1959, vol. 1, pp. 557, 601) has used the explicit form of the ordinary CES function in conjunction with the so-called Jensen inequalities.

A published note by McElroy (1967) contains the first reference to the non- homothetic CES production family. However, it was not until later that Sato (1974) derived an explicit form of the non-homothetic CES production function. The application of Lie group theory to CES production functions was first presented in 1975. This work demonstrated that the 'projective' type of technical change with eight essential parameters can be used most effectively to classify the general non- homothetic CES family of production functions. This work is summarized in Sato (1981, ch. 5).

B4

The Latin phrase 'ceteris paribus', which translates as 'other things the same', is much invoked by economists. Its popularity stems from its prominent use by Alfred Marshall (1920, pp. xiv–xv, 366–70), who invented the metaphor of 'the pound called Coeteris Paribus' – pound being used here in the same sense as in impoundment – in which are imprisoned 'those disturbing causes, whose wanderings happen to be inconvenient' (Marshall 1920, p. 366).

The term 'ceteris paribus' has no clearly settled technical meaning among economists, so that an attempt to chronicle its usage would be both difficult and unrewarding. Instead, it seems preferable to distinguish the most important alternative ways in which the phrase might be employed, alluding only briefly to the pertinent literature. It is important to distinguish at the outset three broad ways in which the phrase might be used. These are:

- As a reminder that any practicable theory must take for granted the stability and continuance of certain background circumstances;
- As a warning, when using a theory predictively, that certain variations in circumstances admitted by the theory have been assumed not to occur;
- As an instruction to hold hypothetically constant some members of a set of *necessarily* covarying variables while changes in the others are contemplated.

For example, an analysis of the movement of a group of adjacent cooling towers during gales might (i) abstract from earthquakes, or (ii) hold constant ambient temperature while considering the effects of varying wind speed, or (iii) analyse the swaying of one tower in a high wind on the assumption that the other towers are perfectly rigid, even though they too must actually sway in a way that subtly alters the wind currents buffeting the first tower. In the language of econometric models, these three usages of 'ceteris paribus' can be characterized as (i) a reminder that the model's structure is assumed not to change, or (ii) a warning that certain *exogenous* variables are presumed to remain constant when others change, or (iii) an instruction to hold constant certain *endogenous* variables while varying others, even though this is not justified by any separability properties of the model's structure.

The first two usages pose no difficulties. In each, the invocation of ceteris paribus merely serves as a reminder that a more comprehensive or elaborate analysis might have been attempted. The risk of earthquakes could have been incorporated into the analysis of cooling-tower stability at the price of added complexity. But a failure to do so is without methodological significance. The incidence of earthquakes is unlikely to be affected by any movement of the towers, so that the exclusion merely singles out a convenient stopping place on the inevitable trade-off between comprehensiveness and complexity. Analogously, in predicting with an econometric model it would be possible to make careful predictions of the changes in all exogenous variables that accompany a tax cut. But a failure to do so involves no logical inconsistency, and the resulting ceteris-paribus prediction of the tax cut's effects will still have substantive interest.

It is the third usage alone, with its implied logical inconsistency, which poses distinct difficulties of interpretation and methodological justification. To start with, the assertion that certain variables are mutually interdependent presumes knowledge, at least in principle, of a correct comprehensive theory in which these variables are endogenous. For economists, the requisite background theory has usually been that of Walrasian competitive general equilibrium. In such a context, the invocation of ceteris paribus in its third sense to freeze hypothetically certain endogenous variables (or, more generally, to treat them as if exogenous) can itself be given at least three alternative rationalizations.

Partial Equilibrium Analysis as an Approximation

The focus here is on the demand-supply interactions in one market or a few closely interrelated markets as exogenous shifts occur, prices in all other markets being treated as hypothetically constant (or perhaps in some cases varied exogenously). Such a procedure is inconsistent with the supposed background general-equilibrium theory which implies that all prices vary interdependently. But it may give an adequate *approximate* representation of the particular markets being examined (see Viner 1953, p. 199). This is more likely the weaker and more diffuse are connections to, and feedbacks from, markets outside the examined set. Smallness relative to the

entire economy is usually helpful in this regard, but such questions have received surprisingly little detailed analysis.

Approach by Successive Approximation

Here the use of ceteris paribus restrictions is viewed as a necessary transitional step towards the evolution or understanding of a fully-comprehensive general-equilibrium theory. The limitations of human comprehension, its need to understand and test only one link of a complete chain at a time, calls for a piecemeal step-by-step progression from the crude but simple to the sophisticated but more complex, even though such a proceeding would appear illogical to an all-comprehending Cartesian intelligence. It should, however, be observed that this progression could well take place by starting with a highly aggregated general equilibrium model and successively reducing the degree of aggregation, instead of by starting with a simple partial-equilibrium model and gradually expanding its coverage until general equilibrium is reached – as is Marshall's clearly stated strategy (Marshall 1920, pp. xiv–xv).

Illuminating Thought Experiment

Conceptual experiments which hold constant certain endogenous variables, or vary them arbitrarily, may perform a valuable heuristic role in aiding comprehension of the attainment and character of general equilibrium, even though they are not part of the theory's logical structure. Thus, the construction of Walrasian market excess demand functions, by the mental experiment of facing each individual with the same arbitrary price vector and then aggregating, is heuristically valuable despite the fact that all market excess demands must be zero in equilibrium. In part this heuristic value comes from pertinence to the disequilibrium meta theory in which any equilibrium theory must be embedded, a meta theory which might be visualized only vaguely and informally. Mental experiments of this type have been termed 'individual' or 'ceteris paribus' experiments by Patinkin, who contrasts them with 'market' or 'mutatis mutandis' experiments in which endogenous variables are always constrained to satisfy the requirements of the underlying general equilibrium structure (Patinkin 1965, pp. 11–12).

These three different ways of invoking ceteris paribus to freeze or 'exogenize' some endogenous variables may be contrasted briefly by saying that the first views partial-equilibrium theory as sometimes preferable to general-equilibrium theory, the second regards partial-equilibrium theory as an interim step towards general-equilibrium theory, and the third interprets ceteris-paribus experiments as heuristic aids sustaining general-equilibrium theory.

The partial-equilibrium approach is closely associated with Marshall, who popularized its use, although Cournot (1838) among others had employed it previously. But Marshall's *methodological* discussion of the use of ceteris paribus restrictions arose in the narrower context of his time-period analysis, which is conducted within a framework already partial-equilibrium in character (Marshall 1920, pp. 366–80). Considering a single industry (his example is fishing), he imprisons in the pound of ceteris paribus those variables, exogenous or endogenous, whose movement is very rapid or very slow compared with those whose equilibrium and comparative-static properties he wishes to explore. The aim is to gain rough insight into likely time paths, given that explicit dynamic analysis is not feasible (see Viner 1953, p. 206).

The use, other than for frank approximations, of ceteris paribus assumptions which conflict with underlying general-equilibrium requirements (that is, the use of individual rather than market experiments) has been attacked as illogical or misleading by Friedman (1949) and Bailey (1954) in the context of demand functions, and by Buchanan (1958) more generally. A judicious assessment and summing up is provided by Yeager (1960).

Applications of ceteris paribus ideas to growth paths rather than stationary equilibria have been pioneered by Fisher and Ando (1962).

In closing, mention might be made of the classical notion of 'disturbing causes' as set out by J.S. Mill (1844, Essay V). Any deductive theorist

who regards his assumptions as true, rather than mere means for generating refutable statements, must view his (valid) deductions as also true in the absence of disturbing causes not allowed for in his assumptions (see Keynes 1891, pp. 204–13). Are such disturbing causes to be viewed as ruled out by a ceteris paribus assumption? According to Mill, they are in the statement of general economic theory (when, for example, other motives than the pursuit of wealth are excluded) but not in its specific applications, when due allowance must be made *ex ante* for all likely disturbing causes. Thus, the ruling out of disturbing causes is meant as nothing but a device to permit statement and development of a common theoretical skeleton which must be fleshed out whenever specific use is made of it.

Ceva, Giovanni (1647/48–1734)

Giancarlo Gandolfo

Keywords
Ceva, G.; Gresham's Law; Mathematical economics; Quantity theory of money

JEL Classifications
B31

Mathematician, hydraulic engineer and mathematical economist, Ceva was born in Milan in 1647 or 1648 and died in Mantua in 1734. He studied at the University of Pisa; later he obtained a post at Gonzaga's court in Mantua, where he became the chief technician and applied his mathematical skill to technical and administrative problems.

As a mathematician he is known for the theorem (1678) concerning the concurrency of the transverse lines from the vertices of a triangle, which is named after him; his work on fluvial hydraulics is summed up in *Opus hydrostaticum* (1728). His studies in economics are contained in a work of 1711, where he studied monetary problems. Here we find a statement of the quantity theory of money: *ceteris paribus*, the value of money varies inversely with its quantity and directly with the number of people. The latter assertion may seem odd, but it is not if we interpret 'number of people' as a proxy for the transaction variable in the quantity theory equation (as is implicit in Ceva's Postulate II). We also find an independent statement of Gresham's Law and a study of the problems of a plurimetallic standard.

The interest of this work, however, does not lie in its economics, where no objectively new contributions are made, but in its methodological content and message. Ceva was the first to conceive, to state lucidly and to apply unhesitatingly the idea of *systematically* employing the mathematical method in economics as an indispensable tool with which to reason rigorously, to understand difficult and otherwise obscure phenomena

and to put them in order. His analytico-deductive treatment, which proceeds by definitions, postulates, remarks, propositions, theorems and corollaries, is indeed the first example of mathematical economics as we now understand it.

Chadwick, Edwin (1800–1890)

P. S. Atiyah

Public administrator and social reformer, Sir Edwin Chadwick was born at Longsight, near Manchester, on 24 January 1800 and died at East Sheen, Surrey, on 6 July 1890. He was trained as a lawyer and qualified for the bar in 1830. His early radicalism led him into contact with the utilitarians and the reforming political economists who drew their inspiration from Ricardo. He acted as Bentham's secretary and assistant for the last two years of his life. He was also a friend of the economist Nassau Senior, and he and Senior were largely responsible for the Report which led to the complete restructuring of the Poor Law in 1834, along lines which the economists had been urging for years. For the next twenty years Chadwick was employed in a variety of public administrative positions, becoming best known for his *Report on the Sanitary Condition of the Labouring Population* (1842) which laid the foundations for modern urbanized sewerage and public health measures throughout the country, and even the world. But he was a difficult man to deal with and was eventually pensioned off by the government in 1854. He wrote a large number of pamphlets, as well as being responsible wholly or partly for many important government reports (Finer 1952).

Chadwick's principal claim to fame lies in the way in which he applied his knowledge of, and passionate commitment to, utilitarian and economic analysis to many social problems of the first half of the 19th century, but only after a minute empirical investigation of the nature of the problems. Much of his work (such as the Poor Law Report) shows the influence of the orthodox economic analysis of the times, but in some respects Chadwick was years ahead of his time. In particular, there are signs of some grasp of the problem of externalities in connection with industrial accidents costs. Chadwick wanted to throw the costs of industrial accidents incurred in the construction of the railways onto the railway companies themselves. He was struck by the heavy social costs imposed by these accidents which were not borne by the railway companies, nor by the actual construction companies, and he argued that the solution to this problem was to internalize these costs to the railway companies themselves (Lewis 1950). But it was fifty years

before workers' compensation legislation was introduced in Britain, and over a hundred before some theoretical justification was offered in economic terms for this legislation.

Chalmers was born in Anstruther, Fife, and died in Edinburgh. Though he was strongly attracted to mathematics and physics in his youth, he is famous as a theologian and economist and as an active worker in the field of poor relief. Appointed to a parish in 1803, he later moved to Glasgow, where he began a famous and influential experiment in the administration of poor relief through dividing up the large parish of St John into small units and relying on a large number of voluntary helpers. He left Glasgow to become Professor of Moral Philosophy at St Andrews in 1823; in 1828 he became Professor of Divinity at Edinburgh and in 1843 he was centrally involved in the famous ecclesiastical divisions which produced the Free Church.

Endorsing Malthus's theory of population, he argued fervently (and repetitively) that the answer to the problem lay in moral education which would, in turn, lead to moral restraint. He opposed the Poor Law: it stimulated population, and interfered with private charity, which, his Glasgow experience had convinced him, was more effective. His work on aggregate demand and gluts – he argued that there could be both overproduction and over-saving since aggregate demand could be diminished not increased in proportion to both production and saving – is generally regarded as following the work of Malthus; but the essence of the argument, in terms of his aggregate demand and employment-creating analysis of trade, is present in his 1808 pamphlet, and thus precedes Malthus's own concern with aggregate demand.

A major innovator in modern microeconomic theory, Chamberlin was born in La Conner, Washington, on 18 May 1899, and died in Cambridge, Massachusetts, on 16 July 1967. He received his Ph.D. from Harvard in 1927, became a full professor there in 1937, and occupied the David A. Wells chair from 1951 until his retirement in 1966. He edited the *Quarterly Journal of Economics* from 1948 to 1958.

Chamberlin's career exhibits a unity of professional purpose and thematic dedication over its more than 40-year length that is rare for modern theorists. Beginning with the start of his thesis research in 1925, its publication in 1933 as the seminal *Theory of Monopolistic Competition*, and continuing through eight editions, Chamberlin devoted his life to his vision of realistic market structures as mixtures of monopoly and competition.

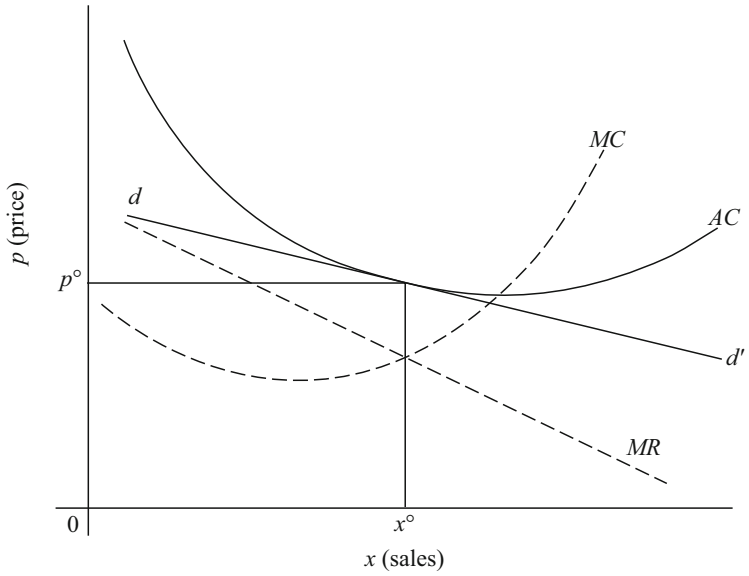
He opposed the alternative polar frameworks of pure competition and monopoly of the 1920s as unrealistic; proselytized for his merger of them at the level of the firm in both broad and narrow contexts; strove tirelessly (and rather stridently) to distinguished his concepts from Joan Robinson's similar constructs; and manned the academic ramparts in full echelon against all who sought either to criticize the concepts or, alternatively, take credit for their genesis.

In so doing, Chamberlin's broad contributions to microeconomic analysis were of fundamental and insufficiently acknowledged importance. His 'large group case' and revival of interest in oligopoly theory created the notion of market structure as a continuum between pure competition and monopoly with location dictated by numbers of firms and product differentiation. With his work he fathered modern industrial organization analysis by giving a theoretical core to what was previously institutional and anecdotal. He reoriented the interest of microeconomics from the industry to the firm, revealing the latter's target variables to include selling cost and product variation as well as price. And his frameworks led economists to comprehend the importance of differentiated oligopoly in developed economies through his emphasis upon product differentiation, his formalization of monopoly power as control over price, and his perception of the core feature of oligopolistic market structure as perceived mutual interdependence of decision making.

Monopolistic Competition Theory

In its generic sense, which Chamberlin stressed increasingly in his later career, monopolistically competitive market structures are those in which the firm feels the external compulsions of competitive forces tempered in varying degrees by a monopolistic power to price its product. Central to monopolistic competition in this wider sense is *product differentiation*, or the ability of the firm to distinguish its product in the preferences of consumers, where product is defined to include a complex of qualities in addition to those inherent in the physical good (for example, location, repair services, ambience and so on). The existence of differentiation (*a*) implies the possibility of *selling costs*, or costs aimed at adapting demand to the product (advertising, catalogues, discounts, and so on) as distinguished from *production costs*, or expenditures that adapt the product to demand, and (*b*) *product variation*, or the variability of the complex of qualities and attributes that characterize the firm's output in the mind of the consumer.

In his original presentation of monopolistic competition and into the 1940s, Chamberlin tended to identify it more narrowly with a specific market structure that isolated product differentiation as its distinctive component. This was the *large-group case* with the 'tangency solution' as the firm's long-run equilibrium position, as shown in Fig. 1. Each firm produces a slightly differentiated product which may be closely approximated by competing firms. Hence, a large number of close substitutes ensure that the firm's demand



Chamberlin, Edward Hastings (1899–1967), Fig. 1 The firm's optimal solution in the large-group case

curve is only slightly tilted from the pure competitor's horizontal position. If, for simplicity, all firms are assumed to have identical cost functions and to share sales equally (the *symmetry* assumption) then competition will reduce profit to zero by equating average cost and price at a tangency of the demand curve dd' and the average cost function *AC*. Where the tangency occurs marginal revenue *MR* will equal marginal cost *MC*. Hence, at price p° and sales x° each firm will be maximizing its profits at zero and neither entry into nor exit from the industry will occur: no internal or external force will exist to upset the long-run status quo.

Despite Chamberlin's later disclaimers, there is little doubt that the large-group case was featured as the novel contribution of his theory, and it became identified with monopolistic competition theory. But from the beginning, Chamberlin did identify a second species in the generic theory: monopolistic competition caused by fewness of sellers of a homogeneous product. In the preface to the first edition of the *Theory* he included oligopoly in the concept of monopolistic competition. Oligopoly – he coined the word independently but later recognized its prior usage in 1914 by Karl Schlesinger – in the pure (that is, undifferentiated product) case formed the mirror image of the large-group case, with small rather than large numbers of sellers and undifferentiated rather than differentiated products. Surprisingly, given the centrality of product differentiation in his thought, he had little to say about differentiated oligopoly as a composite of the two purer cases of monopolistic competition – as late as 1948 the sixth edition of the *Theory* devoted only five pages to informal discussion of it – although he realized increasingly in his later work the prominent position it held in realistic market structures.

Chamberlin's contributions to the theory of pure oligopoly were noted above in listing his broader impacts on the field. More narrowly, they were not great advances. He ignored formal treatment of collusion and tended to urge that tacit collusion would lead to joint profit maximization for pure oligopoly and to a price solution intermediate between joint profit maximization and the large-group case for differentiated oligopoly. In his later, more informal, treatment of oligopoly, however, he asserted a general tendency toward 'live-and-let-live' limitations on oligopolistic rivalry.

But from the 1950s on, Chamberlin moved away from the large-group case as the featured form of monopolistic competition theory and shifted emphasis to oligopoly in its differentiated form. In part this was an aspect of his continuing

desire to distance his theory from Joan Robinson's imperfect competition, in which she had independently developed the large-group case complete with tangency solution in the symmetry case. But, more importantly, the evolution of his thought reflected his increasing awareness that few market structures contained the uniform product competition implied by that solution. Rather, closer investigation of most realistic market structures with large numbers of sellers of slightly differentiated products revealed hierarchical clusters of oligopolistically competing firms. His book of essays (Chamberlin 1957) reveals clearly his attempt to prevent monopolistic competition theory from being too closely identified with the large-group case.

Another aspect of this later effort was the playing down of his pioneering use of marginal revenue and marginal cost curves. In denying P.W.S. Andrews's assertion that full cost pricing was antithetical to monopolistic competition, Chamberlin asserted that it was integral to that body of analysis from the beginning, since profit maximization was never an exclusive motivation of the firm – as it was in Robinson's imperfect competition.

Other Microeconomic Contributions

An implication of the large-group equilibrium illustrated in Fig. 1 is that firms would have long-run *excess capacity* in the sense that they would be operating at a production rate less than the rate associated with minimum average cost. This led to a dispute with Sir Roy Harrod, who seemed to believe that Chamberlin's results occurred because he was using short-run demand and cost curves in the large-group analysis. Harrod argued that businessmen would follow their long-run revenue and cost prospects and that excess capacity would not result. Chamberlin properly pointed out that his functions were long-run functions and that the long-run demand in Harrod's case did not attain the horizontality needed to eliminate excess capacity (Harrod 1952, Essays 7, 8; Chamberlin 1957, pp. 280–95; Kuenne 1967, pp. 67–70). Later, Chamberlin argued that excess capacity also occurred in an industry when entrants flooded in irrationally even when profits disappeared (whose counter-argument was probably what Harrod had in mind) (Chamberlin 1957, p. 290).

Chamberlin devoted a large portion of his writing to rationalizing the U-shaped average cost curve that was so fundamental to his market structures. Building upon the notion of the long-run average cost curve as the envelope of short-run average cost curves with fixed plants, he distinguished between using a fixed plant curve optimally in the short-run at its minimum-cost rate and producing a given rate of output optimally in the long-run by building an over-sized plant and using it at less than minimum cost capacity. Also, he denied that the rising portion of the long-run average cost curve was caused solely by management complexity or lumpy factors at higher output rates. In so doing, Chamberlin challenged the assertions of Knight (1921, pp. 98–9), Lerner (1944, pp. 165–7, 174–5), Stigler (1952, pp. 133, 202n.), and Kaldor (1934, p. 65n, 1935, p. 42) that, if all factors could be reduced to finely divisible units with (explicitly or implicitly assumed) constant efficiency, the average total cost would be constant as all product would be produced with optimal factor proportions. He argued that such factors would experience economies of scale as a function of factor-complex size owing to the ability to exploit specialization possibilities. These possibilities – $100 in capital might be concretized in ten shovels but $10,000 in capital might materialize as one back-hoe – permitted resource aggregates to become qualitatively different complexes with increased scale, rendering the notion of factor units with unchanged efficiency meaningless. The argument turns upon the semantics of constant efficiency units and the usefulness of the assumption, however, and was seen by most theorists to be non-illuminating and, as Chamberlin emphasized, tautological.

Two other contributions by Chamberlin are worthy of brief note. One was his destruction of Joan Robinson's notion of worker 'exploitation', because in non-purely competitive industries workers received marginal revenue product rather

than marginal value product. Chamberlin demonstrated conclusively that the difference between the two was not received by any other factor, including the entrepreneur, but was experienced as an external revenue constraint by the firm. The second, quite different, contribution was Chamberlin's role as a founder of modern experimental market research by his publication of the results of mock market operations with his students.

The Debate with Robinson

Chamberlin, like most microeconomic theorists of his generation, was thoroughly Marshallian in vision and methodology, and his innovations integrated neatly into the concerns of the post-Marshallian school. It was somewhat ironic, therefore, that Chamberlin found his major (and reluctant) opponent in Joan Robinson, as thoroughly Marshallian as himself. Chamberlin spent much of his professional life urging the fundamental divisions between his theory of monopolistic competition and Robinson's theory of imperfect competition.

The basis of the distinction changed fundamentally over his career. In the earlier objections, Chamberlin perceived correctly that Robinson's aim was to implement Sraffa's suggestion that microeconomic theory be rewritten in terms of a general theory of monopoly (Robinson 1933, p. v). In so doing, he urged, Robinson failed to achieve the true blending of monopoly and competition that his theory achieved. Robinson evolved the large-group case in every detail, but passed quickly over it in pressing on to her larger goal of creating a general theory of 'monopoly' in industries with more than one firm. To Chamberlin, who in this early period stressed the large-group case, her emphasis upon near-homogeneous commodities with some differentiation of sellers in the consumers' minds slighted the competition among differentiated products and resulted in an analysis of industry 'monopoly', very close to the one-firm monopoly of standard theory.

There was some truth in this, although Chamberlin was ungenerous to Robinson in interpreting her achievements, for in addition to her large-group case development she paralleled him in isolating selling costs and in defining two types of imperfect markets: (*a*) firms which were not alike in customers' preferences, and (*b*) oligopoly. But she saw the threat to the existence of the 'industry' that non-homogeneous products posed, and her overall goal needed that solid Marshallian construct. Chamberlin from the beginning was willing to abandon the concept and speak of 'product groups'.

However, as the large-group case came under criticism as incorporating too much of the purely competitive, and as oligopolistic structures received more attention in the literature, Chamberlin, as we have seen, shifted his ground and began to criticize Robinson for the opposite fault. The problem was, he now said, that imperfect competition failed to achieve the union of the competitive and the monopolistic because there was not enough monopoly content at the level of the firm. Implicitly, Robinson's large-group case was now focused upon for this fault, in comparison with his increasingly emphasized generic concepts that stressed oligopolistic elements.

The profession has ignored Chamberlin's strictures as distinctions without meaningful differences, and quite properly rewarded both theorists for their innovations. But the goals of the theorists were different, and, in most instances, Chamberlin's greater stress upon product differentiation and variation, selling cost and oligopoly proved to be more seminal in their professional impact.

JEL Classifications

B31

It was fortunate for the economics profession that the schoolboy Champernowne, a keen and able mathematician, was advised to read something in the school library to broaden his horizons: he chose Marshall's *Principles*.

David Champernowne was born on 9 July 1912 into an Oxford academic family. He was sent to school at Winchester and went from there as a scholar to King's College, Cambridge. While still an undergraduate he published his first paper (on 'normal numbers'). Early contact with Dennis Robertson confirmed his previous interest in economics, and he was advised by J.M. Keynes to abandon his thoughts of becoming an actuary and switch to the Economics Tripos by taking his Part II Mathematics in one year rather the normal two. He obtained firsts throughout in both subjects.

His academic career spanned the London School of Economics (1936–8) Oxford (1945–59), and Cambridge (1938–40 and 1959–78). During the war period he served with Lindemann as Assistant in the Prime Minister's Statistical Section (1940–1) and worked with Jewkes at the Ministry of Aircraft Production's Department of Statistics and Programming.

He proved to be a genuine pioneer both in economic theory and statistics. His King's fellowship dissertation (submitted in 1936, but published 27 years later in the *Economic Journal*) laid the foundations for the application of stochastic process models to the analysis of income distributions; this work has been of importance in recent economic research on fat-tailed distributions and scaling laws. His pre-war interest in Frank Ramsey's theory of probability led on to work at Oxford on the application of Bayesian analysis to autoregressive series (at a time when the Bayesian approach was decidedly unfashionable), and culminated in his major trilogy on *Uncertainty and Estimation* (1969). However although he is thought of today primarily as a theoretician, his flashes of technical insight were always been tempered with healthy doses of practical scepticism. This is evident in his early work with Beveridge on the regional and industrial distribution of employment and unemployment.

Champernowne acted as midwife to a number of major theoretical contributions over and above his own work. He provided an invaluable 'translation' to von Neumann's seminal paper on multi-sector growth. His role as behind-the-scenes expert at Cambridge over many theoretical issues is legendary: Joan Robinson acknowledged the assistance of his 'heavy artillery' in underpinning, and extending, her major work on capital and growth: A.C. Pigou's later writings on output and employment, Nicholas Kaldor's work on savings and economic growth models, and Dennis Robertson's *Principles* were all indebted to his intellectual influence.

He held Chairs at both Oxford and Cambridge, was director of the Oxford Institute of Statistics and was editor of the *Economic Journal*. He was elected Fellow of the British Academy in 1970.

Alfred D. Chandler Jr. (15 September 1918–9 May 2007), a Pulitzer Prize-winning historian who pioneered the field of business history, was born in Guyencourt, Delaware, near Wilmington. He received a bachelor of arts degree from Harvard College in 1940 and served in the US Navy from 1941 to 1945. In the late 1940s, Chandler returned to school to study history, attending the University of North Carolina before going back to Harvard to complete his Ph.D. in 1952. He published a revision of his dissertation as his first book, *Henry Varnum Poor: Business Editor, Analyst, and Reformer* (1956). Poor (1812–1905), Chandler's paternal greatgrandfather, was the long-time editor of the *American Railroad Journal* and *Poor's Manual of Railroads of the United States*. Chandler's book explained how Poor, through his detailed reports on individual railroad companies and their operations, helped to invent the role of the modern business analyst and investment advisor.

From 1950 to 1963, Chandler taught at the Massachusetts Institute of Technology, and then left to join the history department at Johns Hopkins, where he remained until 1970. While at Hopkins, he edited the papers of President Dwight D. Eisenhower. From 1970 to 1989, Chandler was a professor at Harvard Business School, where he held the Isidor Straus Chair in Business History. While there, Chandler inaugurated the course entitled 'The Coming of Managerial Capitalism:

The United States'. He encouraged other historians to come to the school, including his successors in the Straus Chair, Thomas K. McCraw and Geoffrey Jones, and he sponsored research fellowships for graduate students and international scholars to travel to the business school's Baker Library. From the 1970s onward, he lived in a building within walking distance of the campus, in a large 17th-floor apartment overlooking the Charles River and filled with artwork, including paintings by his wife, the former Fay Martin.

Chandler was the sole author of six books and co-author or editor of more than 30 others. His most famous works focused on the rise of big business and the coming of a managerial class: *Strategy and Structure: Chapters in the History of Industrial Enterprise* (1962); *The Visible Hand: The Managerial Revolution in American Business* (1977); and *Scale and Scope: The Dynamics of Industrial Capitalism* (1990). As many commentators acknowledged, these books were so original in their approach and so impressive in their depth of research that they set the agenda for the entire field of business history for many years afterward.

The first of these, *Strategy and Structure*, analysed DuPont, General Motors, Sears and Standard Oil, and showed how each of these four companies came to adopt a multidivisional structure, or M-form, by the 1920s. No previous historian had provided such a rich account of how big businesses actually worked, or described how middle managers confronted the complexities of daily business life, filled as it was with committee meetings, budget decisions and forecasts. 'Only by showing these executives as they handled what appeared to them to be unique problems and issues can the process of innovation and change be meaningfully presented,' Chandler wrote in 1962. His detailed investigations were the basis for his influential argument that a company's strategy must shape its structure, not the other way around, as was often the case.

In *The Visible Hand*, Chandler sought to explain the rise of big business in the United States in the decades from 1840 to 1920, and to answer the question why large firms arose in some industries and not in others. Chandler argued that in industries whose firms were able to benefit from economies of scale and scope, the 'visible hand' of management came to replace the 'invisible hand' of the market in coordinating the production and distribution of goods. This was to become his most famous book, winning not only the Pulitzer, but also the Bancroft Prize and the Thomas Newcomen Book Award.

In *Scale and Scope*, Chandler branched out into comparative international history, comparing his story of the ascendancy of capitalism in the United States, from the late 19th to the mid-20th century, with the histories of Britain and Germany. Success in steel, chemicals, automobiles and other industries that emerged during the second industrial revolution, Chandler argued, was achieved through making a three-pronged investment: in mass-production facilities, in international marketing and distribution networks, and in proper management of resource allocation. While Chandler praised German industry, which had developed strong capacities in research engineering, banking, and the production of producer goods, he believed that Britain's tradition of 'personal capitalism' had prevented that country from making progress in developing large-scale industries.

These three books attracted their share of admirers throughout the world, and 'Chandlerian' business history quickly became the focus of conferences and academic papers. In 1973, Derek F. Channon published *Strategy and Structure of British Enterprise*; this was followed three years later by Gareth P. Dyas and Heinz T. Thanheiser's *The Emerging European Enterprise: Strategy and Structure in French and German Industry*. The First Fuji conference, held in Japan in January 1974, was devoted to the 'Strategy and Structure of Big Business'. Chandler's work was also central to curricula at business history units formed at the London School of Economics (in the late 1970s), and in the decades afterward at such places as the universities of Glasgow, Leeds and Reading in the United Kingdom, Bocconi University in Italy, and the Copenhagen Business School in Denmark.

Chandler also received his share of criticism, in part because of his narrow focus on the rise of big business and his relative neglect of the roles of

politics, finance, and culture in explaining the growth of the American economy. Some, including Philip Scranton (1997) and Charles F. Sabel and Michael Piore (Pire and Sabel 1984), argued that Chandler downplayed the contribution of small and medium-sized firms and overlooked the ways in which the supplanting of independent artisans and flexible manufacturers by middle managers created problems for the American economy. Chandler's most controversial book was *Scale and Scope*. British writers, in particular, bristled at Chandler's view that the preponderance of family-owned firms in the United Kingdom had contributed to that country's relative decline. Barry Supple, writing in the *Economic History Review* (1991), argued that Chandler's assumption that the American model should be the 'standard against which to assess the structural characteristics and achievements of the business systems of other countries has some pitfalls' (p. 512).

But Chandler was not an apologist for American industry, nor was he wholly enamoured with business success. He objected to many trends that were taking place in American management practice in the 1960s, including the conglomerate movement. Late in his career, he wrote admiringly of the triumph of Japanese industry over US competitors in the electronics industries in the final third of the 20th century. In the 1990s, Chandler became fascinated with the question of why some industries failed and others rose in their place. He completed his final two books, both touching on these themes, while in his 80s: *Inventing the Electronic Century: The Epic Story of the Consumer Electronics and Computer Industries* (2001); and *Shaping the Industrial Century: The Remarkable Story of the Modern Chemical and Pharmaceutical Industries* (2005).

While most historians have focused on these core books, Chandler's other works should not be neglected. He co-wrote (with Stephen Salsbury) *Pierre S. du Pont and the Making of the Modern Corporation* (1971), a long and rich primarysource study that recounts Pierre's role in making DuPont the largest US chemical and explosives company and General Motors the world's biggest car manufacturer. Chandler also edited, or co-edited, many volumes, including, with Franco Amatori and Takashi Hikino, *Big Business and the Wealth of Nations* (1997); and with James W. Cortada, *A Nation Transformed by Information: How Information has Shaped the United States from Colonial Times to the Present* (2000). He published 60 articles, many of which are listed in the bibliography of Thomas K. McCraw's edited collection, *The Essential Alfred Chandler* (1988). One extremely insightful article, published in 1994 and hence not mentioned in McCraw's volume, is his 72-page international comparative study, published in *Business History Review*, 'The competitive performance of U.S. industrial enterprises since the Second World War.' Chandler was also the general editor of the scholarly monograph series Harvard Studies in Business History, published by Harvard University Press.

Throughout his career, Chandler's work attracted attention because he continued to ask and answer broad and challenging questions. In the 1950s and 1960s, he analysed the workings of firms, while most economists and historians at the time found them uninteresting. In the 1970s and 1980s, he turned his attention to international business and to comparative analysis. The influence of Chandler's work extended far beyond the discipline of history. He made vital contributions to organizational sociology, global business studies, and to the field of strategic management. Among his many honours he had the distinction of being listed as an eminent scholar by the Academy of International Business.

Chandler's significance to business history has been summarized in McCraw (1988) and in Richard John's 1997 essay "Elaborations, revisions, dissents:

Alfred D. Chandler, Jr.'s, The Visible Hand after twenty years." In 2008, a year after Chandler's death, both *Business History Review* and *Enterprise & Society* published reflections by prominent scholars on his legacy.

Changes in Tastes

M. S. McPherson

It is often analytically convenient to abstract from the phenomenon of changing tastes in explaining or evaluating economic phenomena. Alfred Marshall for example defended the assumption of given wants as a useful, if crude, starting point in developing utility theory. Since the 1930s, however, the assumption of given wants has hardened increasingly into dogma. A notable step in that direction was taken in 1932, when Lionel Robbins gave wide currency to the definition of economics as the study of the relations between ends and means, the ends taken as given (Robbins 1932, Chapter 2).

Nobody, of course, supposes that tastes for goods and services are literally biological givens (Stigler and Becker (1977) do deploy this claim, perhaps for its shock value, but it is natural to read them as saying that certain deep-lying wants, as for nourishment and self-esteem, are given and these deep-lying preferences interact with prices and incomes to explain changes in tastes for particular goods and services.)

The more common view is that it is efficient to divide the intellectual labour between economists who study the consequences of given tastes and sociologists, psychologists and others who explain formation of and changes in tastes. Yet on the whole, economists (with a few notable exceptions like Scitovsky (1976)) have shown little interest in what psychologists and others have had to say about preference formation and change. At a minimum, there would seem to be a need for interdisciplinary collaboration on problems, such as long run economic development or cross-national comparisons in consumption patterns, where both causes and consequences of tastes are likely to be important (see, e.g. Felix 1979). If the causes of the taste changes are non-economic, the economists on such teams might usefully concentrate on analysing their consequences.

Sometimes, however, the division of labour will not be so neat. First, tastes may change because of changes in economic variables, making tastes *endogenous* to the economic system. The alleged influence of advertising on tastes is a standard example; another is the claim that the extension of market production into traditional societies affects tastes for material consumption relative to communal 'leisure' activities (Galbraith 1958; Hefner 1983). When such interactions are empirically important, adequate economic models need to include them.

Second, when a consumer's tastes differ at different points in time, problems of temporal inconsistency in preferences and of intrapersonal preference conflict arise. A consumer who expects to have different preferences in the future faces a planning problem between his present and future self somewhat analogous to that involved in allocating resources between two consumers with different tastes. The challenge of extending the theory of rational intertemporal choice to cover such cases – with the consumer making plans he or she will actually carry out and will not regret – is considerable (Hammond 1976). Further problems arise when preferences change rhythmically or recurrently (Winston 1980). A consumer who is periodically assailed by an impulse to spend or to overeat may take steps in advance to control the consequences of those impulses, burning credit cards or locking the refrigerator. Thomas Schelling has given the label *egonomics* to the study of such strategic attempts to reconcile intrapersonal preference conflicts (Schelling 1978, 1980; Elster 1979, 1985).

The taste changes discussed so far may simply 'happen' to consumers, without their active participation or indeed sometimes without their knowledge. A further degree of complexity is introduced when it is recognized that consumers may have preferences regarding what their tastes should be. A consumer may, for example, prefer that she lose the taste for smoking, say, or acquire a taste for jogging. An adequate economic theory of consumer choice should include such second-order preferences or *meta-preferences* (Frankfurt 1971; Sen 1977). Such an extension is necessary, most simply, in order to explain the non-trivial expenditures that consumers in advanced societies make on deliberately changing their own tastes – for example, through music-appreciation classes, weight-control clinics, and SmokEnders. More broadly, tension between consumers' everyday expenditure patterns and their larger views about how they should live – what one might call their *values* rather than mere preferences (Hirschman 1985) – plays a role in explaining various features of human experience, including ambivalence, ideological commitment and the capacity for self-discipline and self-criticism. These features of behaviour will not always matter for economics, but sometimes they will. Savings behaviour and workplace relations (where willingness to identify with the organization's goals is an important variable) are obvious applications; Albert Hirschman (1982) has argued that the explanation of fluctuations in the 'taste' for political involvement relies heavily on the formation and revision of ideological metapreferences towards politics.

The fact that preferences can change raises issues for the normative as well as the explanatory dimensions of economics. One set of questions involves the role social policy should play in resolving questions of intrapersonal conflict among preferences. Society can provide support for self-control devices, for example by allowing people to enter contracts that bind their future behaviour (such as agreeing to be confined to an alcohol treatment facility). This would then involve overruling the person's future demands to be released. It is difficult to know from what standpoint to judge the effects of a decision either way on the person's welfare or liberty (Schelling 1984). Social policy can also undermine self-control, as state-run lotteries show.

Severe difficulties also arise if economic institutions or policies can change preferences. To evaluate such policies or institutions in terms of either the preferences ex ante or ex post (unless the two happen to agree) seems arbitrary. But to decide which set of preferences is itself 'objectively' better seems to most contemporary economists just as arbitrary, as well as threatening to liberty. (Many earlier economists, including notably Marshall and J.S. Mill, were much more willing to make and defend value judgements about desirable preferences). An appeal to meta-preferences may help – basing judgement on what preferences people themselves prefer. But of course meta-preferences may themselves depend on economic institutions and policies, so this solution doesn't go very deep.

From a normative standpoint, both kinds of problems – those of preference conflict and of endogenous preferences – suggest the need to move away from the strictly 'want-regarding' moral systems that underlie most neoclassical welfare economics. Such moral systems, labelled

'welfarist' by Sen (1979), exclude as morally irrelevant all information about a society except the degree to which individuals' preferences are satisfied. Other information enters the analysis only insofar as it affects the amount of preference satisfaction achieved. (Utilitarianism and Paretian welfare economics are the most important examples of welfarist moral systems.)

Relaxing the welfarist constraint admits several kinds of information that may help with 'preference change' problems. First, procedural issues about how preferences are formed may be recognized as morally important. Processes of preference formation or change that rely on misrepresentation or distortion of facts, or on emotional manipulation, may be morally downgraded irrespective of any judgement about the worth of the preferences that result (McPherson 1982, 1983). Second, measures of individual well-being may be constructed that depend on the *resources* available to an individual or on the *capabilities* he or she can exercise, rather than (only) on the amount of preference satisfaction attained (Sen 1982; Rawls 1982). This may partly free evaluations of states of affairs from dependence on existing preferences. Finally, a society can use its public deliberative processes to come to agreement on the objective value of promoting (say, through education) certain preferences or common values (Scanlon 1975). Such agreement need not presuppose that those same preferences would be valuable in other societies or times, and procedural protections could be applied to the means by which these values are promoted.

All the problems discussed in this essay – the dependence of preferences on institutions and policies, the presence of conflicting desires within the person, and the human capacity to evaluate one's own preferences – were well known to Plato and Aristotle, and were recognized by them as central issues for social theory. That the problems have remained central and largely unresolved for 25 hundred years no doubt makes some economists think it wise to define them out of the discipline, at whatever cost in realism and relevance. Others, however, welcome the resurgence of interest in problems of changing tastes as an opportunity to reestablish links with the other social sciences and with political philosophy.

Chaotic Dynamics in Economics

Jess Benhabib

Abstract

A new literature in the 1980s studied the possibility that endogenous cycles and irregular chaotic dynamics resembling stochastic fluctuations could be generated by deterministic, equilibrium models of the economy, in particular in overlapping generations models and in models with infinitely lived representative agents. Other empirical studies attempted to identify whether various economic time series were generated by deterministic chaotic dynamics or stochastic fluctuations. While dynamic equilibrium models calibrated to standard parameter values can generate chaotic dynamics and endogenous cycles even under intertemporal arbitrage and without market frictions, definitive empirical evidence for chaos in economics has not yet been produced.

When a new literature in the 1980s showed that endogenous cycles and chaos can arise in equilibrium models in economics, it came as a surprise. The possibility of deterministic fluctuations, as opposed to fluctuations driven by exogenous stochastic shocks, had been noted in an earlier literature on business cycles, for example in the well-known multiplier-accelerator models, but not in equilibrium models of the economy with complete markets and no frictions (see for example Frisch 1933, or Samuelson,1939). Yet deterministic fluctuations in equilibrium models with predictable relative price changes should be ruled out by intertemporal arbitrage. Such considerations led to the rejection of regular endogenous cycles in favour of models whose fluctuations are driven by stochastic shocks.

The new literature on chaotic dynamics showed that deterministic cycles and chaos were indeed possible under complete intertemporal arbitrage and without any market frictions, both in standard models of overlapping generations and in calibrated models of infinitely lived representative agents (see for example Benhabib and Day 1980, 1982; Benhabib and Nishimura 1979; Grandmont 1985; and Boldrin and Montrucchio 1986). Of course, relative price fluctuations in such models had to be within the bounds allowed by the discount factor in order to be compatible with intertemporal arbitrage. (For an exploration of the relation between equilibrium cycles, chaos and discount rates in models with infinitely lived agents, see Benhabib and Rustichini 1990; Sorger 1992; Mitra 1996; and Nishimura and Yano 1996.) Furthermore, chaotic dynamics could exhibit not only deterministic endogenous cycles, but generate trajectories that are irregular, and that are statistically indistinguishable from stable linear stochastic AR1 processes (see Sakai and Tokumaru 1980).

We can usually describe a dynamical system in discrete time as chaotic if it can generate cycles of every periodicity, where a sequence $\{x_j\}$ is of period n if $x_j = x_{j+n}$ but $x_j \neq x_i$, for $j < i < n -$

1. In addition, this simple definition of chaos requires the existence of an uncountable number of initial x which give rise to bounded but aperiodic (not even asymptotically) sequences. For example the well-known hump-shaped function, $4x(1 - x)$, when iterated, generates such chaotic dynamics. The kind of chaotic dynamics described above is usually referred to as 'topological chaos'. If in addition we require that the set of initial conditions giving rise to aperiodic sequences are not simply uncountable but also have a positive (Lebesgue) measure, then we also have ergodic chaos. A useful sufficient condition to obtain topological chaos with a simple difference equation $x_{t+1} = f(x_t)$, with f continuous and mapping a closed interval into itself, is the existence of some x such that $f(f(f(x))) \leq x < f(x) < f(f(x))$. (See Li and Yorke 1975; for simple sufficient conditions for chaos in higher dimensions, see Diamond 1976, or Marotto 2005.) Note that this condition will be satisfied if the difference equation has a solution of period three. A particularly interesting feature of some dynamic systems that are chaotic is their sensitive dependence on initial conditions: initial conditions that are arbitrarily close can generate sequences that tend to diverge over time. Thus, small measurement errors in initial conditions may cause large forecasting errors, which may explain some of the difficulties associated with business-cycle forecasting.

The aperiodic but bounded trajectories that characterize chaos and exhibit sensitive dependence on initial conditions cannot continue to diverge for ever. They converge not to a point or a periodic cycle but to a bounded chaotic or 'strange' attractor. The dynamical system which induces the local separation and instability of the trajectories must eventually bend them back. The combination of local stretching and global folding generates the complex nature of the dynamics. Such dynamic behaviour is in fact a familiar theme in economics that highlights the self-correcting nature of the economic system. Shortages create incentives for increased supply; dire necessities give rise to inventions as the invisible hand guides the allocation of resources. An equally familiar theme is that of instability: the multiplier interacts with the accelerator, leading to explosive or implosive investment expenditures; self-fulfilling expectations give rise to bubbles and crashes. In combination, these two themes suggest a nonlinear system, somewhat unstable at the core, but effectively contained further out. The contribution of the new literature on chaotic dynamics starting in the early 1980s has been to demonstrate the compatibility of endogenous irregular fluctuations with equilibrium dynamics in economics.

For a very simple example of chaotic dynamics, consider a simple overlapping generations model where each generation lives two periods. The utility function of a generation born at t is $U(c_0(t), c_1(t + 1))$, where $c_0(t)$ is consumption when young and $c_1(t + 1)$ is consumption when old. This generation faces a budget constraint $c_1(t + 1) = w_1 + r(t)(w_0 - c_0(t))$, where w_0 is the endowment when young, w_1 is the endowment when old, and $r(t)$ is the rate of return on savings. The first order condition to the problem of maximizing utility subject to the budget constraint, on the assumption of interiority, yields $r(t) = \frac{U_1(c_0(t), c_1(t+1))}{U_2(c_0(t), c_1(t+1))}$. Here U_1 and U_2 denote the derivatives of the utility function U with respect to the first and second arguments. During each period t, market clearing requires that the sum of the endowments of the young and the old add up to the sum of their consumptions: $w_1 + w_0 = c_1(t) + c_0(0)$. Now consider the quadratic utility function $U(c, (t), c, (t + 1)) = ac_0(t) - 0.5b(c_0(t))^2 + c_1(t)$, $0 \leq c_0 \leq a/b$, and $a, b > 0$. If we substitute the first order condition into the budget constraint, and use the market clearing condition, the difference equation describing the dynamics is given by $c_1(t + 1) = ac_0(t)(1 - (b/a)c_0(t))$. Note that $c_0(t) \in (0, a/b)$ for all $c_0(0) \in (0, a/b)$, provided $a \leq 4$. This difference equation will exhibit chaotic dynamics in c_0 for $a \in [3.53, 4]$; $b = a$. For example, if $a = 3.83$, the difference equation has a three-period cycle for $c_0(t) = 0.1561$, where $c_0(t + 1) = 0.5096$ and $c_0(t + 2) = 0.9579$. In this simple example utility saturates at $c_0 = a/b$, but the chaotic trajectories and those with a period greater than one never attain b/a, since if $c_0(t) = b/a$, $c(t + i) = 0$ for all $i = 1, 2, \ldots$ Another simple example of an exponential utility function

that will generate chaotic dynamics in this simple overlapping generations model, for $a > 2.692$ and $w_1 > e^{a-1}$,is $U(c,(t),c,(t+1)) = A - e^{a+w_0-c_0(t)} + c_1(t)$. (See Benhabib and Day 1982, s. 3.4.)

Techniques to empirically distinguish between data generated by non-chaotic stochastic systems and deterministic chaotic systems have been developed by physicists and mathematicians (see for example Eckmann and Ruelle 1985). These techniques have been further refined into statistical tests for applications to economic data by Brock (1986) and Brock et al. (1996), among others. Very roughly, these methods exploit the idea that deterministic systems will generate trajectories that are of lower dimension than those generated by stochastic systems, which have more scattered trajectories. For example, if we consider a one-dimensional difference equation that generates chaotic dynamics, say $x_{t+1} = 4x_t\,(1 - x_t)$ for initial $x_0 \in (0, 1)$, plotting x_{t+1} against x_t will yield a curve. By contrast, if the dynamics were generated by a linear or nonlinear stochastic system with noise, the same plot would produce a scatter of points, which could not be captured by a 'relatively smooth', one-dimensional line. By formalizing this idea, we may attempt to distinguish data generated by deterministic chaotic systems and by non-chaotic stochastic systems, even without explicit knowledge of the underlying economic system generating the data. In general, however, such a method is hard to apply because, unlike data generated by scientific experiments, economic time series are often not long enough. If the order of underlying dynamical system generating the data is high-dimensional, say of the order of five or higher, or alternatively if we can only observe the realizations of a subset of the variables of the underlying economic model, distinguishing between stochastically and chaotically generated data becomes very difficult. The difficulty of empirically identifying chaos in high dimensional economic systems may be particularly important if chaotic dynamics is more likely to be manifested in disaggregated sectoral or industry data whose components, because of resource constraints or other scarcities, can move in ways that partially offset one another's cyclic or irregular movements. It would therefore be fair to say that at this point, while we know that standard dynamic equilibrium models with parameters calibrated to values often used in the literature may well generate chaotic dynamics, more definitive empirical evidence for chaos in economics has not yet been produced.

While it may be instructive to set the theories of endogenous economic fluctuations in opposition to the theories of fluctuations driven by stochastic shocks, in practice it is more helpful to consider endogenously oscillatory dynamics as complementary to stochastic fluctuations. In certain environments it may make little difference if endogenous mechanisms by themselves generate regular and irregular persistent fluctuations, or whether they give rise to damped oscillations that are sustained by stochastic shocks. On the other hand, if the underlying equilibrium system is subject to distortions and there is room for stabilization policy, correctly identifying the source of the fluctuations becomes much more important. (See for example Benhabib et al. 2002). Furthermore, recognizing the role of oscillatory dynamics may diminish our reliance on unrealistically large shocks to explain economic data, for example, in real business cycle theory.

Characteristics

W. M. Gorman and G. D. Myles

If Eve had not insisted that 'an apple is an apple is an apple', Adam would probably have brought down the wrath of Jehovah himself by characterizing things, unsurprisingly, by their characteristics, thus bringing man-made order into chaos. There remains the problem: what characteristics? Here a little mathematics is useful. Suppose goods Y are sold only in bundles X, and that there are a_{ij} units of Y_j in X_i. The total quantity of it will be

$$y_j \sum_i a_{ij} x_i, \tag{1}$$

and the total value of a bundle X_i

$$p_i \sum_j a_{ij} q_j, \tag{2}$$

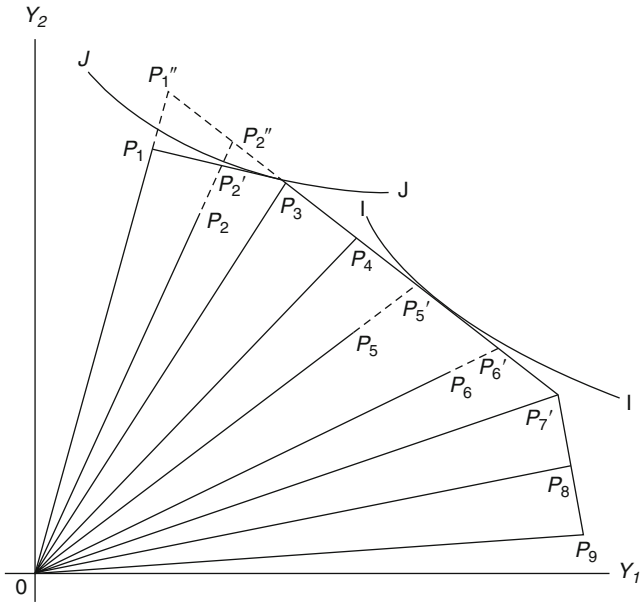
in an obvious notation, so that expenditure

$$\sum_i p_i x_i = \sum_{ij} a_{ij} q_i x_i = \sum_j q_j y_j, \tag{3}$$

for all q, x, and expenditure, m, is invariant, a fact brought to the attention of young economists at large by Samuelson when he published his *Foundations* just after the war. That immediately suggested that we might instead consider the X as goods, thought of as bundles of characteristics Y. Were we to try $y_j = f^j(x), p_i = g^i(q)$, instead of Eqs. 1 and 2, the notion that total expenditure should be invariant would yield $m = \sum g^i(q) x_i \equiv \sum q_j f^j(x)$, so that $\partial^2 m / \partial x_i \partial q_j = f^j_i(x) = g^i_j(q) = a_{ij}$ say, the subscripts denoting differentiation, and hence back to the linear characteristics model (Eqs. 1 and 2), which had already been used extensively, if implicitly, by Rowntree when studying working-class budgets in York before and after World War I, by Miss Schulz in her monthly 'human needs' budgets during World War II, by numerous nutritionists, and finally by Stigler, in a paper cited in Koopmans' Cowles Commission monograph on activity analysis in 1951 as a precursor of linear programming, a topic very fashionable among young economists at the time.

Why did demand analysts not immediately take up a model which was at once so obvious, so often used, and so in keeping with the spirit of the early Fifties? They realized, of course, that people do not eat what is good for them, so that $a_i = (a_{ij})$ each $_j$

Characteristics, Fig. 1



would have to be estimated, not taken from manuals of nutrition. Hotelling's Method of Principal Components, which had been introduced to econometricians at large by Stone in 1947, immediately suggested itself as a way of estimating them, or more precisely and relevantly, the space they span. The real problem was that the model, to be useful, would have to work with many fewer characteristics than goods to be characterized; that this seemed certain, *in practice*, to yield infinite price elasticities; and that at a time when econometric research was consistently turning up what then seemed dramatically low ones.

To see why, return to (Eq. 2). What are these mysterious q's? Nobody buys and sells raw characteristics. In fact the q's are the values which particular households put on the characteristics, and there is no reason why they should be the same for households with notably different tastes or incomes. What happens when there are two characteristics is illustrated in Fig. 1. $P_1,\ldots,P_9$ display the amounts of them available for a dollar spent on $X_1,\ldots,X_9$. One hundred times as much would be available for \$100, so that we can rescale the diagram to match the amounts particular households decide to spend on these goods as a group. Clearly nobody would buy X_2, X_5 or X_6 at these prices, so that p_5 will presumably fall to $P_5' = \left(0P_5/0P_5'\right)p_5$, for instance, at which price X_5 would be at least potentially competitive. Now consider a household whose indifference curve, appropriately scaled, is II. Its chosen bundle, y, of characteristics can be bought equally cheaply in many different ways, so that x_3, x_4, x_5, x_6 and x_7 are indeterminate. In particular it may or may not buy X_5. Should p_5 fall any further, however, it would buy a definite amount $x_5' > 0$, say, of it, while X_4 and X_6 would become uncompetitive from everybody's point of view. Hence the infinite elasticities, as we pass through *equilibrium points*.

Suppose Y_2 is a luxury. Then sufficiently rich households, like that represented by JJ, may value it sufficiently highly to *buy* X_1 and X_2, in the technical sense that it would actually buy either if its price were to fall at all. If there are too few of them to make these goods viable, their prices will have to fall for them to stay in production possibly until P_1'', P_2'', lie on P_7–P_3 extended, but possibly not. Equally, poor households may buy X_8 and X_9.

People who have never heard of a linear characteristics model often talk of the mass market, X_3–X_7, an up-market sector, X_1–X_3; and a down-market one, X_7–X_9. Even the idea of goods at the top and bottom end of the mass market, like X_3

and X_7, is quite common. That is mildly reassuring. They tend to speak of specialist markets, too, such as that for sports cars; these can easily be handled when there are more than two characteristics.

If we know the goods which fall into any one of these sectors we can fit a stochastic version of (Eq. 2) to them using, for instance, some variant of principal components analysis, given enough data. The key phrase here is 'given enough data'. Demand analysts have to deal with short inter- and autocorrelated series, subject to error, generated by the interactions between many agents, and have to be sure that the goods in question remain in the same sector throughout the period under analysis, or over the regions, for example. In practice, therefore, there have to be far fewer characteristics than goods in each sector they examine, and they commonly deal with goods bought by virtually everyone.

It is, we think, fairly generally accepted that such models are most appropriate for groups of closely related goods, to which the obvious alternative, additive separability, seems particularly badly adapted, though it has often been used by theorists interested in monopolistic competition. This is because they seem likely to differ in several ways, or, if you like, interact through several channels, which is impossible under additive separability; while the fact that they are often somewhat similar to each other suggests that linear approximations such as (Eqs. 1 and 2) may work quite well. It is consistent with the evidence from market research that households buying breakfast cereals, for instance, commmonly buy many types in quite a short period, and has been borne out by studies in the demand for related foods – although these are perhaps particularly favourable cases since we can imagine each mouthful being churned up in the stomach, the relevant components being extracted and possibly processed further to yield the characteristics in question. Labour economists quite soon began to make valiant efforts to estimate the characteristics of individual workers, or groups of workers, and to fit them to those of the functions they perform, though segmentation of the market seems more likely here, while the existence of specialization suggests that two workers with the endowment (y_1^*, y_2^*) appropriate to the job in hand may be more productive than one with $\left(y_1^* + \delta, y_2^* - \in\right)$. and another with $\left(y_1^* - \delta, y_2^* + \in\right)$.

There remains the problem of infinite elasticities.

There are two obvious routes around it: to drop linearity and hence the strong invariance property (Eq. 4), or to recognize that we are oversimplifying, so that the characteristics in question do not represent the goods perfectly. In the latter case, the natural requirement would be that the characteristics catch what these goods have in common, allowing each to have a specific value of its own, in addition, largely to be explained by the amount of it consumed. This model has been tried out with some limited success: for instance it would require at least six common characteristics Y to fit data on sources of meat protein taken from the British National Food Survey (NFS), as one plus the specific just mentioned, and either does much better than the specific alone, which is rather like an old-fashioned demand equation; the estimates were reasonably consistent in different regions; while the own price elasticities, the shadow prices of the characteristics being held constant, almost always lay between 0 and −2. Stephen Pudney estimated it by more sophisticated methods in 1980 and submitted it to formal statistical tests. It failed the tests, but did better than the alternatives he had considered – *in the particularly favourable case of food*.

If one drops linearity, the same statistical methods can be used to estimate models with

$$y_j^{\in} = \sum_i a_{ij} x_i^{\in}, \quad \text{each} \quad j, \tag{4}$$

for instance. When $\varepsilon < 1$ these are strictly concave, so that we can no longer match any particular good perfectly by baskets of others. In this case, each unit of X_i contributes towards each Y_j for which $a_{ij} \neq 0$. An alternative model

$$y_j^{\in} = \sum_i a_{ij} x_{ij}^{\in}, \quad \sum_j x_{ij} = x_i, \tag{5}$$

implies that some electricity, for instance, is used for cooking, some for lighting, some for heating,

etc. Since the consumer has to get the same value at the margin in each use, these are best characterized in the dual. In that case, they become a special, additive, example of the composite commodities described in the entry "► Separability", which were not included among the alternatives examined by Pudney. As it happens, much modern demand analysis runs in terms of composites like Eq. 5, though these are commonly interpreted as modes of behaviour appropriate to *households with particular characteristics* – of which income is the most important – rather than as *characteristics of goods*. The ε, too, are usually taken to vary from one composite commodity Y_j to another in such analyses, because poor families are commonly thought to have less flexibility in their budgets. As against this, they cannot deal with utility functions which are general in terms of the components in question, while the linear characteristics model can and does.

In practice characteristics models have commonly been applied to survey data. In the case of the NFS, for instance, each household keeps detailed records for a week. Even if this had no effect on their behaviour, they clearly buy quite different goods in different weeks quite independently of any variations in prices, and the like. The smallest units to which research workers had access contained about one hundred households: even at this level of aggregation, variability between households buying fresh beef and veal, for instance, commonly contributed less to the variance in their consumption per household than did the decision to buy it, rather than fresh mutton and lamb, and so on. This would not matter were it not for the fact that different foods may commonly be bought together: pork and apples, for instance, or strawberries and cream. Principal components analysis is based on the covariances; those between 'temporary' components may therefore contaminate the estimates of the 'permanent' characteristics, which commonly interest us most, though this should be mitigated by the use of instrumental variables as in Pudney's later work.

An alternative route would be to model the decision to buy explicitly on its own. Here the most obvious analogue is that of modal choice in transport economics, though that is considerably simplified by the fact that just one mode is chosen on any single occasion, while many different and overlapping collections of goods might be. Here the leading work was done by McFadden in 1974, building on foundations laid by Quandt and the psychologist Luce, employing an additively separable stochastic utility function to obtain choice probabilities based on the characteristics of each mode. In a manner similar to hedonic analysis these characteristics and their values for each model are assumed known, both to the consumer and to the econometrician, in contrast to the models discussed above whose aim was to identify the relevant components.

The early applications of the theory estimated, on the grounds of computational ease, multinomial logit models but this specification suffers from the 'Independence of Irrelevant Alternatives', introducing a new transport mode changes the probabilities of choosing existing modes so as to keep their ratios constant. However, alternatives are now available: Hausman and Wise discuss and estimate a conditional probit model and McFadden has introduced generalized extreme value models. At this stage, application has not yet caught up with theory.

Domenich and McFadden visualized utility being separable into seven components, one encompassing non-travel decisions and the other six travel-related decisions. These six would be made sequentially, first residential location, then vehicle ownership, trip no-trip, destination, times of day and finally mode of travel, each based on optimal decisions at lower stages. Furthermore, each choice would be made on the basis of the characteristics of the alternatives.

Despite this rich framework, studies reported in the economic journals have concentrated on either a single level or, at most, two levels of this process taking other decisions as given. This is no doubt due to the formidable data requirement of a broader analysis, detailed disaggregated data are required both on those who choose a particular mode and those who do not.

Given these difficulties, the studies that have been completed should be considered illustrative of possibilities rather than definitive. The results obtained are certainly promising, with a typical

model predicting in excess of 85 per cent of actual choice correctly. However, there is as yet no basis for evaluating the forecasting ability of the model. Winston has recently used this approach to forecast the demand for a newly established West Coast shipping line but does not provide data on the actual impact; he notes, however, that the response of incumbents to the additional competitor may invalidate his forecast.

The other main use of characteristics in empirical work is in the hedonic analysis of the prices paid for goods like houses, of which families commonly own one, so that linearity and additivity are beside the point, while the characteristics at risk are normally taken to be known. The obvious tool here is the compensating variation – that is the money $h(p, y, u) = g(p, y, u) - g(p,\overline{y}, u)$, say, required to compensate a family for living in a house with characteristics y rather than a standard house $\overline{y}$, in the obvious definition, on the demand side, and the extra cost $k(p, y) = \phi(p,\overline{y}) - \phi(p, y)$, say, of providing y rather than y, on the supply. Clearly the distribution of household characteristics is important in any equilibrium analysis, as is the structure we put on these functions. The temptation to assume separability, $h(p, y, u) = H(p, \psi(y), u)$, should probably be rejected.

How much more people are willing to pay to live in one environment rather than another is obviously important evidence in the planning of land use: how much more for a better gearbox, for directing research. Yet hedonic analysis has not provided much hard evidence so far, for lack of a secure theoretical foundation until Sherwin Rosen entered the field in the Seventies; because the potential characteristics tend to be numerous, and highly intercorrelated, while principal component analysis has often been inappropriately used; and finally because, in comparing different results, people have tended to forget what was held constant when the characteristic which interested them was varied to determine its shadow price.

A great deal of theoretical work, both in industrial and fiscal economics, has run in terms of the characteristics of the goods produced or potentially produced. Such studies are at once highly important, and difficult. Lacking hard information about the differences between goods, protagonists have tended to go for analytical convenience, or comparability with earlier work. In particular, the analogy with geographical position is often used, as has symmetry in the analysis of monopolistic competition, though there seems to be no obvious justification for them other than custom and convenience, not that either is to be despised. The results have been illustrative, therefore, of what might happen, rather than statements of what would, and in what circumstances.

There are two bridges between the empirical and theoretical schools.

Houthakker (1952) is itself purely theoretical, but clearly springs from the need to make sense of the budget data which he and Prais had been studying. He distinguishes n goods, each available in a range of qualities $\upsilon_i^- \leq \upsilon_i \leq \upsilon_i^+$, for instance at prices $p_i = a_i + b_i\upsilon_i$, where a_i and b_i are parametrically variable. He shows that a reduction in the price b_i of 'quality' accompanied by an increase in the base price a_i which leaves a family just as well off as before, leads to it buying less of i, but of a higher quality, for instance, and envisages future applications in industrial economics, in which υ_i might be a vector.

Building on earlier work with Cowling, Cubbin (1975) looked at the car market in Britain in the Sixties, combining a well-chosen characteristics model, with explicit consideration about pricing, changes in quality, and advertising; concluding from the profit margins that the industry acted oligopolistically, effective monopoly being ruled out by competition in quality.

Return to Adam. Had he known how long the first five days had lasted in the other foundation myth, and that the species around him had evolved slowly, prospering when they fitted appropriate niches, dying when they did not, he would probably have used a dynamic model, in which the characteristic space itself expanded, as new species defined new niches and new possibilities as Nalebuff and Caplin have recently argued. The economies of scale, and the political power associated with them, probably make a direct analogy with economic production inappropriate; but something like it seems to be needed when technology is changing as fast as now.

One last point. We have talked throughout as if everybody was hungry for all the characteristics. That is by no means necessarily the case. Some may be universally hated, some positively liked by some, disliked by others, though that would lead to a segmented market in the linear case.

C

Charitable Giving

James Andreoni

Abstract

Charitable giving is a significant vehicle for providing needed goods and services around the world. In the United States, for example, charitable giving accounts for nearly two per cent of income. Moreover, the tax deduction for charitable giving is one of the oldest and most widely used tax policies in the US tax code. This article describes the known facts on charitable giving, how and why people give, and discusses the impacts of government policies on giving.

In 2005 charitable giving in the United States totalled over 260 billon dollars, or around 1.9 per cent of personal income, making it a significant fraction of the economy. Individual giving

accounted for 77 per cent of this total, while foundations accounted for 12 per cent, bequests for 7 per cent, and corporations for 5 per cent (Giving USA 2006). Almost 70 per cent of US households report giving to charity. While the United States typically has one of the largest and most extensively studied charitable sectors, other countries around the world also have significant philanthropy (Andreoni 2001, 2006).

There are three sets of actors in markets for charitable giving, and understanding each and their relationships to each other is essential to an understanding of charity. The first set is the donors who supply the dollars and volunteer hours to charities. The second is the charitable organizations, that is, the demand side of the market. They organize donors with fund-raising strategies, and produce the charitable goods and services with the money and time donated. The third player is the government. Governments are involved in charities in a number of ways. In many countries, including the United States, individual taxpayers may be able to deduct charitable donations from their taxable income. Governments also give directly to charities in the form of grants.

The following highlights the most important and fundamental aspects of research on charitable giving.

What Motivates Giving?

Why would a self-interested agent give away a considerable fraction of his income, often for the benefit of complete strangers? Obviously, acting unselfishly must be in his self-interest. One model of this is that the public benefits of the charity enter directly into a giver's utility function, that is, charity is a privately provided public good. This approach is advanced by Warr (1982) and Roberts (1984), who show theoretically that, if giving is a pure public good, then we would predict that government grants to charities will perfectly crowd out private donations, meaning government spending is largely ineffective. Bergstrom et al. (1986) develop this model further to provide a series of elegant derivations, including the (unrealistic) prediction that redistributions of income will be 'undone' if everyone gives to a public good. Andreoni (1988) pushes this model to its natural limits and shows that in large economies we would predict a vanishingly small fraction of people who will give to a public good, which is clearly contradicted by the statistics presented above.

For this reason, economists have felt more comfortable assuming that, in addition to caring about the total supply of charity, what could be called pure altruism, people also experience some direct private utility from the act of giving. While there are numerous models and justifications for such an assumption, they have often been gathered under the general (and slightly pejorative) term, the 'warm glow' of giving (Andreoni 1989, 1990). In large economies, in fact, it is easy to show that this motive must dominate at the margin (Ribar and Wilhelm 2002). The intuition is clear. If large numbers of others are collectively providing a substantial amount of charity, the incentive to free ride must be so overwhelming that the only remaining justification for giving is that there is some direct benefit to the act of giving.

The consequence of assuming a warm-glow motive is that we can treat individual donations as having the properties of a private good. When income is higher or when the price of giving is lower, we predict that individuals will give more.

What Is the Impact of the Tax Deduction for Charitable Giving?

Studies of the charitable deduction are aimed at understanding just how individual giving is responsive to changes in income and price. If t is the marginal tax rate faced by a giver, and if (in the United States) the person itemizes deductions, then the charitable deduction makes the effective price of a dollar of donations $1 - t$. The policy questions are how responsive is giving to the price, and is the policy successful in promoting additional giving.

Let g be the giving of the household. If the policy is effective, then the new giving received by the charity should exceed the lost revenue of the government, that is, total spending on giving

will rise with the deduction. This means $d(1-t)g/dt > 0$, which holds if $\varepsilon = [dg/d(1-t)]/[(1-t)/g] < -1$. This means that the policy is effective if giving is price-elastic, $\varepsilon < -1$. Since the first studies on giving (Feldstein and Clotfelter 1976), researchers have debated whether this 'gold standard' has been met.

Dozens of studies of this question have been undertaken. Most employ cross-sectional data, either from surveys about giving or from tax returns. Each of these data sources has advantages and weaknesses, and each presents special challenges for identification and estimation (see Triest 1998, for a careful discussion). These studies are summarized by Clotfelter (1985), Steinberg (1990), and Andreoni (2006). Prior to 1995, a consensus had formed that the income elasticity was below 1, typically in the range of 0.4 to 0.8, and that the price elasticity was below minus 1, generally in the range minus 1.1 to minus 1.3, thus meeting the gold standard. Only a few studies found giving was price-inelastic.

This consensus was upset by an important study of Randolph (1995). There are two important features of his analysis. First, he uses a panel tax returns rather than a cross section. Second, the period of his sample, 1979–89, spans two tax reforms. These reforms provide independent variation in price that can be helpful in identifying elasticities. Moreover, his instrumental variables analysis allows him to separate short-run and long-run elasticities. Contrary to the prior literature, he estimates a long-run price elasticity of only minus 0.51, meaning that the policy no longer satisfies the gold standard. Short-run elasticities, by contrast, are high, at minus 1.55. This means that givers are sophisticated at substituting giving from years of low marginal tax rates to years with high marginal tax rates. His analysis suggests that cross-sectional studies conflate short- and long-run elasticities and thus mislead policy analysts.

Auten et al. (2002) challenged Randolph's results. They use a similar (although longer) panel of tax payers, but employ a different estimation technique. Their analysis capitalizes on restrictions placed on the covariance matrices of income and price by assumptions of the permanent income hypothesis. Their analysis again returns estimates to the consensus values, with a permanent price elasticity of minus 1.26. The sensitivity of the estimates to the estimation technique and the identification strategy has left the literature unsettled as to the true values of price and income elasticities.

C

Giving by the Very Wealthy

Most of the data available, for reasons of confidentiality, exclude the very wealthy. Yet, the richest 400 US tax filers in the year 2000 accounted for about seven per cent of all individual giving in that year. Auten et al. (2000) provide a fascinating analysis of wealthy givers drawn from income tax filings at the Internal Revenue Service. Among the most interesting findings is that giving as a percentage of income rises only modestly with income, up to about four per cent for those earning over 2.5 million dollars. However, the variance in giving rises sharply. The inference is that wealthy givers are 'saving up' for larger gifts. These larger gifts may allow them to exert some control over the charity, such as providing a seat on the board of directors, or may garner a monument, such as naming a university building after the donor.

In discussing the wealthy, one must also address the effects of the estate tax on giving. Bakija et al. (2003) use 39 years' worth of federal estate tax filings to study the sensitivity of estate giving to the estate tax. They rely on variation in estate tax rates across states for identification and find that charitable giving from estates is extremely sensitive to the tax. They measure the price elasticity of estate giving to be around minus 2.0, while the 'wealth elasticity' is about 1.5. This indicates that the 2001 changes in US estate tax laws, which greatly reduce (and eventually eliminate) estate tax rates, can have huge impacts on giving.

Do Government Grants Crowd Out Individual Giving?

There are many studies on crowding out, and most show that crowding is quite small, often near zero,

and sometime even negative (Kingma 1989; Okten and Weisbrod 2000; Khanna et al. 1995; Manzoor and Straub 2005; Hungerman 2005). Payne (1998), however, noted that the government officials who approve the grants are elected by the same people who make donations to charities. Hence, positive feelings toward a charity will be represented in the preferences of both givers and the government. This positive relationship between public and private donations means that some of the prior estimates could be biased against finding crowding out.

Payne (1998) turns to two-stage least squares analysis to address this endogeneity. As an instrument for government grants she uses aggregate government transfers to individuals in the state, and finds that estimates of crowding out rise to around 50 per cent, which is significantly above the zero per cent crowing that comes when she applies prior techniques to her data. This is a significant new finding.

None of this analysis, however, has accounted for the fact that government grants may also have an impact on the fund-raising of charities. Andreoni and Payne (2003) ask what happens to a charity's fund-raising expenses when it gets a government grant. Does it fall, and by how much? They look at 14-year panel charitable organizations and find there are significant reductions in fund-raising efforts by charities after receiving government grants. This raises the possibility, therefore, that grants crowd out fund-raising, which then indirectly reduces giving, and that this may be the actual channel through which 'crowding out' occurs.

Incorporating Fund-Raising Into Research on Charitable Giving

One of the exciting new challenges for research on charitable giving is accounting for the strategic actions of charities in the analysis. This typically means understanding how charities choose fund-raising strategies, and how givers respond. A theoretical literature has emerged to provide a framework for analysing fund-raising (see Andreoni 2006, for a review). At the same time researchers have begun considering field and laboratory experiments on charitable giving. These studies look at the effectiveness of ideas proposed by the theoretical literature, and evaluate some of the standard practices of charities.

Rege and Telle (2004) and Andreoni and Petrie (2004) show in laboratory studies that the common practice of revealing the identities of givers, and reporting amounts given in categories (Harbaugh 1998), can have positive impacts on donations. Soetevent (2005) shows similar social effects in a field experiment.

List and Lucking-Reiley (2002) use a field experiment to establish that when charities require a minimum amount of contributions before a new initiate can be pursued, having a 'seed grant' can be greatly effective (Andreoni 1998), as can be guarantees of refunds in the event that the threshold of donations is not met (Bagnoli and Lipman 1989).

Landry et al. (2006), explore the use of lotteries in raising money for charities (Morgan 2000) in an actual door-to-door fundraising campaign. They find that lotteries increase giving, as expected. Perhaps surprisingly, however, they find that the physical attractiveness of the fundraiser has a significant affect on the amounts raised, and that this was at least as important as any economic incentives offered.

Conclusion

Charitable giving has been one of the perennial topics for economists. It presents challenges for the theorists to understand the motives and institutions for giving, for policy analysts to measure and identify the effects of price and income, and for experimenters to explore innovations in the market for giving. As governments become increasingly reliant on private organizations to provide public services, and as charities become increasingly sophisticated at raising money and delivering needed services, understanding the relationships among the suppliers and demanders of charity will become essential for calculating the social costs and benefits of charitable institutions.

Chartism

E. C. K. Gonner

The chartist movement was in its origin and its aim economic. It arose out of the economic necessities of the time, and its leaders had before them, as their ultimate object, social and industrial amelioration. To understand fully this aspect of chartism we must study the movement in its two phases: (1) from 1836 to 1839; (2) from 1840 to 1848.

1. 1836 to 1839. Three circumstances may be regarded as bringing about the chartist movement: the commercial and industrial distress immediately preceding it in time; the introduction of machinery with its effects; and the new poor law of 1834. Various men were of course variously affected by these causes; but their common action was secured by the predominant influence of one man, and the action of another, supported as he was by his colleagues. The influence referred to was that of Robert Owen, who had preached the gospel of optimism and social regeneration when all around seemed overshadowed with a gloomy present and a threatening future, and, further, urged on his followers and all with whom he came in contact, the need of education and moral elevation. It was, however, the action of Lord John Russell that brought into united action bodies so diverse in aim and constitution as the working men's association of London, the Birmingham political union, and the unions of the north, these latter being under the guidance of Feargus O'Connor. Briefly described, the first was educational and moderate, the second unstable, partly desirous of bringing about the adoption of Mr Attwood's currency scheme, and partly anxious for general industrial amelioration, while the latter formed centres for violent denunciation of the rise of machinery, and of the application of the new poor laws. All, however, hoped to attain their ends by bringing pressure to bear on parliament, itself to be rendered more amenable by a further extension of the franchise; and hence Lord John Russell's declaration against all further reform united them together and led to the formation of the national convention. The task to which this body devoted itself was mainly political, and to attain its object recourse was had first to menaces and then to open revolt. The former were disregarded and the latter was suppressed. Meantime, however, in the northern unions an almost socialistic attitude had been taken by some of the leaders. Throughout the entire movement, indeed, there had been symptoms that many were thinking of and aiming at an entire social reconstruction.
2. 1840 to 1848. The second phase of chartism differed essentially from the first. It was of smaller account in every way but one. Its strength was less, its adherents fewer, its organization less stable; but the views of its leaders were much more advanced. In theory, Bronterre O'Brien stood far ahead of any other. He was socialistic in his aims, but, unlike some of his associates, he did not confuse socialism and industrial retrogression. His schemes were, it is true, somewhat immature, but he may be described as feeling about for a new social organization. Feargus O'Connor, on the other hand, was neither so consistent nor so advanced in his aims. Thus at one time he was advocating the claims of the 'National Charter Association', for so the organization of the chartists was called, while at another, in defiance of the advice of his associates, he advocated a new scheme for bringing the people into connection with the land. In opposing the Anti-Corn Law League, it should be noticed, however, that he based his antagonism on the need which he alleged to exist of general

social reconstruction (see especially speech, 5 August 1844). But the direct effect of the agitation at this period was small. Discussions among the leaders and mutual accusations 'of interested motives' diminished their following, and it was to little or no purpose that O'Connor sought to win them back by his apparent advocacy of their interests in a periodical called *Labour*, or by his national land scheme. The latter, as a matter of fact, was financially unsound. The movement failed. That the leaders were really in earnest in their agitation is probable from the circumstances which have been alluded to, as also from their decided refusal to form any alliance with the middle class, or capitalist, reformers of Birmingham.

In its two phases, then, chartism was of economic importance. During the earlier period it aimed at economic regeneration; during the second, it not only aimed at this, but assumed a socialistic character.

Chartism: The Points of the Charter

G. Wallace

The Charter itself was a document in the form of an act of parliament, drafted by Francis Place from materials supplied by William Lovett. Its proposals were always summed up under six heads or 'points' viz. Universal, i.e. adult male, Suffrage, the Ballot, Annual Parliaments, Payment of Members, Equal Electoral Districts, and Abolition of Property Qualification. No one of these proposals was in any sense new, and the great majority of them had been continuously agitated for more than fifty years. The Duke of Richmond introduced a proposal for adult suffrage and equal electoral districts into the House of Lords in 1780. All or nearly all the charter 'points' were adopted by the Society of the Friends of the People, and the Corresponding Society in the earlier years of the French Revolution, and by that Edinburgh Convention for taking part in which Muir and Palmer were sentenced in 1793. The 'points' were generally spoken of as the Duke of Richmond's, or Sir Francis Burdett's, or Major Cartwright's 'plan of radical reform', and were undisguisedly intended by all their working class supporters to be used for bringing about economic as well as political equality. During the ten years following the French war every period of high prices and low wages produced a fierce agitation for 'radical reform' in the manufacturing districts and sometimes also in London. In 1830–32 the 'plan' was for a time given up in favour of the Reform Bill, but in London amendments in favour of universal suffrage were carried at the public meetings held in support of Lord Grey's bill. These were generally moved by members of the 'Rotunda Gang', or national Union of the Working Classes, many of whom had been personal disciples of Robert Owen. The reformers of 1790–1820 had advocated Tom Paine's proposal of a graduated income tax, or had been followers of 'Spence's plan' of land municipalization. These men went further, and were strongly though vaguely socialistic in tone. Place describes them as filled with bitter notions of animosity against everybody who did not concur in the absurd notions they entertained, that everything which was produced belonged to those who by their labour produced it, and ought to be shared among them; that there ought to be no accumulation of capital in the hands of any one to enable him to employ others as labourers, and thus by becoming a *master* make slaves of others under the name of workmen, to take from them the produce of their labour, to maintain themselves in idleness and luxury while their slaves were ground down to the earth or left to starve. They denounced every one who dissented from these

notions as a *political economist* under which appellation was included the notion of a bitter foe to the working classes – enemies who deserved no mercy at their hands.

Place also gives a good specimen of their teaching in a song published about this time:

> 'Wages should form the price of goods,
> Yes, wages should be all;
> Then we who work to make the goods
> Should justly have them all.
> But, if the price be made of rent,
> Tithes, taxes, profits all,
> Then we who work to make the goods
> Shall have – just none at all.'

From among these men came Lovett, Cleave, Hetherington, and others who were afterwards leaders of the chartist movement. It is significant that their organization was called successively the 'British Association for Co-operative Knowledge' (i.e. of Robert Owen's principles) in 1829; 'The Metropolitan Trades Union' in 1830, when one of their declared objects was to 'enhance the value of labour by diminishing the hours of employment', and 'The National Union of the Working Classes', for nominally political purposes, in 1831.

After the complete failure of the chartist movement in 1848, working-class reformers generally returned to the work of co-operation and trade-unionism, so that the economic side of the agitation which carred the Reform Bills of 1867 and 1884 was not so apparent as the political side. But the bill of 1867 was opposed on economic grounds by Robert Lowe (afterwards Lord Sherbrooke), Lord Shaftesbury, and others. Lord Shaftesbury on that occasion said:

I am sure that a large proportion of the working classes have a deep and solemn conviction – and I have found it among working people of religious views – that property is not distributed as property ought to be; that some checks ought to be kept on the accumulation of property in single hands; that to take away, by a legislative enactment, that which is in excess, with a view to bestow it on those who have insufficient means, is not a breach of any law, human or divine.

Chayanov, Alexander Vasil'evich (1888–1939)

Amiya K. Bagchi

Chayanov is the best-known exponent of the theory of peasant economy developed by the Organization and Production School of Russian agricultural economists. The latter were active from around 1905 down to the period of the New Economic Policy adopted by the Soviet regime.

Little is known of Chayanov's early life except that he probably came of genteel stock in European Russia. He came into early prominence and in 1913 was appointed assistant professor at the Agricultural Institute of Petrovskoe Razumovskoe (later renamed the Timiriyazev Agricultural Academy), near Moscow. In 1919, he was put in charge of the seminar on agricultural economics of the Timiriyazev Academy, later to be renamed once again as the Institute of Agricultural Economy. He directed the Institute until 1930 when, at the height of the collectivization campaign, he was dismissed. He is alleged to have died on 30 March 1939 at Alma-Ata (Smith 1976).

Chayanov was a tireless investigator into the conditions of agriculture in Russia in the era succeeding the Stolypin reforms and in the first ten years or more of the Soviet regime. He published numerous studies on cooperation, credit, peasant farming etc. in other European countries such as Italy, Belgium and Switzerland. But his main area of research centred on problems of Russian peasant production, including the question of cooperation among the peasant producers. He also took part in the organization of cooperation among the peasantry. In 1914 Chayanov proposed the organization of a central cooperative for the export of flax. Russia was then the leading exporter of flax in the world. In 1916–17 the Central Cooperative Association of

Flax Growers, of which Chayanov was a director, obtained a monopoly of flax exports, after signing an agreement with a private firm interested in the same field.

During and after the period of the Bolshevik Revolution, Chayanov became concerned with the appropriate form of agrarian reforms. He emphasized the diversity of production conditions in the different regions of Russia and of the needs of different types of products such as grain or flax. He also stressed the need to give the peasant adequate incentive to produce and market the crops needed by other sectors of the economy. By and large, he was against forcible collectivization and nationalization of land, and for voluntary cooperation among peasants who would retain control over their land. But in the period when the creation of state farms came on the political agenda, he worked out a locational plan for such farms and tried to figure out their optimum size.

The most complete bibliography of Chayanov's works available so far lists one hundred items of economic or agro-economic studies under his own name, spanning the years 1909–1930, sixteen items edited or with a preface by him (published over the years 1915–28), and twelve other works by him in the field of literature, history and arts, published over the period 1912–28 (Thorner et al. 1966, pp. 279–96). Chayanov was a cultured Russian intellectual, typical of his generation, and he wrote many of his 'non-professional pieces' under a variety of pseudonyms such as 'Botanik X', 'Moskovskii Botanik X', and 'Ivan Kremnev'. The utopia published by him under the last guise has been translated into English as *The Journey of my Brother Alexei to the Land of Peasant Utopia* (Kremnev 1920). However, it is the translation of two of his major theoretical studies into English in 1966 that kindled interest in his work among English-language readers (Thorner et al. 1966).

The centrepiece of Chayanov's theory is the concept of the family labour farm. Such a farm is supposed to employ only family labour on the family farm and on other activities such as crafts and services; on the other side, no part of this labour is hired out. Chayanov largely ignored the non-farm activities of the family labour farm. Then the equilibrium output of the farm was taken to be determined by the equation of the consumption needs of the family and the drudgery of effort (Kerblay 1966, p. xxxii).

Chayanov claimed that 90 per cent of the farms in Russia before the October Revolution were family labour farms. He used the area sown per family as the primary criterion for stratifying peasant households and claimed, on the basis of the data anlaysed by himself and by other researchers such as B.N. Knipovich, N.P. Makarov and S.N. Prokopovich, that it was the size of the family that determined the size of the area sown rather than the other way round. The direction of causality was established by means of a life cycle theory: a young family would have a high proportion of consumers to producers, and as the children grow up, the size of the family farm would increase at first to accommodate the growing needs of the family. The farm would in turn grow as more working hands are added to the family units. Then some of the young adults would move away, and settle down either on a portion of the partitioned family farm or on a new farm (Chayanov 1966, pp. 53–69).

Chayanov considered the family farm or the 'family economy' to be not only typical of pre-revolutionary or early post-revolution Russia, but to underlie a wide variety of economic systems (Chayanov 1924; this has been translated as 'On the theory of non-capitalist economic systems' in Thorner et al. 1966, pp. 1–28). In Chayanov's view, this family economy underlies not only the natural economy and 'the commodity economy' but is really at the basis of what he calls the feudal system, where the peasant household and the landlord's demesne form a symbiotic unity.

Chayanov's views on the structure of Russian rural society as well as his general view of the peasant economy as more or less a universal category have been challenged by his critics, who include the Russian Agrarian Marxists led by

L.N. Kritsman (1926) and later researchers (Harrison 1975, 1977a, b, 1979; Littlejohn 1977; Ennew et al. 1977; Chandra 1985). It has been claimed that once a multidimensional matrix of stratification is used, Russian rural society is found to have been highly stratified along class lines as Lenin had argued in his *Development of Capitalism in Russia* (1899) and later works. Chayanov's critics point out that changes in social structure cannot be explained by demographic factors alone so that the life cycle theory advanced by him does not have much of an empirical basis. Chayanov failed to take into account the fact that small peasants, rich peasants, and 'family labour farms' are held together in a web of market relationships, and that family labour farms are vulnerable to vagaries of the market as well as to natural or biological factors (see Bagchi 1982, ch. 6). Once capital is assumed to be mobile as between different farms and other sectors of the economy, the theoretical basis of an enduring family labour farm is thoroughly undermined. A peasant mode of production cannot have a theoretical validity either, because it ignores the relations of production that hold the peasantry together but also differentiate them in particular ways.

Although Chayanov's life cycle model would hold ideally only in a land-abundant economy, attempts have been made to adapt the model of the self-exploiting family farm to densely populated underdeveloped countries with widespread underemployment of labour (Georgescu-Roegen 1960) and to Polish feudalism (Kula 1962). The utopianism underlying some of the theories favouring small peasant farming under capitalist countries and explicitly spelled out by Chayanov (Kremnev 1920), has been assailed for its lack of realism and its reactionary overtones (Patnaik 1979). But there is no doubt that Chayanov raised a number of questions which, in combination with the work of Kautsky, Lenin, Mao and other Marxists, will provide a rich crop of research programmes on rural social structures wherever the peasantry formed or continue to form a large fraction of the population (Harrison 1979; Chandra 1985).

Cheap Money

Susan Howson

'By a long-established convention the rate of discount or the short-term rate of interest is called the "price" of money, so that "dear money" means a high rate, "cheap money" a low rate' (Hawtrey 1938, p. 28n). By the time Hawtrey was writing, however, the meaning of cheap money was changing, as a result of changes in both economic theory and monetary policy, to include low *long*-term interest rates. In the late 20th century money has not often been cheap in either sense, so that cheap or cheaper money now usually refers simply to a fall in (real) interest rates.

In the late 19th century and early 20th century, 'cheap money' meant low money market rates of interest, the rate at which commercial bills could be discounted. Since in England these rates were strongly influenced by the Bank of England's rediscount rate (Bank Rate), which was generally higher than the market rate, a 3% Bank Rate could be regarded as the upper limit of cheap money (Hawtrey 1938, p. 133). On this criterion there was cheap money for varying periods of time in all but nine years from 1844 to 1914 (Palgrave 1903, p. 98; Hawtrey 1938, Appendix I). The Bank of England, committed to maintaining the pound sterling on the gold standard with the aid of a relatively small gold reserve, varied its rate very frequently, so that these periods were of short duration, except for the spells of cheap money that followed upon the dear money of financial crises. In 1844–5, 1848–53, 1858–60, 1867–8, 1876–7, 1893–6, and 1908–9 Bank Rate was usually *below* 3% for a year of more. The most prolonged of these spells, occurring in the last years of the 'Great Depression', was permitted by a large inflow of American gold into Britain, at a time of increasing gold production, falling prices, and high unemployment (Hawtrey 1938, pp. 110–12; Sayers 1936, ch. 1; Sayers 1976, p. 51). Bank Rate stood at 2% for 2½ years, the longest period at its historical minimum before the 1930s. In the previous decade, though Bank Rate was more variable, interest rates had also been generally low. As they were to do again in the 1930s, the British government took advantage of falling long-term rates to reduce the interest paid on a large proportion of outstanding national debt: the famous 'Goschen conversion' of 1888 reduced the interest rate on 3% Consols to 2¾% until 1903 and 2½% thereafter (Clapham 1944, Vol. 2, pp. 318–21; Spinner 1973, pp. 139–503; G.J. Goschen was Chancellor of the Exchequer).

After World War I Bank Rate changes were less frequent than before 1914, partly because a high Bank Rate was now associated with high unemployment (Committee on Currency and Foreign Exchanges after the War 1918; Moggridge 1972; Sayers 1976, chs 6, 7, and 9; Howson 1975, chs 2 and 3). At the same time Bank Rate was generally higher than before the war, having been raised and kept high to curb the postwar boom in 1919–20, and again as part of the attempts to return to and stay on the gold standard at prewar parity. It was 3% only twice

in 1919–31, in 1922–3 and 1930–31, and 2½% once, for 10 weeks in mid-1931. By the time Britain left the gold standard there was a widespread desire for 'cheap money', for the sake of both the economy and the budget. Developments in monetary theory in these years (for example, Robertson 1926; Keynes 1930) implied that low *long-term* interest rates would be needed to increase investment in fixed capital and hence income and employment, rather than just low short-term rates to boost investment in working capital (inventories) as in the older views of, say, Hawtrey (1913, 1919, 1938). In 1932 the British government embarked upon a 'cheap money policy' to provide a spell of low long-term rates as well as to enable the conversion of high interest bearing government debt contracted during World War I. This also involved the establishment of an Exchange Equalization Account (EEA) to manage the exchange rate and provide sterilization of the effects of reserve changes on the monetary base. The announcement of the conversion of £2000 million 5% War Loan 1929–47 to 3½% War Loan 1952 or after was made on 30 June 1932, when Bank Rate was reduced to 2%. Apart from a short-lived rise at the outbreak of World War II, Bank Rate remained at 2% until 7 November 1951 (Nevin 1953, 1955, ch. 3; Howson 1975, ch. 4, 1980; Sayers 1976, ch. 18).

Similar, although more complex, developments in monetary theory and policy had been taking place in the USA in the interwar years (Friedman and Schwartz 1963, chs 6, 7, 8, and 9; Chandler 1971, chs 8). On both sides of the Atlantic the persistence of low interest rates and high unemployment in the 1930s induced considerable scepticism as to the efficacy of cheap money (however defined) as well as increased confidence in the monetary authorities' power to bring it about (Sayers 1951, 1957, chs 3 and 6; Keynes 1936; Wallich 1946; Morgan 1944). The decisions to maintain cheap money during and immediately after World War II reflected the scepticism, the confidence, and the desire to avoid the high borrowing costs of World War I. Monetary policy became a matter of issuing sufficient quantities of suitable debt instruments to satisfy the public's asset preferences and allowing the money supply to expand to whatever extent was necessary to maintain the fixed pattern of interest rates (Sayers 1956, chs 5 and 7; Friedman and Schwartz 1963, ch. 10; Chandler 1971, pp. 346–8). Interest rates ranged from 3/8 on Treasury bills to 2½% for long-term government bonds in the USA, and from 1% on Treasury bills to 3% for long-term government bonds in the UK. In Britain after the war, Hugh Dalton, Chancellor of the Exchequer 1945–7, also tried to go further and pursue a 'cheaper money policy', specifically to lower interest rates for government debt by ½% all the way along the yield curve. There was soon a reaction against the monetization of debt implied in these policies, and in 1947 official support of the markets for government securities was weakened in both countries, although the cheap money policies were not finally abandoned until 1951 (Paish 1947; Sayers 1957, ch. 2; Friedman and Schwartz 1963, ch. 11; Dow 1964, ch. 2 and 9; Howson 1985).

Monetary theory and practice have changed the concept of 'cheap money' again since 1951. In a more inflationary world the importance of controlling the money supply has been recognized – in the 1970s if not before – as have the inadequacies of interest rates (short or long) as an indicator of monetary conditions. When prices are rising rapidly, money can be 'cheap' even if nominal interest rates are at historically high levels. The stance of a central bank's monetary policy is now more often represented by the rate of the growth of the money supply, rather than by interest rates.

Cheap Talk

Vijay Krishna and John Morgan

C

Abstract

Cheap-talk models address the question of how much information can be credibly transmitted when communication is direct and costless. When a single informed expert, who is biased, gives advice to a decision maker, only noisy information can be credibly transmitted. The more biased the expert is, the noisier the information. The decision maker can improve information transmission by: (*a*) more extensive communication, (*b*) soliciting advice from additional experts, or (*c*) writing contracts with the expert.

In the context of games of incomplete information, the term 'cheap talk' refers to direct and costless communication among players. Cheap-talk models should be contrasted with more standard signalling models. In the latter, informed agents communicate private information indirectly via their choices – concerning, say, levels of education attained – and these choices are costly. Indeed, signalling is credible precisely because choices are differentially costly – for instance, high-productivity workers may distinguish themselves from low-productivity workers by acquiring levels of education that would be too costly for the latter.

The central question addressed in cheap-talk models is the following. How much information, if any, can be credibly transmitted when

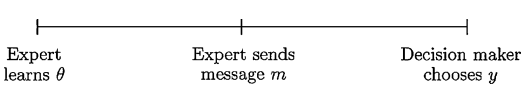
communication is direct and costless? Interest in this question stems from the fact that with cheap talk there is always a 'babbling' equilibrium in which the participants deem all communication to be meaningless – after all, it has no direct payoff consequences – and as a result no one has any incentive to communicate anything meaningful. It is then natural to ask whether there are also equilibria in which communication is meaningful and informative.

We begin by examining the question posed above in the simplest possible setting: there is a single informed party – an expert – who offers information to a single uninformed decision maker. This simple model forms the basis of much work on cheap talk and was introduced in a now classic paper by Crawford and Sobel (1982). In what follows, we first outline the main finding of this paper, namely, that while there are informative equilibria, these entail a significant loss of information. We then examine various remedies that have been proposed to solve (or at least alleviate) the 'information problem'.

The Information Problem

We begin by considering the leading case in the model of Crawford and Sobel (henceforth CS). A decision maker must choose some decision y. Her payoff depends on y and on an unknown state of the world θ, which is distributed uniformly on the unit interval. The decision maker can base her decision on the costless message m sent by an expert who knows the precise value of θ. The decision maker's payoff is $U(y, \theta) = -(y - \theta)^2$, and the expert's payoff is $V(y, \theta, b) = -(y - (\theta + b))^2$, where $b \geq 0$ is a 'bias' parameter that measures how closely aligned the preferences of the two are. Because of the tractability of the 'uniform-quadratic' specification, this paper, and indeed much of the cheap talk literature, restricts attention to this case.

The sequence of play is as follows:



What can be said about (Bayesian-perfect) equilibria of this game? As noted above, there is always an equilibrium in which no information is conveyed, even in the case where preferences are perfectly aligned (that is, $b = 0$). In such a 'babbling' equilibrium, the decision maker believes (correctly it turns out) that there is no information content in the expert's message and hence chooses her decision only on the basis of her prior information. Given this, the expert has no incentive to convey any information – he may as well send random, uninformative messages – and hence the expert indeed 'babbles'. This reasoning is independent of any of the details of the model other than the fact that the expert's message is 'cheap talk'.

Are there equilibria in which all information is conveyed? When there is any misalignment of preferences, the answer turns out to be no. Specifically,

Proposition 1 If the expert is even slightly biased, all equilibria entail some information loss.

The proposition follows from the fact that, if the expert's message always revealed the true state and the decision maker believed him, then the expert would have the incentive to exaggerate the state – in some states θ, he would report $\theta + b$.

Are there equilibria in which some but not all information is shared? Suppose that, following message m, the decision maker holds posterior beliefs given by distribution function G. The action y is chosen to maximize her payoffs given G. Because payoffs are quadratic, this amounts to choosing a y satisfying:

$$y(m) = E[\theta | m] \tag{1}$$

Suppose that the expert faces a choice between sending a message m that induces action y or an alternative message, m', that induces an action $y' > y$. Suppose further that in state θ' the expert prefers y' to y and vice versa in state $\theta < \theta'$. Since the preferences satisfy the *single-crossing* condition, $V_{y\theta} > 0$, the expert would prefer y' to y in all states higher than θ'. This implies that there is a unique state a, satisfying $\theta < a < \theta'$, in which the expert is indifferent between the two actions.

Equivalently, the distance between y and the expert's 'bliss' (ideal) action in state a is equal to the distance between action y' and the expert's bliss action in state a. Hence,

$$a + b - y = y' - (a + b) \tag{2}$$

Thus, message m is sent for all states $\theta < a$ and message m' for all states $\theta > a$.

To comprise an equilibrium where exactly two actions are induced, one would need to find values for a, y, and y' that simultaneously satisfy Eqs. (1) and (2). Since m is sent in all states $\theta < a$, from Eq. (1), $y = \frac{a}{2}$, Similarly, $y' = \frac{1+a}{2}$. Inserting these expression into eq. (2) yields

$$a = \frac{1}{2} - 2b \tag{3}$$

Equation (3) has several interesting properties. First, notice that a is uniquely determined for a given bias. Second, notice that, when the bias gets large $\left(b \geq \frac{1}{4}\right)$, there is no feasible value of a, so no information is conveyed in any equilibrium. Finally, notice that, when the expert is unbiased ($b = 0$), there exists an equilibrium where the state space is equally divided into 'high' $\left(\theta > \frac{1}{2}\right)$ and 'low' $\left(\theta < \frac{1}{2}\right)$ regions and the optimal actions respond accordingly. As the bias increases, the low region shrinks in size while the high region grows; thus, the higher the bias is, the less the information conveyed.

For all $b < \frac{1}{4}$, we constructed an equilibrium that partitions the state space into two intervals. As the bias decreases, equilibria exist that partition the state space into more than two intervals. Indeed, Crawford and Sobel (1982) showed that:

Proposition 2 All equilibria partition the state space into a finite number of intervals. The information conveyed in the most informative equilibrium is decreasing in the bias of the expert.

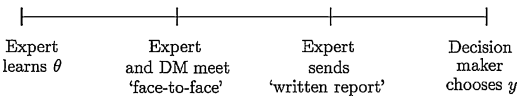
If the expert were able to commit to fully reveal what he knows, *both* parties would be better off than in any equilibrium of the game described above. With full revelation, the decision maker would choose $y = \theta$ and earn a payoff of zero, while the expert would earn a payoff of $-b^2$. It is easily verified that in any equilibrium the payoffs of both parties are lower than this. The overall message of the CS model is that, absent any commitment possibilities, cheap talk inevitably leads to information loss, which is increasing in the bias of the expert. The remainder of the article studies various 'remedies' for the information loss problem: more extensive communication, delegation, contracts, and multiple experts.

Remedies

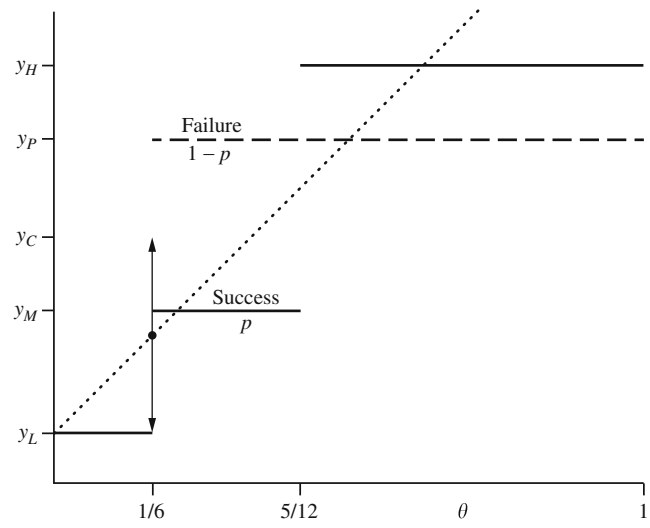
Extensive Communication

In the CS model, the form of the communication between the two parties was onesided – the expert simply offered a report to the decision maker, who then acted on it. Of course, communication can be much richer than this, and it is natural to ask whether its form affects information transmission. One might think that it would not. First, one-sided communication where the expert speaks two or more times is no better than having him speak once, since any information the expert might convey in many messages can be encoded in a single message. Now, suppose the communication is two-sided – it is a conversation – so the decision maker also speaks. Since she has no information of her own to contribute, all she can do is to send random messages, and at first glance this seems to add little. As we will show, however, random messages improve information transmission by acting as *coordinating devices*.

To see this, suppose the expert has bias $b = \frac{1}{12}$. As we previously showed, when only he speaks, the best equilibrium is where the expert reveals whether the state is above or below $\frac{1}{3}$. Suppose instead that we allow for *face-to-face* conversation – a simultaneous exchange of messages – and that the sequence of play is:



The following strategies constitute an equilibrium. The expert reveals some information at the face-to-face meeting, but there is also some randomness in what transpires. Depending on how



Cheap Talk, Fig. 1 Equilibrium with face-to-face meeting

the conversation goes, the meeting is deemed by both parties to be a 'success' or a 'failure'. After the meeting, and depending on its outcome, the expert may send an additional 'written report' to the decision maker.

During the meeting, the expert reveals whether θ is above or below $\frac{1}{6}$; he also sends some additional messages that affect the success or failure of the meeting. If he reveals that $\theta \leq \frac{1}{6}$, the meeting is adjourned, no more communication takes place, and the decision maker chooses a low action $y_L = \frac{1}{12}$ that is optimal given the information that $\theta \leq \frac{1}{6}$.

If, however, he reveals that $\theta > \frac{1}{6}$, then the written report depends on whether the meeting was a success or a failure. If the meeting is a failure, no more communication takes place, and the decision maker chooses the 'pooling' action $y_P = \frac{7}{12}$ that is optimal given that $\theta > \frac{1}{6}$. If the meeting is a success, however, the written report further divides the interval $\left[\frac{1}{6}, 1\right]$ into $\left[\frac{1}{6}, \frac{5}{12}\right]$ and $\left[\frac{5}{12}, 1\right]$. In the first subinterval, the medium action $y_M = \frac{7}{24}$ is taken and in the second sub-interval the high action $y_H = \frac{17}{24}$ is taken. The actions taken in different states are depicted in Fig. 1. The dotted line depicts the actions, $\theta + \frac{1}{12}$, that are 'ideal' for the expert.

Notice that in state $\frac{1}{6}$, the expert prefers y_L to y_P (y_L is closer to the dotted line than is y_P) and prefers y_M to y_L. Thus, if there were no uncertainty about the outcome of the meeting – for instance, if all meetings were 'successes' – then the expert would not be willing to reveal whether the state is above or below $\frac{1}{6}$; for states $\theta = \frac{1}{6} - \varepsilon$, the expert would say $\theta \in \left[\frac{1}{6}, \frac{5}{12}\right]$, thereby inducing y_M instead of y_L. If all meetings were failures, then for states $\theta = \frac{1}{6} + \varepsilon$, the expert would say $\theta < \frac{1}{6}$, thereby inducing y_L instead of y_P.

There exists a probability $p = \frac{16}{21}$ such that when $\theta = \frac{1}{6}$ the expert is indifferent between y_L and a $(p, 1-p)$ lottery between y_M and y_P (whose certainty equivalent is labelled y_C in the figure). Also, when $\theta < \frac{1}{6}$, the expert prefers y_L to a $(p, 1-p)$ lottery between y_M and y_P, and when $\theta > \frac{1}{6}$, the expert prefers a $(p, 1-p)$ lottery between y_M and y_P to y_L.

It remains to specify a conversation such that the meeting is successful with probability $p = \frac{16}{21}$. Suppose the expert sends a message (*Low*, A_i) or (*High*, A_i) and the decision maker sends a message A_j, where $i, j \in \{1, 2, \ldots, 21\}$. These messages are interpreted as follows. *Low* signals that $\theta \leq \frac{1}{6}$ and *High* signals that $\theta > \frac{1}{6}$. The A_i and A_j messages play the role of a coordinating device and

determine whether the meeting is successful. The expert chooses A_i at random and each A_i is equally likely. Similarly, the decision maker chooses A_j at random. Given these choices, the meeting is a

$$\begin{array}{ll} Success & \text{if} 0 \leq i - j < 16 \text{ or} \\ & j - i > 5 Failure \text{otherwise} \end{array}$$

For example, if the messages of the expert and the decision maker are (*High,* A_{17}) and A_5, respectively, then it is inferred that $\theta > \frac{1}{6}$ and, since $i - j = 12 < 16$, the meeting is a success. Observe that with these strategies, given any A_i or A_j, the probability that the meeting is a success is exactly $\frac{16}{21}$.

The equilibrium constructed above conveys more information than any equilibria of the CS game. The remarkable fact about the equilibrium is that this improvement in information transmission is achieved by adding a stage in which the *uninformed* decision maker also participates. While the analysis above concerns itself with the case where $b = \frac{1}{12}$, informational improvement through a 'conversation' is a general phenomenon (Krishna and Morgan 2004a):

Proposition 3 Multiple stages of communication together with active participation by the decision maker always improve information transmission.

What happens if the two parties converse more than once? Does every additional stage of communication lead to more information transmission? In a closely related setting, Aumann and Hart (2003) obtain a precise but abstract characterization of the set of equilibrium payoffs that emerge in sender–receiver games with a finite number of states and actions when the number of stages of communication is infinite. Because the CS model has a continuum of states and actions, their characterization does not directly apply. Nevertheless, it can be shown that, even with an unlimited conversation, full revelation is impossible. A full characterization of the set of equilibrium payoffs with multiple stages remains an open qst.

Delegation

A key tenet of organizational theory is the 'delegation principle', which says that the power to make decisions should reside in the hands of those with the relevant information (Milgrom and Roberts 1992). Thus, one approach to solving the information problem is simply to delegate the decision to the expert. However, the expert's bias will distort the chosen action from the decision maker's perspective. Delegation this leads to a trade-off between an optimal decision by an uninformed party and a biased decision by an informed party.

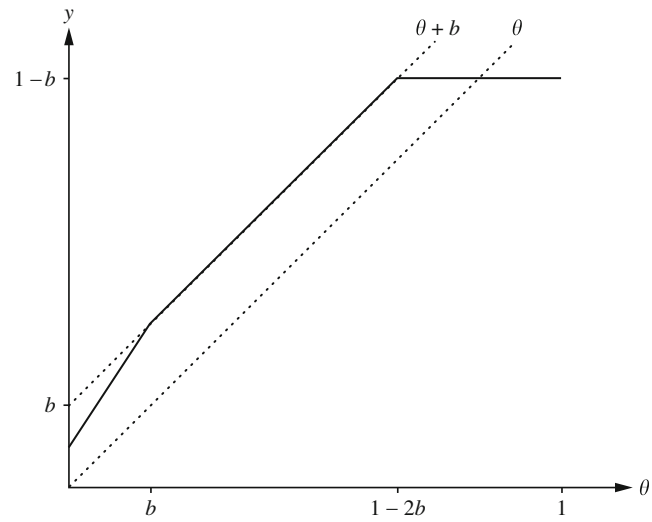
Is delegation worthwhile? Consider again an expert with bias $b = \frac{1}{12}$. The decision maker's payoff from the most informative partition equilibrium is $-\frac{1}{36}$. Under delegation, the action chosen is $y = \theta + b$ and the payoff is $-b^2 = -\frac{1}{144}$. Thus delegation is preferred. Dessein (2002) shows that this is always true:

Proposition 4 If the expert's bias is not too large $\left(b \leq \frac{1}{4}\right)$, delegation is better than all equilibria of the CS model.

In fact, by exerting only slightly more control, the decision maker can do even better. As first pointed out by Holmström (1984), the optimal delegation scheme involves limiting the scope of actions from which the expert can choose. Under the uniform-quadratic specification, the decision maker should optimally limit the expert's choice of actions to $y \in [0, 1 - b]$. When $b = \frac{1}{12}$, limiting actions in this way raises the decision maker's payoff from $-\frac{1}{144}$ to $-\frac{1}{162}$.

Optimal delegation still leads to information loss. When the expert's choice is 'capped', in high states the action is unresponsive to the state.

An application of the delegation principle arises in the US House of Representatives. Typically a specialized committee – analogous to an informed expert – sends a bill to the floor of the House – the decision maker. How it may then be amended depends on the legislative rule under effect. Under the so-called *closed rule* the floor is limited in its ability to amend the bill, while under the *open rule* the floor may freely amend the bill. Thus, operating under a closed rule is similar to delegation, while an open rule is similar to the CS model. The proposition above suggests, and Gilligan and Krehbiel (1987, 1989) have shown, that in some circumstances the floor may benefit by adopting a closed rule.



Cheap Talk, Fig. 2 An optimal contract, $b \leq \frac{1}{3}$

Contracts

Up until now we have assumed that the decision maker did not compensate the expert for his advice. Can compensation, via an incentive contract, solve the information problem? To examine this, we amend the model to allow for compensation and use mechanism design to find the optimal contract. Suppose that the payoffs are now given by

$$\begin{aligned} U(y,\theta,t) &= -(y-\theta)^2 - tV(y,\theta,b,t) \\ &= -(y-\theta-b)^2 + t \end{aligned}$$

where $t \geq 0$ is the amount of compensation.

Using the revelation principle, we can restrict attention to a direct mechanism where both t and y depend on the state θ reported by the expert. Notice that such mechanisms directly link the expert's reports to payoffs – talk is no longer cheap.

Contracts are powerful instruments. A contract that leads to full information revelation and first-best actions is:

$$t\left(\hat{\theta}\right) = 2b\left(1-\hat{\theta}\right) \quad y\left(\hat{\theta}\right) = \hat{\theta}$$

where $\hat{\theta}$ is the state reported by the expert. Under this contract, the expert can do no better than to tell the truth, that is, to set $\hat{\theta} = \theta$, and, as a consequence, the action undertaken in this scheme is the 'bliss' action for the decision maker. Full revelation is expensive, however. When $b = \frac{1}{12}$, the decision maker's payoff from this scheme is $-\frac{1}{12}$. Notice that this is worse than the payoff of $-\frac{1}{36}$ in the best CS equilibrium, which can be obtained with no contract at all. The costs of implementing the fully revealing contract outweigh the benefits.

In general, Krishna and Morgan (2004b) show:

Proposition 5 With contracts, full revelation is always feasible but never optimal.

The proposition above shows that full revelation is never optimal. No contract at all is also not optimal – delegation is preferable. What is the structure of the optimal contract? A typical optimal contract is depicted as the dark line in Fig. 2. First, notice that, even though the decision maker could induce his bliss action for some states, it is never optimal to do so. Instead, for low states ($\theta < b$) the decision maker implements a 'compromise' action – an action that lies between θ and $\theta + b$. When $\theta > b$, the optimal contract simply consists of capped delegation.

Multiple Senders

Thus far we have focused attention on how a decision maker should consult a single expert. In

many instances, decision makers consult multiple experts – often with similar information but differing ideologies (biases). Political leaders often form cabinets of advisors with overlapping expertise. How should a cabinet be constituted? Is a balanced cabinet – one with advisors with opposing ideologies – helpful? How should the decision maker structure the 'debate' among her advisors?

To study these issues, we add a second expert having identical information to the CS model. To incorporate ideological differences, suppose the experts have differing biases. When both b_1 and b_2 are positive, the experts have *like bias* – both prefer higher actions than does the decision maker. In contrast, if $b_1 > 0$ and $b_2 < 0$, then the experts have *opposing bias* – expert 1 prefers a higher action and expert 2 a lower action than does the decision maker.

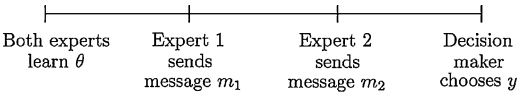
Simultaneous Talk

When both experts report to the decision maker simultaneously, the information problem is apparently solved – full revelation is now an equilibrium. To see this, suppose the experts have like bias and consider the following strategy for the decision maker: choose the action that is the more 'conservative' of the two recommendations. Precisely, if $m_1 < m_2$, choose action m_1 and vice versa if $m_2 < m_1$. Under this strategy, each expert can do no better than to report θ honestly if the other does likewise. If expert 2 reports $m_2 = \theta$, then a report $m_1 > \theta$ has no effect on the action. However, reporting $m_1 < \theta$ changes the action to $y = m_1$, but this is worse for expert 1. Thus, expert 1 is content to simply tell the truth. Opposing bias requires a more complicated construction, but the effect is the same: full revelation is an equilibrium (see Krishna and Morgan 2001b).

Notice that the above construction is fragile because truth-telling is a weakly dominated strategy. Each expert is at least as well off by reporting $m_i = \theta + b_i$ and strictly better off in some cases. Battaglini (2002) defines an equilibrium refinement for such games which, like the notion of perfect equilibrium in finite games, incorporates the usual idea that players may make mistakes. He then shows that such a refinement rules out all equilibria with full revelation regardless of the direction of the biases. While the set of equilibria satisfying the refinement is unknown, the fact that full revelation is ruled out means that simply adding a second expert does not solve the information problem satisfactorily.

Sequential Talk

Finally, we turn to the case where the experts offer advice in sequence:



Suppose that the two experts have biases $b_1 = \frac{1}{18}$ and $b_2 = \frac{1}{12}$, respectively. It is easy to verify (with the use of (2)) that, if only expert 1 were consulted, then the most informative equilibrium entails his revealing that the state is below $\frac{1}{9}$ or between $\frac{1}{9}$ and $\frac{4}{9}$, or above $\frac{4}{9}$. If only expert 2 were consulted, then the most informative equilibrium is where he reveals whether the state is below or above $\frac{1}{3}$. If the decision maker were able to consult only one of the two experts, she would be better off consulting the more loyal expert 1.

But what happens if she consults both? It turns out that, if both experts actively contribute information, then the decision maker can do no better than the following equilibrium. Expert 1 speaks first and reveals whether or not the state is above or below $\frac{11}{27}$. If expert 1 reveals that the state is above $\frac{11}{27}$, expert 2 reveals nothing further. If, however, expert 1 reveals that the state is below $\frac{11}{27}$, then expert 2 reveals further whether or not it is above or below $\frac{1}{27}$. That this is an equilibrium may be verified again by using (2) and recognizing that, in state $\frac{1}{27}$, expert 2 must be indifferent between the optimal action in the interval $\left[0, \frac{1}{27}\right]$ and the optimal action in $\left[\frac{1}{27}, \frac{11}{27}\right]$. In state $\frac{11}{27}$, expert 1 must be indifferent between the optimal action in $\left[\frac{1}{27}, \frac{11}{27}\right]$ and the optimal action in $\left[\frac{11}{27}, 1\right]$.

Sadly, by actively consulting both experts, the decision maker is worse off than if she simply ignored expert 2 and consulted only her more loyal advisor, expert 1. This result is quite general, as shown by Krishna and Morgan (2001a):

Proposition 6 When experts have like biases, actively consulting the less loyal expert never helps the decision maker.

The situation is quite different when experts have opposing biases, that is, when the cabinet is balanced. To see this, suppose that the cabinet is comprised of two equally loyal experts biases $b_1 = \frac{1}{12}$ and $b_2 = -\frac{1}{12}$. Consulting expert 1 alone leads to a partition $\left[0, \frac{1}{3}\right], \left[\frac{1}{3}, 1\right]$ while consulting expert 2 alone leads to the partition $\left[0, \frac{2}{3}\right], \left[\frac{2}{3}, 1\right]$. If instead the decision maker asked both experts for advice, the following is an equilibrium: expert 1 reveals whether θ is above or below $\frac{2}{9}$. If he reveals that the state is below $\frac{2}{9}$, the discussion ends. If, however, expert 1 indicates that the state is above $\frac{2}{9}$, expert 2 is actively consulted and reveals further whether the state is above or below $\frac{7}{9}$. Based on this, the decision maker takes the appropriate action. One may readily verify that this is an improvement over consulting either expert alone. Once again the example readily generalizes:

Proposition 7 When experts have opposing biases, actively consulting both experts always helps the decision maker.

Indeed, the decision maker can be more clever than this. One can show that, with experts of opposing bias, there exist equilibria where a portion of the state space is *fully revealed.* By allowing for a 'rebuttal' stage in the debate, there exists an equilibrium where *all* information is fully revealed.

The chemical industry is among the largest manufacturing industries; its products range from acids to intermediate chemicals such as synthetic fibres and plastics, and to final products such as soaps, cosmetics, paints and fertilizers. Perhaps as a result, the chemical industry is under-studied by economists, though not by economic and business historians (e.g., Hounshell and Smith 1988).

The modern chemical industry has its origins in the discovery of synthetic dyes in Britain in the 1850s. German chemical firms such as BASF, Bayer and Hoechst soon dominated the production of synthetic dyestuffs and related organic compounds. The American chemical industry grew by exploiting the rich American natural resource endowments, initially using European technology.

After the First World War, American firms, especially Du Pont, invested in R&D. The inter-war period saw rapid product innovation in synthetic fibres, plastics, resins, adhesives, paints, and coatings, based on polymer science. To succeed commercially, these products had to be produced cheaply, which meant large-scale production and, in turn, the development of chemical engineering. The Second World War marked a watershed. The chemical industry became closely linked with the oil industry, as many chemicals used petroleum-based inputs instead of coal byproducts. The United States was the first country to develop a petrochemicals industry, mainly due to its abundant oil reserves, as well as wartime government programmes for aviation fuel and synthetic rubber.

The early advantage of the US chemical industry in petrochemicals was eroded as technologies diffused widely, first to Europe and Japan; and in the 1970s China, Taiwan and S. Korea emerged as leading producers. Increased competition, the oil shocks of the 1970s, and waning possibilities for product innovation together resulted in exit: larger, multi-product firms exited earlier, but larger plants closed later (Lieberman 1990). In addition, firms reshuffled product portfolios so as to focus on fewer products but in more geographical markets (Arora and Gambardella 1998). The restructuring took a heavy toll of incumbents; and many familiar names such as Hoechst, Union Carbide, Ciba-Geigy, Sandoz, and American Cynamid have vanished.

A number of interesting themes emerge, some of which have been studied by economists. Others remain as potentially rich veins to be mined.

International competition Why did British firms fail to exploit the rich potential of organic chemistry despite a head start, access to cheap inputs (coal tar) and to the British textile industry, and a well-functioning capital market? Many explanations, none entirely persuasive, have been offered, including the alleged bias of the British financial system towards low risk-projects (Da Rin 1998), the weak links between English universities and industry (Murmann and Landau 1998), and inferior management (Chandler 2005).

Patents Overenthusiastic patent protection in the 1870s nearly killed the French dyestuff industry, while German firms strategically used patent protection (Arora 1997). The confiscation of German patents and industrial property in Britain, France and the United States after both world wars was a setback to German firms but proved insufficient for the Americans and British to catch up. Systematic analysis of this natural experiment can shed light on the role of patents in shaping oligopolistic competition.

Markets for technology Arrow (1962) observed that Du Pont appeared to have profited as much from innovations it had licensed from others as from its own products, perhaps reflecting imperfections in the market for technology. Yet technology licensing has been extensive in chemicals (Arora et al. 2001). The market for technology dramatically changed industry structure, with accumulated production experience of incumbents insufficient to deter successful entry (Lieberman 1989).

Complementarities and industrial convergence After the Second World War, oil refining and the production of synthetic fibres and plastics came to share a common technical base. The convergence led to vertical integration by oil firms into chemicals and chemical firms into petrochemicals (Lieberman 1991). Thanks to a market for petrochemical technology, the European chemical industry was able to switch to petrochemicals

very rapidly, despite very substantial investments in coal-based technologies.

Division of labour and vertical industry structure Specialized engineering firms, which arose to provide plant construction and design services to chemical firms, led the way in diffusing petrochemical technologies worldwide (Freeman 1968). This competition prodded even large chemical firms such as Union Carbide to give licences to others, further diffusing technology and promoting entry (Arora et al. 2001). The chemical industry thus provides a clear example of the benefits of vertically disintegrated industry structures in promoting entry and competition.

The enduring lesson of the history of the chemical industry for economists is the important role of firms – their history and their capabilities – which largely explains why some countries dominated the industry for such long periods. But that history is also a strong reminder to that, in the end, even the mightiest firms must eventually bow to market forces.

Chenery, Hollis B. (1918–1994)

Shantayanan Devarajan

Abstract

Hollis Burnley Chenery was born in Richmond, Virginia, in 1918. He received his Ph.D. at Harvard University, worked for the Marshall Plan in Europe, taught at Stanford University, served as Assistant Administrator of the US Agency for International Development before joining the World Bank in 1970 for a distinguished, 13-year career there. He returned to Harvard as a professor in 1983. He died in 1994.

Hollis Burnley Chenery was the consummate development economist. He defined the contours of the field with his ground-breaking research on patterns of development and development strategy. He developed tools that helped translate research into policy, and, as Vice-President for Development Policy at the World Bank, he helped shift the focus of development economics from a narrow one of economic growth to the alleviation of poverty.

Patterns of Development

In the tradition of Kuznets and Denison, Chenery was interested in how economies grow, whether there were systematic patterns in the process of development. His 1960 paper in the *American Economic Review,* 'Patterns of Industrial Growth', grew into a decade-long research project with Moshe Syrquin culminating in their 1975 book, *Patterns of Development, 1950–1970.* Many of the patterns that Chenery and Syrquin found are received wisdom today: as countries grow, the share of agriculture in GDP declines, and the shares of industry and services increase; and overall GDP growth is typically accompanied by an increase in total factor productivity (TFP) growth. Chenery and Syrquin were the first to document these patterns, using the statistical techniques available at the time, for a large number of countries in the modern era. Their work has led to Chenery–Syrquin 'norms' (interestingly, a word they never used) whereby countries could benchmark their progress in the development process. They were also aware of the limitations of this approach, identifying for example the differences between large countries and small ones, work that has been extended by Perkins and Syrquin (1989). The observed pattern of TFP growth has been questioned by, among others, Young (1995) and is still a topic of vigorous debate.

Development Strategy

In contrast with the recent work on cross-country growth (see Barro 1991), the *Patterns* work was silent on what countries could do to grow faster. Chenery answered this question in a series of major pieces on development strategy. He entered the debate between outward- and inward-looking development strategies in his 1961 *American Economic Review* paper, 'Comparative Advantage and Development Policy'. While countries should only produce those goods in which they have a comparative advantage, Chenery conjectured that comparative advantage in certain goods could be developed through careful investment policies. Chenery's notions saw a resurgence in the 1980s in the Brander and Spencer (1985) and other models of policy-induced comparative advantage. Of course, policies to create comparative advantage have to be carefully designed, especially because public investment has economy-wide impacts, as Chenery showed in his 1959 book with Peter Clark, *Interindustry Economics.*

Chenery's thinking on development strategy evolved over time. He became convinced that a country's underlying economic structure – the functioning of its labour and capital markets, its resource endowments – influenced the choices it could make in trying to create 'dynamic comparative advantage'. Using case studies, cross-country analysis and model-based analysis, he distilled this work in his 1984 book with Sherman Robinson and Syrquin, *Industrialization and Growth: A Comparative Study.*

Structure also determines how foreign aid affects the economy, as Chenery showed in his 'two-gap' model (see Chenery and Strout 1966; Chenery and Bruno 1962). *Ex ante,* an economy may be foreign-exchange-constrained or fiscally constrained. Since foreign aid is both foreign exchange and resources to the government, its impact depends on which constraint is binding. An extended version of this simple model became the workhorse model of aid agencies such as the World Bank. It saw a resurgence during the debt crises of the 1980s. It has also been criticized for neglecting the role of prices and incentives (see Easterly 1999), although it can be shown that, as long as domestic and foreign capital are imperfect

substitutes, most of the results of the two-gap model survive in a fully specified, intertemporal, general-equilibrium model.

Tools

Building on his work on the interdependence of investment decisions, Chenery and his collaborators pioneered the development of multisectoral models for investment planning, collected in his co-authored book, *Studies in Development Planning*. This work saw applications in various planning agencies, notably in India. Recognizing the limitations of linear programming approaches, Chenery encouraged the development of computable general-equilibrium (CGE) models at the World Bank and in universities. Today, CGE models are commonly used to inform policy in developing and developed countries, although they too have their limits (see Devarajan and Robinson 2005).

Redistribution with Growth

Arriving at the World Bank in 1970, Chenery proceeded to establish the first, and eventually one of the most influential, research programmes in economic development. In addition to producing academic-quality research, Chenery's group helped shape Bank policies. In 1974, Chenery and his associates published *Redistribution with Growth*, a seminal book that, while recognizing the need for direct action to alleviate poverty (especially since the high growth of the 1960s had not significantly reduced poverty), showed that wealth redistribution can and should be consistent with the promotion of economic growth. Chenery's approach has been the leitmotif of the World Bank's (and indeed most development agencies') strategy since then.

Cherbuliez, Antoine Elisée (1797–1869)

R. F. Hébert

Swiss lawyer and economist, Cherbuliez was born in Geneva into a family of French Protestants who were uprooted by the Edict of Nantes. Trained in law, Cherbuliez held a judgeship until 1835, at which time he succeeded Pellegrino Rossi at the University of Geneva as professor of public law and political economy. He also served in the Swiss Constituent Assembly and the Grand Council, but after the fall of the Conservative Republican Party in 1848 he moved to Paris and became a naturalized French citizen. A short time later, however, he returned to his homeland as professor of political economy at the University of Lausanne, preceding Léon Walras in the position. Concurrently, he held the chair of political economy at the University of Zurich from 1855 until his death in 1869.

As an economist, Cherbuliez produced nothing original, but he excelled in exposition. His writings represent a kind of mature classicism. The diadem in a collection of sparkling gems is his *Précis de la science économique et ses practicales applications*, a masterpiece of erudition, described by Schumpeter (1954, p. 501) as 'one of the best textbooks of "classic" economics'. Luigi Cossa (1880) put it on a par with Mill's *Principles*, judging it 'possibly superior'. J.E. Cairnes, in quiet affirmation of Cossa's judgement, followed Cherbuliez in his reformulation of the classical theory of value.

Cherbuliez wrote for the *Dictionnaire d'économie politique* and for the *Journal d'économie politique*, on such topics as socialism (which he opposed), charity, transportation, money and banking, taxation (he accepted Canard's theory), entrepreneurship, economic history and the history of economic thought. If he was an apostle at all, he followed Say and Bastiat. Like the former, he partitioned economics systematically into 'theory' and 'practice'. Like the latter, he wrote pamphlets in support of liberalism and the deductive method. Despite the clarity of his style and exposition, however, Cherbuliez was not widely read. He left no distinctive imprint on French economics, nor is he remembered by most textbooks in the history of economic thought.

Chernyshevskii, Nikolai Garilovich (1828–1889)

M. Falkus

Nikolai Chernyshevskii was born in Saratov in 1828 and died there in 1889. He was one of a group of 'revolutionary democrats' which included Herzen and Belinskii among its number, and Chernyshevskii became the group's outstanding intellectual leader during the critical decade following the accession of Tsar Alexander II in 1855. His greatest period of activity thus came in the aftermath of the European revolutionary upheavals in 1848–9, and coincided with Russia's defeat in the Crimean War (1853–6), the debate leading up the Emancipation of the Serfs (1861), and the subsequent post-emancipation reaction and gathering of revolutionary sentiment.

Chernyshevskii's influence both on his contemporaries and on later generations of Russian revolutionaries was profound. He undoubtedly

influenced both Marx and Lenin, and Lenin admired Chernyshevskii more than any other non-Marxist revolutionary writer. Chernyshevskii therefore holds an honoured place in Soviet literature on the development of socialist thought, and he is viewed as the main precursor of Marxism in Russia. His ideas also helped prepare the way for the development of Russian Populism (the Narodnik movement) in the 1870s.

Several major threads run through Chernyshevskii's voluminous and wide-ranging writings. He was an admirer of Western achievements and believed that Russia must modernize in order to catch up with the more civilized West. Thus although he was opposed to capitalism, he was by no means opposed to industrialization and urbanization. In this he was at odds both with the Slavophils and with the later *Narodniki*. He was a strong believer in individualism and in the benefits of enlightened self-interest. He believed that societies, shorn of such oppressive institutions as autocracy and serfdom, or of exploitative capitalism, could grow towards socialism in a rational manner. His ideas were rooted also in a belief in the Laws of History, and in the 'necessary' transition from one stage of development to another. But he also believed that societies, like individuals, could progress by revolutionary means at an accelerated pace. In particular, he argued that Russia could progress to a socialist state without having to undergo a period of capitalism (a viewpoint unacceptable to Leninists, who argued that Russia already was a capitalist country). Chernyshevskii was thus the first Russian writer to put forward a theory of accelerated social change.

In so far as Chernyshevskii perceived that Russia might 'skip' a stage of historical development by virtue of her backwardness, he may be considered a precursor of the 'concept of relative backwardness' later elaborated by Alexander Gerschenkron. In particular, Russia could take advantage of her backwardness by borrowing both institutional forms and technology from the more developed West without incurring the costs of the pioneer. But Chernyshevskii failed to develop the concept, and, as Gerschenkron has pointed out, added little to the ideas already advanced by Herzen. Indeed, in Gerschenkron's opinion 'it is not clear at all that Chernyshevskii made any independent contribution to economic analysis' (Gerschenkron 1962, p. 171).

Chernyshevskii came from a humble background. He was the son of a poor village priest and at first trained for the priesthood himself, attending the theological seminary at Saratov between 1842 and 1845. His literary and linguistic skills took him to St Petersburg, where he graduated from the department of history and philology in 1850. It was during these years that he became a radical and a revolutionary, influenced profoundly by the revolutions of 1848–9 and the debate over serfdom in Russia. His ideas were influenced by Herzen and Belinskii and also by the German philosophers (especially Feuerbach and Hegel), by French utopian socialists and by English political economists (especially Ricardo and Mill).

Following two years teaching in his native Saratov, Chernyshevskii returned to St Petersburg in 1853 and in the following year joined the staff of the literary journal *Sovreminnik* (The Contemporary). Between 1854 and 1857 he wrote most of his literary criticism, using this as a vehicle to expound his social views. He rejected any concept of 'art for art's sake', arguing the essentially political nature of aesthetics. From 1857 Chernyshevskii devoted himself almost entirely to political and social issues and wrote a series of major articles. These included *Capital and Labour* (1859), *A Critique of Philosophical Prejudices Against the Communal Ownership of Land* (1858) and *The Anthropological Principle of Philosophy* (1860). He also translated John Stuart Mill's *Principles of Political Economy* in (1860) and wrote a lengthy critique of Mill's theories.

In these and other works Chernyshevskii criticized the workings of liberal capitalism, which he condemned for its exploitation of the masses and for periodic economic crises. From Mill's wage-fund theory Chernyshevskii drew a theoretical demonstration of the inevitability of mass poverty under capitalism. He thought that under capitalism the division of labour would inevitably decrease wages, as each operation would require less skill and training and therefore would be rewarded less. And he drew the conclusion that industry, while not to be avoided, must have a different form of social organization. Social evils sprang ultimately from

poverty, and 'whoever says "poverty of the people" also says "the government is bad"'.

Chernyshevskii was a strong defender of the peasant village commune (*mir*) both on social and economic grounds. He viewed the village commune as a possible bridge which would enable Russia to avoid the capitalist stage of development, and he argued that the commune should be modernized along rational lines and become similar to workers' associations in western Europe. He attacked vehemently the terms of the Emancipation, arguing that the peasants should be given their land without having the obligation to pay redemption taxes.

Long under suspicion for propagating revolutionary views (though their message was always subtly disguised in order to escape censorship), Chernyshevskii was arrested on a pretext in July 1862 and imprisoned in the Fortress of St Peter and Paul. He was charged with 'plotting the overthrow of the existing order', and after a trial lasting two years, was ultimately sentenced to seven years' hard labour and exile for life in Siberia.

During his imprisonment Chernyshevskii continued to write a number of important works, including his most famous and influential novel *Chto Delat*' (*What is to be Done*?) (1862–3). The heroes of the novel were the 'new radicals', guided by rational self-interest ('egoism') rather than irrational beliefs. The message of the book was an optimistic one – much could be achieved by individuals who were guided by sound principles even though living in a corrupt society. The novel was serialized in *The Contemporary* (due to an oversight by the censor) and it had an immediate and profound impact on the Russian intelligentsia.

After his exile in 1864 Chernyshevskii's productive life was virtually over. He remained in Siberia – despite vain attempts by radical groups to free him – until 1883, when he was allowed to live in Astrakhan under police supervision. But only in 1889, shortly before his death, was he allowed to return to his native Saratov.

There is no doubt that Chernyshevskii's honoured place in Soviet histories of revolutionary thought owes much to the approval given his writings by Marx, Engels and Lenin. This in turn may be explained in part by Chernyshevskii's championship of the masses, his emphasis on historical forces and his materialism, as well as his own humble origins and his suffering at the hands of the Tsarist authorities. If his writings seem turgid and sometimes coarse, he was nonetheless a powerful and original thinker who did much to adapt the various strands of Western European political economy and philosophy to Russian conditions. He influenced a generation of Russian revolutionaries and did much to prepare the ground in Russia for the *Narodnik* movement of the 1870s and, later, for the spread of Marxism. There is no evidence that Chernyshevskii himself was influenced by Marx, or even that he had read Marx's works. It is probable, though, that he had read the *Communist Manifesto*, and the first volume of *Das Kapital* was sent to him in Siberia in 1872.

Chevalier, Michel (1806–1879)

P. Bridel

Keywords

Chevalier, M.; Free trade; Leroy-Beaulieu, P. P.; Liberalism; Rossi, P.L. E.; Saint- Simon, C. H.; Walras, L

JEL Classifications
B31

Born in Limoges, 13 January 1806; died in Paris, November 1879. Undoubtedly one of the most eminent 19th-century French economists, Chevalier belongs to that most typical brand of engineer-economists. First in his class (*major*) at the Ecole Polytechnique in 1830 and member of the Corps des Mines as an economist, Chevalier came very early under the spell of Saint-Simon's utopian doctrine. From his early editorship of the Saint-Simonian newspaper *Le Globe* (1830–2) and his subsequent sentence to a year in jail (for 'outrage to morals' for publishing advanced ideas on the liberation of women, sexual liberty and the need for communal life) to a made-to-measure niche as economic adviser to Napoleon III and 'éminence grise' to the Second Empire business and banking establishment, Chevalier applied his brilliant mind to various current problems and policy issues without managing, however, to escape completely from the Saint-Simonian mystique. His main claim to fame, the Anglo-French Treaty of 1860 (the Cobden–Chevalier Treaty), an important if short-lived interruption in the general protectionist policy of France, is one of the best illustrations of these twin components of Chevalier's approach to economics and economic policy: weak on the analytics and very strong on the factual analysis with a touch of Saint-Simonian idealism.

Together with public works, cheap bank credit and education, free trade is one of the articles of faith he took over from the Saint-Simonian doctrine. Chevalier returned to these issues throughout his life (notably in his penetrating analysis of the American economy and banking system in the early 1830s which earned him later the nickname of 'Economic Tocqueville'). Binding these various elements with a quasi-philosophical concept of association (as the cornerstone of social order), Chevalier suggests a broad theory of economic growth which he considered flexible enough to be applied to different times and countries.

His Saint-Simonian antecedents and his extensive travelling (to England, Egypt and foremost to the United States) rendered Chevalier suspicious of all 'absolutist' economic theory. In fact, in his most technical chapters (particularly on money) Chevalier never digs beneath the surface of things and contributes very little, if anything, to analytic economics. His only systematic work, his *Cours* (1843; 1844; 1850) delivered at the Collège de France offers little more in the field of theory than a lengthy (and flat) apology for Say's brand of 'vulgar' liberalism. With Rossi, his predecessor, and Leroy-Beaulieu, his successor at the Collège de France, Chevalier was in fact largely responsible for introducing and perpetuating in academic circles the liberal orthodoxy that was to bar Walras from getting an appointment in the 1860s and that dominated French economics for so long that as late as 1939 Keynes could still quip about its lack of 'deep roots in systematic thought' (1939, p. xxxii).

Cheysson, Jean-Jacques Emile (1836–1910)

R. F. Hébert

French engineer, economist and statistician, Cheysson was born in Nîmes and died in the Swiss Alps. Schooled at the Ecole Polytechnique and the Ecole des Ponts et Chaussées, he served with distinction in the Corps of Civil Engineers,

demonstrating his ingenuity during the German siege of Paris (1870) by converting train stations to flour mills (using locomotive engines as the power source), thereby increasing bread production. Only when wheat supplies were eventually exhausted did the city finally capitulate. After the armistice, Cheysson became factory director at Creusot, the huge industrial complex that was bombed during World War II, where he immersed himself in the microeconomics of the firm and began to develop an analytical programme which anticipated the main lines of what we now call econometrics.

Calling his method 'geometric statistics', Cheysson presented its outline to the Paris Statistical Society in 1885 as a scientific approach to 'the practical solution of business problems'. His technique rested on the twin pillars of theory and observation. It combined the spirit of Cournot's economics with attention to recorded data, using geometry to display concrete facts and to interpolate gaps in available statistics. In spirit and scope, but considerably ahead of its time, it mirrored the objectives of the Econometric Society, established at Lausanne in 1931.

A potential alliance between Cheysson and Léon Walras eventually soured, thus cutting off what might have been a productive channel of communication for Cheysson's new method. Cheysson taught geometric statistics to his students at the Ecole des Mines and the Ecole des Sciences Politiques (he held the first chair of economics at each institution), but he inspired no group of followers the way Walras or Marshall did, and the powerful originality of his contribution gradually faded, only to be rediscovered in the present century by Staehle (1942, p. 322) and Schumpeter (1954, p. 842), and reconstructed piecemeal by Hébert (1972, 1973, 1974).

Within the narrow compass of 35 pages Cheysson enriched the theories of statistical demand; revenue and cost curves; profit maximization; spatial market boundaries for raw materials and finished products; wages; product and quality variation; investment; and taxation. His deft handling of these difficult subjects while the titans of economic theory were debating the psychological premises of value theory, constitutes a remarkable performance, even by modern standards.

After 1890 Cheysson turned his energies increasingly towards that branch of ideas that the French call 'social economy'. A follower of LePlay since their first meeting in 1864, Cheysson shared his colleague's interest in social and economic reform. LePlay's school emphasized moral and religious considerations in the economic order, especially the primacy of the family, the rights of workers and the duties of employers. Under Cheysson's leadership, the Société d'Economie Sociale (founded by LePlay in 1856) wedged itself between the socialists on the left and the liberals on the right. Unwilling to accept the evils of poverty and the misfortunes of the workers, yet rejecting socialist remedies, LePlay's school sought amelioration through the encouragement of private initiative. They considered social reform as much a matter of economics as morality. Cheysson was thrice president of the Société d'Economie Sociale, and was elected to the Académie des Sciences Morales et Politiques in 1901. He left behind a literary legacy that numbered over 500 publications, embracing such diverse topics as economics, statistics, geography, agriculture and social hygiene.

Chicago School

M. W. Reder

Abstract

This article deals with the history and main protagonists of the Chicago School from c. 1930 to 1985. The two main beliefs of members of the School are (*a*) that neoclassical price theory can explain observed economic behaviour, and (*b*) that free markets efficiently allocate resources and distribute income, implying a minimal role for the state in economic activity. Chicagoans maintain that no opportunity for arbitrage gains goes unexploited, and subscribe to the efficient markets hypothesis. Their 'disciplinary imperialism' leads them frequently to challenge conventional wisdom by applying price theory to seemingly non-economic topics.

To identify a Chicago School of economics requires some demarcations, both of ideas and persons, that may not be universally accepted. Justification for these decisions must be heuristic; that is, they facilitate the story to be told. But it is not denied that there may be alternative accounts that would entail different demarcations. In this account, the 'Chicago School' is and has been centred in the University of Chicago's Economics Department from about 1930 to the present (1985). However, it is convenient to define the School so as to include many members of the large contingent of economists in the Graduate School of Business and the group of economists and lawyer-economists in the Law School. Largely because of the intellectual loyalty of former students, the influence of the Chicago School extends far beyond the University of Chicago to the faculties of other universities, the civil service, the judiciary and private business. Moreover, this influence is not confined to the United States.

To restrict the retrospective horizon of the School to 1930 implies exclusion of a number of famous economists who had been on the University of Chicago faculty before that time; for example, Thorstein Veblen, Wesley C. Mitchell, J.M. Clark, J. Laurence Laughlin, C.O. Hardy. However, none of these shared the intellectual

characteristics that have typified members of the Chicago School as defined here.

In a nutshell, the two main characteristics of Chicago School adherents are: (1) belief in the power of neoclassical price theory to explain observed economic behaviour; and (2) belief in the efficacy of free markets to allocate resources and distribute income. Correlative with (2) is a tropism for minimizing the role of the state in economic activity.

Before discussing these characteristics in detail, let me give a brief historical account in which it is convenient to divide the history of the School into three periods: (1) a founding period, in the 1930s; (2) an interregnum, from the early 1940s to the early 1950s; and (3) a modern period, from the 1950s to the present.

During the founding period, the Chicago Economics Department contained a wide diversity of views both on methodology and public policy. Institutionalist views were well represented among the senior faculty, and institutionally oriented students constituted a large part of the graduate student population. Among the prominent Institutionalists were the labour economists H.A. Millis and (one side of) Paul H. Douglas; the economic historians John U. Nef and C.W. Wright, and Simeon E. Leland, a Public Finance specialist and long-time department chairman.

Like other social science departments at Chicago, economics was actively engaged in developing the (then) embryonic 'quantitative techniques'. The leading figures in quantitative methods were Henry Schultz, a pioneer student of statistical demand curves, who taught the graduate courses in mathematical economics and mathematical statistics, and Paul Douglas who was (during the 1920s and 1930s) a leader in the estimation of and the measurement of real wages and living costs.

However, it is generally agreed that the progenitors of the Chicago School were Frank H. Knight and Jacob Viner. These two scholars shared an intense interest in the history of economic thought and both were, broadly speaking, devotees of neoclassical price theory. However, their intellectual styles and temperaments were quite different, and their personal relations were not close. Apart from his interest in the history of thought, Viner was primarily an applied theorist working on problems in international trade and related issues in monetary theory. Knight's work was focused on the conceptual underpinnings of neoclassical price theory, and his main concerns were to clarify and improve its logical structure.

Temperament and intellectual focus combined to make Knight a formidable critic, both of ideas and their protagonists. This led to a good deal of friction between him and both Douglas and Schultz. Personalities aside, Knight was strongly averse to the quantification of economics and was very outspoken on this, as on most other matters (For further details, see Reder 1982, pp. 362–5).

By contrast, Viner was rather sympathetic to the aspirations of 'quantifiers', though sceptical of their prospects for success, at least in the near future. Viner's sympathy for quantitative work was prompted by the strong empirical bent of his own research, although friendship for Douglas and Schultz may also have been involved. On the other hand, Knight's purely theoretical studies of capital theory, risk, uncertainty, social costs, and so on, generated neither need for empirical verification nor exposure to research that might have offered it. As a result, Knight's relations with Douglas and Schultz were ridden with conflict, and theoretical disagreements with Viner spilled over into barbed comments to graduate students and kept personal relations (between Knight and Viner) from becoming more than merely correct (Reder 1982, p. 365).

What Knight and Viner had in common was a continuing adherence to the main tenets of neoclassical price theory and resistance to the theoretical innovations of the 1930s, Monopolistic Competition and Keynes's *General Theory.* This theoretical posture paralleled an antipathy to the interventionist aspects of the New Deal and the full employment Keynesianism of its later years. Viner, who was actively consulting the government throughout the period, was much less averse to New Deal reforms than Knight and his protégés. However, there was a sharp contrast between the views of Knight and Viner, on the one hand, and those of avowed New Deal

supporters such as Douglas, Schultz and some of the Institutionalists.

As a result of the division of faculty views, on both economic methodology and public policy, the graduate student body was exposed to a diversity of thought patterns and did not exhibit a great degree of conformity to any particular one. But despite their many disagreements, an effective majority of the Chicago faculty concurred in a set of degree requirements (for the PhD) that stressed competence in the application of price theory. These requirements were quite unusual in the 1930s and the process of satisfying them exercised a great influence in forming a (common) view of the subject among the students, in which price theory was of major importance.

The most important of the requirements was that all PhD candidates, without exception, pass preliminary examinations in both price theory and monetary theory. These examinations were difficult and attended with an appreciable failure rate. Even on second and third trials, there was a non-negligible probability of failure, with the result that some students were (and are) unable to qualify for the doctorate. For most students, the key to successful performance on the examinations was mastery of the material presented in relevant courses, especially the basic price theory course (301) and study of previous examinations.

For over half a century, the need to prepare for course and preliminary examinations, especially in price theory, has provided a disciplinary–cultural matrix for Chicago students. Examination questions serve as paradigmatic examples of research problems and 'A' answers exemplify successful scientific performance. The message implicit in the process is that successful research involves identifying elements of a problem with prices, quantities, and functional relations among them as these occur in price theory, and obtaining a solution as an application of the theory.

Although the specific content of examination questions has evolved with the development of the science, the basic paradigm remains substantially unchanged: economic phenomena are to be explained primarily as the outcome of decisions about quantities made by optimizing individuals who take market prices as data with the (quantity) decisions being coordinated through markets in which prices are determined so as to make aggregate quantities demanded equal to aggregate quantities supplied.

Of course, students vary in the degree to which they assimilate price theoretic ideas to their thought processes, and resistance to these ideas was probably greater in the 1930s than later. Nevertheless, regardless of their special field of interest, all students were compelled to absorb and learn to use a considerable body of economic theory. In the 1980s these skills are very widespread, but in the 1930s they were rarely found and served to distinguish Chicago-trained PhD's – especially in applied fields – from other economists.

Despite the common elements of their training, as in other institutions, doctoral students tended to identify themselves with one or another particular faculty member, usually their dissertation supervisor. Thus each of the major figures in the department was associated with a cluster of advanced students. One such cluster, associated with Knight in the mid-1930s, became of very great importance in the history of the Chicago School. Key members of this cluster were Milton Friedman, George Stigler and W. Allen Wallis. The group established close personal relations with two junior faculty members, Henry Simons and Aaron Director, who were also protégés of Knight. Another member of the group was Director's sister, Rose, who later married Milton Friedman.

It was this group that provided the multigenerational linkage in intellectual tradition that is suggested by the term 'Chicago School'. Although they admired Knight, and were devoted to him, the intellectual style of Friedman, Stigler, et al. was very different from Knight's. They were thoroughgoing empiricists with a distinct bias toward application of quantitative techniques to the testing of theoretical propositions. In their empirical bent and concern with 'real world' problems, they were much closer to Viner than to Knight, but, whatever the reason, they identified with the latter.

Partly because of his important role in the teaching of theory to undergraduates and (less well-prepared) beginning graduates, in the 1930s and until his untimely death in 1946, Henry

Simons exercised an important influence on Chicago students. But he is remembered mainly for his essays on economic policy (collected in Simons 1948) which constituted the principal statement of Chicago laissez-faire views during this period.

Simons's view had a distinctly populist flavour that is absent from those more recently associated with Chicago economics. For example, he favoured use of government power to reduce the size of large firms and labour unions. Where such policies would lead to unacceptable losses of efficiency (e.g. 'natural monopolies'), Simons favoured outright public ownership. In sharp contrast to more recent Chicago statements on the matter, Simons emphatically supported progressive income taxation to promote a more egalitarian distribution of income (Simons 1938).

Finally, Simons proposed a requirement of 100 per cent reserves against demand deposits and restriction of Federal Reserve discretion in monetary policy in favour of fixed rules designed to stabilize the price level (Simons 1948). In this he was the direct forbear of Chicago monetarism, as later developed by Friedman and Friedman's students.

Historically, Friedman, Stigler and Wallis were both the intellectual and the institutional heirs of Knight and Viner. The story of Chicago economics would be less convoluted if the succession had been a matter of the older generation appointing their best students to succeed them. But it was not that simple. On the eve of World War II there was great concern, within the Economics Department and (probably) in the central administration as well, that Chicago had none of the leading figures in the new theoretical developments of the period; that is, in nonperfect competition and Keynesian macroeconomics.

To rectify this, in 1938, they appointed Oscar Lange as assistant professor. In addition to his credentials as a contributor to the literature of Keynes's *General Theory,* especially its relation to general equilibrium theory, Lange was a leading participant in the current debate on the possibility of market socialism and its (alleged) advantages relative to laissez-faire capitalism in terms of efficiency. Further, he had made a number of contributions to mathematical economics and was able to provide backup support for Henry Schultz in that subject area, and in mathematical statistics as well.

As an outspoken and politically active socialist, Lange's views were diametrically opposed to laissez faire. That he managed to stay on friendly terms with virtually all of his colleagues was a testimonial both to his own tact and to their tolerance of dissent. Of course, it was no accident that the principal socialist in the Chicago tradition should have been a *market* socialist.

Within a few months of Lange's appointment, Henry Schultz was killed in an automobile accident and Lange became the sole mathematical economist in the Chicago department. Within a year the loss of Schultz was compounded by the partial withdrawal of Douglas from academic life to pursue a political career. Still further, with the outbreak of World War II, Viner became increasingly involved in Washington and, ultimately, in 1945, he resigned to accept an appointment at Princeton.

As a result of these losses, the Department had to be rebuilt. The process of reconstruction began during the war years, with Lange taking a leading role. He was very anxious to recruit colleagues who were leaders in current theoretical developments, especially in mathematical economics. Failing to obtain his first choice, Abba Lerner, he readily accepted Jacob Marschak and, for a short period, collaborated with the latter in making further appointments both to the Department and to the Cowles Commission, which had located at the University of Chicago in 1938. The collaboration ended abruptly in 1945 when Lange resumed Polish citizenship to become ambassador to the United States and, subsequently, to fill many other high positions in the socialist government of Poland.

During the war years, T.W. Schultz was attracted from Iowa State. A leading figure in agricultural economics, Schultz soon became chairman, a position from which he exercised much influence for over two decades. In addition to Schultz, in 1946 the Department acquired Lloyd Metzler to teach international trade and a number of younger theorists and econometricians

associated mainly with the Cowles Commission. Whatever was the intention, these appointments served as a counterweight to the more or less contemporaneous appointments of Friedman (to the Economics Department) and Wallis (to the Business School).

There then ensued a struggle for intellectual pre-eminence and institutional control between Friedman, Wallis and their adherents on one side, and the Cowles Commission and its supporters on the other. The struggle persisted into the early 1950s, ending only with the partial retirement of Lloyd Metzler (due to ill health) and the departure of the Cowles Commission (for Yale) in 1953. While not monolithic, the Chicago economics department that emerged from this conflict had a distinctive intellectual style that set it apart from most others.

In positive economics, this style involves de-emphasizing the role of aggregate effective demand as an explanatory variable and stressing the importance of relative prices and 'distortions' thereof. In economic policy, it involves stressing the beneficial effects of allowing prices to be set by market forces rather than by government regulation. In an important sense, 'Chicago economics' in the 1950s and 1960s was simply an extension of the ideas of the Knight coterie of the 1930s. Indeed, some of the key figures – notably Friedman, Stigler and Wallis – of that group were leading Chicago economists in the later period as well. Moreover, they were consciously concerned with explicating the continuity of the tradition and preserving it (see below).

The close personal relations of the members of the Knight coterie, maintained for over a half century, has reinforced the strong common elements in their idea-systems and made it easy to ignore the (important) points of disagreement, both among themselves and with others. As already mentioned, Friedman, Stigler and Wallis, like most Chicago economists of their own and subsequent cohorts, believe strongly in use of statistical data and techniques for testing economic theories. In this they differ from Knight, Simons, James Buchanan, Ronald Coase (1981) and a significant minority of other economists associated with Chicago, either as graduate students or faculty, who believe (on various grounds) that the validity of an economic theory lies in its intuitive appeal and/or its compatibility with a set of axioms, rather than in the conformity of its implications with empirical observation.

A second disagreement concerns the consistency of policy advocacy in any form, with the methodology applied in positive economics (The most influential general description of this methodology is chapter 1 of Friedman 1953). This methodology recommends that explanations of economic behaviour be based on a model of (individual) decisions of resource allocation (among alternative uses) designed to maximize utility subject to the constraints of market prices and endowments of wealth. Market prices are presumed to be set so as to equate quantities supplied with those demanded, for all entities traded.

As traditionally applied by neoclassical economists with a predilection for laissez faire, this methodology coexists with advocacy of government policies designed to promote that objective. But in the late 1960s one group of Chicago economists led by Stigler (who had returned to Chicago in 1958 as Walgreen Professor in both the Economics Department and the Business School) began to apply the tools of economic analysis to the investigation of the determinants of political activity, especially government intervention in resource allocation. Thus study of the regulatory and taxing activities of the state became directed not simply at demonstrating their adverse effects upon economic efficiency, but primarily to explaining their occurrence as an outcome of the operation of 'political markets' for such activities.

So analysed, interventions traditionally viewed as efficiency impairing, such as tariffs, require reinterpretation. An individual's resources include not only his command over goods and services acquired through conventional markets, but also his political influence (however measured). Government interventions are considered to be endogenous outcomes of a political-economic process, reflecting the political as well as the economic wealth of decision making units, and not as aberrations of an exogenous state (e.g. see Stigler 1982). So viewed, criticism of political outcomes

is no more warranted than criticism of the expenditure behaviour of sovereign consumers; both are outcomes of the free choice of resource owners.

This is not to suggest that the 'political economy' wing among Chicago economists has become indifferent to laissez faire. On the contrary, opposition to government intervention (e.g. regulation) among Stigler and his allies is quite as strong as it ever has been. During the past decade many economists and lawyers at some time affiliated with the Law and Economics group at Chicago have been prominent advocates of deregulation. However, tension between advocacy of reform, and positive analysis of the political process through which reform must be achieved, presents a continuing existential problem to the heirs of the Chicago tradition. Although they are well aware of the problem, thus far they have refrained from divisive dispute and treat exercises in political advocacy as a consumption activity by those engaged.

Political science is only one of the fields into which Chicago economics has expanded during the past quarter century. Beginning in the early 1940s and accelerating in the last two decades under Richard Posner's leadership, the economic analysis of legal institutions has become an important area of research both for economists and for legal scholars. Further, using the theory of labour supply as a point of departure, the economic analysis of the family has become an important part of the study of population, marriage, divorce and family structure. This development has challenged sociological and psychological modes of explanation in fields that had long been considered provinces of these other disciplines. Still further, the theory of human capital has had a major impact on the study of education.

It is convenient to date the 'disciplinary imperialist' phase of the Chicago School as beginning in the early 1960s and continuing to the present. However, its roots go back into the 1930s; since that time there has been, at least in the oral tradition, a tropism for application of the tools and concepts of price theory to (seemingly) alien situations, and for taking delight in confronting conventional wisdom with the results. Correlatively, there has been a strong tendency to resist explanations of behaviour that do not run in terms of utility maximization by individual decision-makers coordinated by market clearing prices.

However, until well into the 1950s, the disciplinary imperialist aspect of the Chicago paradigm was overshadowed by the struggle to defend the integrity of neoclassical price theory from the attacks of Keynesians at the macro level and the attempts of various theorists of nonperfect competition to provide alternatives at the micro level. The counterattack on the *General Theory* produced a revival of neoclassical monetary theory in a refined and empirically implemented form; this revival is associated with the work of Milton Friedman (1956).

The struggle to re-establish the competitive industry as the dominant model for explaining relative prices was led by Stigler (1968, 1970), and generated much of the theoretical and empirical literature of the field of Industrial Organization. Both in Industrial Organization and Money-Macro, the earlier debates continue, with Chicago-based participants being identifiable as partisans of the standpoints of Friedman and Stigler a quarter of a century ago. However, in the 1970s and 1980s the topics related to these debates have been forced to share centre stage with newer subjects.

The expansion of Chicago economics beyond the traditional boundaries of the discipline began in the middle and late 1950s; two early examples were H.G. Lewis's application of price theory to the 'demand and supply of unionism' (Lewis 1959) and Gary Becker's dissertation on racial discrimination (Becker 1957). These were followed in the 1960s and 1970s by a number of others, as already mentioned. Many of these are more or less straightforward applications of conventional price theory to new problems. However, the analysis of time as an economic resource (Becker 1965) has led to important improvements in the theory of household behaviour.

The analysis of time is also related to a methodological tendency to reject differences in tastes (including attitudes, opinions and beliefs in 'tastes') as a source for explanations of cross-individual differences in behaviour (Stigler and

Becker 1977; Becker 1976). The rejection is based on the contention that (1) seeming differences of taste are usually reducible to differences of cost and (2) statements about cost differences are much more amenable to empirical test. While this methodological principle has met with resistance, at Chicago as elsewhere, it is reflected in a great deal of ongoing research, especially where cost of time is an important variable.

A separate path of disciplinary expansion has arisen in the field of Finance. Whether, prior to the 1960s, this field was a province of Economics, is a point that it is convenient to bypass. But unquestionably, prior to the theoretical developments initiated by Modigliani and Miller's famous paper (1958) on the (non) relation of stock prices and dividends, the theory of price. Subsequent developments have completely reversed that situation, so that in the mid-1980s, the 'capital asset pricing model' has become an integrating matrix for the theories of security prices, asset structure of the firm, and, via the study of executive compensation, wages.

The dominant idea underlying these developments is that, save for transaction costs, *on average* no opportunity for arbitrage gains goes unexploited. One implication of this is the proposition that there is 'no free lunch'; another implication is that no specifiable algorithm can be found that will enable a resource owner to utilize publicly available information to predict movements of asset prices well enough to gain by trading. The latter implication is tantamount to the 'hypothesis of efficient markets'.

While not formally identical with rational expectations, efficient markets will support any behaviour conforming to rational expectations, but will be compatible with other models of expectations only where one or another set of correlated forecast errors (across individuals) is assumed. Moreover, so long as expectations are rational, and regardless of how they are generated, there is no way in which variables operating through expectations can improve upon the neoclassical explanation of relative prices and quantities. This obviates any need for augmenting economic theory by variables reflecting psychological or sociological factors that operate upon individual decision-making via expectations. Obviously, such a theory of expectations is strongly supportive of the claims of economic theory in interdisciplinary competition.

The interrelated ideas of rational expectations and efficient markets originated at Carnegie-Mellon in the work of Muth (1961) and Modigliani and Miller (1958) rather than at Chicago. However, their consonance with the Chicago paradigm is such that they have found a home in the Chicago Business School under the leadership of Miller and his students, and (since the mid-1970s) in the Economics Department under Robert Lucas, rather than in their place of origin. While the claim of Chicago to be the primary locus for research in these fields is a strong one, it is a claim more subject to challenge than analogous claims in some other fields.

Yet a third Chicago innovation of the late 1950s is the 'Coase Theorem' (Coase 1960). In essence this theorem states that, ignoring transaction costs, if there is any reallocation of goods, claims, rights (especially property) or alteration of institutions that – after making compensating side payments to losers – increases the utility of everyone, said reallocation will occur. If rationality is a maintained hypothesis and transaction costs are negligible, the theorem becomes a tautology. Thus the empirical content of the theorem will vary inversely with the importance attributed to transaction costs, which serve as a conceptual receptacle for all forces bearing upon decision-making other than those explicitly incorporated in the theory of price. To consider the Coase Theorem empirically important is to believe that transaction costs and departures from rationality are unimportant.

Put differently, the Coase Theorem suggests that the real world tends towards a position of Pareto optimality. Of course, for given tastes and technology, there may be a different Pareto optimum for each distribution of wealth. Therefore, to the extent that the distribution of wealth is exogenous and has important behavioural consequences, the predictive implications of both Pareto optimality and the Coase Theorem are less salient. Thus the rise in influence of the Coase Theorem at Chicago has more or less

paralleled a decline in the marked concern with income distribution that existed in the 1930s and 1940s, especially in the work of Henry Simons (Reder 1982, p. 389).

When objects of exchange are taken to include legislation and other political variables, the Coase Theorem strongly suggests that the forces of decentralized decision-making that govern production and exchange also control changes in laws and institutions. Thus belief in the Coase Theorem is – or should be – conducive to political passivity. Nevertheless, not all Chicago economists are politically quiescent. But with few exceptions, they are generally conservative, though with considerable differences of shading and intensity of belief, and in taste for political controversy. Probably these differences parallel differences in the degree to which they accept economic explanations of political behaviour. Perhaps the most common characteristic of Chicago economists is distrust of the state. This distrust, together with the belief that, given time, voluntary exchange will usually generate truly desirable reforms, acts as a powerful brake on wayward impulses to improve society through political action.

The saga of the Chicago School is at once the story of the evolution of a set of ideas – a paradigm – and of a particular institution with which its leading protagonists have been associated. In this essay I have emphasized certain central theoretical ideas and historical events to the exclusion of detailed coverage of applied work and mention of the individuals responsible for it. However, it is the association of these central ideas with an identifiable, multigenerational group of individuals located at a particular institution that justifies the title of this article. Many of the key individuals in this history – Director, Friedman, Stigler, Wallis – are still alive, intellectually active and in close touch with their successors on the Chicago faculty. This continuity, both of personalities and ideas, is a distinctive feature of the intellectual tradition called the Chicago School.

In the mid-1980s the vitality of this tradition is threatened more by the growing acceptance of many of its key ideas than by resistance to them. A quarter century ago, Chicago economics was distinguished by its emphasis on the importance of competition and money supply. Arguably, in 1985, these views and their extensions have become mainstream economics, leaving the story of the Chicago School as a nearly closed episode in the history of economic thought. While such an argument may prove valid, it is too soon to tell.

Chicago School (New Perspectives)

Ross B. Emmett

Abstract

M. W. Reder's entry on the Chicago School closed with the claim that the final chapter of the School's history was about to end. Chicago economics has changed, but it has also stayed the same. Each of the four movements of recent Chicago economics are rooted in common themes of the tradition. As well, our interpretation of economics at Chicago has evidenced both continuity and change. Historians are examining the history of the institutional structure of Chicago economics, as well as the histories of specific fields at Chicago (labour, economic history, quantitative analysis) and finding both change and continuity in the tradition.

The history of Chicago economics remains a story of continuity and change.

M.W. Reder closed the entry on the Chicago School in the first edition of *The New Palgrave* (and reproduced in this edition) with the claim that the final chapter of the School's history was about to end. Perhaps he was right: the apex of the School's influence on public policy – the presidency of Ronald Reagan – ended in 1988. By that time key figures in the School's history had retired, become inactive, left the University of Chicago, or died. Milton Friedman retired in 1977 and moved to the Hoover Institution at Stanford University, where he was eventually joined by Aaron Director (linchpin of the early Chicago law and economics movement) and George Schultz (former dean of the University of Chicago's Graduate School of Business and Secretary of State under President Reagan); he died in late 2006. Arnold Harberger stepped down as chair of the Economics Department in the early 1980s and moved to UCLA shortly thereafter, following the previous departure of long-time graduate advisor H. Gregg Lewis to Duke in 1977. T.W. Schultz, former department chair, was largely inactive as a scholar by the late 1970s; his student and collaborator for many years, D. Gale Johnson, retired in the early 1980s. In international economics, Robert Mundell left the university in the early 1970s and Harry Johnson died in 1979. Of the early leaders, only George Stigler (industrial organization) and Ronald Coase (law and economics) remained active at Chicago, although both were retired.

But it would be a mistake to see the 1980s as the final chapter of the Chicago School. Four major movements in Chicago economics since 1980 are captured in the awarding of more recent Nobel Prizes. Gary Becker was awarded the prize

for his work in the new home and social economics. Robert Lucas won for developments in empirical macroeconomics. Merton Miller was joined by former Chicago researcher Harry Markowitz for their development of finance theory. And James Heckman won the prize for the development of microeconometrics. Alongside these scholars (Miller died in 2000, but the others remain active), the next generation of Chicago economists is making a place for itself. Both Thomas Sargent and Lee Hansen have won the new Erwin Plein Nemmers Prize for significant contributions to new modes of analysis in economics, and Kevin Murphy and Steven Levitt have won the coveted John Bates Clark medal from the American Economic Association.

Each of the four recent movements within Chicago economics – finance, empirical macroeconomics, the new home economics, and microeconometrics – are rooted in common Chicago themes: the application of price theory, the development of methods for the quantitative analysis of social problems, and the notion that economics is an applied policy science. The Chicago approach rests on a three-legged stool which combines an appreciation for the 'simple' analytics of Marshallian price theory (as Reder observes, a constant at Chicago since the early 1930s), the development of quantitative tools as expressed in Friedman's classic article (1953) on 'positive economics,' and the Becker–Stigler prescription to focus attention on the elements of the constraint set, rather than changes in values and preferences, in the explanation of human behaviour (see Becker 1976; Stigler and Becker 1977). Once combined, this three-legged methodological stool provided a stable foundation for the continued expansion of the scope of social scientific problems that Chicago economists have addressed (Becker 1981; Becker and Murphy 2000; Levitt and Dubner 2005). Economic imperialism it may be, but Chicago economists argue that it is the only basis upon which a true social science can be built (see Lazear 2000).

Yet Reder's claim that the book on Chicago economics was about to close was right at least in one regard. Up to the mid-1970s, Chicago economists were an embattled minority (albeit growing in numbers and influence) of the economics profession. After the early 1980s, Chicago was no longer embattled, or even a minority. Its central ideas are still alive, but they are no longer the notions of a contrary-minded small group of scholars; in antitrust, law and economics, monetary theory, labour, finance and applied microeconomics, they comprise a position that has been widely adopted. Chicago economics today is part of the discipline's mainstream; indeed, in some sub-fields it has defined the mainstream. Success outside the confines of Chicago has also changed the School itself: since 1980, Chicago economics has gradually accommodated itself to the common standards of the discipline. Finally, the role of the Chicago School themes within the university has also been rendered more complicated by the remarkable expansion of the Graduate School of Business and the Law School as centres of Chicago-style economic, legal and public policy analysis.

Change and Continuity in Chicago Economics

The 1980s were a period of transition in Chicago economics, in several regards. For most of the period from the late 1940s until the early 1980s, the department of economics was chaired by either T. W. Schultz, D. Gale Johnson or Arnold Harberger; the required price theory course (ECON 301) was taught by either Milton Friedman, Harberger or Gary Becker, and required thorough familiarity with the canon of Chicago price theory – the theory texts of Knight (1933), Friedman (1962), Stigler (1966), Becker (1971), and Alchian and Allen (1969); and the other required first-year course was titled 'money' (not macroeconomics). The continuity in leadership was disrupted in the early 1980s (just as it had been 30 to 40 years earlier by the departures of Jacob Viner, Oskar Lange and the Cowles Commission, and the retirement of Frank Knight), as the early luminaries retired and passed responsibility on to the next generation (although Becker still shares some of the teaching in ECON 301). But a successful programme

is not built around individual scholars, even if they are luminaries like Friedman, Stigler, and Becker. Chicago's success, even in the period from the 1940s to the 1980s, is misunderstood if it is interpreted simply as the product of the unique cluster of scholars that it managed to attract (compare Van Overtveldt 2007, with Emmett 1998). In the early 1950s, the economics department replaced the traditional lone-scholar model of graduate education and faculty research with a workshop model that created an educational environment for graduate students and faculty members more closely akin to a scientific laboratory within which students and faculty pursued a collaborative intellectual project. While the Chicago model is reasonably well-known today and emulated, it was quite unique in the post-war period, and is central to Chicago's success. After passing the core examinations in price theory and money at the end of the first year, students not only continued to take courses but also associated themselves with a workshop (most workshops were open, so students often attended more than one; but each student was primarily associated with one workshop). Faculty were also associated with at least one workshop, and frequently defined the workshop's style: Friedman's money workshop; Stigler's industrial organization workshop; Fogel and McCloskey's economic history workshop; Harberger's Latin American finance workshop; and Coase's law and economics workshop. In the early years no common model had been established, and the workshops varied significant. Eventually, most workshops adopted the 'Chicago rules': the workshop met once per week, papers were distributed beforehand and therefore assumed to have been read, and presenters knew that discussion of the paper might begin as soon as five minutes into their presentation. Most of the workshop time was spent dissecting the paper's thesis, method, and data. Because the pattern of discussion was repeated every week in a dozen or more workshops, students and faculty became quite adept at working within Chicago's rules, applying Marshallian price theory to a wide range of policy-relevant topics. By the early 1980s, the number of economics workshops in the department, the Graduate School of Business, and the Law School was approaching 20. Today, in 2006, it still numbers in the teens.

The transition of key personnel in the early 1980s, therefore, did not affect the structure of the research and educational enterprise which supports the Chicago School. However, it did have an impact on the nature of the research and education of Chicago economists. By the end of the 1980s, the texts which comprised the canon of Chicago price theory lost their pride of place in the reading lists for ECON 301. At about the same time, the 'money' course (ECON 302) became a study of 'income, employment and the price level' built around standard Walrasian general equilibrium models that characterize macroeconomic analysis in most economics programmes. As well, the development of more sophisticated econometric models and techniques came to play a larger role in economic research at Chicago. 'Quantitative methods' was added as a core examination that all students had to pass in order to continue beyond the first year. In short, Chicago economics today looks a lot like economics everywhere else (in part, of course, because Chicago's approach is taught elsewhere and other programmes have created collaborative research environments like the Chicago workshops), although there remains a distinct Chicago 'flavour' that distinguishes it from MIT, Harvard, Berkeley and Yale, if not from Stanford, UCLA and Washington.

Change and Continuity in the Interpretation of Chicago Economics

Even as the contemporary evolution of Chicago economics continues to involve both continuity and change, our understanding of the history of Chicago economics has also evidenced both continuity and change. Reder's original essay was constructed on a model of Chicago economics which placed a small group of key individuals and their ideas at the centre of the School; one could envision his essay as an examination of concentric circles emanating out from the inner

circle that started with Viner and Knight and then included Friedman, Stigler and Becker. While not rejecting Reder's model entirely, historians have begun to construct a story of the development of Chicago economics that complicates the model significantly. Three aspects of Chicago School historiography can be highlighted to illustrate the direction of contemporary historical research on the School, and indicate the potential for further research. First, the transition from the Chicago economics of the inter-war period to the Chicago School of the 1950s and 1960s involved several significant changes. The elements of continuity that Reder emphasized remain – the pre-eminent role of price theory, for example – but discontinuities have crept in. Daniel Hammond's recent work on Milton Friedman's early career provides a glimpse into how that transition influenced even one of the mainstays of Chicago economics. Arguing against the continuity thesis about Chicago price theory articulated by Mirowski and Hands (1998), Hammond shows that Friedman had as much in common with NBER-style statistical work as he did with Knight's Chicago approach (Hammond 2005; see also Hammond 2008, and Rutherford 2008) In fact, even Friedman's famous methodological essay may be more a statement of his experiences with the NBER and the Statistical Research Group at Columbia University (associated with Harold Hotelling) than any earlier Chicago economist. In more recent work, Mirowski and van Horn (2008) argue that, whatever the continuities of Chicago's price theoretic tradition are, the Chicago School of the 1950s and 1960s was shaped more by new research projects initiated in the effort to define a new liberalism to in the Cold War period than it was by the classical liberalism of the Knight–Simons agenda in the 1930s and 1940s (see also Amadae 2003). Thus, while the Chicago School of Friedman and company should not be seen as a totally new tradition, historical reconstructions of their work have opened the door to further exploration of continuities and potential discontinuities between 'old' and 'new' Chicago.

We have already seen the second aspect of contemporary historical reconstruction in the earlier discussion of the institutional framework of the Chicago School. Rather than seeing individual scholars and their ideas transforming modern economics (as suggested even recently by Van Overtveldt 2007), contemporary historiography suggests that the intellectual success of the School was built upon a unique research infrastructure, focused in the workshops. Constructing the history of the workshops involves investigating the support network they developed, ranging from private foundation funding to international connections for research and students. Mirowski and van Horn (2008) focus on the role of the Volcker Fund, but other foundations and external research organizations like the Ford Foundation, Rockefeller Foundation (which funded many activities across the University of Chicago from its inception), Earhart Foundation, and the RAND Corporation participated in supporting Chicago's research infrastructure. In terms of international connections, much has been said of the role of the 'Chicago boys' in Chile, who set the groundwork for economic liberalization in Latin America and elsewhere, but were appointed to their positions by General Pinochet (Valdés 1995; Barber 1995). However, the institutional history of the Chile connection, which goes back to the early 1950s with an educational exchange between the University of Chicago and the Catholic University in Chile, has yet to be completely told. And we also do not have any histories of Chicago's other international research and student connections, including the equally unique relationship with the Hebrew University in Jerusalem and the University of Tel Aviv, despite the fact that Chicago was one of the few American academic institutions that welcomed Jewish scholars.

The third aspect of the Chicago School points toward two potential areas of research which would deepen the type of historical work illustrated above, while also providing insight into the degree of continuity and change within the School. Neither of these areas of research has made significant inroads into contemporary research. The first is the story of the integration of econometric developments at Chicago into the story of Chicago economics (as opposed to their place in the econometric literature). How did we go from Friedman and Stigler to Heckman,

Hansen, and Levitt? Was it just Chicago accommodating itself to the mainstream of the discipline, as is often suggested? Did Zvi Griliches and the development of quantitative analysis in agricultural economics play a role? Or Gregg Lewis and Albert Rees and labour economics? Did a quiet revolution go on at Chicago in the fields outside the core exams that gradually changed the School as a whole? These stories need to be examined in greater detail (see Kaufman 2008, for the history of Chicago labour economics in this regard). Second, the Chicago School's laissez-faire reputation is offset by the fact that a large portion of its graduates have gone into public service both in the United States and elsewhere. Harberger alone can count approximately 20 former students who have become central bank governors and ministers of finance. And countless Chicago students staff national and international economic ministries, commissions, and other organizations. If Chicago economists do believe that economics is a policy science, then the history of their interaction with policy, both as policy advocates and as policymakers, needs to be incorporated into our history. Again, what we do know about this history is piecemeal or quite general (for a start in the right direction; see Banzhaf 2008).

The new perspectives on Chicago economics open the door to both reconstructing the story of the Chicago School and to extending that story forward to the present. While Reder may have been premature to suggest the School's demise, both the reconstruction of its history and the story of its recent developments suggest both continuity and change.

Child Health and Mortality

Janet Currie

C

Abstract

Child health is a major indicator of the direction and well-being of society. It is a significant factor predicting health and productivity in adult life, and the health of adults in turn affects the well-being of the next generation of children. The most important outstanding issues include determining the most cost-effective investments in child health, explaining the relationship between health and socioeconomic status over the life course, and finding the interventions that are most effective in breaking the inter-generational cycle of ill health and poverty. As children are economic actors in their own right, their well-being is worthy of study.

Child health and mortality are of interest to economists for three reasons. First, they are important indicators of the success or failure of government policy. Second, children's health has long-term impacts on their health and productivity as adults. Third, there is increasing recognition that children are economic actors in their own right. Hence, their well-being is worthy of study.

The most common model of child health is one in which health is 'produced' by families using

health 'inputs' (Grossman 2000). Examples of inputs include the goods and services families buy to improve child health. Families maximize an intertemporal utility function subject to the production function, prices, and budget constraints. Inputs are valued only because of their effect on health. Children start with a 'health endowment' that depreciates over time in the absence of health inputs. Public policy affects either the price of inputs or the form of the production function. The model predicts that child health will be influenced by the price of health inputs. The inter-temporal nature of the model highlights the idea that health inputs are investments with long-term payoffs.

Studies of children in developing countries often focus on the 'production' of mortality rates, nutrient intakes, height, weight and other objective measures. In contrast, studies of children in richer countries often focus on the utilization of medical care. But health care is only one input into the production of child health, and it is not the most important. Improvements in standards of living, advances in knowledge about disease and hygiene, and public health measures such as improved sanitation have done more to improve child health in the past 150 years than even the most spectacular advances in personal medical care (Preston 1977). Today, accidents and violence, rather than disease, are the major killers of young children in wealthy countries after the first year of life (UNICEF 2001).

Measures of Child Health

Health is multidimensional and difficult to measure. Mortality and parent-reported health fall at two ends of a spectrum. Mortality is an objective but narrow measure. In countries with high death rates, child mortality is a relatively sensitive indicator of economic and social conditions. For example, in Zimbabwe mortality among children under five years old increased from 80 to 126 per 1,000 live births between 1990 and 2003 as the economic crisis deepened (United Nations Common Database). In countries with lower child mortality rates, the relationship between economic conditions and mortality may be masked by the effects of economic cycles on fertility. For example, some recent papers demonstrate that in developed countries poorer people have fewer children during economic downturns so that the average health of infants increases (see, for example, Lleras-Muney and Dehejia 2004). The relationship between mortality and economic conditions is also masked by strong underlying downward trends in mortality due to technological advances.

A typical survey question eliciting parent reports about child health asks respondents to rate child health on a scale of 1 to 5. An advantage of this measure is that it applies to all children. A disadvantage is that parent reports may be biased. For example, sick parents are more likely to report sick children. Parents are also often asked about limitations on children's activities (for example: Did a health problem prevent school attendance?) and about the presence of chronic conditions. These questions have the advantage of being more specific, but capture only one dimension of health and also suffer from potential biases (Baker et al. 2004; Strauss and Thomas 1996).

In between are anthropometric measures such as birthweight, height, weight, height for age, and body mass index (Martorell and Habicht 1986). Anthropometrics are objective measures that apply to large numbers of children. But, like mortality, they may not be sensitive measures in healthy populations. For example, American children are unlikely to be stunted (low height for age) and are increasingly likely to survive low birthweight (less than 2,500 grams) without significant impairments. American children are increasingly likely to be obese, however, suggesting that body mass index is likely to become a more important health indicator in the future.

A fourth class of measures involve 'risky behaviours' such as precocious or dangerous sexual activity, involvement in crime or victimization, use of handguns, and use of alcohol, tobacco, and illegal drugs. Given the importance of accidents and violence among children, these are important questions. But the stigma associated

with these activities makes it likely that they will be under-reported. Also, risky behaviours may or may not lead to poorer health. Unfortunately, the actual health effects of many behaviours are very poorly reported. For example, there is little information available about injuries that do not lead to deaths.

Some surveys include clinical assessments of children's health by doctors or other trained professionals in addition to some of the information about economic status that is usually collected in social surveys. Examples include the British birth cohort studies, the American National Health and Nutrition Examination Surveys, the World Bank's Living Standards and Measurement Surveys and the Indonesia Family Life Survey. Some of the most interesting work being done in this area involves measures of children's genetic make-up. Caspi et al. (2002) show, for example, that New Zealand men with a specific genetic marker were more likely to be violent adults, but only if they had been maltreated as children.

Given the broad range of health outcomes, researchers should look at a range of outcomes and carefully consider whether the chosen ones are likely to be affected by the phenomena under study.

Health Care Utilization

The human capital model makes a clear distinction between health and health inputs. In the model, parents care about health rather than health inputs. Yet this distinction is often blurred. Williams and Miller (1992, p. 991) state that 'One of the most impressive aspects of health policy implementation [in Europe is] that the programs were put in place not because of extensive documentation on cost effectiveness, but out of a value system that cherishes equity in health care.' The underlying assumption is that all health care produces health. Yet the market for health care is plagued with imperfections. Some care is likely to be superfluous, for consumption rather than investment purposes, or even injurious.

Models of physician-induced demand show that asymmetric information can lead to excessive consumption of medical services if physicians take advantage of their superior information to 'sell' services that patients do not need (Pauly 1980; Dranove 1988). There may be considerable scope for inducement in the market for children's health care. Many child treatments are inexpensive but have a high clinical value when they are warranted, so parents perceive a low cost set against a potentially high benefit. The availability of insurance compounds the problem by further reducing costs to parents.

Researchers should focus on measures of utilization that have a clear benefit. Whether or not a child visited a doctor in a year and whether a child is immunized are good examples. Measures such as the number of hospitalizations are problematic since many hospitalizations could be prevented with appropriate outpatient care. Some recent work focuses on 'preventable hospitalizations' as a measure of inadequate utilization of care (Casanova and Starfield 1995).

Health as an Investment

Child health affects adult health. Poor health in childhood also lowers future utility through its effects on future wages and labour force participation (Currie and Madrian 1999) and through its effects on schooling. Currie (2005) provides a survey of literature linking several specific health conditions to cognitive outcomes and schooling achievement.

Using data from the 1999 Panel Study of Income Dynamics, James Smith (2005) shows that a retrospective self-reported question about health during childhood is remarkably predictive of future outcomes. Comparing siblings, he finds that those who were in excellent or very good health earn 25 per cent more as adults. Currie (2000) surveys some of the many studies that find positive associations between cognitive test scores and anthropometric measures of health such as birthweight, weight, height, head circumference, and the absence of abnormalities in children of various ages. More recently Currie and Moretti (2005) have shown that differences in birthweight between sisters are predictive of differences in education and median income in the

zip code of residence at the time the sisters deliver their own children many years later.

But low birthweight is only one of a number of health shocks that low-income children are more likely to experience (Newacheck et al. 1996). Case et al. (2002) show that the gap in health status between rich and poor US children widens as children age. Currie and Stabile (2003) replicate this finding using Canadian data, and argue that the widening gap reflects the greater frequency of negative health shocks among poor children. The comparison between the United States and Canada suggests that public health insurance is not sufficient to shield children from the negative health consequences of poverty (since Canada has universal insurance). However, in Britain the gap between rich and poor children is smaller than in North America and does not widen as children age (Currie et al. 2004). This suggests that some other aspect of the social safety net may be responsible for protecting child health in Britain.

Poor children are more likely than rich children to suffer from mental health problems (Currie 2005, 2002). Mental health problems account for the largest share of days lost due to health problems in the United States. Many mental health conditions have their roots in childhood, but the relationship between mental health and child outcomes has been largely ignored in economics. Currie and Stabile (2005) investigate the relationship between symptoms of Attention Deficit Hyperactivity Disorder Activity disorder (ADHD) and educational attainment using US and Canadian panel data. We find large negative effects even in rich sibling-fixed effects models. Other research has shown that childhood behaviour problems predict negative future outcomes (cf. Gregg and Machin 1998). The prevalence and potential economic importance of child mental health problems suggest that more work is warranted.

Policy and Child Health

It is easy to justify government intervention in the market for health care. In addition to asymmetric information between patients and providers, there are other informational problems. For example, imperfect information in the market for insurance can lead to market failure. And although parents make most decisions about child health inputs, these decisions have consequences for society. Parents who do not take account of externalities may not provide the optimal level of care for their children (cf. Kremer and Miguel 2004). Finally, the health sector accounts for a large and growing share of the economy, and the government is already the major player in the health care markets in most countries, including the United States. Policies can be divided into those that intervene in the market for health care and those that affect health through other means. Public health insurance is the most prominent example in the first category. It is difficult to study the impact of universal health insurance because there is only a single 'before/after' comparison. But over the late 1980s and early 1990s, the United States greatly expanded its public health insurance coverage of pregnant women and children. Forty per cent of US births are now covered by public insurance. The expansion took place at an uneven rate across states, yielding a potential source of identification.

The effects of this expansion of insurance coverage are surveyed in Gruber (2003). It reduced infant and child mortality, increased utilization of preventive care, and reduced preventable hospitalizations among children. But increases in coverage also increased the inappropriate use of care (for example, increased rates of Caesarean section). And some who took up public health insurance would have had private health insurance in the absence of the expansions. Hence, public health insurance improves child health, but does not necessarily result in efficient service delivery.

Health care utilization is only one input into health production. Other inputs such as a healthy lifestyle and the avoidance of injury are arguably much more important. Government policy has a large role to play in affecting many health inputs beyond health care. A few examples follow.

Pollution is likely to be more harmful to children than to adults both because they are still developing and because of their small size.

Hence, any policy that affects the environment may affect child health. For example, Chay and Greenstone (2003) show that the recession of the early 1980s reduced infant mortality. Currie and Neidell (2005) show that reductions in carbon monoxide pollution in California over the 1990s (largely due to cleaner vehicles) saved at least 1,000 infant lives.

Child obesity is a growing problem that threatens future health. The potential role for government ranges from the provision of information (for example, revising the 'healthy food pyramid' to reflect the most recent nutritional knowledge) to regulation (for example, eliminating Coke machines in schools). The government plays a similar role with respect to discouraging children from using alcohol and tobacco, though in these examples government also directly controls the price of the products through taxation. A good deal of research documents the relationships between prices, advertising, and youth consumption of tobacco and alcohol. But we know much less about the effectiveness of newer policies aimed at curbing obesity (see Gruber 2001).

Although injuries remain a major cause of death, the incidence of accidental death has declined dramatically since the 1970s, especially in the United States (UNICEF 2001). Glied (2001) argues that the decline is due to improvements in education resulting in increased use of, for example, bicycle helmets and seat belts. But many products, including cars, cribs, and medicine bottles, are much safer than they used to be. Is this a result of random technical innovation, government mandates, or fear of lawsuits? Similarly, trauma care has improved greatly. So there are many possible explanations for the reduction in mortality.

While health affects education, maternal education affects child health. Currie and Moretti (2003) find that increases in the availability of colleges increased women's education, leading to better infant health outcomes. Hence, there is an intergenerational payoff to government investments in education that leads to 'increasing returns' to investments in education (Rosenzweig and Wolpin 1994). Finally, as discussed above, poor children are more likely than rich children to suffer virtually all forms of health insult. Hence, improving health is a goal of general poverty alleviation programmes such as public housing and income maintenance.

Summary

Child health is an important indicator of the direction and well-being of society. Health in childhood is one of the more important factors predicting health and productivity in adult life, and the health of adults will in turn affect the well-being of the next generation of children.

Many policies have impacts on child health. Some simple improvements in data collection efforts could have a large research payoff in terms of identifying these impacts. These include: allowing the release of geographical identifiers so that health data can be merged to other data; the inclusion of family income and demographics in health data-sets; and the collection of more objective measures of child health. What are the most interesting outstanding questions? First, what are the most cost-effective investments in child health? Second, what explains the relationship between health and socio-economic status over the life course? And third, what interventions are most effective in breaking the inter-generational cycle of ill health and poverty?

Child Labour

Kaushik Basu

Abstract

According to latest available estimates, somewhere between 14 to 18 per cent of all children between the ages of 5 and 14 years in the world

are labourers. The causes of child labour are many but the primary one is poverty, since for most parents sending children to work is an act of desperation. The availability of decent schools and the provision of small incentives, such as school meals, can help limit child labour. Hence, the best policy response is to improve conditions on the adult labour market, provide better schooling and, on rarer occasions, use legal interventions.

O1

According to the International Labour Organization (ILO 2002) there were 186 million child labourers in the world in 2000, that is, children between the ages of 5 and 14 years doing regular economic work. This implies a 'participation rate' (the number of labouring children as percentage of all children of that age group) of 15.5 per cent. Of these, 111 million were engaged in 'hazardous work'. But by 2004 the number was down to 166 million – a participation rate of 13.7 per cent – and the number of children in hazardous work was down to 74 million. Some details and regional distribution estimates are available in Hagemann et al. (2006), but (at the time of writing) these new numbers are yet to be absorbed and analysed.

It is a truism that the incidence of child labour is hard to estimate, both because it is often illegal and so respondents would not proffer information too readily and because the work is usually in the informal sector where record keeping is weak. Not surprisingly, there are other estimates of child labour, higher and lower. According to the UNICEF (2006), which collates data from different sources from 1998 to 2004, the participation rate is 18 per cent.

These data sources have both upward and downward biases along different dimensions. Domestic work that is done in one's own household is usually recorded very poorly or not at all. But we have micro evidence that in poor regions children, especially girls, do huge amounts of work in their homes, ranging from fetching wood to hazardous work like cooking over open fires. Indirect evidence for this comes from the gender breakdown of child labour. According to ILO data, boys do more labour than girls; their participation rates are respectively 15.9 per cent and 15.2 per cent. But detailed micro studies that try to include heavy domestic work, such as that by Cigno and Rosati (2005, ch. 5), show that girls tend to do 30 per cent more work than boys. Hence, there is a downward bias in the macro numbers mentioned above.

On the other hand, one source of upward bias comes from 'work' being equated with doing more than one hour of work in the 'reference period', and from the fact that for most studies the reference period is one week. It is arguable that children who answer 'yes' because they barely satisfy that cut-off ought not to be classified as child labourers.

The reason for not becoming too weighed down by these statistical debates is that, no matter how one measures it and, as a consequence, whether the participation rate turns out to be 14 per cent or 18 per cent, it is easy to agree that the incidence of child labour is unacceptably high. In a world with as much opulence as ours there should not be so many children working and that too in grinding poverty and in intolerable working conditions.

This raises the question of the causes of child labour and the appropriate policy response. The primary cause is poverty. Well-off parents living in the same nation and under the same laws as poor ones almost never send their children to work. Hence, a child's non-work (whether this be leisure or schooling) is a luxury good. Sufficiently poor parents cannot afford this. This was called the 'luxury axiom' in Basu and Van (1998), and there is ample empirical evidence for it (see discussion in Ray 2000; Basu and Tzannatos 2003; Edmonds and Pavnick 2005). But there are other causes as well. There are parents on the borderline of poverty, who, if they knew that there were decent schools in the area and/or that their

children would get a square meal in school, would take the children out of labour and send them to school. Hence, the provision of schooling and, ideally, having some added incentives for sending children to school can make a large difference to the incidence of child labour (Ravallion and Wodon 2000; Bourguignon et al. 2003).

The presence of other determinants is also evident from the fact that the location of a child in the rural–urban spectrum affects the probability of the kind and amount of work the child is likely to do. This was always believed to be true. There were commentators at the time of the Industrial Revolution in Britain who argued that the alleged increase in child labour was really not an increase but a shift of child labour from agriculture to industry and a dramatic change in the *nature* of work (see Horrell and Humphries 1995, for discussion). Contemporary, casual evidence seems to support this. And a recent empirical study of child labour in Nepal (Fafchamps and Wahba 2006) formally confirms for the first time that urban proximity matters in a significant way. Children who live in or close to cities participate significantly less in labour and have a higher incidence of schooling than their rural counterparts. The health effects of these two kinds of child labour – agrarian and industrial – remain to be investigated systematically. Work in factories can be in dark and dank settings; on the other hand, agricultural work can mean exposure to not just the elements but also to pesticides and fertilizers. The net effects of these deserve investigation.

Given the multiplicity of causes, one has to be careful about the policy response to child labour. It is no surprise that, despite attempts by the British government from 1802 till the mid-19th century to deter child labour through a series of Factory Acts, the participation rate remained consistently and intolerably high. Indeed, the participation rates in Britain in the first half of the 19th century were higher than those found in today's China or India. Likewise in the USA, despite a variety of legislative measures starting in 1837 in Massachusetts, the incidence of child labour remained high and in fact continued to rise till the end of the 19th century.

While there is no final word on policy, we know that some measures are likely to be more effective than others. Ameliorating poverty, improving adult labour market conditions and providing better schooling, as already discussed, can have a significant effect. The law – bans and fines – can also play a role but should be used with caution and after empirical tests of whether the context deserves such measures. It has been argued (see Basu and Van 1998; Dessy and Pallage 2001; Emerson and Souza 2003) that the labour market can in different ways (such as the general equilibrium impact on market wages, coordination with technology and intergenerational dynamics) give rise to multiple equilibria. That is, the market, left to itself, can settle into different grooves; for instance, one with no child labour and another with a high participation rate. In such a case, if the economy settles into the latter equilibrium, a ban can be an effective tool. Otherwise a ban can lead children labouring in factories to worse outcomes, such as starvation or prostitution. Minimally, in such situations the law has to be combined with complementary interventions to ward off the extreme poverty and deprivation that can arise as a side effect of its implementation.

The second son of Richard Child, a London merchant, Sir Josiah Child was born in 1630 and enjoyed a highly successful merchant career during which he amassed a considerable fortune. His business ventures, which included the provisioning of Navy ships, led to his appointment as Deputy to the Navy's Treasurer at Portsmouth in 1655 and he became Mayor of that city in 1658. He was appointed a director of the East India Company in 1674, and with the exception of 1676 he was re-elected to a directorship in every subsequent year until his death. In 1681 he was elected governor of the company and established a close relationship with the Crown. Following the Revolution of 1688, and in response to mounting attacks on his conduct of company affairs, he relinquished some of his active management responsibilities.

Child's claim to recognition as an economist rests on his *Brief Observations concerning Trade and Interest of Money,* first published in 1668 and reissued (anonymously) in expanded form as *A Discourse about Trade* in 1690 and again as *A New Discourse of Trade* (with Child's name on the title page) in 1693. The work summarizes the views he presented to the Council of Trade appointed by the King in 1668 (following the appointment of a Select Committee on the State of Trade by the House of Commons in the preceding year) and to a similar House of Lords Committee in 1669.

Among the reasons for the mercantile supremacy of the Dutch, he cites the establishment of banks and the widespread use of transferable bills of exchange, which he strongly argued should be adopted in England. He argued for a reduction of the legal maximum rate of interest from six to four per cent (referring to this as 'my old theme'), claiming that the lower rate of interest in the Netherlands was 'the *causa causans* of all the other causes of the riches of that people'. He saw the beneficial effects on trade of a lower cost of money capital, but he did not discuss, as did John Locke at the same time, the relation between a legally established rate of interest and the rate established by natural market forces.

Child's argument that the beneficial effect of lower interest rates would cause 'all sorts of labouring people that depend on trade (to be) more constantly and fully employed' took up the then widespread concern with the employment problem and he concluded: 'it is our duty to God and nature so to provide for and employ the poor'. A significant discussion of the question of the poor and a scheme for their relief and

employment is included in Chapter II of the *Discourse of Trade.*

Notwithstanding his scattered observations that appear to support free trade principles and his assertion of the principles of competitive markets, Child was an exponent of monopoly when it suited his and the East India Company's advantage. He recognized the need to export bullion if that gave rise to further export trade opportunities. But his work abounds in arguments for trade restrictions in specific cases, such as those requiring the transportation of traded commodities in English vessels and requiring that colonial trade should be conducted only with England, thereby emphasizing the domestic employment-creating effects of the colonies. He stands as a latter-day mercantilist rather than an analytical anticipator of the laissez-faire doctrines of genuine and generalized freedom of trade.

Childcare

David M. Blau

Abstract

The market for childcare and the role of the government in the childcare market have grown enormously as mothers of young children have entered the labour force in very large numbers. Economists have made important contributions to understanding many aspects of childcare. This article focuses on (*a*) the effect of the price of childcare on labour force participation of mothers of young children, (*b*) the effect of childcare and early childhood interventions on children, and (*c*) the rationale for and effects of government involvement in childcare. Fruitful avenues of additional research are suggested.

The market for childcare in advanced economies has grown enormously in response to the dramatic increase in labour force participation by mothers of young children. In 1950 12 per cent of married women in the United States with children under age six were in the labour force, compared to 63 per cent in 2000. Labour force participation of single mothers with children under six has also increased rapidly, reaching 65 per cent in 2000. As the market has grown, the role of the public sector in subsidizing, regulating, and providing childcare has increased substantially. One- third of all expenditure on childcare and preschool in the United States is financed by government subsidies or by direct provision of services. The public sector plays an even larger role in childcare in many European countries. Three aspects of childcare have received the most attention from economists: (*a*) the effect of the price of childcare on labour force participation of mothers, (*b*) the effect of childcare and early childhood interventions on child development, and (*c*) the rationale for and effects of government involvement in

childcare. Childcare is interpreted broadly here to include care provided by someone other than a child's parent either to facilitate employment of parents or to enhance child development.

Blau and Currie (2006) summarize the findings of 20 studies that estimate the elasticity of maternal labour force participation with respect to the price of childcare. The estimates vary widely across studies, but studies that account for the availability of informal unpaid childcare options usually estimate relatively small elasticities, in the range of − .09 to − .20. These studies use a multinomial choice framework that allows for the possibility that a mother can work without using paid childcare. Use of unpaid childcare by family members, relatives, and others is very common. The relatively small elasticity estimates suggest that a price increase induces substitution of informal unpaid childcare for paid care, dampening the sensitivity of maternal employment to the price of childcare. Some evidence suggests that the price elasticity is larger in absolute value for lower-wage women. This evidence confirms that childcare costs are a significant but not major barrier to employment of mothers. The evidence also implies that childcare subsidies increase work incentives of mothers, a finding confirmed by a small number of studies that directly analyse the impact of subsidy programmes on employment.

An important concern about childcare is that low-quality care could be harmful to the development of young children. Conversely, high-quality care may help compensate children from low-income families for the disadvantages of growing up in poverty. The effect of childcare on child development has traditionally been the domain of developmental psychology, but in recent years economists have contributed to this literature, noting its similarities to the 'education production function' literature for school-age children.

The quality of childcare can be characterized by 'structural' features such as the size of the group in which care is provided, the ratio of adult caregivers to children, and the education and specialized training of providers. Alternatively, direct observation of the developmental appropriateness of the care received by children can be made by trained observers using standardized instruments. These 'process' measures of quality are more proximate determinants of child development than are the structural features.

The small amount of evidence available suggests that higher-income parents do not choose higher-quality childcare on average: among users of day-care centres, there is no systematic relationship between family income and the quality of childcare used, if other factors are controlled for (Blau 2001). This is true whether the quality of care is measured by structural characteristics or process measures. This suggests that parents are either unable to discern the quality of care, or unwilling to pay the additional cost associated with higher-quality care, or both.

Several random assignment demonstration projects have evaluated the impact of high-quality preschool programmes for disadvantaged children (see reviews in Blau 2001; and Blau and Currie 2006). The results show that such programmes have delivered substantial long-run benefits to the participants and society: lower school dropout rates, higher earnings, fewer out-of-wedlock births, and lower public expenditures on welfare, criminal justice, and special education. Benefit-cost calculations show that these interventions have a very high social rate of return. This evidence is compelling, but it is based on very intensive and costly programmes that are of exceptionally high quality and are targeted at highly disadvantaged children. It is unclear whether childcare of moderately high quality provides positive but proportionately smaller developmental benefits, or whether there exists a threshold of quality below which benefits are negligible. It is also unclear how the quality of childcare affects children who are not highly disadvantaged. In non-experimental studies that follow children over time, higher-quality childcare is associated with better developmental outcomes in the short run (one to three years). However, it remains uncertain to what extent this is a causal impact. Recent studies that control for many other potentially confounding factors find that the quality-development association is smaller than in models with fewer controls, but remains significantly different from zero.

Two main arguments have been used to rationalize a role for government in the childcare

market. The arguments are based on attaining economic self-sufficiency, and childcare market imperfections. On self-sufficiency, childcare subsidies might help low-income families achieve economic self-sufficiency, defined as being employed and not enrolled in welfare programmes. Self-sufficiency is a desirable goal because it may inculcate a work ethic and generate human capital through on- the-job training and experience. These arguments explain why many childcare subsidies require employment or work-related activities such as education and training. Subsidies for childcare and other work-related expenses paid to employed low-income parents may cost the government more today than would cash assistance. But these subsidies could result in increased future wages and hours worked and lower lifetime government support than the alternative of cash assistance both today and in the future. This argument has nothing to do with the effects of childcare on children, and there are few restrictions on the quality of childcare that can be purchased with employment-related childcare subsidies. However, evidence on wage growth of low-skill workers suggests that wages grow only modestly with experience, too slowly to lift low-skill workers out of poverty (Gladden and Taber 2000). Middle and upper-income families are generally not at risk of going on welfare, so it is not obvious that there is an economic rationale for subsidies for their employment-related childcare expenses.

As for market imperfections, the imperfections that are often cited are imperfect information available to parents about the quality of childcare, and positive external benefits to society generated by high-quality childcare (Walker 1991). Imperfect information exists because consumers do not know the identity of all potential suppliers, and the quality of care offered by any particular supplier is not fully known. A potential remedy for the first problem is government subsidies to resource and referral agencies to maintain comprehensive and accurate lists of suppliers. The second information problem arises because consumers know less about product quality than does the provider, and monitoring the provider is costly to the consumer. This can lead to moral hazard and/or adverse selection. The limited evidence available suggests that parents are not well-informed about the quality of care in the arrangements used by their children. Childcare subsidies targeted at high-quality providers could induce parents to use higher-quality care.

The externality argument is a standard one that closely parallels the reasoning applied to education. High-quality childcare leads to improved intellectual and social development, which in turn increases school readiness and completion. This reduces the cost to society of problems associated with low education: low earnings, unstable employment, crime, drugs, teenage childbearing, and so forth. If parents are not fully aware of these benefits, or account for only the private and not the social benefits, then they may choose childcare of less than socially optimal quality. This argument could rationalize subsidies targeted to high-quality providers, such as Head Start, a US programme aimed at enhancing cognitive and social development of low-income children.

As this discussion implies, childcare policy can be used to facilitate employment of mothers and enhance development of young children. There is likely to be a trade-off between these goals because higher-quality care is more expensive. There is not a political agreement in the United States to spend enough to achieve both goals, or on which goal should have the highest priority. This is due in part to conflicting views on the proper role of the government in a domain that was mainly left to families until the last quarter of the twentieth century. But it also reflects lack of knowledge about the magnitudes of important parameters that affect the costs and benefits of alternative policies. Economists could make significant contributions to knowledge by careful empirical studies that produce reliable estimates of such parameters. The following issues seem important and well-suited to analysis by economists. Despite a large number of studies, there is considerable uncertainty about the magnitude of the elasticity of maternal employment with respect to the price of childcare. A careful sensitivity analysis could help resolve this uncertainty. Research on the price-responsiveness of low-income mothers would be especially useful.

Consumer demand for quality in childcare is not well-understood, and new research could be valuable. Research on the take-up decisions of families eligible for childcare subsidies would be useful in order to determine the likely effectiveness of different forms of subsidies. New research on the supply of childcare would be useful. Subsidies to consumers may bid up the price of childcare, and it is important to be able to quantify such effects. It would also be useful to examine the quality supply decisions of providers, in order to determine how responsive the supply of high-quality care might be to subsidies.

China, Economics in

Kiichiro Yagi

Abstract

Although pre-modern China possessed rich ideas pertaining to economic matters, they were not separated from the discourse of morality and politics. Even in the late 20th century, Chinese thinking, often unconsciously, reflected traditional ideas. Liberal economics missed the chance to guide the modernization of China. Marxian economics established its monopoly under the reign of the Communists. However, China had Marxian economists who supported its gradualist transition to a market economy. In the 1990s, the task of guiding economic reforms in China was handed over to a new generation of economists who absorbed 'Western' (non-Marxian) economics.

Economics in China has not been able to disassociate itself from politics. The Chinese word for economy or economics, *Jingji*, is the abbreviation of *Jingshi* (or *Jingguo*) *Jimin,* which means 'ruling the society or state and saving the people'. In traditional Chinese learning, this is a generalized concept that covers almost the entire range of a state's administrative activity. However, the viewpoint implied in this word is that of the rulers or administrators and not that of individuals engaging in economic activity on their own account.

The Quest for Wealth and the Control of Morality

Policies oriented towards the attainment of 'wealth and power' had appeared already in ancient China,

the Eastern Chou Period (722–256 BC), when the rule of Chou dynasty became in title alone and powerful vassal lords struggled with each other for leadership, which was based on the power of their feudal states. A crucial insight pertaining to economic growth that emerged during this period was that fostering the material welfare of the people was a precondition for a strong state. The famous saying 'Man will care about honour and disgrace only when he has enough clothing and food' is attributed to Guan Zhong (730–645 BC), the prime minister of a ducal state. He implemented policies that would bring stability to people's lives; these policies included the promotion of agriculture, monopolizing salt and iron, state intervention in the public distribution system, maintenance of a balanced budget and the consolidation of taxation and military services. Practical policies were further developed by many politicians in the Warring States Period (475–221 BC). These became part of the arsenal of policy measures adopted by the administrators of the unified state of successive dynasties from the Qin (221–206 BC) to the Qing (AD 1644–1911). A text named after Guan, *Guan Zi,* was compiled in the Western Han Period (206 BC–AD 8). This contains detailed discussions of the practical economic policies of ancient China.

In ancient China, before the unification by the Qin, political control over merchants was not strict. Wealthy merchants in the pre-Qin period were vividly described in *Records of the Historian* ('*Shiji*'). The editor–historian, Sima Qian (145–87 BC) clearly favoured a liberal economic policy that permitted the innovative activities of talented merchants.

Competitive Schools in Ancient China

Confucius (551–479 BC) also recognized the quest for wealth as a natural human trait. However, he stressed that the teachings of morality (*Ren*) should control the quest for wealth. According to him, superior men can understand and adhere to the virtues of righteousness and benevolence in their deeds, while inferior men (common people) cannot. The former belong to the ruling class and the latter are the ones who are ruled, who must be guided by the former. Confucius stressed the educational effect of a ruler on the people's perception of societal order. He was opposed to the levying of heavy taxes and unnecessary state intervention, since that might jeopardize the common man's standard of living. He maintained that a peaceful and fair reign of a virtuous ruler fosters allegiance. As long as people follow the basic order of society, the wealth of the state emerges as a spontaneous result of the growth in the population.

Meng Ke (c. 390–c. 305 BC), whose name is often mentioned together with Confucius, strictly excluded the consideration of material benefits from the political discourse of superior men. During his first meeting with the king of Liang, Meng declared that he spoke only of 'righteousness' (*Yi*) and not of 'benefits' (*Li*). However, he also stated that the dominance of 'righteousness' presupposes the maintenance of a 'permanent property' of the people in order to secure the morality of the people (*Mencius*).

Mo Di (c. 468–c. 367 BC) and his School (Mohists) grounded their altruistic teaching on the extended approval of 'benefits'. They believed that economic transactions are acts of 'mutual benefit', which will eventually support the doctrine of 'universal love'. From a utilitarian viewpoint, they regarded righteousness as a material benefit; this is in clear contradiction with the Confucians. Mohists further advocated a ban on war and simple burial. Apparently, this School originated from the craftsmen who were not entirely integrated into the social hierarchy existing in the pre-Qin period.

Legalists such as Shang Yang (c. 390–338 BC) and Han Fei (c. 310–238 BC) differed from the Confucians with respect to the measures to be adopted for guiding people. They stressed the effective control of people by the strict enforcement of punishment. They prioritized agricultural production and considered manufacturing and commerce as tertiary activities. The Legalists were prepared to collaborate with princes and politicians who sought to enhance the wealth and power of their states.

Omnipotent State Versus Virtuous Reign

Ancient China was unified by the Qin dynasty, which had adopted the policies of Legalists. The first emperor of the Qin (221–206 BC) suppressed Confucians who criticized his reign as measured against the criterion of virtuous ruler. However, under the following dynasty, the Han, Confucianism established its position as the state orthodoxy, which continued until the end of the Qing dynasty. Still, a Legalist direction survived in the pragmatic mentality and policies of administrative bureaucracy. Thus, Chinese political history witnessed repetitive conflicts between the moralistic direction of Confucianism and the bureaucratic administration in the direction of Legalists.

One of the most noteworthy debates was the dispute on salt and iron (81 BC), in which San Hongyoung (152–80 BC) – the finance minister of the Western Han dynasty – had to defend his policy against the criticism of Confucian scholars. In order to compensate for the deficit in the state finance caused by an expansionary policy, San extended the state monopoly of salt and iron and introduced a state- managed storage and distribution system. Such a system could be legitimized if it was successful in guaranteeing the nationwide provision of necessaries and a stabilization of their prices. However, coupled with a heavy tax burden, San's system made a devastating impact on the nation. Confucian scholars voiced the dissatisfaction of the people and pressed for the abolition of San's system.

A similar constellation appeared in the dispute around the economic reforms of Wang Anshi (1021–86). Wang's attempt to consolidate public finances by suppressing the annexation of lands by rich families and establishing a strict taxation system was opposed by traditional scholars, who were in alliance with the richer families.

Apart from the taxation and market control, Chinese administrators showed their expertise in the area of currency. They are the first to have issued paper money (*Jiao Zi*) in the 11th century. The Yuan dynasty (1271–1368) adopted the idea of inconvertible notes in its monetary system. The paper currency ordinance of 1287 drafted by Ye Li (1242–92) contained sound measures to maintain the value of paper money in relation to the regularly inspected silver reserve fund. This paper currency system of the Yuan dynasty exerted a certain influence over the currency system of other countries through the commercial networks under the grand Mongolian rule.

The Demand for Equalization

Support for equality is another persistent trait of traditional Chinese economic thought. The equalization of land and wealth was a typical demand raised by numerous peasant rebellions. The Taiping Rebellion (1851–64) put into effect an equal distribution of land, and the rural revolution under Mao Zedong's (1893–1976) directive displayed a similar kind of egalitarianism. However, the ideal of equality in the distribution of wealth can also be found in Confucian classics. Confucius himself remarked that rulers must worry 'not about the scantiness of wealth but its inequality of distribution' since 'there will be no feeling of poverty under equal distribution' (*Analects*). Here, equality is appreciated with respect to its ability to maintain harmony and tranquillity among the ruled. Meng Ke also proposed an egalitarian *Jin* land system, in which peasants, who were allotted equal amounts of land, jointly cultivated public land for the sake of generating public finance. This proposal was revived several times by reformist politicians as well as by egalitarian rebels.

A vision of an egalitarian ideal society, the Great Harmony (*Datong*), where neither private property nor egoistic interests exist, is mentioned in the Confucian classic *Li Ki. Xiaokang*, a society in which the people are guided by order and institutions is not an ideal but a second best, suited to the age of a civilized society. However, towards the end of the Qing dynasty, Kang Youwei (1858–1927), a reformist politician and scholar, revived the ideal of the Great Harmony to regenerate the whole nation.

Preconditions for Chinese Modernization

The nationwide examination system for the recruitment of government officials was established under the Sui dynasty (581–618) and continued until 1905. Based on the Confucian orthodoxy, it moulded the thought of Chinese intellectuals over a millennium. However, Confucian orthodoxy was not totally exempt from change. In addition to the ideas that had emerged in the ancient period, it absorbed heterogeneous ideas from other intellectual schools of thought, such as Buddhism and Taoism. The effect of the development of a rationalistic Neo-Confucianism guided by Zhu Xi (1130–1200) and the emergence of the countervailing school of Wang Yangmin (1472–1528), which introduced an inner integrity to Confucianism, are interesting issues that need to be further researched. Towards the end of the Ming dynasty (1368–1644), these developments promoted a critical attitude towards the traditional order of the empire. Huang Zongxi (1610–95) and Wang Fuzhi (1619–95) developed a utilitarian concept of hierarchy based on the private property and self-interest of the people. Further, the diffusion of the teaching of Wang Yangmin (*Xinxue*) that stressed purity of mind nourished the morality of the merchants (Yu 1987). However, these developments were not sufficient to modernize the Chinese intellectual tradition from within. The landlord class that recruited state officials through a nationwide examination formed the ruling alliance of the society. Merchants had no other option but to join this alliance as subordinate participants. However, the intellectual legacies of old China were preconditions for the Chinese to cope with the modernization that was initially forced on them by external forces.

Introduction of Western Economics

It was the publication by Wei Yuan (1794–1857) of the *Geography of the Maritime Countries* (1843) that initiated the movement among Chinese intellectuals of learning from the West. However, Western economics was not introduced until two decades later. Using H. Fawcett's *A Manual of Political Economy* as a textbook, W.A.P. Martin, an American Christian missionary, began a course on policies for the wealth of nations at a government school in Beijing in 1867. Later, in 1883, this course was translated and published in Shanghai under the same title. A second significant contribution pertaining to the translation of Western economics was that of a British missionary, J. Edkins, who translated W.S. Jevons's *Primer of Political Economy* into Chinese. This translation was published in 1886 with the Chinese title, *Policies for the Wealth of Nations and Support of People*. Fawcett and Jevons were neither mercantilists nor interventionists. However, both Chinese titles suggest that the Chinese people of this period regarded Western economics as a policy measure to strengthen the state.

Between 1901 and 1902, Yan Fu (1853–1921) published the translation of Adam Smith's *Wealth of Nations* in Shanghai under the title *Elements of Wealth* ('*Yuan Fu*'). In his commentary on this translation, Yan clearly stated that the principles of economics advocate free competition, are against state intervention and limit the scope of state involvement in those tasks that are not suited for the private sector. However, most Chinese intellectuals, including Yan himself, accepted the theory of liberal economics because of its contribution to the recovery of the power of the nation (Schwartz 1964).

However, the principles of liberal economics do not appear to have contributed much to the modernization of China. Late 19th-century reformers had to fight against the obsolete bureaucracy of the Qing dynasty. As was typical of revolutions in the 20th century, the social dimension of the Chinese revolution increased in significance with the passage of time. Democrats and liberals worked together on the cultural front of the 4 May Movement (1919). However, this collaboration soon broke down, since democrats shifted their position to that of Communist revolutionaries and began to attack liberals as 'bourgeois intellectuals'.

The ideology of Western socialists and social reformers was introduced by Sun Yatsen (1866–1925) through his 'Three People's

Doctrines'. Sun regarded Western capitalism as the root cause of the social problems in the West and searched for an alternative route towards economic development for China. He recognized Henry George's idea of land nationalization and the German socialist idea of capital regulation. After experiencing the state of anarchy that followed the Xinhai Revolution (1911), he sympathized with the Russian Revolution and led his Nationalist Party, the Guomingdang, in cooperation with the Communists.

Period of the Republic of China

Despite continued struggles among the warlords and an unstable security environment in both domestic as well as external affairs, the period of the Republic of China (1912–49) marked the emergence of economic academism in China. Most of the renowned universities of today originated in this period, and specialized economists, some of whom were educated in the United States, Europe and Japan, began to teach there. There were 16 Chinese publications on economics in the decade following Yan's translation of Adam Smith's *Wealth of Nations;* this number increased to 20 between the 1911 revolution and the 4 May Movement. It further increased to 228 in the decade following 1919 and to 1,116 after 1929 (Shanghaishi 2005, pp. 114–15).

The Chinese Economic Society was established in 1923, and after a decade its membership amounted to c. 600. In 1930, it launched the quarterly journal *Jinngjixue Jikan* in Shanghai. Ma Yinchu (1882–1982), a Ph.D. holder from Columbia University who had taught economics at Beijing University since 1915, was its president. He served the Guomingdan government as its economic advisor and published his views on the currency problems, banking and public finance in China. The Chinese economists of this period actively participated in policy discussions, such as the currency reforms of 1936, financial problems and industrial development plans.

However, it was the problem of agriculture that most concerned Chinese economists. A large-scale research project in rural economy headed by Chen Hansheng (1897–2004) gave birth in 1933 to the Research Forum in Chinese Rural Economy. This forum gathered a membership of about 500 members and trained economists who continued their research activity in the post-1949 period. The most prominent member among them was Xue Muqiao (1904–2005), who edited *Rural China* ('*Zhongguo Nongcun*') from 1934.

Social scientists influenced by Marxism eagerly discussed the nature of existing Chinese society (1929–1931). This debate contained a political element since those who supported the Chinese Communist Party (CCP), which was founded in 1921, regarded Chinese society to be a semi-feudal and semi-colonized society, whereas the Trotskyists emphasized the dominance of the capitalistic elements. Such debates on the nature of Chinese social history and its periodization (1931–3) and on the Asiatic mode of production continued in the field of economic history.

Marxist Monopoly Under the PRC

The People's Republic of China (PRC) started in 1949 with the programme of the 'New Democracy' that was to be based on the alliance between Communists and democrats from all sections of the society. The government requested non-resident Chinese scholars to participate in the reconstruction of China.

Ma Yinchu, who was exiled to Hong Kong as a result of a dispute with the Guomingdang government, returned to take over as the president of Beijing University. Initially, several of his colleagues were those who had been educated in American universities. Thus, in the beginning of the PRC, universities in China had non-Marxian economists on their staff. However, the socialist reconstruction of academic system based on the Soviet–Russian model, and the intensifying confrontation with the United States, soon deprived 'bourgeois economists' of freedom. Abridged translations of Russian textbooks pertaining to Marxian economics became the standard education materials. In 1957, when the CCP declared a liberal policy towards intellectuals with the

appealing phrase 'Let a hundred flowers blossom', Ma proposed his idea of population restraint to the People's Congress of the PRC. This offended Mao Zedong's positive view of population growth. The ensuing continuous attacks on 'Malthus in China' signalled the expulsion of non-Marxian ideas from the academic world under the PRC.

According to the original concept of the New Democratic Economy, the development of capitalism in China, except for 'monopoly capital', was to be welcomed as the basis for initiating future socialist transformations. However, in 1953 the success of the agrarian reforms motivated Mao to practise 'the solution to the problem of ownership'. Through the socialization of the ownership of the means of production, a Soviet Russian-type of planned economy was established in the sectors of industry and commerce during 1953–6. This was followed by the establishment of people's communes in the rural areas in 1958.

Reform Economists in China

The first criticism levelled against a centrally planned economy also emerged in the years of 'Let a hundred flowers blossom'. In 1956 and 1957, Sun Yufang (1908–83) proposed an economic model of decentralization with the use of profit targets in the management of manufacturing sector. Sun was a Marxian economist who had studied in Moscow. He grounded his proposal on the validity of the 'law of value' in a socialist economy, which is distinguished from the 'law of market'. In this respect, the views of Gu Zhen (1915–74) were more progressive, in that he openly criticized the abolition of the market mechanism under socialism. During the wave of the Anti-Rightist Struggle that occurred during the latter half of 1957, Sun and Gu were labelled 'revisionist' and 'bourgeois rightist' respectively.

Chinese economists were aware of the shortcomings of a Russian-type planned economy and the need for reform. However, the ideological rejection of the 'material interest' as a tool of 'revisionists' prevented the introduction of reforms in the management system of state-owned enterprises (SOEs). Ideological politicians stuck to the appeal to 'spiritual incentive'. Reforms were then directed towards an administrative decentralization, in which powers and benefits were divided among various administrative organs.

It was only after the declaration of the end of the Great Cultural Revolution (1966–1976) and with Deng Xiaoping (1904–1997) taking over the leadership of China that the damage caused by excessive decentralization and the need for management reforms were seriously taken into consideration. After the strategic decision of the CCP for economic reforms and an 'open door' policy, China implemented various policies such as the creation of special economic zones and township and village enterprises as well as the approval of private enterprises and households contracting in agriculture. Under the concept of the 'planned commodity economy' (1984), the market economy was theoretically subordinate to the planned economy. The existence of private sectors was legitimized by the theory of the 'early stage of socialism' (1987). At last, in the 1990s, by the definition of the 'socialist market economy' (1992), the private sector was clearly approved as the main and normal element of Chinese socialist economy.

A group of veteran economists, namely, Xue Muqiao, Du Rensheng (born 1913), Yu Guangyuan (born 1915), Liao Jili (1915–93), Lieu Guogang (born 1923), and others contributed to the transformation of the concept of 'socialist economy'. In the early 1980s, they re-examined the orthodox and heterodox texts of Marxism, studied reform economics of former socialist eastern European countries, and endeavoured to draw conclusions from the empirical research on agriculture and manufacture sectors. They formed the 'theory of the socialist commodity economy'.

After Mao's death and the end of the Great Cultural Revolution, academic economists soon regained their energy. The Chinese Academy of Social Sciences (CASS) was established in 1977. The oldest Shanghai Economics Society, whose origin can be traced back to 1950, resumed its activities in 1978. In the same year, the Chinese Research Forum of Overseas Economics was established and began to work for the diffusion

of the 'Western' (non-Marxian) economics among Chinese economists.

In the 1980s, Chinese economists recovered their communications with the world community of economists. The government invited renowned Western economists to academic conferences pertaining to the economic reforms in China. It began to send young people to the graduate courses of top Western universities, and encouraged them to assimilate advanced analysis of modern economics. By the mid-1990s, China already had a group of talented economists who could analyse economic reforms in China in a manner similar to the Western (non-Marxian) economists. In the fields of research, economic teaching, and policymaking, the activities of non-Marxian economists became more significant with each passing year. Thus, the monopoly of the Marxian economists was broken.

Present Situation of Economics in China

The ideological/political control exercised by the CCP over Chinese intellectuals had been considerably reduced at the outset of the 21st century. Economists in China can now keep themselves abreast of the latest developments in the field of economics. However, the following three features are noteworthy when compared with economics in other countries.

The first is the peculiar position of Marxian economics in China. At present, it is clear that Marxian economics is just a sub-area in the whole gamut of research activities undertaken by Chinese economists. It is therefore symbolic that the Marxian economists organized themselves into a society named the Chinese Forum for the Study of *Capital* (founded in 1981). However, Marxian economics still influences society by two privileged routes. One is that Marxian economics continues to be an obligatory course of political economy (*Zhengzhi Jingjixue*) in most Chinese universities. It is virtually a part of the political education imposed on academicians. The other route is the ideological function for the ruling CCP. The CCP needs Marxian economists to defend its policy on ideological grounds.

The second noteworthy feature of Chinese economics is the focus on institutional economics and political economy. Leading economists of the post-Great Cultural Revolution generation such as Lin Yifu (born 1952) and Fan Gang (born 1953) adopted the framework of institutional economics. Lin attributed the success of the Chinese economy after the implementation of the 'open door' policy to the switch of the development strategy and the institutional reforms accompanying it. Fan provided an analysis of the incremental reforms in China by applying the public choice approach. The theories pertaining to modern institutional economics – transaction cost theory, property rights theory, contract and corporate governance theory, and comparative institutional analysis – are widely accepted by Chinese economists.

Lastly, a new divide between the supporters of the prevailing liberal policy and its critics emerged in 2004, and a debate between these two groups has continued since then. First, Lang Xianping (born 1956), a professor at the Chinese University in Hong Kong, attacked managers of the firms whose stocks were newly listed on the stock market. They were charged with smuggling national property by the application of various techniques such as management buyouts. His attack on the privatization policy encouraged economists who were concerned about the increasing inequality in society and diminishing state intervention. They criticized over-hasty privatization and demanded a policy that would enhance the level of equality in society. They stressed the need to implement reforms in the field of social policy, and rejected the unconditional integration of the Chinese economy within the global market. Liberal economists, who stressed efficiency, rebutted them. Another group of economists declared themselves as taking a middle-of-the-road position. The government is said to have attentively followed the debate.

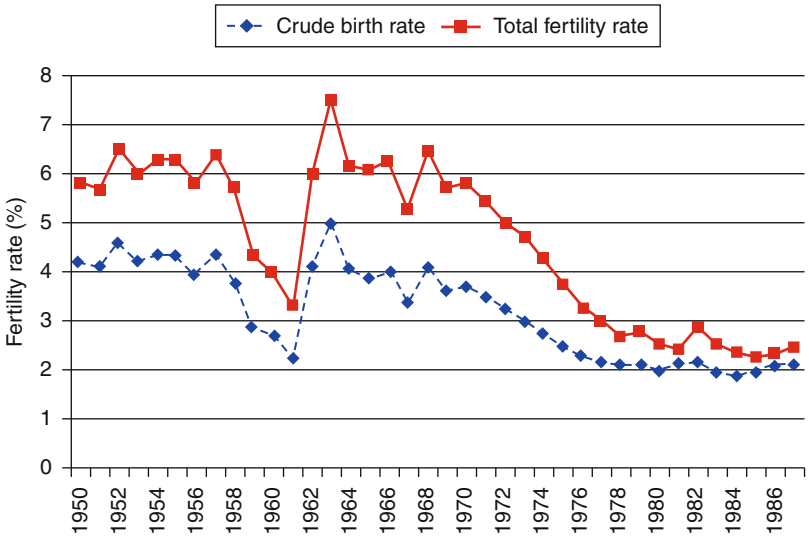
Background

When the Communist Party came to power in China the country was recovering from the Second World War and its civil war. The war-torn country desperately needed people to rebuild the nation. Consequently, the country's population policy at that time was to encourage a high birth rate. Along the lines of the Soviet model, China awarded mothers of many children "Mother-Hero" status and, like most post-Second World War western countries, China had a baby boom, with the total fertility rate hovering around six births per mother. This period of high fertility lasted until the great famine in the late 1950s. The three-year famine significantly reduced the birth rate, but soon after population growth bounced back to over and above the pre-famine level (sees Fig. 1). China's total fertility exceeded six births per mother throughout the 1960s (Banister 1987).

Low agricultural productivity, economic stagnation and economic isolation as a result of the Cold War, coupled with vivid memories of the Great Famine, led to concern that China might again not be able to feed its growing population. In the early 1970s, in the middle of the Cultural Revolution, a philosophical 'debate' over the possibility of a Malthusian Population Trap was initiated, and soon after, at the end of 1973, the policy of 'Later, Longer, and Fewer' was introduced (Center for Population Studies, CASS 1986; Peng 1991; Feeney and Wang 1993; Cai 2010; Ebenstein 2010). The policy encouraged couples to get married later, have longer periods in between children, and have fewer children. The policy had a significant impact on the birth rate, especially amongst the urban population. During the course of the 1970s the total fertility rate fell from above 5 to just around 2 (Wang 2011). In January 1978 a new policy of 'One is the Best and Two is the Most' and 'Reward Having One Child and Punish Having Three' was introduced. This was soon followed by the introduction of the 'One



China's One Child Policy, Fig. 1 China's fertility rates, 1950–1987 (Sources: The data for years 1950 to 1972 are from Banister (1987) and for the years from 1973 to 1978 are from Feeney et al. (1989))

C

Child per Couple' policy (hereinafter the One Child Policy (OCP)) at the second meeting of the fifth People's Congress in June 1979 (see, for example, Center for Population Studies, CASS 1986; Peng 1991).

Although the OCP was originally intended to cover the country as a whole, by and large, rural areas have always allowed a second birth if the first child is a girl (Peng 1991). The proportion of the population with rural household registration (*hukou*) was more than 80% in 1980 and was still above 70% in 2010. Some rural areas over some periods have even allowed three children. In addition, there are different rules for minority groups, which are subject to much looser restrictions. In urban areas, however, the policy has been strictly enforced since it was introduced (Kane and Choi 1999; Zhang and Sturm 1994). Those who obey the policy are rewarded financially while those who violate the policy are subject to fines and their children face higher fees for accessing education and health services. In some cases children are denied these services (Peng 1991; Zhang and Sturm 1994).

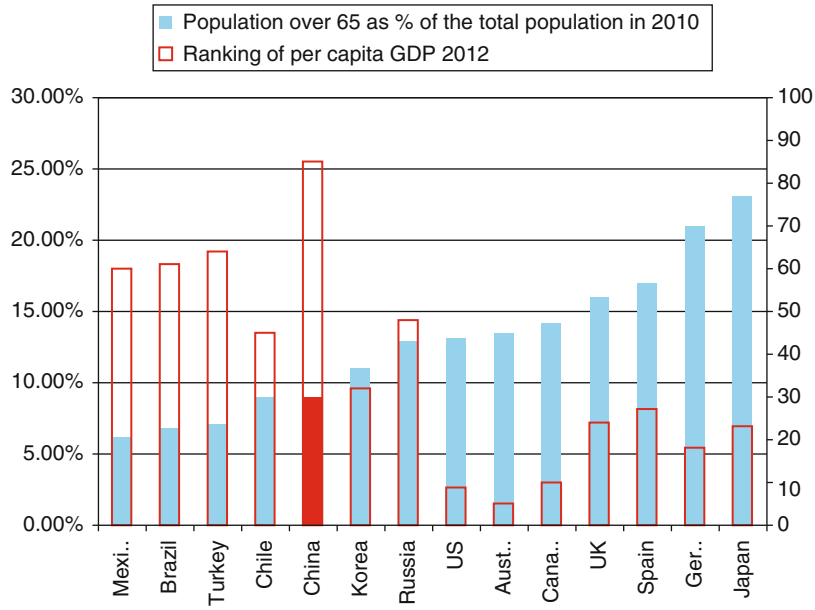
Impacts

Population Size

The ultimate objective of the introduction of the OCP was to control population size. To be specific, the goal was to keep the total population at no more than 1.2 billion by 2000 (Wang et al. 2012). During the past few years, there has been heated debate in the literature over the magnitude of the impact of the policy on population size in China.

The official Chinese government claim is that some 400 million births were prevented due to the OCP. According to Wang et al. (2012), the original '400 million' figure came from a simple extrapolation conducted by Yang et al. (2000) to project what the crude birth rate would have been if it had continued to decline as it did from 1950 to 1970. Wang et al. (2012) challenge the 400 million estimate for two reasons: (1) they argue that Yang et al.'s (2000) original projection used the wrong counterfactual. (They did not take into account the fact that between 1970 and 1979, before the introduction of the OCP, China's fertility rate had already dropped by 50%.); and (2) many countries which had similar fertility rates to China in 1970 also experienced significant drops in fertility in the absence of the OCP. For example, Thailand and China have had almost identical fertility trajectories since the 1980s, but Thailand did not adopt a one child policy.

Using the actual Chinese fertility rate in 1979 (just before the introduction of the OCP) and the fertility trends in 16 other countries, which had similar fertility rates to China in the year 1970,



China's One Child Policy, Fig. 2 Share of population over 65 and economic development (Source: Aging population data are from OECD StatExtracts: http://stats.oecd.org/Index.aspx?DataSetCode=ALFS_SUMTAB, while per capita GDP data are from World Economic Outlook Database – October 2013, International Monetary Fund)

Wang et al. (2012) use a Bayesian model to project China's counterfactual fertility trend. Their projection is that fertility would have continued to decline after 1980 and would have fallen to 1.5 children per woman, as currently observed. In other words, without the OCP China would have had the current population size anyway.

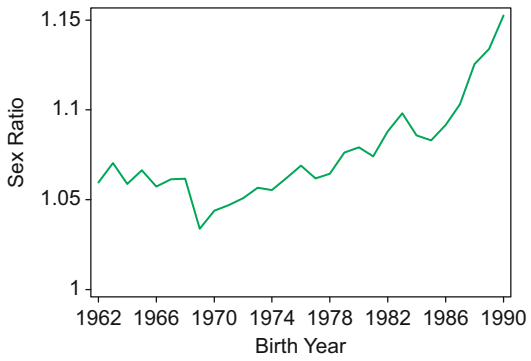
The main issue in this debate is whether the 16 other countries are a credible counterfactual. Most of the 16 countries have very different income levels, institutional structures, and cultures to China and all these potentially contribute to fertility behaviour. In addition, Wang et al. (2012) acknowledge that the proportion of households that have only one child in China is very high and admit that the proportion would never have reached the high level observed without the OCP. If this is the case, then the OCP must have played some role in curtailing population growth.

Population Aging

If one accepts that the OCP did reduce the fertility rate, then population aging is one of the significant consequences of the reduction in births over more than three decades. Concomitant increases in life expectancy have further exacerbated population aging. In 1980 around 5.8% of China's population were aged 65 and over. Three decades later, this ratio had increased to 9%. Although, relative to many developed countries, this is not an especially high proportion (for example, in the same year the USA and Japan had, respectively, 13% and 23% of their populations over 65), China is aging with much lower income levels.

Figure 2 compares China's aging population ratio with several other countries. China is ranked below the median level, but all the countries listed have much higher per capita income levels than China. For example, in 2012 Chinese per capita GDP was ranked 85th (US $6,569) among the 183 countries, while Chile, a country with the same aging population ratio as China, was ranked 45th in per capita GDP (US$ 16,834). The country closest to China's income level is Turkey, with per capita GDP ranked 64th (US$ 10,745), and whose aging population ratio was much lower than China, at 7.1%.

Lower income with a rapidly aging population inevitably creates a financial burden on the government. This is because aged care, especially medical care, is costly. China's Health and Retirement Survey team report that a large fraction of China's elderly have physical health limitations (CHARLS Research Team 2013). The problem is even more serious when one considers the



China's One Child Policy, Fig. 3 Sex ratios by birth cohort (Source: Replicated from Fig. 1 in Li et al. (2011). Calculated based on the 1990 Chinese population census (1% sample))

proportion of households in which the responsibility for looking after elderly parents and/or grandparents falls on only one child (an average of 40% of households across the country as a whole and 86% of households with urban residency (*hukou*); Wang et al. (2012)). China has traditionally relied heavily on families to provide aged care. Even today the Elderly Rights and Security Law states that adult children have financial and emotional responsibility for their elderly parents (Zhang 2000). Previously the parental old age care responsibilities could be shared among siblings. However, this will not be possible for the single-child generation. Thus additional social care and social expenditure will be called upon.

Gender Equality

Figure 3 shows China's sex ratio from 1950 (almost three decades prior to the introduction of the OCP) until 1990. For most of 1950 to the late 1970s China's sex ratio remained very close to 106. Since the introduction of the OCP in 1979 the sex ratio has increased to over 113. That is an extra 13 boys for every 100 girls born.

The OCP, in concert with the strong cultural preference for sons and the availability of gender selection technology such as ultrasound scans and induced abortion, is widely believed to be the major reason for the increase in the sex ratio (Ebenstein 2010; Das Gupta 2005; Zeng et al. 1993), and various studies have sought to quantify the policy's impact. It has been estimated that in excess of 40 million women are 'missing' in China (Klasen and Wink 2002). Li et al. (2011) use minority groups who are not subject to the OCP as a control group and estimate that the policy led to 4.4 extra boys per 100 girls in the 1980s, and to 7.0 extra boys per 100 girls for the period 1991–2005. This corresponds to approximately 94% of the total increase in the 1980s and about 55% for 1991–2005. Bulte et al. (2011) use a similar methodological strategy to identify the policy's impact and attribute 50% of the missing women to the policy. As with the policy's impact on population size, and because China was experiencing substantial change over this period with economic and other reforms accompanying the introduction of the OCP, there is some ongoing debate as to the extent to which the OCP is responsible. Other explanations put forward to explain increasing sex ratios include increasing gender wage gaps due to changes in centrally determined agricultural crop procurement prices (Qian 2008) and land reform (Almond et al. 2013). Oster (2005) argued that Hepatitis B infection is associated with an increased probability of giving birth to a son and so could potentially explain the sex ratio imbalance. This point was, however, disputed by Das Gupta (2008) on the basis of Lin and Luoh (2008)'s finding that Hepatitis B only increased the probability of having a boy fractionally in a large medical data set for Taiwan. Oster et al. (2010) subsequently also found no increases in the probability of having a boy associated with Hepatitis B prevalence in China and conceded that the disease did not drive the increases in China's sex ratio.

The sex ratio imbalance has serious consequences. Guilmoto (2012) estimates that the number of prospective grooms will exceed the number of prospective brides by more than 50% for at least three decades. The number of unmarried men at age 50 is estimated to peak at 15% in 2055. The excess of men has resulted in women marrying older men and a lesser education gap between men and women. To increase marriageability, families with boys are increasing their savings (Wei and Zhang 2011). Some men will not be able to find partners though, regardless of how much

savings they have. Das Gupta et al. (2010) project that unmarried males will likely be concentrated in poorer provinces with lower ability to provide social protection to their citizens and predict that such geographic concentration of unmarried males could be socially disruptive. Indeed, Edlund et al. (2013) find that increases in the sex ratio account for almost 15% of the recent large increases in crime rates in China.

As egregious as sex-selective abortion and female infanticide are, females who survive beyond infanthood are benefitting from their scarcity in some ways. The high sex ratio gives women greater bargaining power within the household, which consequently results in them bearing fewer children and investing more heavily in children's health (Porter 2007). Higher sex ratios are also associated with married women being less likely to live with their in-laws Li (2012). Lee (2011) finds that the OCP has reduced the gender education gap, as girls who are only children are no less likely to be educated than boys who are only children. Ultimately son preference will diminish as parents prefer to have a girl who they will be able to marry off rather than a boy with worse marriage prospects, Edlund (1999).

Behavioural Consequences

Over the past 30 years the OCP is felt to have had a marked impact on the behaviour of the one-child generation. There are claims in the media as well as some psychologists that this new generation could be different (see, for example, Lee (1992), Fan (1994) and Wang et al. (1998)). People are concerned that parents have not been teaching their only children traditional values and that the children of the one-child generation are more self-centred and less cooperative than previous generations. This sentiment is captured in the common phrase that the only child is the 'little emperor' of the family. As the first cohorts of the one-child generation entered the labour market, employers started to include phrases such as 'no single children need apply' in job ads (see Chang 2008).

Empirical evidence of these behavioural differences is limited. Results of studies that compare only children with others produce mixed results (Chen and Goldsmith 1991; Falbo and Poston 1993; Shen and Yuan 1999; Wang et al. 2000; Liu et al. 2005). These comparisons are, however, unlikely to be a comparison of like with like, as they ignore that families who are able to have more than one child under the OCP are often substantially different from families who have had to comply with the policy. A comparison of people (whether only children or otherwise) born just before and just after the introduction of the OCP in 1979 avoids this problem, as for the majority of the population having more than one child was no longer a choice after the policy's introduction. Such a comparison was conducted by the authors (and their co-authors) in Beijing in 2010. Personality surveys and economic experiments designed to elicit the extent of pro-social and other behaviours revealed strong behavioural differences, largely in line with the anecdotal reports – the OCP was found to have produced a less trusting, less trustworthy, more risk-averse, less competitive, less conscientious, more pessimistic and more neurotic generation (Cameron et al. 2013).

Economic Consequences

The overall economic impact of the OCP is very difficult to determine. On the one hand, the policy has reduced the country's stock of labour and generated a heavy burden on the younger generation, as only children struggle to support their parents and four grandparents financially. Entrepreneurial spirit has also possibly been sapped as the result of the generation's reduced willingness to take risks (Cameron et al. 2013). On the other hand, the policy seems to have stimulated saving, although recent studies have found that the general equilibrium effect of the OCP on savings could be small (Banerjee et al. 2011, 2014; Choukhmane et al. 2013). Investment in education for both genders has also increased (Rosenzweig and Zhang 2009). Zhu et al. (2013) argue that the demographic changes caused by the OCP may not harm China's longterm growth. Their model, which focuses largely on fertility decreases coupled with increased educational attainment, estimates that by 2025 China's GDP will be about 4% higher than it would have been without the OCP.

Potential Implications of Policy Changes

In late 2013 China announced that it was relaxing its OCP. Couples in which at least one is an only child will now be allowed to have two children.

The government predicts that the relaxation of the policy will be associated with a significant increase in the total birth rate in the initial stage to above 1.8, but in the long run the birth rate is estimated to settle at around 1.6 to 1.7 (*People's Daily* 2013). The relaxation of the OCP is unlikely to have a large impact on population size for the following reasons:

1. Currently, 70% of the Chinese population has rural household registration (*hukou*), and for these people the OCP was never binding. The majority of rural *hukou* households have two or more children and hence for them the new policy will not have an effect.
2. For the remaining urban *hukou* population (30%) the past thirty years of economic growth has likely changed people's fertility preferences. This change in fertility preferences reflects that the majority of urban women are going to university and hence delay their first birth and have a shorter period in which they wish to bear children. Further, the cost of rearing children has risen sharply in cities.

Many demographic studies support the second point. For example, Cai (2010) uses differences in the implementation of the family planning policy in two economically fairly developed provinces, Zhejiang and Jiangsu, as a natural experiment to examine the effect of the OCP versus a policy which allows for two children on the total fertility rate. He finds that despite the differences in the family planning policy, the total fertility rate is similar across the two provinces, suggesting that economic growth has dominated individuals' fertility behaviour.

If the relaxation of the OCP does not have a large effect on the population size in the long run, it will also not have a large effect on the aging of the population. The official government view however is that it will improve the age structure of the Chinese population. The *People's Daily* reports that the change in policy will gradually reduce the share of the aging population, so that by 2100 34.3% of the population are elderly, compared to 39.6% of the population in the absence of any policy change (*People's Daily* 2013).

The changes in the OCP promise to reduce the sex ratio and some of the associated consequences described above. Parents living in urban areas who were subject to the strict one-child version of the policy and who may have aborted a first child daughter are now likely to resort to sex selectivity only if the first two children are daughters. As discussed above, most rural areas already allowed couples whose first child was a daughter to have a second child. This is often referred to as the '1.5 rule'. Zeng (2007) shows that sex ratios are higher in 1.5 child areas than 2 child areas. He found the sex ratio at birth in 2000 in areas where there are '1.5 children' rules to be 119.7, compared to 108.3 in 2 child policy areas (see also Goodkind 2011).

The decline in the sex ratio at birth will, with time (approximately two decades), relieve the stress in the marriage market and reverse many of the phenomena described above – men will start being able to marry at younger ages. Female labour supply may increase as a result of reduced female bargaining power. There may be adverse effects on resources devoted to children. Some changes are, however, unlikely to be reversible, as cultural norms will have shifted irretrievably. This is probably true of son preference, which has weaker foundations in a modern economy in which wages are rising in the female-dominated service sector relative to manufacturing and blue collar jobs. Market forces are also likely to counter any reductions in investment in the human capital of girls. A smaller pool of unmarried men is likely to have positive impacts on social cohesion.

The extent to which the behavioural impacts of the policy can be ameliorated by the policy's relaxation will depend on its impact on fertility. If one-child families remain the norm, the behavioural tendencies identified by Cameron et al. (2013) can be expected to persist, unless they are offset by specific educational and institutional efforts. The increasing marketization of society is further eroding pro-social values, so

those who wish for a return to a society of traditional values are likely to be disappointed.

Chinese Economic Reforms

Loren Brandt and Thomas G. Rawski

Abstract

Why did China's modest reforms unleash an enormous boom? Three decades of socialist planning created vast untapped potential. China captured this potential by focusing on 'big reforms' linked to incentives, markets, prices, mobility, openness and competition. Advances in these areas created sufficient momentum to overcome the drag associated with remaining distortions and institutional shortcomings. China's political economy, which incorporates substantial local autonomy, facilitated experimentation that repeatedly identified feasible reform paths. Because China's political economy delivers undesirable outcomes along with rapid growth, and because China's success is linked to unique historical circumstances, the beneficial outcomes associated with Chinese policies and institutions may be limited in time and space.

Since the late 1970s, China's economic performance has astonished the world. Official figures show that, after adjusting for inflation, China's GDP grew at an annual rate of 9.7 per cent between 1978 and 2006, and at a rate of 8.4 per cent in per capita terms (Yearbook 2006, p. 60; National Bureau of Statistics 2006). By 2006, the Chinese economy, measured in terms of purchasing power parity, was the world's second largest, behind only the United States: per capita incomes, measured on the same basis, rose from 324 dollars to 5,772 dollars between 1978 and 2004 (Heston et al. 2006). China's new dynamism includes a major shift towards intensive growth, with productivity change, which had contributed negatively to Chinese growth between 1957 and 1978, accounting for 40 per cent of overall growth after 1978 (Perkins and Rawski forthcoming).

Reform began in the late 1970s. The impetus for modifying the plan system came from two sources: general awareness that China's neighbours were running far ahead in the economic sphere, and stagnation of living standards, especially China's persistent problems with food supply. The initial objective was to improve economic results under the system of central planning.

Initial Reform Efforts

Not surprisingly, early reform efforts focused on agriculture. Starting in 1978, household cultivation swiftly replaced collective tillage as the norm in China's vast farm sector, as hundreds of millions voted with their feet to abandon collective farming, the central feature of the people's communes.

Introduction of the household responsibility system meant that farmers could claim the fruits of extra effort for themselves. This brought an immediate multiplication of work effort, which was further encouraged by modest relaxation of restrictions on marketing and price flexibility, and by a considerable increase in procurement prices (Sicular 1995). The result was a sudden upsurge of farm production and productivity (Lin 1992). With the expansion of food supply, millions of farmers no longer needed to work the land and so began to move into non-farm employment. Improved diets raised the energy levels and hence the productivity of formerly undernourished villagers. Relaxation of efforts to enforce local selfsufficiency in favour of historic patterns of crop specialization, along with new opportunities to diversify into animal husbandry, horticulture, and aquaculture, also contributed to steep gains in farm output (Lardy 1983).

The response to agricultural reform quickly spread beyond the farm sector. Rural factories, which had enjoyed a brief boom during the Great Leap Forward of 1958–60 (a massive and chaotic push to organize villagers into communes and to transfer rural labour into steel and other industries), suffered considerable retrenchment during the 1960s, and then expanded rapidly during the 1970s. Following the revival of agriculture, collectively owned rural industry, now fortified by greater access to the cities, rising rural incomes, increased supplies of agricultural inputs, and throngs of job-seekers, bounded ahead. In addition, new freedom encouraged a wide range of non-farm self-employment and family businesses. The resulting shift out of farming initiated what eventually became a massive exodus of labour from the countryside.

The explosive response to rural reform spurred officials to press forward with urban initiatives focused on 'enlivening' state-owned enterprises. While these early measures achieved only limited progress towards their main objective, they benefited rural and urban collective industry by opening new markets as well as new sources of materials, subcontracting opportunities, and technical expertise.

As the influence of markets, price flexibility, and mobility expanded, a separate strand of reform began to move China's isolated system towards greater participation in international trade and investment. China's leaders agreed to

establish four tiny 'special economic zones' in the southern provinces of Guangdong and Fujian. Initial operations in these zones seemed directionless and inconsequential, but the arrival of ethnic Chinese entrepreneurs, most from Hong Kong and Taiwan, turned the zones into drivers of regional and eventually national growth. This novel combination of low-cost Chinese labour with the market knowledge and entrepreneurial capabilities of overseas Chinese businessmen gradually developed into an export bonanza that nudged China towards its subsequent embrace of economic globalization.

Although the limited extent of domestic reform restricted the initial response to growing openness, the buoyant prosperity of the new zones prompted cities along the coast, and eventually across the nation to clamour for access to the same tax, legal, and regulatory concessions that had powered their growth.

China's initial reforms focused on limited changes directed at specific sectors. These changes proved sufficient to accelerate growth despite the continued importance of state ownership, price controls, material-balance planning, and other key features of the socialist system. Early reform was particularly successful in removing long-standing constraints formerly imposed by limited availability of food and of foreign exchange.

Further Reforms: Expanding the Cage

During this period, China's gathering boom encouraged a growing array of jurisdictions, constituencies, and interest groups to pursue the advantages enjoyed by reform participants, including expanded managerial autonomy and access to the special economic zones. The image of China's economy as a caged bird advanced by Chen Yun, an economic specialist within the leadership group, illustrates the underlying economic thinking (Lardy and Lieberthal 1983). Chen argued that expanding the cage (reform) allows the bird to beneficially spread its wings; an overlarge cage threatens loss of control – thus the slogan 'planned economy as the mainstream, market allocation as a supplement'.

Implementation of the dual price system, which partitioned allocation of most commodities into plan and market components and allowed the distribution of afterplan residuals at increasingly flexible prices, stands as the central policy achievement of this period. The expansion of market transactions began to whittle away at longstanding barriers to mobility, which had restricted the transfer of labour, capital, commodities and ideas across administrative boundaries, with negative consequences for growth of output and productivity.

Developments in the international sphere, including the continued growth of foreign trade, the northward spread of special zones, and the expansion of foreign direct investment, now involving multinational corporations as well as overseas Chinese entrepreneurs, extended the impact of market forces. The growth of crossborder transactions and the increased presence of foreign business operations on Chinese soil intensified pressures for contract arbitration, codification of urban landuse rights and other legal and institutional reforms needed to facilitate new activities.

The main impact of these reforms fell on flows – of labour, commodities, profits, and new investments. New entrants to the workforce, for example, including college graduates, were increasingly left to find their own positions, rather than receiving job assignments from local labour bureaus. Existing stocks, including assets or employees of extant firms, especially in the state sector, were not yet exposed to the full impact of market forces. Mergers appeared, but only on a microscopic scale. Despite the enactment of bankruptcy legislation, floundering companies rarely disappeared. Nor did redundant workers face the sack, although the 'optimal labour programme', which invited managers to identify essential and surplus workers, foreshadowed the mass layoffs of the late 1990s.

Economic Reforms Since 1992: Towards a 'Socialist Market Economy'

The brief recession, triggered by efforts to quell inflation during the late 1980s, together with the

anti-reform backlash and pullback of foreign investment that followed the June 1989 suppression of popular unrest, slowed both growth and reform. The setback, however, was short. Deng Xiaoping's call for expanded reform during his southern tour of 1992, together with the Communist Party's 1992 decision to pursue a socialist market economy with Chinese characteristics gave fresh impetus and as well as new direction to economic reform.

The Party's 1992 decision replaced vague ideas of 'doing better' with a clear reform objective: a market economy in which the eventual role of the state will resemble the current circumstances of major economies such as those of France or Japan: macroeconomic management; regulation of health, environment, and so on; and strategic planning, with other functions explicitly assigned to the sphere of market determination.

Although the 1992 decision is a statement of principle rather than a description of reality, the ensuing 15 years witnessed decisive strides towards market outcomes, which we summarize in terms of four major shifts:

1. *From plan to market*: price liberalization extended beyond the substantial achievements of the first reform decade: despite significant exceptions (energy, credit, foreign exchange) supply and demand now determine most prices (Li 2006, pp. 104–7). The growing influence of market forces brought a considerable (but incomplete) hardening of budget constraints, even in the state sector. Market pressures compelled the dismissal of more than 50 million workers, most from state-owned factories. Mergers and acquisitions extended the reach of market pressures to much of China's capital stock. Barriers to the free flow of labour and goods continue to recede, and migrant workers have begun to attain normal citizenship rights in China's cities and towns. Growing expansion of wage differentials and of income inequality reflect the new prominence of market outcomes.
2. *From village to town and city* and from agriculture to industry and services. The primary sector's GDP share dropped from 27.9 per cent in 1978 to 11.8 per cent in 2006. Following the departure of 150–200 million villagers from the land, survey data indicate that the primary sector's labour force share has declined from 69.2 per cent in 1978 to 31.8 per cent in 2004 (National Bureau of Statistics 2006; Yearbook 2006, p. 58; Brandt et al. 2008).
3. *From public to private ownership*. At the start of reform, the public sector (including collectives) held nearly all China's fixed capital. The growth of private business, while rapid in percentage terms, started from a tiny base. It was only from the late 1990s that the non-public sector, swollen by the privatization of rural collective enterprises, the transfer of (mostly small and medium) state-owned firms into private hands, and the rapid expansion of direct foreign investment, began to take on a prominent role in the national economy. The share of state-owned firms in industrial output fell from 81 per cent to 55 per cent between 1980 and 1990, and to 15–35 per cent in 2005/6 (depending on the treatment of state shareholdings; see National Bureau of Statistics 2006; Perkins and Rawski 2008). The pace of change has accelerated: by 2003, the private sector's GDP share had risen to 59.2 per cent (OECD 2005, p. 125). The state sector's share in industrial output and non-farm employment during 2004/5 declined to 15.2 and 13.1 per cent (Yearbook 2006, p. 505; Brandt et al. 2008). Following lengthy reform efforts China's major banks and financial firms have begun to sell partial ownership stakes to overseas financial companies.
4. *From isolation to global engagement*. Beginning from near-autarchy during the 1960s and 1970s, China has gradually emerged as a leading participant in global trade. China's 2001 entry into the World Trade Organization (WTO) capped a gradual process of opening that has raised the ratio of combined imports and exports to GDP from under ten per cent prior to the reform to over 63 per cent in 2005 – surpassing comparable figures for all other large and populous nations (Lardy 2002; Brandt et al. 2007). China has become the world's largest recipient of foreign direct

investment, which initially clustered in manufacturing, but has recently extended into finance, property, retailing, logistics, infrastructure and R&D. Foreign firms have taken the lead in integrating China into multinational supply chains for manufacturing, research and design. Chinese firms have also begun to increase their own overseas investment in pursuit of raw materials, market access and knowledge.

Changes in institutions and public policies reflect these new economic realities. Administrative reforms have recast government ministries (of machinery, textiles and so on) as industry associations, which now engage in informal discussions and negotiations with official agencies, as do individual companies and interest groups (Kennedy 2005). Fiscal reforms have sought to redress imbalance between central and local revenue shares and to enhance revenue buoyancy to keep pace with growing demands for spending on education, health care, pensions, infrastructure and environment.

Three decades of reform have reshaped China's economy into a hybrid that is increasingly responsive to domestic and international market forces even though some segments, for example, capital markets and investment spending, reflect the continued legacy of planning.

Key Factors in China's Reform Success

Although the period since the late 1970s has brought huge increases in output, productivity, and incomes, China's reforms remain far from complete (Lardy 1998). The costs and inefficiencies associated with unfinished or delayed reform are large. They include remnants of the plan era, for example the underpricing of energy, water, and bank loans, which exacerbates China's environmental and employment problems. Some stem from the reform itself, for instance the continuing epidemic of rent-seeking and graft. Others, including the consequences of weak systems of environmental management, law, public finance, banking, and investment allocation, reflect halfway houses that combine inherited political and economic structures with partial reform efforts (Pei 2006).

How has China's reform achieved so much when its economic system contains so many weak links? China's recent experience encourages us to think of a hierarchy of desirable features that support growth or, if absent, hinder it. These growth enhancing conditions are not equally important. In China, partial measures affecting incentives, prices, mobility, and competition – what we might term 'big reforms' – created a powerful momentum that overwhelmed the friction and drag arising from a host of 'smaller' inefficiencies associated with price distortions, imperfect markets, institutional shortcomings, and other defects that retarded growth and increased its cost but never threatened to stall the ongoing boom (Perkins 1994).

In the presence of large gaps between current and potential output, and of neglected opportunities for expanding the production frontier, limited reform that even partially ruptures the shackles surrounding incentives, marketing, mobility, competition, price flexibility and innovation may accelerate growth. Begin with an economy operating well below its potential, partly because its workers, perceiving that effort hardly affects their incomes, withhold much of their available energy (which itself is reduced by chronic undernutrition). Now restore the link between effort and reward, permit a partial market revival, and open the door to experimentation with international trade and investment. Without disruptive changes in trade flows and political structures that accompanied early reform efforts in the former Soviet Union and Eastern Europe, such simple initiatives – which approximate the circumstances of China's early reforms – can readily ignite a burst of growth, even if prices, financial institutions, judicial enforcement, policy transparency, corporate governance and many other features of the economy remain far from ideal.

A review of what we call 'big reforms' explains the unexpected coincidence of stunning growth with deeply flawed institutions.

Incentives. In China, restoring the link between effort and reward was hugely beneficial even with

large price distortions and a limited market activity. The shift from collective to household farming produced an immediate surge in agricultural production even though the farm sector of the 1980s embodied fewer 'free market' characteristics than Chinese agriculture of the 1920s and 1930s, or even the early 1950s. The same observation applies to private business, which has expanded rapidly and become the largest source of new employment despite its limited access to official support, legal protection and formal credit markets.

Prices. The expansion of price flexibility, most notably through the dual price system, thrust market forces into the economic lives of all Chinese households and businesses. Participants in China's economy – including the large state-owned enterprises at the core of the plan system – suddenly faced a new world in which market prices governed the outcome of marginal decisions to sell above-plan output or to purchase materials and equipment. This partial and gradual liberalization of pricing opened the door to what Naughton (1995) has dubbed 'growing out of the plan,' in which directing incremental output towards market allocation gradually reduced the importance of the plan sector without a political struggle.

Mobility. As the reform progressed, rising urban incomes created new demands for labour in China's cities and towns, especially in construction, services and in new export industries. Responding to this demand, individual villagers began to circumvent regulations that had long barred rural workers from moving to the cities. With the assistance of would-be urban employers and of rural governments, the initial trickle of migration expanded into the largest internal migration in world history.

Partial liberalization of prices, which allowed cash markets to sell food and other necessities with no requirement for residence-based ration tickets, provided essential support for this growing flow of migrant labour. As with the earlier shift from collective to household farming, massive change responded to price signals that, however imprecise, indubitably reflected underlying resource scarcities. Villagers did not need an exact calculation to see that they could raise their incomes by taking up non-farm occupations; several hundred million recognized the opportunity and made the choice.

Competition. Planning attempts to reduce economic uncertainty by pairing suppliers with customers and by specifying the nature of future transactions. Planning also controls the entry of new firms and the exit of weak enterprises. In China, the expansion of incentives, mobility, and markets created unprecedented opportunities to rearrange supply links, to establish new enterprises and to develop existing firms (both domestic and foreign) by commercializing new products and pursuing new markets. Entry squeezed profits (Naughton 1992). The state, as the main owner of enterprise assets, suffered the financial consequences, as the GDP share of fiscal revenue suffered a long decline (Wong and Bird 2008). The resulting fiscal pressures encouraged officials at all levels to respond to pleas from hardpressed enterprises by allowing piecemeal expansion of reform (Jefferson and Rawski 1994).

The scale of entry and exit is startling. The number of industrial firms rose from under 0.4 million in 1980 to nearly 8 million in 1990 and 1996; the 2004 economic census, which excluded enterprises with annual sales below RMB5 million, counted 1.33 million manufacturing firms (Jefferson and Singh 1999, p. 25; Economic Census 2004, pp. 1, 2, 23); in construction, the number jumped from 6,604 to 58,750 between 1980 and 2005, with the latter total excluding subcontractors (Yearbook 2006, p. 579). On the exit side, bankruptcy and restructuring have eliminated many weak firms: between 2001 and 2004, for example, the number of state enterprises in all sectors declined by 177,700 (State Council 2005). Employment in state-owned industry dropped from 45.2 to 8.9 million between 1992 and 2005 (Yearbook 1996, p. 402; 2006, p. 505).

Although Young (2000) and others argue that internal trade barriers limit domestic competition by obstructing the flow of goods and funds across provincial and other administrative boundaries, we believe that the impact of such barriers has faded, allowing rapid expansion of road traffic, telecommunications, chain stores, supply

networks and other new developments to push China's economy towards extraordinarily high levels of competition. Despite pockets of monopoly and episodic local trade barriers, intense competition now pervades everyday economic life. The auto sector provides a perfect illustration: two decades of competition have sucked a lethargic state-run oligopoly into a whirlwind of rivalries in which upstarts such as Chery and Geely wrestle for market share with state-sector heavyweights and global titans. The payoff – rapid expansion of production, quality, variety, and productivity, along with galloping price reductions – has injected a dynamic new sector (not just manufacture of vehicles, components and materials, but also auto dealers, service stations, parking facilities, car racing, publications, motels, tourism, and so on) into China's economy.

The auto sector also illustrates how economic opening has ratcheted up competition throughout China's economy. With few sectors sheltered from imports and with foreign-linked firms participating in a growing array of domestic activities, incumbent suppliers of soybeans, machine tools, retail services, and an endless array of other goods now face competition from rival producers in America, Japan or Brazil as well as Jilin, Zhejiang and Sichuan.

Price wars and advertising, two unmistakable signs of competition, have become commonplace. Chinese newspapers are filled with accounts of fierce price competition among producers of autos, televisions, microwaves, air conditioners, and many other products. Advertising expenditure in 2006 matches total urban retail sales for 1990 (Nielsen Media Research, 2006; Yearbook 2006, p. 678). The decline of former industry leaders like Panda (televisions) and Kelon (home appliances) and the ascent of new pacesetters like Wahaha (beverages), Wanxiang (auto parts) and Haier (home appliances) from obscure beginnings show how competition has added new fluidity to Chinese market structures.

Innovation. Prior to reform, China experienced a general failure of dynamic efficiency. Under the plan system, apart from exceptional instances of direct highlevel intervention ('innovation by order'), producers neglected innovation in favour of pursuing short-term targets for physical output ('fulfilling the plan'). As a result, the expansion of society's production frontier lagged behind the potential embodied in available knowledge and resources. The consequences are readily visible: First Auto Works, one of China's premier manufacturers, found its 'obsolescence of equipment and models worsening day by day' following '30 years of standing still' under the planned economy (Li Hong 1993, p. 83).

Reform put an end to this stand-pat mentality by widening the gap between financial outcomes for strong and weak firms, their managers and their employees. The presence of price distortions, subsidies and official intervention could not obscure the central issue: do we pursue innovation in order to maintain and perhaps expand our sales, market share, profits, wages, and employment security, or do we sit tight and hope that current or potential rivals do not leave us behind? Especially since China's entry into WTO, the proportion of firms engaging in R&D has grown rapidly, as has the ratio of R&D spending to GDP (Hu and Jefferson 2008).

On the supply side, efforts to upgrade the quality and variety of products benefited from rapid increases in China's supply of educated workers. China's growing engagement with the global economy created immense inflows of new technology, not just from imports of equipment and know-how, but from new links connecting millions of Chinese workers, engineers, and managers with the technical standards, engineering processes and management practices needed to compete in global markets.

Key Elements in the Political Economy of Chinese Reform

What of the policy process associated with these extraordinary changes? Despite the authoritarian nature of China's political system, pre-reform policy structures allowed widespread experimentation and regional variation within broad guidelines set at the centre. This encouraged local officials to develop strategies whose success

might attract high-level attention and also allowed national leaders to 'play to the provinces' (Shirk 1993) by assembling coalitions of like-minded officials to demonstrate the merits of their preferred policy options and to lobby for nationwide implementation of those policies.

This arrangement, under which national policies emphasized broad principles or parameters rather than specific instructions or regulations, continued into the reform period. What changed is the content of the directives articulated at the centre, formerly directed towards ideological matters, which now focused increasingly on issues surrounding economic growth.

Looking beyond the principles emanating from the top, we see three additional elements as completing the skeleton of China's reformist political economy. *Decentralization* endows provinces and localities with both the resources and the incentive to experiment with local approaches to specific policies (for example, rural industrialization) and difficulties (for example how to deal with redundant statesector workers), providing they observe central guidelines. *Competition* within the political system is not new, but now focuses on economic outcomes, which exercise increasing leverage over the career paths of leaders at every level. Continued promotion and recruitment of leaders whose reputation and career prospects rest on past and future economic success has gradually created a large and expanding *coalition among growth-minded, market oriented individuals and groups* within China's policy elite, whose power and influence helps to shift the content of central guidelines towards market outcomes.

Broad Guidelines: What They Can and Cannot Do

Chinese tradition emphasizes the government of men (and, beginning in the late 20th century, some women) rather than laws. In the absence of detailed instructions, how do China's top leaders direct the behaviour of lower-level governments and individual officials? Functionaries at all levels study and discuss the speeches and writings of top leaders, which lay out the desired course of public policy and explain what lower levels of officialdom should and should not do. These guidelines become encapsulated in catchy slogans that gain wide currency. In turn, these slogans, and the policy guidelines that inform them, direct the flow of policy implementation at all levels.

From the start of China's reform in the late 1970s, these directives increasingly emphasized economic matters. Indeed, China's political economy has come to rest on a grand but unspoken bargain between the Communist Party and the Chinese public in which the party ensures economic growth and promotes China's global standing in return for public acquiescence to its autocratic rule and anachronistic ideology (Keller and Rawski 2007b). As a result, the articulation and fulfilment of key economic objectives now constitute core ingredients in extending the political legitimacy of the Chinese state. Economic objectives embedded in documents, speeches, and slogans reverberate at every level of society, where they become benchmarks for evaluating current or proposed actions. Deng Xiaoping's praise of reform during his southern tour of 1992 was widely seen as a favourable signal for policy innovations, including many that received no specific mention from him. In similar fashion, emphasis (or omission) of praise for 'small and medium enterprises' will be interpreted as high-level encouragement of (or caution against) policies favouring private business.

Decentralized Experimentation

The experience of the 20th century surely qualifies the Chinese as the world's leading practitioners of economic experimentation. China's reform economy amply displays this characteristic. We see the national government conducting trials of novel institutions, for example 'special economic zones', while provinces and localities develop their own variations of pension systems, industrial regulation, and so on.

The decentralization of industry, which placed all but the largest enterprises under the control of

lower-level governments, and of public finance, which, especially prior to the 1994 fiscal reforms, assigned major revenue streams to provincial and local administrations, provided regional and local governments with ample resources with which to pursue such experimentation.

Competition

Prior to the inception of reform, China developed a tradition of policy entrepreneurship in which local figures compete for high-level attention by demonstrating the beneficial implementation of the principles enshrined in broad central directives. This competition intensified under the reform, with GDP growth and other economic criteria replacing ideological benchmarks as the arbiters of success. Thus Li and Zhou (2005) find that promotion prospects for provincial leaders rise, and the likelihood of termination declines as provincial economic performance improves. Whiting (2001) makes similar observations about local officials.

Officials at all levels possess the authority as well as the resources needed to promote local growth. They also have strong incentives to do so, because their career prospects, as well as personal financial opportunities for themselves and their families, are closely tied to the economic trajectory of the jurisdictions under their leadership. Growth expands the pools of public revenue and enterprise profits over which officials exercise varying degrees of control, enlarges business opportunities available to the families and associates of local leaders, and swells the flow of (legal and illicit) rents directed towards official agencies and their managers.

These circumstances have transformed China's local and provincial governments into eager champions of development, each striving to outdo its neighbours in expanding infrastructure and strengthening the foundations of 'pillar industries'. This competition contributes mightily to the persistent 'investment hunger' visible in China's economy, as local administrations resist central calls for restraint in enlarging existing facilities and building new ones.

Pro-growth Coalition

China's reform leaders, like politicians everywhere, endeavour to appoint and promote like-minded successors and subordinates. As Shirk (1993) and others have noted, the reform movement's initial successes acted as a powerful recruiting device, with the lure of rich payoffs adding many influential converts to the cause of reform. As the reform gained momentum, the circulation of elites, including the assignment of successful officials to lagging regions for the express purpose of jump-starting growth, created mentor-student relationships between growth-oriented officials and increasing numbers of would-be imitators. The widespread practice of sending study teams to absorb the 'advanced experiences' of dynamic localities further expanded the reform constituency among China's policy elites.

Of particular importance is the legacy of the Cultural Revolution, which truncated educational opportunities for whole cohorts of Chinese. This historical accident created a unique opportunity to advance the reform agenda. When the retirement of Deng Xiaoping and other 'revolutionary elders' focused attention on generational change, reformist leaders managed to bypass the customary emphasis on seniority, skipping over the 'lost generation' of Cultural Revolution victims to promote younger candidates. The increasing prominence of university graduates, including returnees from overseas study and young professionals with close ties to international business, accelerated the development of what became a loose and unorganized but increasingly potent coalition of like-minded officials whose objectives centred on growth-promoting and increasingly market-oriented reforms.

Despite these gains, the evolution of policy towards private business demonstrates the difficulty of translating power and influence into genuine institutional change. Legal documents confirm the painfully slow expansion of official protection. At the start of reform, private business operated in a legal limbo. Some entrepreneurs disguised their firms as collectives; others purchased informal protection from powerful

individuals or agencies. A succession of amendments to China's 1982 constitution slowly expanded recognition of the non-public economy, first as a 'complement' to the state sector (1988), than as an 'important component' (1999) of the 'socialist market economy' (itself a new term dating from 1993). The 'Law on Solely Funded Enterprises', which took effect in 2000, guaranteed state protection for the 'legitimate property' of such firms, but without using the term 'private' or specifying any agency or process to implement this promise.

Further constitutional amendments adopted in 2004 breached the former taboo on the term 'private' by stating that 'citizens' lawful private property is inviolable'. The long march towards official recognition of private business came to an end only in 2007 when, following five years of fierce debate, China's legislature enacted a landmark Property Rights Law which, for the first time, explicitly places privately held assets on an equal footing with state and collective property.

Conclusion

Reform has delivered enormous economic gains despite deep and potentially dangerous flaws in China's institutions and policy structures. The same framework of structures and incentives that spurs rapid economic advance also generates ambiguous and often disturbing consequences along other socioeconomic dimensions. Environment and inequality illustrate the range of outcomes.

Economy (2004) and others demonstrate how China's unbridled rush to maximize GDP growth, together with weak regulatory and legal structures, has produced environmental degradation on a scale that far exceeds internationally acceptable standards. Historical comparisons also show that improved technology and the spread of environmental consciousness among China's growing middle class are pushing China towards regulation and remediation of atmospheric and water pollution at an earlier stage of the development process than occurred in Japan, Korea, or the United States.

China's reforms have literally pulled hundreds of millions out of poverty, especially in the countryside. Reform has also increased China's income inequality to levels that now approach some of the highest in the developing world. Although attention focuses on income gaps between urban and rural areas and between coastal and interior provinces, growing income differences between neighbours within provinces and within the urban and rural sectors account for most of the increase in inequality (Benjamin et al. 2008). In rural areas, this increase is tied to the disequalizing role of some forms of non-agricultural income, and laggard growth of farming income, especially beginning in the mid-1990s. In urban areas, a decline in the role of subsidies and entitlements, increasing wage inequality related to labour market and enterprise reform, and the effect of SOE restructuring on some cohorts and households have enlarged the dispersion of incomes. Rising returns to human capital and differences in access to education have widened income differences in all sectors. Corruption, although difficult to quantify, may also have contributed to growing inequality of wealth and welfare.

Despite these and other difficulties, China's recent experience demonstrates that activating key economic drivers, including incentives, mobility, prices, competition, and innovation, can unleash sufficient momentum to overwhelm a variety of system costs. China's economic boom, in 2007 completing its third decade, rests on a unique set of historical circumstances, some favourable, others less so.

China's success cannot ensure the efficacy of 'Chinese policies' in other times and places. There is also no guarantee that the mechanism described in this article can enable China to extend its enviable record of high speed growth. Even so, China's continuing accumulation of physical resources and human capital, the intense focus of public policy on promoting growth, and the willingness of China's leaders to implement bold initiatives create a favourable climate for further reform and continued economic expansion.

Choice of Technique and the Rate of Profit

N. Okishio

Capitalistic Criterion

In a capitalistic economy the main production decisions are made by private capitalists. The choice of technique is one of the decisions in their hands, and the criterion for that choice is to maximize the expected profit rate. In order to calculate that rate they must have expectations of the prices of various commodities, and of the wage rate.

Assuming a linear technology, in the *i*th sector capitalists have T_i alternative techniques:

$$a_{i1}(k_i), a_{i2}(k_i), \ldots, a_{in}(k_i), \tau_i(k_i)$$
$$k_i = 1, 2, \ldots, T_i$$

where $a_{ij}(K_i)$ is the amount of the *j*th commodity used as input to produce one unit of the *i*th commodity by the k_ith technique and $\tau_i(K_i)$ is the amount of labour necessary to produce one unit of the *i*th commodity by the k_ith technique.

Capitalists have expected prices and the wage rate:

$$p_1^e, p_2^e, \ldots, p_n^e, w^e,$$

where p_i^e is the expected price of the *i*th commodity and w^e is the expected wage rate.

The expected profit rate from the k_i technique, which is denoted as $r_i^e(k_i)$, is calculated as

$$p_i^e = \left[1 + r_i^e(k_i)\right]\left[\sum a_{ij}(k_i)p_i^e + \tau_i(k_i)w^e\right].$$

Capitalists choose the technique which yields the highest expected profit rate. If

$$r_i^e\left(k_i^e\right) \geqq r_i^e(k_i) \quad k_i = 1, 2, \ldots, T_i \tag{1}$$

then they choose the k_i^* th technique among T_i alternatives. As is easily seen, (1) can be rewritten as

$$\sum a_{ij}\left(k_i^*\right)p_i^e + \tau_i\left(k_i^*\right)w^e \leqq \sum a_{ij}(k_i)p_j^e + \tau_i(k_i)w^e$$
$$k_i = 1, 2, \ldots, T_i \tag{2}$$

The means that the expected unit cost is smallest in the k_i^* th technique. So in this case *the maximum profit rate criterion* is equivalent to *the minimum unit cost criterion*. However, this equivalence does not hold in general. If we introduce durable equipment the two criteria are not equivalent. But for simplicity here we will ignore durable equipment.

Profit Rate and Techniques

In the *i*th sector by the minimum unit cost criterion capitalists adopt the technique

$$a_{i1}, a_{i2}, \ldots, a_{in}, \tau_i$$

and labourers receive the commodity basket

$$b_1, b_2, \ldots, b_n$$

per unit of labour. Then an equal rate of profit *r* between *n* sectors is determined by the following equations:

$$p_i = (1 + r)\left(\sum_{j=1}^{n} a_{ij}p_j + \tau_i w\right)$$
$$i = 1, 2, \ldots, n \tag{3}$$
$$w = \sum_{i=1}^{n} b_i p_i$$

From these equations it is clear that the profit rate r depends on techniques (a_{ij}, τ_i) and the real wage basket (b_i).

In order to examine the relationship between the profit rate and techniques in various sectors, we must introduce a new concept: *basic sectors*. P. Sraffa has used this terminology, defining basic sectors as those whose outputs are directly or indirectly necessary in the production of every commodity (see ch. 2 in Sraffa 1960).

However, it is not guaranteed a priori that such basic sectors exist; and even if they do exist, the concept is not useful for our purpose here.

Now we redefine basic sectors as those whose products are wage goods, or whose products are directly or indirectly necessary to produce wage goods. 'Wage goods' means commodities which are included in the real wage basket (b_1,. . .,b_n). If $b_i > 0$ then the ith commodity is a wage good. Basic sectors in this sense necessarily exist, for there must be at least one commodity which is a wage good.

Suppose there are m basic sectors, with $m \leqq n$; after renumbering, let the 1st, 2nd,. . .,mth sectors be basic sectors. Then the equations

$$\begin{aligned} p_i &= (1+r)\left(\sum_{j=1}^{m} a_{ij}p_j + \tau_i w\right) \\ & i = 1, 2, \ldots, m \\ w &= \sum_{i=1}^{m} b_i p_i \end{aligned} \qquad (4)$$

are sufficient to determine the profit rate r, where prices (p_1,. . .,p_m) and the wage rate w are both positive. Therefore we can say that the profit rate does not depend on techniques in the non-basic sectors. For example, pure luxury goods are non-basic commodities. Whatever great improvement may occur in the techniques in those sectors, the (equalled) rate of profit is not influenced at all. This conclusion was first found by Ricardo, but Marx did not accept it (Ricardo 1821, p. 132; Marx 1867–94, Vol. III, ch. 5, pp. 83–4).

Hereafter in this essay we confine ourselves to techniques in the basic sectors only, and we assume that the classification into basics and non-basics remains unaffected by the technical changes considered here.

Technical Progress

Let us suppose the profit rate r to be determined by Eq. 4, and that in the kth sector ($1 \leqq k \leqq m$) a *new* alternative technique

$$a'_{k_1}, a'_{k_2}, \ldots, a'_{k_m}, \tau'_k$$

becomes feasible. Capitalists must then calculate the expected profit rate of this new technique and compare it with those of alternative techniques to decide whether or not to adopt it, so we now need an assumption about how capitalists form their expectations. For simplicity we assume

$$p_i^e = p_i, \; w^e = w \qquad i = 1, 2, \ldots, m$$

i.e. capitalists expect that current prices and the wage rate, as given by Eq. 4, will remain the same (static expectations).

If the following inequality holds, capitalists adopt the new technique:

$$\sum_{j=1}^{m} a'_{kj}p_j + \tau'_k w < \sum_{j=1}^{m} a_{kj}p_j + \tau_k w \qquad (5)$$

Supposing this to be so, the previous technique in the kth sector (a_{k1}, $a_{k\,2}$,. . ., a_{km},τ_k) is replaced by the new technique $\left(a'_{k_1}, a'_{k_2}, \ldots, a'_{k_m}, \tau'_k\right)$. How does the profit rate r as given by Eq. 4 then change, under the requirement that the real wage basket remain unchanged? We can prove that the profit rate r necessarily rises, as follows:

Putting

$$\beta = 1/(1+r), \qquad q_i = p_i/w,$$

Eq. 4 are rewritten as

$$\beta q_i = \sum a_{ij} q_j + \tau_i \qquad i = 1, 2, \ldots, m \qquad (6)$$

$$1 = \sum b_i q_i \qquad (7)$$

Let the solution of Eqs. 6 and 7 be

$$(\beta, q_1, \ldots, q_m)$$

When $(a_{k1}, a_{k\ 2}, \ldots, a_{km}\tau_k)$ is replaced by $\left(a'_{k_1}, a'_{k_2}, \ldots, a'_{k_m}, \tau'_k\right)$, the profit rate is determined by

$$\beta q_i = \sum a_{ij} q_j + \tau_i,\ i = 1, \ldots, k-1, k+1, \ldots, m \tag{8}$$

$$\beta q_k = \sum a'_{kj} q_j + \tau'_k \tag{9}$$

and Eq. 7. Let the solution of Eqs. 8, 9 and 7 be

$$(\beta', q'_1, \ldots, q'_m).$$

As $q'_i > 0$ for all i, the coefficients matrix of q_i ($i = 1,2,\ldots,m$) satisfies the Hawkins-Simon conditions (see Simon and Hawkins 1949).

From Eq. 6 to Eq. 9, we get

$$\beta' \Delta q_i = \sum a_{ij} \Delta q_j - q_j \Delta\beta,\quad i = 1, \ldots, k-1, k+1, \ldots, m \tag{10}$$

$$\beta' \Delta q_k = \sum a'_{ij} \Delta q_j - q_k \Delta\beta + \left\{\sum q_j \Delta a_{kj} + \Delta\tau_k\right\} \tag{11}$$

$$0 = \sum b_i \Delta q_i \tag{12}$$

where

$$\Delta q_i = q'_i - q_i, \quad \Delta\beta = \beta' - \beta$$
$$\Delta a_{kj} = a'_{kj} - a_{kj}, \quad \Delta\tau_k = \tau'_k - \tau_k$$

The third term on the right side of Eq. 11 is negative, by Eq. 5. If $\Delta\beta \geqq 0$, then in Eqs. 10 and 11 $\Delta q_k < 0$ and $\Delta q_i \leqq 0$ for all $i \neq k$, because as shown above the coefficient matrix of Δq_i in Eqs. 10 and 11 satisfies the Hawkins–Simon conditions. If the kth commodity is a wage good, $\Delta q_i < 0$ contradicts Eq. 12. If the kth commodity is a means of production (that is it belongs to the basic sectors), there must be at least one kind of wage good whose $\Delta q_i < 0$; again this contradicts Eq. 12. So $\Delta\beta > 0$, or in other words the profit rate r rises.

The proposition that any new technique which satisfies the profit rate criterion Eq. 5 and so is introduced into the basic industries necessarily increases the general rate of profit, cannot be compatible with the Marxian law of the tendency for the profit rate to fall. However large the organic composition of production may become, the general rate of profit must increase without exception, provided that the newly introduced technique satisfies the profit rate criterion and the rate of real wage remains constant (see Okishio 1961, for further discussion).

Joint Production

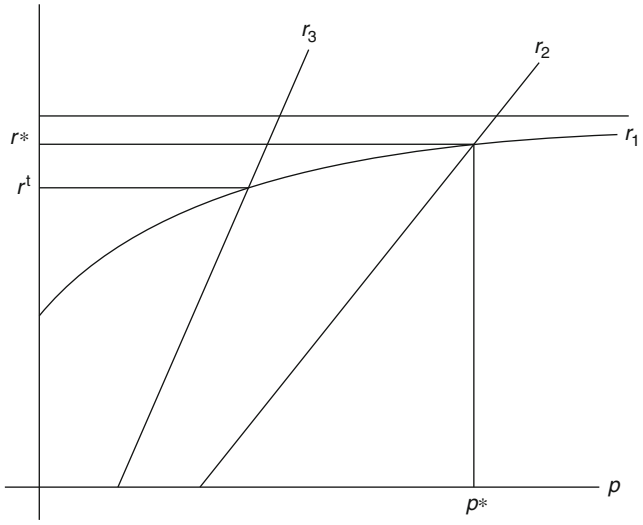
So far we have disregarded joint production as well as durable equipment. Even if we introduce durable equipment, the conclusion obtained in the former section still holds (see Nakatani 1984). However, when we consider the joint production it is possible (though not necessary) to find a case in which the proposition does not hold, a perverse conclusion that was originally presented by Salvadori (1981).

In order to show such a case we examine the following numerical example. In this economy, shown in Table 1, there are two kinds of commodity. The second commodity is a wage good and it is produced jointly with the first commodity. Let

Choice of Technique and the Rate of Profit, Table 1

Input			Output		
Technique	1	2	Labour	1	2
1	0.5	0.5	1	1	2
2		0.5	1	1	
3		0.5	1	2	

Choice of Technique and the Rate of Profit, Fig. 1



the real wage rate be 0.7 unit of the second commodity. At the first stage we assume that techniques 1 and 2 only are feasible.

The profit rates of techniques 1 and 2 are determined by

$$p_1 + 2p_2 = (1 + r_1)(0.5p_1 + 0.5p_2 + w)$$
$$p_1 = (1 + r_2)(0.5p_2 + w)$$
$$w = 0.7p_2$$

where r_1, r_2 are the profit rates of techniques 1 and 2, respectively. Putting $p = p_1/p_2$ these equations are rewritten as

$$p + 2 = (1 + r_1)(0.5p + 1.2)$$
$$p = 1.2(1 + r_2)$$

The profit rates of both technique are drawn on Fig. 1.

Now we examine the condition in which both techniques 1 and 2 are used. If technique 1 only is used at activity level x, then the surplus products consist of $(1–0.5)x$ units of commodity 1 and $(2–0.5 \simeq 0.5)x$ units of commodity 2. Therefore if the capitalists' demand for the surplus products (for their consumption or investment) are 100 units of commodity 1 and 50 units of commodity 2, then there must be excess demand for commodity 1 or excess supply for commodity 2 and the relative price p_1/p_2 increases.

When p rises above p^* the expected profit rate r_2 becomes greater than r_1, so technique 2 is introduced. However, technique 2 cannot replace technique 1 completely because technique 2 cannot produce commodity 2. Therefore both techniques must be used, which requires that the equal rate of profit be determined at r^*.

At the next stage we assume that technique 3 becomes feasible. Technique 3 is apparently superior to technique 2, because in the new technique capitalists get more output from the same input, so it replaces technique 2. The profit rate of technique 3 is calculated from

$$2p_1 = (1 + r_3)(0.5p_2 + w)$$
$$w = 0.7p_2$$

which can be rewritten as

$$2p = 1.2(1 + r_3)$$

This equation is also plotted on Fig. 1, from which it can be seen that the equalized rate of profit falls to r'.

Substitutional Technical Change

In the previous sections we treated the relationship between the profit rate and technical change

under the condition that the real wage basket remain unchanged. The change in the technique adopted was not induced by a change in the real wage rate, but was caused by the introduction of a new process.

The question now is the relationship between the profit rate and technical change that is induced by a change in the real wage rate. We define the level of the real wage rate λ as follows.

Assume that each labourer spends his wage income on various wage goods in fixed proportions. Then we have

$$w = \lambda \sum b_i p_i,$$

where the b_i are all constant and λ is the level of the real wage rate.

At the first stage $\lambda = 1$, and the profit rate is determined by Eqs. 6 and 7. At the next stage $\lambda > 1$, which means a rise in the real wage rate. Then the profit rate is determined by the following equations

$$\beta q_i = \sum a'_{ij} q_j + \tau'_i \qquad i = 1, 2, \ldots, m \quad (13)$$

$$1 = \lambda \sum b_i q_i \quad \lambda > 1. \quad (14)$$

As shown in Eq. 13 the techniques used in every sector may differ from the techniques used at the first stage, because of the rise of the real wage rate and the change of prices which accompanies it. What can we say about the relationship between the newly adopted technique a'_{ij}, τ'_i and the old technique (a_{ij}, τ_i) ? (Of course we assume that no technique becomes newly feasible for capitalists between the first stage and the next stage.)

Let the solution of Eqs. 6 and 7 be

$$(\beta, q_i, \ldots, q_m).$$

Then

$$\sum a_{ij} q_j + \tau_i \leqq \sum a'_{ij} q_i + \tau'_i \quad (15)$$

because technique (a_{ij}, τ_i) would not have been adopted at the first stage if inequality Eq. 15 had *ij i*not held; rather they would have adopted (a'_{ij}, τ'_i).

Let the solution of Eqs. 13 and 14 be

$$(\overline{\beta}, \overline{q}_1, \ldots, \overline{q}_m).$$

Then, arguing as for Eq. 15,

$$\sum a_{ij} \overline{q}_j + \tau_i \geqq \sum a'_{ij} \overline{q}_j + \tau'_i. \quad (16)$$

Using inequalities Eqs. 15 and 16 we can prove that in going from the first stage to the second the profit rate necessarily falls, as follows:

From Eqs. 6, 7, 13 and 14 we get

$$\overline{\beta} \delta q_i = \sum a'_{ij} \delta q_j + q_i \delta \beta + \left\{ \sum_{i = 1, 2, \ldots, m} \left(a'_{ij} - a_{ij} \right) q_j + \left(\tau'_i - \tau_i \right) \right\} \quad (17)$$

$$0 = \sum b_i \delta q_i + (\lambda - 1) \sum b_i \overline{q}_i \quad (18)$$

where

$$\delta q_i = \overline{q}_i - q_i, \qquad \delta \beta = \overline{\beta} - \beta.$$

From Eq. 15 we know that the third term on the r.h.s. of Eq. 17 is non-negative. If we assume $\delta\beta \leqq 0$ then all the δq_i become non-negative because the coefficient matrix of δq_i satisfies the Hawkins-Simon conditions. But since $\lambda > 1$ that contradicts Eq. 18. So $\delta\beta$ must be positive, or in other words the profit rate must fall.

When the real wage rate rises capitalists cannot avoid a fall in the profit rate, even if they substitute techniques to avoid it; only the introduction of new and superior feasible techniques can prevent the fall. However, we cannot say that the capitalists' efforts to substitute with exciting techniques are of no use to them. Though they cannot avoid a fall in the profit rate, they can mitigate it. We can prove this as follows.

If in spite of the rise in the real wage rate capitalists adhere to the techniques adopted at the first stage, the profit rate is determined by

$$\beta q_i = \sum a_{ij} q_j + \tau_i \qquad i = 1, 2, \ldots, m \quad (19)$$

$$1 = \lambda \sum b_i q_i \quad \lambda > 1 \tag{20}$$

Let the solution of Eqs. 19 and 20 be

$$\left(\beta^*, q_1^*, \ldots, q_m^*\right).$$

From Eqs. 13, 14, 19 and 20 we get

$$\begin{aligned} \beta^* dq_i = & \sum a_{ij} dq_j - q_i^* d\beta \\ & + \left\{ \sum \left(a'_{ij} - a_{ij}\right) \overline{q}_j + \left(\tau'_i - \tau_i\right) \right\} \\ & i = 1, 2, \ldots, m \end{aligned} \tag{21}$$

$$0 = \lambda \sum b_i dq_i \tag{22}$$

where

$$dq_i = \overline{q}_i - q_i^*, \qquad d\beta = \overline{\beta} - \beta^*.$$

From Eq. 16 the third term of the r.h.s. of Eq. 21 is non-positive. However, if we now consider the case in which substitution actually occurs, then for some i the third term on the r.h.s. of Eq. 21 is negative. If we assume $d\beta \geqq 0$, then all the dq_i become non-positive and some actually negative, because the coefficient matrix of dq_i satisfies the Hawkins–Simon conditions. This contradicts Eq. 22 so $d\beta < 0$. In other words, when the substitution is carried out the profit rate is greater than it would have been if capitalists had adhered to the old optimal technique, which corresponded with the former level of the real wage rate.

C

Chrematistics

M. I. Finley

A Greek word occasionally taken over into English (and some other western European languages) to mean ‘money-getting’, often but not always with pejorative overtones. After a great flurry in the fifth and fourth centuries BC in the original Greek, the word became uncommon and would not be worth noticing here were it not that the major debates among Greek thinkers, chiefly ethical, were revived in the thirteenth century by the scholastic philosophers though without actually using the term ‘chrematistic’. The earliest English example given by the *Oxford English Dictionary* dates from the mid-eighteenth century, in Henry Fielding’s last novel, *Amelia* (1752): ‘I am not the least versed in the chrematistic art . . . . I know not how to get a shilling, or how to keep it in my pocket if I had it’ (Book IX, ch. 5). This pedantry implied no familiarity by readers, for Fielding promptly gave them the sense of it. Nor is there much to be drawn from the unimportant nineteenth-century terminological disagreement over the propriety of the term ‘political economy’, for which Gladstone and a few others preferred ‘chrematistics’.

The word had a long and complex history in early Greek, which we cannot trace properly because of insufficient evidence. The ultimate root was the verb *chrao*, to 'need' or 'use', hence *chrema* (more common in the plural form, *chremata*), 'goods', 'property', 'wealth', and the verbal forms meaning 'to seek wealth' (Other extensions, such as 'to engage in discussion or negotiations' or 'to consult an oracle' need not concern us.). Alongside these *chrao* words there were others with the same sense of goods, property, wealth, but all attempts to codify distinctions in usage, for instance between real property and moveable wealth, have proved not to reflect the actual practice of Greek speakers and writers.

Concomitant with this linguistic history there was a related development in commercial practice and attitudes. One thread that persisted in attitudes, however, was a distrust, even outright condemnation, of trading for profit, of making a profit out of the sheer act of exchange without any additions to, or transformation of, the goods being traded. This motif was already apparent in the *Odyssey*: when Odysseus declined the invitation to join in the games arranged following a feast at the court of King Alcinous of the Phaeacians, he was taunted by one of the courtiers with an unbearable insult:

> No indeed, stranger, I do not think you are like a man of games, . . . but like one who travels with a many-benched ship, a master of sailors who traffic, one who remembers the cargo and is in charge of merchandise and coveted gains (*Odyssey*, 8, 145–64).

This distrust of trade can be amply exemplified right through pagan antiquity and then among the Church Fathers (on whom see Baldwin 1959, pp. 12–16), with differences in nuance from culture to culture and from author to author that are sometimes interesting and at times paradoxical in their practical implications. Cicero provides a neat illustration. In the *De officiis* (1, 150–1) he dismisses those 'who buy from merchants in order to re-sell immediately, for they would make no profit without much outright lying', whereas commerce that is 'large-scale and extensive, importing much from all over the distributing to many without misrepresentation (*vanitas*), is not to be greatly censured'. In that nuance there was an exception because of the social usefulness of the large-scale merchant in his role as importer, with the consequent suggestion that he, unlike the petty trader in the market, was able to avoid outright lying. Not all moralists allowed such an exception, and Cicero gives no hint why one was in practice possible in this particular instance.

What I have been calling a paradox revealed itself when the moral judgements of a given culture or society conflicted with its legal system and rules of practice. Obviously large numbers of Greeks and Romans behaved contrary to the norms of commercial exchange laid down by Aristotle or Cicero, and on the whole both Greek and Roman law accepted the validity of private agreements provided only that they did not require actions specifically prohibited by the law. However, there were also major differences between the two, most obviously with respect to usury. Barring unimportant exceptions, especially in emergency situations, it was the rule among Greek states that no attempt was made to restrict or otherwise regulate rates of interest, whereas from earliest times the Roman law kept a tight reign on moneylending. Hence in Rome the professional moneylender, the *fenerator*, was a figure of distrust and contempt while men of means ranked moneylending at legal rates second only to land ownership as a source of income, and did not often blanch at charging exorbitant rates for loans to communities outside the sphere of the Roman law. There we see several paradoxes at work simultaneously.

This apparent detour has brought us back to the heart of the discussion of money-getting, of chrematistics. We can examine the formulations of moralists and we can match them against the legal precepts, but the critical question of practice in actual exchanges largely escapes us. Not only are we driven to outright guesses about pricing procedures (as about the actual practice with respect to interest charges), but there is no useful ancient testimony about the mechanism of price determination. Much of what is written about the meaning or the reality behind Aristotle's ambiguous formulation, or about Aquinas' concept of just

price, is nothing but a backward projection of a modern author's own notions, for which there is no warrant (and often contrary evidence) in the ancient texts themselves (Finley 1970).

In the end, we have only one surviving analysis from antiquity of the complex of issues raised by the notion of chrematistics (and no reason to think that other systematic accounts once existed and were eventually lost). That is the account by Aristotle and it is not only unsatisfactory but there can be no doubt that Aristotle himself thought it merely tentative and incomplete. It is enough to indicate that the term 'chrematistics' is used in three incompätible senses, with the pejorative one predominant (see in detail Newman 1887–1902, II, 165–208). Nevertheless, Aristotle had made a serious start in grappling with a major social and moral problem, and one could have expected further discussion and development. Instead, the whole discussion promptly died for some 1,500 years until it was apparently revived with Albertus Magnus and Thomas Aquinas in the thirteenth century following the translation into Latin of the *Ethics* and the *Politics.* This is a curious puzzle in the history of ideas, and it must be said that modern accounts are dominated by illusions.

One is that not only was Aristotle one of the greatest figures in the history of philosophy, but that this was acknowledged in the generations after his death by the way in which philosophical questions were treated. Perhaps this was not often stated explicitly (since there was no textual foundation for such a view), but the implication was never far beneath the surface. Yet it is a fact that in the field of social thought the *Politics* was effectively lost sight of and unknown for some three centuries after the death of Aristotle's successor Theophrastus (see Sandbach 1985), and that it continued to be neglected for a millennium. Between Cicero and the thirteenth century no more than a dozen references in Greek are known, half of them in Byzantine lexica and scholia (Susemihl and Hicks 1894, p. 18 n.7). Stoicism had quickly become the dominant school and the concept of natural law was its pivotal one. From the Greeks it passed to the Romans, and under the influence notably of Cicero and Seneca, it became one of the three foundation-stones of European ethics until the beginning of the modern era (and even beyond). How 'pure' this Stoic ethics remains is irrelevant. What is essential is its dominance and the fact that it by-passed the Aristotelian concern with chrematistics, justice in exchange, and the like.

The second foundation-stone was the Roman law, a confusing and ambiguous one. The Roman jurists were in practice firm supporters of the principle that any agreements made in good faith and not specifically prohibited by the law were acceptable. There was no place in that sphere for Aristotelian doctrines about chrematistics. Nor was there in the third foundation, the Church Fathers, despite their 'misgivings about the merchant' (Baldwin 1959, pp. 12–16). The attitude of the New Testament to economic matters, unlike the Old, was a subject of controversy from the beginning, but what matters in our context is first that there was a hardening of attitudes on some matters, especially usury and the morals of commerce, over the final centuries of antiquity and the early Middle Ages, and that secondly, chrematistics hardly entered the discussion. From the sixth century on, church councils and later, in the Carolingian period, imperial enactments produced a stream of warnings about the 'morally dangerous character of buying and selling' (Baldwin 1959, p. 34). The fullest account of this material remains Schaub (1905), with its revealing subtitle, 'eine moralhistorische Untersuchung'. By the twelfth century, an impressive body of doctrine had been developed regarding usury, business practices and trade. The contrast is striking with the almost total emptiness on these subjects in the vast corpus of the writings of St Augustine (Cranz 1954).

It is remarkable how the conventional histories of economic thought tend to skip over some seven centuries of 'moral history' as they leap from antiquity to the rediscovery of Aristotle and the apogee of scholasticism in the thirteenth century. In an important and neglected article published by the Pontifical Medieval Institute in Toronto, Eschmann (1943, p. 134) rightly concluded that in that century, dominated by Albertus Magnus and Thomas Aquinas, the rediscovery of Aristotle

merely 'reinforces the Roman–patristic ideas and plays a decorative rather than a constructive role'. By then the fundamental principles had already been laid down in the solution of concrete problems arising from usury, buying and selling, and the conduct of trade. Aquinas may have codified such doctrines as just price, but he neither invented them nor found them in Aristotle. Because of the way he worked, in particular because he never produced a synthesis of social philosophy, there are puzzles that continue to plague commentators.

How, in particular, was the just price determined? That was Aristotle's problem (though in different language) with chrematistics, and, as we have seen, he never resolved it satisfactorily. But at least he made a serious effort: we know of none made by Aquinas. The common view today is that for the latter the just price was the prevailing one in normal practice, and I cannot avoid the suspicion that this is merely a projection into scholasticism of the thinking of neoclassical economists (e.g., Viner 1978). As one historian who accepts the common view has conceded, nowhere did Aquinas 'state in practical terms what exactly comprised the just price' and the only textual support for the notion that the just price is the prevailing price comes from writers in the next generation or two (Baldwin 1959, pp. 75–6). There is an alternative interpretation that at least merits more consideration than it has hitherto received: Aquinas, writes a neo-Thomist economist (Stark 1956, p. 5), 'does not stop to consider the question how the just price is arrived at' because 'it is taken for granted . . . like all the other rules and regulations of an orderly social existence'; 'the price is part and parcel of the system of custom on which all social life is built'.

Ironically, at the moment when the Aristotelian questions in their latter-day versions reached their intellectually most sophisticated formulation they were already moribund in practice, and they soon effectively dropped from sight, despite the lingering canon law and theological interest, in usury in particular. The slogan 'treasure by foreign trade' can be thought to have been the death-knell.

Christaller, who never held an academic post but worked throughout his life in association with the University of Erlangen, is known for one seminal book *Die zentralen Orte in Süddeutschland* [Central Places in Southern Germany]. Published in Germany in 1933 it remained largely unnoticed

by English-speaking scholars until a translation of August Lösch's *Economics of Location* (1954) brought it widespread attention. Later an accurate translation of Christaller's book by C.W. Baskin (in 1966) confirmed the elegance of his deductive theorizing.

Christaller sought to clarify and explain the laws which determine the number, sizes and distribution of towns. Drawing upon the work of von Thünen, Alfred Weber and Engländer, Christaller developed a general theory of why a *hierarchy* of villages and towns providing different services should appear and why this hierarchy should differ region by region. Making use of key concepts of market threshold, and normal travelling distance, he showed how the geographical extent of the trading areas for different goods and services vary and how low order centres provide limited ranges of goods to small trading areas whereas larger centres service much wider areas and contain all the goods of the lower centres as well as goods unique to their size.

Christaller's work has been criticized as ignoring the role of manufacturing in shaping the growth of towns and cities, of underplaying the effects of an unequal distribution of natural resources and of an all too rigid expression of the laws of market size and of the hierarchy of central places. Of the last point Christaller was fully aware and by 1950 he had modified his stance allowing for greater variability in the determinants of the hierarchy. And though his general theory of spatial relations is incomplete, all subsequent analysts of retail trade, of the location of services and of urban growth, recognize the rigour of his approach and the elegance of his attempt to provide the 'economic theoretical foundations of town geography'.

Christian Socialism

E. Cannan

Christian Socialism is a name which properly belongs to the propagation of cooperative production or working men's associations by F.D. Maurice and his disciples in the years 1849 to 1853. Its origin is to be found in a letter from J.M. Ludlow to Maurice (March 1848) saying that the socialism of Paris workmen was a real power which would shake Christianity if it were not Christianized. After the publication of Henry Mayhew's letters on the London poor in the *Morning Chronicle,* in 1849, Maurice and his followers at Lincoln's Inn, who had already been trying to persuade the Chartists, in *Politics for the People* (6 May to 29 July 1848), and in discussions at the Cranbourne Tavern, that moral and sanitary reform were of much more importance than extension of the suffrage, turned their attention to economic questions. They were led to deny any beneficence to the operation of self-interest. 'Free competition', said Ludlow, 'mars every-where, instead of making, the wisest distribution of labour' (*Christian Socialism,* p. 35). 'We have protested', Maurice wrote to Dr Jelf, 12 November 1851, 'against the spirit of competition and rivalry precisely because we believe it

is leading to anarchy, and must destroy at last the property of the rich as well as the existence of the poor' (*Life*, ch. ii, p. 83). As a remedy they proposed 'Christian socialism', or friendly association for productive purposes. They sometimes went so far as to imagine a state of things in which all producers might 'combine regularly into one body which should, after mutual explanations and by mutual concert, fix the terms upon which each member should dispose of his wares to the others' (Ludlow, *Christian Socialism,* p. 35); but they suggested no principle of distribution on which this agreement should be based. They founded an association of tailors (February 1850) of which Walter Cooper, formerly a Chartist, was manager, and organized a society for promoting working men's associations under a council of promoters among whom were Maurice, Charles Kingsley, T. Hughes, E.V. Neale, and F.J. Furnivall. *Alton Locke,* which represents the ethical side of the Christian Socialist doctrine, was published early in 1850, and was followed by *Tracts on Christian Socialism, Tracts by Christian Socialists*, and the *Christian Socialist*, a weekly penny paper which lasted from 20 November 1850 to the end of 1851. Its place was then taken by the *Journal of Association,* which endured till 28 June 1852. The evidence of the 'Promoters' before Slaney's Committee of the House of Commons on 'Investments for the savings of the middle and working classes' in 1850, aided in bringing about the legislation of cooperative societies by the 'Industrial and Provident Partnerships Act' of 1852. After the passing of that Act the society for promoting associations was remodelled and the term 'Christian Socialism', as employed in this connection, was abandoned. It was offensive alike to theologians, economists, and socialists. The hostility displayed towards the Christian Socialists in many quarters was more due to the name they assumed, and to the vehemence with which Kingsley denounced competition, than to dislike of their Associations, though these were doubtless looked on with some suspicion as copies from French models.

Circular Flow

Giorgio Gilibert

JEL Classifications
E1

The analysis of the social process of production and consumption must start from some notion of commodity circulation. Consideration of the simple cycle of agricultural production suggests that production is an essentially circular process, in the sense that the same goods appear both among the products and among the means of production. From this viewpoint, commodity (as well as money) circulation is a triviality, whose discovery cannot really be attributed to any particular economist.

It has been suggested that the notion was originally developed by François Quesnay, a surgeon, by analogy with the circulation of the blood. However the popular analogy between money and blood is much older (see for instance 'Money is for the state what blood is for the human body', *Etats généraux,* 1484); and the process of money and commodity circulation among different classes (landlords, labourers, merchants) and areas (town and country) was clearly described by Boisguillebert and Cantillon several decades before the physiocrats.

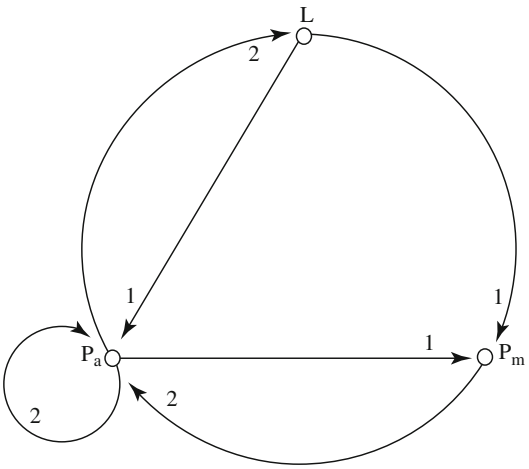
What is truly novel with Quesnay is the idea that the essential task of economic science is the

investigation of the technical and social conditions which allow the repetition of the circular process of production. This approach (at least in the extreme form given it by the physiocrats), and the peculiar model building activity that sprang from it, was later abandoned by economists. More than a century had to pass before the theme could be resumed, following the publication of Marx's own *tableaux* in the second volume of *Capital* (Marx 1885), but merely within the rather limited and isolated group of the German and Russian theoretical economists.

Tugan-Baranowsky considered circularity as the essential feature of capitalist economy, in which production was the end of consumption rather than the other way round; in his view, the economists were unable to understand this 'paradox' because (with the remarkable exception of Marx) they had strayed from the way opened up by Quesnay. The young Schumpeter, in a justly celebrated essay, dated the birth of economics as a science from the physiocratic analysis of the circular flow. And Leontief (1928) wrote in a similar vein, arguing in favour of the substitution of the principle of circular flow (the 'reproducibility viewpoint') for that of *homo oeconomicus* (the 'scarcity viewpoint') as the cornerstone of economic theory.

The reproducibility viewpoint is shared by the whole classical tradition of political economy. However, within this broad theoretical tradition, we can single out a radical strand which considers the economic behaviour of every individual as completely determined by the reproduction requirements of the system. This peculiar approach characterizes the pure theorists of the circular flow, with whom we will now briefly deal. Not surprisingly, this theoretical approach is often associated with a practical attitude in favour of some sort of central planning (as a consequence of the distrust for the 'anarchy' of the market).

The *Tableau Economique* depicts all the transactions taking place during the year among the three basic classes of society: the class of landowners (L), the 'productive' class of farmers (P_a), and the 'sterile' class of manufacturers (P_m). These transactions can be summarized by a graph, where three points – one for each class – are connected by lines, representing the transactions; the lines are oriented according to the direction of the money flows, whose value is shown by numbers (thousand millions of *livres*). Figure 1 is drawn on the data of Quesnay (1766); since the sum of the money flows leaving each point equals that of those coming in, the system is reproducible.

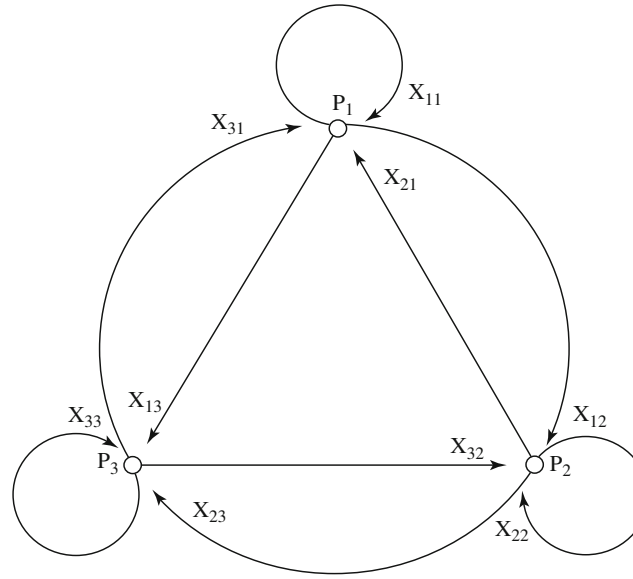


Circular Flow, Fig. 1

Marx's (simple) reproduction scheme can also be easily adapted to the same type of three-point graph, once capitalists are substituted for landowners, and the two industries producing intermediate goods ('constant' capital) and consumption goods ('variable' capital and luxuries) are substituted for the two classes of manufacturers and farmers respectively. It should be noted that, while Quesnay's *tableaux* are inherently static, Marx does also consider expanded reproduction: in his own words, the picture shifts from a circle to a spiral. A modern example of a circular representation of an expanding economy is the well-known von Neumann model, which, from this point of view, can be considered as the most sophisticated heir to the Marxian schemes.

Quesnay's and Marx's *tableaux* were offered in value terms; but there is no conceptual difficulty in imagining analogous schemes in physical terms. Now, if all the physical transactions taking place

Circular Flow, Fig. 2



among all the agents of the economy are known, there is a unique set of relative prices which makes it possible for the process to be repeated.

Let us consider an economy in which n producers produce n goods. If we know all the physical amounts x_{ij} of the various goods consumed by the different producers, and if the economy is closed (i.e. production equals consumption for each good), relative prices p_i are determined by the following linear homogeneous equations:

$$\sum_i x_{ij} p_i = p_j \sum_h x_{jh}.$$

This theory or prices has now come to be associated with the closed Leontief model (Leontief 1941), but it was originally formulated in the late 18th century by Achille Isnard. He considered a simple example with three producers and consistently computed the corresponding prices.

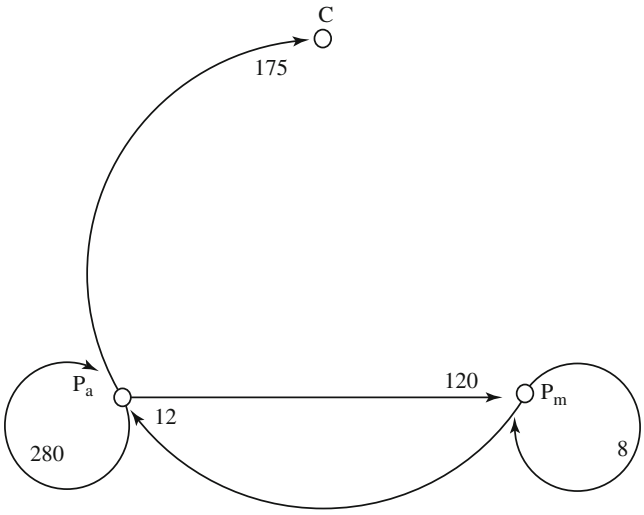
His example is illustrated by the graph of Fig. 2: three points, one for each producer, are connected by lines, corresponding to the physical amounts exchanged; the lines are now oriented according to the physical commodity flows. Relative prices have to be such as to equalize the value of the flows leaving each point with that of the flows coming in; the loops at the vertices (self-consumption) are not relevant to our problem.

When Leontief, a century and a half later, rediscovered the theory, he recognized in it the 'objective' theory of value. One year later, the German mathematician Robert Remak interpreted system (1) as determining the rational prices for an economy in which the individual standards of living are fixed by a central authority. He showed that the system has in general meaningful solutions; and maintained that these prices could be practically computed and implemented.

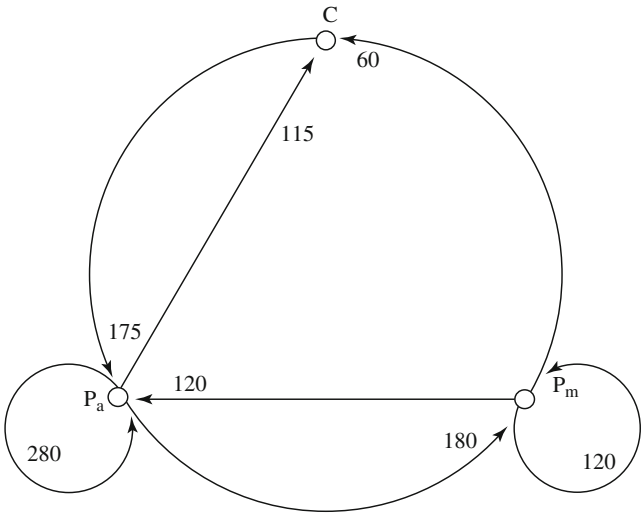
Until now, we have considered only closed systems, in which all transactions are assumed as known irrespective of their nature (technical inputs or human 'final' uses). We can now open the model, by considering as given only those transactions which are dictated by the technology in use (including workers' subsistence) and leaving undetermined the final utilization of the surplus thus appearing.

There is now room for an additional relation, stating the way in which the surplus is distributed. If we assume that it is entirely appropriated by profit-earners in proportion to the capital advanced, we land on the familiar ground of the classical theory of production prices.

Circular Flow, Fig. 3



Circular Flow, Fig. 4



The case can be illustrated by a simple numerical example supplied by Sraffa: there are only two industries, producing wheat (P_a) and iron (P_m) respectively; the class of capitalists (C) gets the entire surplus, consisting only of wheat. In Fig. 3 the numbers on the oriented graph refer to the physical quantities (quarters and tons) in the example.

The uniform profit rate has to be such as to equalize the value of the surplus bought by capitalists to the profits accruing to them; and the exchange value between the two commodities has to be such as to enable each industry to replace its advances and to distribute profits in proportion to their value. Loops are now relevant.

The system is then reproducible when the money flows leaving each point are equal to those coming in; the situation is illustrated in Fig. 4, and corresponds to a price of iron in terms of wheat equal to 15 and to a common profit rate equal to 25 per cent.

Finally, if we allow the wage earners to share the surplus with the capitalists, we generate the pure theory developed by Piero Sraffa (1960).

We are now able to interpret the abstract transition from our original circular theory to the classical theory of production prices, and eventually to its modern Sraffa version, as successive steps in a gradual opening of the model. From an initial system in which the economic behaviour of every individual is assumed to be rigidly determined by reproduction requirements, we have passed to a system in which capitalists (and rentiers) are assumed to be free in determining their final demand; and finally we have also granted some degree of freedom to the workers.

The term 'free' means here only that the composition of final demand is an issue which lies outside the domain of the pure theory of prices; of course, it can be the object of a distinct section of economic theory. In this perspective, we could say that the neoclassical theory of prices corresponds to a vision of the economy in which the individuals are supposed to be undifferentiated (i.e. there are no classes) and all equally free (the reproduction requirements do not play any essential role in determining prices).

Circulating Capital

Mark Blaug

Abstract

This article summarizes the history of the distinction between circulating capital (whose full value returns to the capitalist from the sale of final goods) and fixed capital (whose value is never fully recovered in one production cycle) from its introduction by Smith and development by Ricardo to its treatment by Marx and the Austrian capital theorists. It gave rise to the wages fund doctrine, the problem of joint production, and the issue of the optimum rate of depreciation and replacement of old equipment.

The explicit distinction between fixed and circulating capital first makes its appearance in Book II, chapter 1 of Adam Smith's *Wealth of Nations,* who derived it from ample hints in Quesnay and Turgot. Circulating capital goods, according to Smith, consist of those intermediate goods that embody a quantity of purchasing power that perpetually returns to the capitalist as he disposes of the final goods into the making of which they entered, in contrast to fixed capital goods, whose value is never fully recovered in one production cycle. The simplest example of circulating capital is raw materials, just as the simplest example of fixed capital is buildings and machines. However, all the classical economists, including Smith, included in circulating capital not just raw materials but also the consumer goods that support labour during the process of production; that is, wage goods.

This is the origin of the notorious 'wages fund doctrine', according to which wages are said to be 'advanced' to workers at the outset of a production period as a result of which they are determined by the ratio between the volume of capital advanced and the size of the labour force. The notion arose out of a pronounced tendency in 18th-century economics to regard agriculture as an industry typical of production as a whole and to view wheat as both a representative output of agriculture and the staple article of consumption of workers. The fact that wheat only becomes available in the form of annual harvests, which must be willy-nilly stored as a 'fund' for future consumption if its actual use is to be more or less continuous throughout the year, made it possible to define capital simply as 'advances' to workers to support them from seed-time to harvest. Despite the fact that this agrarian model was gradually abandoned in the century after Smith, the wages fund doctrine lived on until J.S. Mill's recantation of the doctrine in 1867, and with it the definition of circulating capital as including all consumer goods that enter into the wage basket (Blaug, 1985, pp. 185–8). Surprisingly enough, this conception of capital as consisting largely if not solely of wage goods survived even beyond the 'marginal revolution': it lies at the heart of the theoretical schema adopted by Böhm-Bawerk in his *Positive Theory of Capital* (1887).

Adam Smith noted that fixed and circulating capital combine in different proportions in different industries, but it was Ricardo who converted this observation into one of the central facts of industrial life in a capitalist economy and a major problem for the theory of value. Ricardo wanted to argue that relative prices are determined by relative labour costs but, as he candidly admitted in the first chapter of the *Principles of Political Economy and Taxation*, this cannot be true, because not only does the ratio of fixed to circulating capital differ between industries but, in addition, the two kinds of capital may differ in durability between industries. Indeed, he added in a footnote, the distinction between fixed and circulating capital is not essential because any difference between them is solely a matter of degrees of durability; that is, the different time periods for which capital is locked up in the productive process: circulating capital is the sum of goods tied up in production for only as long as the period of production in question, whatever its length, whereas fixed capital is a joint output of this production period in the shape of a slightly older building or a slightly older machine. To put it in a nutshell: the distinction between fixed and circulating capital is not the difference in their absolute durability but rather the difference in their durability relative to the length of the production period in which they are employed.

Thus, despite the fact that Marx in *Capital* rejected the Smithian distinction between fixed and circulating capital and chose instead to distinguish 'constant' and 'variable' capital, confining the former to the wage bill and the latter to everything else on the grounds that wages might vary for a given production system even if all the technical input coefficients remained the same, he operated throughout the first volume of the book with a circulating capital model by virtue of the assumption that the capital stock of every industry in the economy turns over once a year: despite all the references to machinery in this first

volume, all the analytical problems created by the use of fixed capital are eliminated by assuming that every industry operates with an annual production period. It is only in volume 2 of *Capital,* and particularly chapters 8–14, that Marx takes account of differences in the durability or turnover rates of capital invested in different industries, and it is here that he begins to confront the problems created by the fact that fixed capital, unlike circulating capital, only transfers part of its value to the final product during each turnover of capital. This is the now famous problem of joint production, which, it has been argued (Steedman 1977, ch. 10), may produce such anomalies as negative labour-costs for some products.

In the same way, all of the work of Böhm-Bawerk and most of that of Wicksell on the theory of capital is confined to the question of the optimum investment period of continuously applied circulating capital; that is, to what Ragnar Frisch has called the 'flow input–point output' case. It is only when we take up the 'point input–flow output' or the even more typical case of 'flow input–flow output' that we confront the question of fixed capital, an issue that Böhm-Bawerk consistently avoided and that Wicksell only took up in one essay in later life (Blaug 1985, pp. 563–4). The difficulty created by the use of fixed capital is simply that there is no obvious way of linking particular units of input embodied in fixed capital with particular units of finished output: all the inputs embodied in fixed equipment are jointly responsible for the whole stream of future outputs. Thus, by limiting itself to circulating capital, Austrian capital theory avoided such vexing questions as the optimum rate of depreciation and replacement of old equipment that are always linked with the decision to invest in new equipment, questions which perhaps are not completely resolved even to this day.

The increasing use of fixed capital is said to be one of the distinguishing characteristics of a capitalist system. If so, we might well expect capital theory to have been largely devoted to an analysis of fixed capital. It is one of the ironies of the history of economic thought, however, that capital theory from Turgot to the late Wicksell always treated circulating and not fixed capital as 'capital' *par excellence.*

City and Economic Development

J. Vernon Henderson

Abstract

As countries develop they urbanize, with resources shifting from labour-intensive agricultural production to manufacturing and services, which are located in cities because of agglomeration economies. This entry discusses the economic determinants of this process. But urbanization also moves populations from traditional rural environments with informal political and economic institutions to the relative anonymity and more formal institutions of urban settings. A major issue in the development process is development of institutions and national policies which allow cities to operate in markets that are well structured and conducive to good urban outcomes.

JEL Classification

O18

The city in economic development is fundamental to the urbanization process. Urbanization, or the shift of population from rural to urban environments, is a transitory process which is socially and

culturally traumatic. As a country develops, it moves from labour-intensive agricultural production to labour being increasingly employed in industry and services. The latter are located in cities because of agglomeration economies. Thus, urbanization moves populations from traditional rural environments with informal political and economic institutions to the relative anonymity and more formal institutions of urban settings. That in itself requires institutional development within a country.

Once urbanization is complete, one might be tempted to simply move on to the traditional analysis of systems of cities, with the idea that the issues that face systems of cities in developed economies are the same as those that face cities in developing but fully urbanized economies (as in Latin America and the Middle East). But in practice this is not the case; countries still face problems of developing institutions and national policies which allow cities to operate in markets that are well structured and conducive to good urban outcomes. Here, we discuss both the urbanization process and then the institutional-policy issues that face cities in developing countries.

The Urbanization Process

There are several models of the urbanization process. The traditional ones are two- sector models, where population moves from a rural sector to an all-purpose urban sector, due to exogenous factors such as unexplained shifts in technology (Lewis 1954). Dual-sector models focus on the question of urban 'bias', or the effect of government policies on the urban–rural divide, and the efficient rural–urban allocation of population at a point in time. Generally, these models are static, and any urbanization is the result of exogenous forces – technological change favouring the urban sector or changes in the terms of trade favouring the urban sector. There is a new generation of two-sector models, namely, the core–periphery models, which have more of a spatial flavour (Krugman 1991; Puga 1999). Core–periphery models ask when in a two-region country industrialization, or 'urbanization', is spread over both regions rather than being concentrated in just one region. The models explore a key issue: the initial development of a core (say, coastal) region and a periphery (say, hinterland) region, as technology improves (transport costs fall) from a starting point with two identical regions. However core–periphery models have limited implications for urbanization per se. They are unidimensional in focus, asking what happens to core–periphery development as transport costs between regions decline; they are really regional models, with limited urban implications. Urban models are focused on the city formation process, where the urban sector is composed of numerous cities, endogenous in number and size. Efficient urbanization and growth require timely formation of cities and appropriate institutions.

Henderson and Wang (2005) develop an endogenous growth model with accumulation of human capital, where there is a shift out of the rural sector into an urban sector as per capita human capital and income grow. The urban sector is composed of multiple cities which grow in size with knowledge accumulation and in numbers with national population growth and rural–urban migration. Urbanization occurs because demand for food products is postulated to be income inelastic, so as per capita incomes rise the relative demand for food products declines, while at the same time productivity in the rural sector is growing. That releases labour from the rural sector to migrate to the urban sector, where the relative national demand for urban products is rising overtime.

As the urban sector grows, new cities form in national land markets. Efficient city sizes are limited, reflecting a trade-off between marginal agglomeration economies as a city grows and steadily rising urban diseconomies in the form of commuting, congestion and other urban disamenities. Efficient city sizes are at or near the peak to each city's inverted-U shape relationship between real income per worker and city employment where, with economic growth, such peaks and efficient city sizes may be shifting out over time. With urbanization and national population growth, if existing cities are to stay near efficient sizes, new cities need to form in a timely fashion. That timely formation requires local

governments to have the autonomy to tax land rents and exclude entrants through zoning provisions. Moreover, developers or local governments must have the autonomy to utilize land and undertake enormous urban infrastructure investments so as to form new large- scale settlements. Such institutions and market environments may not be in place or may be slow to develop, and national politics may delay their evolution, especially in developing countries. These factors retard the timely formation of cities, forcing migrants into existing oversized cities. We discuss these issues below.

Empirics and Policy Issues

The policy and empirical literature on urbanization addresses three broad questions. These deal with the determinants of the rural–urban allocation of resources at any point in time, spatial convergence, and excessive urban concentration.

Rural–Urban Allocation of Resources

Dual economy models in the traditional development literature ask whether market failures bias the allocation of resources between the urban and rural sectors or between bigger and smaller cities. Renaud (1981) makes the related point that it is not just market failures but explicit government policies that bias or influence urbanization through their effect on national sector composition. Policies affecting the terms of trade between agriculture and modern industry or between traditional small town industries (textiles, food processing) and high-tech large city industries affect the rural–urban or small–big city allocation of population. Such policies include import tariffs, price controls and product subsidies.

Spatial Convergence

The issue of convergence across spatial units in a country was initially posed at the regional level. Williamson (1965) argued that national economic development is characterized by an initial phase of internal regional divergence of per capita incomes and the allocation of industrial resources, followed by a phase of later convergence. There is a related urban model of this divergence–convergence phenomenon, which looks at urban primacy and the quantity allocation of resources across cities. Following Ades and Glaeser (1995), conceptually the urban world is collapsed into two regions: the primate city versus the rest of the country, or at least the urban portion thereof. The question is: to what extent is urbanization concentrated in, or confined to, one (or a few) major metro areas, as opposed to being spread more evenly across a variety of cities? Primacy is commonly measured by the ratio of the population of the largest metro area to the entire urban population in the country. Ades and Glaeser (1995) and Davis and Henderson (2003) find that primacy first increases, peaks, and then declines with economic development, indicating a later spread of urban resources from the primate city to other cities over time.

As part of this spatial convergence process, Lee (1997) and Kolko (1999) explore the relationship between changes in urban concentration and industrial transformation for Korea since 1975 and for the USA since 1900. The idea is that manufacturing is first concentrated in primate cities at early stages of development, and then decentralizes to such an extent that at the other end of economic development it is relatively more concentrated in rural areas. Initial concentration fosters ‘incubation’ and adaptation of technologies from abroad in a concentrated urban environment. But once manufacturing has modernized with fairly standardized technologies, firms decentralize to hinterland locations where rent and wage costs are cheaper. For example, in Korea Seoul’s urban primacy peaked around 1970, when Seoul had a dominant share of national manufacturing. During the next 10 or 15 years, manufacturing suburbanized from Seoul to nearby satellite cities, as well as to satellite cities surrounding the two other major metro areas, Pusan and Taegu. But then in the early 1980s manufacturing spread rapidly from the three major metro areas and their satellites to rural areas and other cities. The largest metro areas became business service-intensive, relying on economies of diversity in local business services, often purchased by headquarter units of

firms as part of marketing, financing, and exporting activities for their goods produced by plants in hinterland locations. This spatial separation, with headquarters' activities of firms in large metro areas and production facilities in smaller specialized cities, is called 'functional specialization' by Duranton and Puga (2005).

Urban Concentration

A third set of questions asks whether the degree of urban concentration in countries is too little or too much. Are there policies which bias development towards bigger, say, politically dominant coastal cities at the expense of smaller, say, hinterland cities? The basic idea is that the political system favours the national capital (or other seat of political elites such as São Paulo in Brazil). For example, direct restraints on trade for hinterland cities such as an inability to access capital markets or to get export or import licences favour firms in the national capital. Policymakers and bureaucrats may gain as shareholders in such firms, or they may gain rents from those seeking licences or other exemptions from trade restraints. Indirect trade protection for the primate city can also involve underinvestment in hinterland transport and communications infrastructure. Another strategy can be to retard development of institutions and national land markets that allow timely formation of large-scale, competitor hinterland cities. Whether as true beliefs or as a cover for rent-seeking behaviour, policymakers often articulate the view that large, favoured cities are more productive and thus should be the site for government-owned heavy industry (such as São Paulo or Beijing–Tianjin, historically). Unfortunately these heavy industries don't benefit sufficiently from the agglomeration economies in such large cities and can't afford their higher costs of land and labour, which is one reason why they lose money in such cities.

Favouritism of a primate city creates a non-level playing field in competition across cities. The favoured city draws in migrants and firms from hinterland areas, creating an extremely congested high-cost-of-living metro area. Local city planners can try to resist the migration response to primate city favouritism by, for example, refusing to provide legal housing development for immigrants or to provide basic public services in immigrant neighbourhoods. Hence squatter settlements, bustees, kampongs and so on may develop. But still, favoured cities tend to draw in enormous populations.

What is the econometric evidence indicating that politics plays a role in increasing sizes of primate cities? Based on cross-section analyses, Ades and Glaeser (1995) find that, if the primate city in a country is the national capital, it is 45% larger. If the country is a dictatorship, or at the extreme of non-democracy, the primate city is 40–45% larger. The idea is that representative democracy gives a political voice to hinterland regions, so limiting the ability of the capital city to favour itself; and fiscal decentralization helps level the playing field across cities, giving hinterland cities political autonomy to compete with the primate city. Davis and Henderson (2003) explore these ideas further, examining in a panel context the impact of democratization and fiscal decentralization upon primacy. Examining democratization and fiscal decentralization together, they find moving from most to least democratic form of government reduces primacy by 8%, and moving from most to least centralized government reduces primacy by 5%. They also find transport infrastructure investment in hinterlands reduces primacy, a prediction of core–periphery models.

Given the urban primacy relationships, it is natural to ask whether urban concentration is important to growth. Is there an optimal degree of urban primacy with each level of development where significant deviations from this level detract from growth? Optimal primacy would involve a trade-off between the benefits of increasing primacy (enhanced local scale economies contributing to productivity growth) and the costs (more resources diverted away from productive and innovative activities to shoring up the quality of life in congested primate cities). Henderson (2003) examines this question with panel data methods and finds that there is an optimal degree of primacy at each level of development which maximizes national productivity growth. That optimal degree rises as country income declines: high relative agglomeration is important

when countries have low knowledge accumulation, are importing technology, and have limited capital to invest in widespread hinterland development. There is an international tendency to excessive primacy, with effectively non-federated countries such as Argentina, Chile, Peru, Thailand, and Algeria having extremely high primacy.

While for countries where people are allowed to migrate freely across cities and from rural to urban areas the focus is on excessive urban concentration, in the former planned economy countries the concern goes the other way. Countries such as China have formal migration restrictions limiting the visas given to rural people to move to cities and limiting migrants' access to jobs, housing, medical care and schooling in destination cities to reduce the incentive to migrate. Other former planned economies primarily limited migration through restrictions on housing provision and land development in cities. Planned economies have much lower urban concentration than other large countries. The efficiency loss there derives from unexploited urban agglomeration economies.

Sir John Clapham, who became in 1928 the first professor of economic history in the University of Cambridge, was born in Lancashire, the son of a prosperous jeweller. From the Cambridge boarding school (Leys) to which he was sent at the age of 14, he went up to King's College in 1892 to read history at a time when Acton, Maitland and Cunningham dominated the history school. It was as a graduate student at King's, researching into the French Revolution, that he attracted the attention of Alfred Marshall, who characteristically set about pressuring the promising young historian to devote his research efforts to filling the gaps in modern English economic

history. There is an oft-quoted letter which Marshall wrote in 1897 to Acton saying:

> I feel that the absence of any tolerable account of the economic development of England during the last century and a half is a ... grievous hindrance to the right understanding of the problems of our time ... but till recently the man for the work had not yet appeared. But now I think the man is in sight. Clapham has more analytic faculty than any thorough historian whom I have ever taught: his future work is I think still uncertain: a little force would I think turn him this way or that. If you could turn him towards XVIII or XIX century economic history, economists would ever be grateful to you.

Unfortunately Marshall did not live to read Clapham's massive, three-volume *Economic History of Modern Britain,* the first volume of which appeared in 1926 (dedicated to Marshall and his old enemy William Cunningham), and the last in 1938. No doubt he approved of the scholarly monograph on *The Woollen and Worsted Industries* (1907), written when young Clapham was professor of economics at the University of Leeds – an appointment in which it is hard not to suspect that Marshall's influence was decisive. Nevertheless, when Clapham returned to a King's fellowship in 1908, he resumed his researches in French political history and joined his fellow historians in criticizing the new Economics Tripos for being far too theoretical. It was not until after the First World War (during which he served in the Board of Trade and gained first-hand experience of the process of economic decision-making as a member of the Cabinet Committee on Priorities) that he in effect rejoined the path that Marshall had pointed out to him. His *Economic Development of France and Germany* (1921) was the first modern study in comparative economic development, but typically it involved juxtaposing his detailed analyses of two differing experiences of development, rather than relating them to a general theory of economic development, or even generalizing from these case histories.

The truth is that Clapham had no interest in theoretical economics except in so far as it supplied concepts and categories that would permit him to classify and analyse the empirical detail of economic history. He was repelled by the blatant unrealism of orthodox theorizing. His famous article 'Of Empty Economic Boxes', published in the September 1922 *Economic Journal*, accused the theorists of operating with concepts which were empty and irrelevant. 'I think a great deal of harm has been done', he complained, 'through omission to make clear that the Laws of Return have never been attached to specific industries: that we do not, for instance, this moment *know* under what conditions of returns coals or boots are being produced'. But his complaints fell on deaf ears. The interwar theorists saw no point in relating the strategic concepts of their models to real-world constructs and were agreed that, as Keynes put in, Clapham was 'barking up the wrong tree'.

What Clapham had learned from Marshall was that economics is the study of mutually interacting quantities and that it was the function of an economic historian to put the key quantitative questions to the historical record – for example, how large? how long? how often? how representative? – when spelling out the chains of cause and effect linking economic events. He made it his business to demolish, or qualify, facile generalizations that did not stand up to the available statistical evidence; for example, the Malthusian law of population, or the Marxian predictions of the pauperization of the masses. Though alive to the defects of historical statistics, he was bold enough to make the best of them, 'to offer dimensions, in place of blurred masses of unspecified size' and to analyse the bare aggregates into their strategic components. His training as a historian, however, kept a balance between quantitative and qualitative data, and his large-scale study of the economic development of modern Britain was diversified and illuminated by a continuous stream of vivid factual detail. His last book, *The Bank of England: A History, 1694–1914* (1944), commissioned by the Bank to commemorate its 250th anniversary, gave him access to the voluminous manuscript records of the first central bank. Writing its history and setting its operations and policies within its political and economic context was a task which by training and interests he was peculiarly well-equipped to perform. His intellectual energy seemed enhanced rather

than diminished by his retirement from the Cambridge chair, and his sudden death in 1946 cut short a research programme which was still in full swing.

Colin Clark, one of the most fertile minds in 20th-century applied economics, was born in London. After graduating in chemistry at Oxford University in 1924, he worked as assistant to W.H. Beveridge, Allyn Young and A.M. Carr-Saunders, stood unsuccessfully as a Labour candidate in the May 1929 general election, then joined the staff of the Economic Advisory Council, recently set up by Ramsay MacDonald, of which Keynes was a member. In 1931, rather than agree to write a protectionist manifesto for MacDonald, he accepted an appointment as lecturer in statistics at Cambridge, where he remained until, in 1937, he went to Melbourne University, initially as visiting lecturer. In Australia he occupied government posts, chiefly as economic adviser to the state government of Queensland, until 1952. After spells as visiting professor at the University of Chicago and as Director of the Oxford Institute of Agricultural Economics, he returned to Australia in 1968. He remained active as a research consultant at the University of Queensland.

In the first decade of an astonishingly prolific half-century of research and writing, Colin Clark established himself as one of the pioneers of national income estimates. He greatly improved existing estimates for the United Kingdom, and later for Australia and the Soviet Union, and in so doing made methodological contributions so fundamental that he has justly been described as co-author, with Simon Kuznets, of the 'statistical revolution' that accompanied the revolution in macroeconomics of the 1930s. He was the first to use the gross national product (GNP) and to present estimates in the framework of the main components of aggregate demand ($C+I+G$); he made some of the earliest estimates of Keynes's multiplier and, in an article published in 1937, one of the first international comparisons of the purchasing power of national currencies and thus of real national product. These were carried further in his monumental *Conditions of Economic Progress* (1940), which was important chiefly because it signalled the revival of interest among the profession in secular economic growth and development but which also supplied the first substantial statistical evidence of the gulf in living standards between rich and poor countries (the 'Gap') and developed the thesis that, in the course of economic growth, the occupational structure

shifts from primary to secondary and tertiary industries. During the Second World War, in *The Economics of 1960* (1942), Clark made one of the first ambitious attempts at a macroeconomic model of the world economy.

Recognized also as one of the 'Pioneers in Development', Colin Clark made significant contributions to empirical study of the relations between food supply and population growth, the economics of irrigation and subsistence agriculture, of determinants of economic growth and of productivity in agriculture in developing countries. At the same time, he was a gadfly in the political economy of developed countries, arguing against growthmanship, against high taxation and against welfarism long before it became fashionable to do so.

John Bates Clark, the first American economist to deserve and gain an international reputation, was born at Providence, Rhode Island, on 26 January 1847 into a modestly prosperous merchant family. His father's struggle with tuberculosis prompted a move to Minneapolis in search of a better climate and later required Clark to discontinue his studies at Amherst (he had transferred from Brown after two years) in order to run the family business. The business involved selling a line of ploughs to receptive but credit-needy country storekeepers throughout Minnesota. Following his father's death, the business was sold at a profit and Clark returned to Amherst, graduating with highest honours in 1872.

Clark's New England forebears had included many Congregational ministers and he seriously considered entering the Yale Divinity School. (He remained a communicant throughout his life and saw one son enter the ministry.) But encouraged by President Julius Seelye of Amherst, who had taught him political economy out of Amasa Walker's textbook, he chose instead the high-risk

course of an academic career in a country still without universities. After Amherst, he went abroad, enrolling for two years at Heidelberg and six months at Zurich.

While Clark has left no detailed account of his European studies, his early work indicates that he was much influenced by the German Historical School, and especially by the lectures of Karl Knies. Whether the influence was for good or ill is not clear. It probably slowed his development as a theorist. (His formulation of the marginal utility principle was worked out before he had heard of Jevons.) But it also taught him that an economist needed a far more professional training than that provided by the thin textbook gruel offered in the American colleges of the day. Clark was one of three young 'Germans' (the other two being Richard Ely and Henry Carter Adams) who, at a meeting of the American Historical Society at Saratoga in 1885, issued the call that led to the formation of the American Economic Association. Their plainly avowed purpose was to encourage German-style empirical research and give a sympathetic hearing to the critics of laissez faire. The dogmatic social Darwinism of William Graham Sumner epitomized all that they disliked in American economics. Clark became the third president of the new group and his diplomacy and moderation are credited with making it more acceptable to the country's older economists, most of whom eventually joined (but not Sumner).

Shortly after going to his first professorship at Carleton College in Northfield, Minnesota, in 1876, Clark was incapacitated for two years by an illness that, according to his son, John Maurice, permanently lowered his energy level. Whatever its nature – the family memorial to Clark provides no details – the illness seems only to have strengthened his determination and powers of organization. Following his recovery, Clark worked steadily and with a notable economy of effort until shortly before his death at the age of 91. Most of his contributions to economic theory, however, were worked out in the first 15 years of his career though the most polished formulations did not come until *The Distribution of Wealth* (1899). Clark's need to choose his projects carefully may explain why, despite his admiration for the work of historians and institutionalists, he never tried to emulate them. All of his life Clark remained a theorist who often wrote on issues of the day.

Clark first gained recognition with a series of articles in *The New Englander* that, with revisions, were published in 1886 as *The Philosophy of Wealth*. Clark's admirers have found this first book something of an embarrassment, and not without reason. It is a young Victorian's book, full of grand historical generalizations and the elevated expressions of sentiment that have long been out of fashion. Still, on close reading, it reveals the qualities that were to make him a major figure in the history of economics – a superb command of language (Böhm-Bawerk, who debated capital theory with Clark, claimed that his literary elegance gave him an unfair advantage), a willingness to take a position on controversial issues, and, above all, a remarkable talent for economic theory.

The collection contains a totally original and quite sophisticated statement of the principle of marginal utility ('effective utility' in Clark's vocabulary), a reasoned rejection of Malthusian pessimism, and many perceptive comments on the rise of labour unions, cartels, and corporations. Even the main outlines of Clark's treatment of capital and interest are discernible in the *Philosophy.*

Clark's intellectual distinction was fully revealed two years later with the publication of his monograph, *Capital and its Earnings* (1888a) which has a good claim to stand as the foundation stone of modern capital theory. While the distinction between labour and capital is still accepted (though even here Clark wavers), all other things including land that directly or indirectly enter into the production of consumer goods are treated as capital. The existence of interest is firmly placed in the productivity of capital. The creation of income as a concomitant of the destruction of individual capital goods is emphasized. The irrelevance of the 'period of production' of individual capital goods to anything of importance is shown and the fallacy underlying the wages fund doctrine is exposed.

Clark has been criticized for introducing the 'neoclassical fairy tale' into capital theory – the

notion that capital is some strange substance that, 'transmutes itself from one machine form into another like a restless reincarnating soul' (Samuelson 1962). While the neoclassical fairy tale has its limitations as a construct for understanding capital accumulation in the real world, Samuelson's jibe is off target. Clark's view of the production process is perfectly correct. Machines do 'transmute' themselves into other machines in the course of wearing out.

A more serious challenge to capital theory in the Clark tradition goes back to Böhm-Bawerk. If there is such a thing as a quantity of capital 'embodied' at any given moment in a set of heterogeneous specialized capital goods, what is its unit of measure? Unlike Irving Fisher, Clark faced the question squarely and attempted an answer. Unfortunately, the effort led him to bring forth his 'universal measure of value' – the product of a strange and nearly unintelligible fusion of utility analysis and the labour theory of value. While Clark was inordinately proud of his measure (and credited its inspiration to some lectures of Knies) it quickly found a merciful oblivion.

Later writers in the Clark tradition – or, at any rate, those who have felt the need for an impeccably consistent set of assumptions – have curbed their ambitions and been content to solve (or evade) the measurement problem by positing a surrogate production function where all capital goods are moulded from some homogeneous putty-like substance. The limit case in the Clark tradition is the 'Crusonia plant' named by Frank Knight but first suggested by W.S. Jevons's 'whole produce'. It supplies all human wants and, in the absence of consumption, grows at a constant geometric rate. Here the quantity of capital can be found either by measuring Crusonia directly or by dividing the plant's yield (income) in perpetuity by its natural growth rate, that is, the marginal (and average) productivity of investment.

Whether one prefers capital theory in Clark's tradition to its principal rival – capital theory in the Sraffa tradition – is ultimately a matter of personal taste. Both employ simplifications that take one far from reality. However, notwithstanding the measurement conundrum, to date capital theory in the Clark tradition has provided the basis for virtually all empirical work on wealth and income. This is not surprising. To statisticians, measuring changes in the quantity of capital (which they rename the real value of the stock of capital assets) is just another index number problem.

Very early in his career Clark began to work on the problem of factor shares (possibly because of his interest in Henry George) and concluded that the treatment of land rent as a surplus whose size is not determined by marginal productivity was gross error. The most complete statement of his views on distribution is in *The Distribution of Wealth* (1899) which drew heavily on his earlier articles and monographs. Despite its flaws (which include the universal measure of value) the *Distribution* is a remarkable book and, by any reasonable test, a landmark treatise in the development of economics.

The *Distribution* represents an advance on the prior art in two important respects. It offers a discussion of the relation of statics to dynamics – the terms were introduced into economics by Clark – superior to that of previous treatments. And it offers, for the first time, a complete and lucid exposition of the neoclassical theory of distribution. The *Distribution* also brought Clark's views on capital to a much wider audience.

Clark was as conscious of the rapid pace of economic change as any German or American institutionalist of his day, but he stressed that, at any given moment, there are 'natural' values in the marketplace and permanent pressures pushing actual values toward them.

> Reduce society to a stationary state, let industry go on with entire freedom, make labor and capital absolutely mobile – as free to move from employment to employment as they are supposed to be in the theoretical world that figures in Ricardo's studies – and you will have a regime of natural values. These are the values about which rates are forever fluctuating in the shops of commercial cities. You will also have a regime of natural wages and interest; and these are the standards about which the rates of pay for labor and capital are always hovering in actual mills, fields, mines, etc.

Only by a careful separation and delineation of static and dynamic forces, Clark believed, can the

process of price formation in real-world markets be understood. His methodology is not as formal and austere as F.H. Knight's in *Risk*, *Uncertainty*, *and Profit* (1921), but it is essentially the same. (In the version of Knight's doctoral dissertation accepted at Cornell in 1916 his intellectual debts to Clark are gratefully and fully acknowledged; for reasons unknown, almost all of the favourable references to Clark are omitted in the rewritten version published five years later).

To demonstrate that, in the static state, payments to the factors exhaust the product when each receives its marginal product, Clark devised a set of diagrams to show that, in a two-factor model, what is viewed as rent and what is viewed as a factor payment is a matter of perspective. One becomes the other by interchanging the fixed and variable factors in the diagrams. Clark's treatment of rent has been followed by an admiring Paul Samuelson in all of the many editions of his *Economics*.

Clark's approach to distribution is set forth in 'words and pictures' (his mathematical training did not include calculus) and so lacks the precision of the versions of Wicksell and Wicksteed. But, being more accessible to student readers, it was Clark's treatment that first gained widespread attention for the neoclassical theory of distribution.

Clark has often been reproved for implying both that factor payments ought to be according to marginal productivity and that in a real-world market economy most factor payments do closely approximate marginal productivity (see, for example, Stigler 1941). A reading of the *Distribution* without reference to Clark's other writings would indicate that he did hold these views. Certainly his advocacy of compulsory arbitration to end long labour disputes assumed that economic justice consisted in giving striking workers the wages prevailing in comparable employments elsewhere. However, a brilliant essay, 'The Theory of Economic Progress' (1896), leaves no doubt that he placed a far higher value on economic growth than on short-run justice or efficiency.

Well before Schumpeter, Clark wrote:

> The picture of a stationary state presented by John Stuart Mill as the goal of competitive industry is the one thing needed to complete the impression of dismalness made by the political economy of the early period. A state could not be so good that that lack of progress would not blight it; nor could it be so bad that the fact of progress would not redeem it. . . . The decisive test of an economic system is the rate and direction of movement.

Clark was a leading participant in the trust controversy that occupied American politics in the 30 years before the First World War. His moral seriousness and literary ability (and, one suspects, his ability to meet deadlines) made him a favourite of magazine editors – he once described himself as 'writing my trust article again'. Like all economists of that era he had to think through his attitude toward the many large firms with large market shares that had so suddenly appeared.

As recorded in the *Philosophy of Wealth*, Clark's first reaction to the American business scene on returning from Germany was one of fascinated revulsion joined to an expression of hope that businessmen could be led to behave in more acceptable ways by pressures from labour unions, Church, and State. As the years passed, his views of commerce became much more favourable and his policy recommendations more worldly and specific. He early pointed out that the conduct of most so-called trusts was influenced by the fear of entry and he never depreciated the efficiency gains made possible by large-scale production. At first he urged only a modest amount of government intervention as in, *The Control of Trusts*: *An Argument in Favor of Curbing the Power of Monopoly by a Natural Method* (1901). Clark's 'natural method' was little more than the competition of the marketplace purged of its 'destructive' ingredients plus government regulation of railroad rates to prevent unjustified differentials. A much expanded version of *The Control of Trusts*, with John Maurice Clark, his son, as co-author and the subtitle omitted, appeared in 1912. The revisions were mostly the work of the son and contain a virtual blueprint for an antitrust policy. The Clayton and Federal Trade Commission Acts of 1914 which followed shortly received their enthusiastic approval.

By his writing Clark did more than any other economist to confer intellectual respectability on

an antitrust policy that had had its origins in the populist discontent that produced the Sherman Act. In retrospect, this may seem to have been a dubious achievement. But in Clark's favour it can be said that he was dealing with new and difficult issues and approached them with more objectivity than most of his contemporaries, for example, W.Z. Ripley and F.A. Fetter.

Clark's life as a teacher was at Carleton, Smith, Amherst, and from 1895 to 1923 at Columbia. At Carleton his kindness helped Thorstein Veblen (a thoroughly unpopular undergraduate in that church college) to find his way. At Columbia it helped Alvin Johnson to gain the income needed to complete his doctoral programme. His encouragement led F.H. Giddings to leave provincial journalism for a seminal career in sociology. He was, of course, the omnipresent influence in the life of John Maurice Clark, who succeeded to his chair at Columbia. Still, Clark's direct influence through the classroom seems to have been surprisingly limited. His quiet and self-sufficient personality did not require disciples and his probing but loosely organized lectures appealed only to very able students. Then too, Clark was a theorist in an era when, in the United States, institutional economics, not theory, was the height of academic fashion.

From 1911 onward Clark's great concern became the contribution that social scientists could make to ending war. When the Carnegie Endowment for International Peace was formed in 1910, he became the first director of its economics and history section serving until 1923. There he took the initiative in obtaining support for the studies that became the *Social and Economic History of the World War*. The general editor was his friend and Columbia colleague in history, James T. Shotwell. The Carnegie *History* ultimately ran to over a hundred volumes and still stands as the most ambitious research project in the social sciences ever undertaken by a private foundation. Unfortunately, its initial promise was never realized. Shotwell sought to organize the Carnegie *History* on the strange principle that an accounting of the great war was too important to be left to historians. As a result, while the series contains a few memorable studies, for example, J.M. Clark, *The Costs of the World War to the American People* (1931), it served mainly to preserve the recollections of wartime ministers and civil servants that would otherwise have been lost. J.M. Keynes disdainfully withdrew from the *History* in the planning stage.

Clark's work for peace continued to the end of his life. His last small book was a moving plea for collective action to deter aggression, *A Tender of Peace*: *The Terms on Which Civilized Nations Can*, *if They Will*, *Avoid Warfare* (1935). Clark died in New York City on 21 March 1938.

An abundance of honours came to him in his lifetime both in the United States and abroad. They were all deserved.

Clark was born on 30 November 1884 in Northampton, Massachusetts, and died on 27 June 1963 in Westport, Connecticut. Educated at Amherst College and Columbia University (Ph.D., 1910), he taught at Colorado College (1908–10), Amherst (1910–15), University of Chicago (1915–26) and Columbia University (1926–52), where he succeeded his father, John Bates Clark. He was president of the American Economic Association in 1935 and received its Francis A. Walker Medal in 1952. His dissertation, 'Standards of Reasonableness in Local Freight Discrimination', was written under the supervision of his father. He was associated with the National Bureau of Economic Research, the National Resources Planning Board, the Twentieth Century Fund, the Attorney General's National Committee to Study the Anti-Trust Laws, and other organizations.

Clark worked within both orthodox and heterodox economics, making important contributions to microeconomics, macroeconomics and institutional, or social, economics. Eclectic and open-minded, he was critical of the apologetic uses of economic theory, particularly of the drawing of narrow and misleading welfare implications. He emphasized the limits of economics as a science.

Clark's contributions within conventional theory dealt principally with economic dynamics. He developed and stressed the implications of overhead, fixed costs in capital intensive industry for competitive structure, business pricing policy, and economic stability. He was the principal of several discoverers of the acceleration principle, with its important implications for instability. His career-long concern with competitive structure and behaviour led to his formulation of the concept of 'workable competition', with a stress on potential competition and intercommodity substitution. The major result of his equally long work in macroeconomics was an exploration of the strategic factors in business cycles which effectively summarized, in a general theoretical context, the state of empirical knowledge at the time. He also

wrote extensively on railroad and public utility rates, basing-point pricing, economic planning, the economics of war and of peacetime conversion, wage-price (cost-push inflation) theory and policy, and related topics.

Clark departed from the conventional mainstream in his social economics, which was akin to the institutional economics of John R. Commons and Wesley C. Mitchell and which reflected the influence of Thorstein Veblen and John Dewey. Clark's work on the social control of business and the theory of regulation explored the fundamental legal-economic nexus of society in a non-ideological manner stressing the substance and inexorable presence of formal (legal) and informal controls in an economic system, even in a pluralistic and voluntaristic economy, controls typically obscured in conventional analysis of markets. Law was important to the structure of freedom, not something solely antagonistic to freedom. His work in welfare economics emphasized the role of institutions, the necessity of psychological realism, and the inexorable role of moral or ethical values. His concern with the costs of labour that are registered in neither the market nor by industry presaged later institutional work on externalities and social costs.

Class

David B. Grusky

Abstract

The structure of inequality has historically been represented with an income paradigm that treats well-being as adequately indexed by income alone. By contrast, the class-analytic tradition treats inequality as fundamentally multidimensional, with such variables as health, education and social relations all deemed important nonincome constituents of well-being. These variables may assume a class-based form in which social groups within the division of labour define characteristic constellations of scores. The class model is further supported in so far as class membership has true causal effects on behaviours that are not reducible to the effects of income or other correlates of class.

The labour market of contemporary societies is rife with various types of 'classes' that impede the free flow of labour by restricting entry to those who have the requisite degrees, certificates, memberships or capital. These classes take the form, for example, of occupations (such as economist, carpenter), aggregates of occupations (such as manager, farmer), or groups that represent competing factors of production (such as worker, capitalist). Although such classes are ubiquitous in contemporary labour markets, their effects on labour market processes are not

always incorporated into formal economic models. The main type of class to which attention has historically been paid is that of industry. The bifurcation of labour markets into industry classes, while clearly a relevant and well-developed topic in the literature, is not covered here. For purely historical reasons, the term 'class' has been reserved for non-industrial forms of bifurcation, a usage that is adopted in the following discussion as well.

The descriptive rationale for a class model is usefully introduced in the context of a multidimensional representation of inequality. This representation, which is presented below, makes it possible to motivate the class concept, to consider how classes may be empirically revealed, and to assess whether the class concept is needed to represent the structure of labour markets.

The Clustering Rationale

It has become increasingly fashionable to claim that inequality is multidimensional, that income inequality is accordingly only one of many important forms of inequality, and that income redistribution in and of itself would not eliminate inequality (see, for example, Sen 2006). If this line of argument is taken seriously, an obvious prescription is to examine separately each of the many variables that constitute the multidimensional space of interest. For example, one might usefully distinguish between the eight forms of inequality listed in Table 1, each such form pertaining to a type of good that is intrinsically valuable (as well as possibly an investment). The multidimensional space formed by these variables may be labelled the 'inequality space'. The social location of an individual within this

Class, Table 1 Types of valued goods and examples of advantaged and disadvantaged groups

Valued goods		Examples	
Type	Example	Advantaged	Disadvantaged
1. Economic	Wealth	Billionaire	Bankrupt worker
	Income	Professional	Laborer
	Ownership	Capitalist	Employee
2. Power	Political power	Prime minister	Disenfranchised person
	Workplace authority	Manager	Subordinate worker
	Household authority	'Head of household'	Child
3. Cultural	Knowledge	Intelligentsia	Uneducated
	Popular culture	Movie star	High-culture 'elitist'
	'Good' manners	Aristocracy	Commoner
4. Social	Social clubs	Country-club member	Non-member
	Workplace associations	Union member	Non-member
	Informal networks	Washington 'A list'	Social unknown
5. Honorific	Occupational	Judge	Garbage collector
	Religious	Saint	Excommunicate
	Merit-based	Nobel Prize winner	Non-winner
6. Civil	Right to work	Citizen	Illegal immigrant
	Due process	Citizen	Suspected terrorist
	Franchise	Citizen	Felon
7. Human	On-the-job	Experienced worker	Inexperienced worker
	General schooling	College graduate	High-school dropout
	Vocational training	Law-school graduate	Unskilled worker
8. Physical	Mortality	Person with long life	A 'premature' death
	Physical disease	Healthy person	Person with AIDS, asthma
	Mental health	Healthy person	Depressed, alienated

inequality space can then be characterized by specifying her or his constellation of scores on each of the eight types of variables in this table.

At least implicitly, scholars of inequality long ago adopted precisely such a multidimensionalist approach, as revealed by the burgeoning research literatures that monitor not just income inequality but also inequality of health, social networks, education, computer usage and all manner of other valued goods. This line of research typically takes the form of an exposé of the extent to which seemingly basic human 'entitlements', such as living outside of prison, being gainfully employed, freely participating in digital culture, or living a reasonably long and healthy life, are unequally distributed in ways that may amplify or somehow complement well-known differentials of income or earnings.

Does the inequality space take on a simpler form than might be implied by the convention of analysing each of these variables separately and independently? Two possible simplifications may be considered here. First, scholars have frequently combined scores on the underlying variables to form indices, with sociologists often combining education and income into a socio-economic index (for example, Hauser and Warren 2001) and development economists often combining measures of health, income, education and literacy into a ' Human Development' index (for example, UNDP 2005). There is, however, growing concern that such standard multidimensional scales are excessively abstract and fail to capture the social organization of inequality, especially the emergence of social networks, norms, and adaptive preferences or tastes among individuals in similar life situations and circumstances. The socio-economic scale, for example, is a purely statistical tool that groups together individuals of similar income or education levels without any consideration of whether these individuals associate with one another or are comembers of some real group, such as a union or occupation.

This critique motivates a second, class-based approach to understanding the structure of the inequality space. The class model is defensible insofar as (*a*) individuals tend to cluster into a relatively small number of characteristic combinations or packages of scores on the underlying variables, and (*b*) the clusters are defined by such structural locations as detailed occupations (doctor, secretary, plumber), aggregates of detailed occupations (professional, manager, clerk, craft worker, labourer, farmer), or other types of 'big classes' (for example, capitalist, worker). These clusters generate a labour market that, instead of being a seamless distribution of incomes, is a lumpy entity with deeply institutionalized groups that constitute pre-packed combinations of valued goods.

The class of craft workers, for example, has historically comprised individuals with moderate educational investments (secondary-school credentials), considerable occupation-specific investments in human capital (vocational or on-the-job training), average income, relatively high job security, middling social honour and prestige, quite limited authority and autonomy, and comparatively good health outcomes (by virtue of union-sponsored health benefits and regulation of working conditions). By contrast, the underclass is characterized by a rather different package of scores, one that combines minimal educational investments, limited opportunities for on-the-job training, intermittent labour force participation, low income, virtually no opportunities for authority or autonomy on the job (during brief bouts of employment), relatively poor health (by virtue of lifestyle choices and inadequate health care), and much social denigration and exclusion. The other classes appearing in class schemes (such as professionals, managers, clerks, labourers, farmers) may likewise be understood as particular combinations of scores on the variables of interest.

In a class-based society, the inequality space will accordingly have relatively low dimensionality, a dimensionality no more or less than the number of classes. This understanding of the class principle implies that the variables constituting the inequality space must be independent of one another *within* each class. If the independence assumption begins to break down within a postulated class, we can then speak of 'subclasses' forming by virtue of developing their own distinguishable packages of scores. It is useful in this

context to distinguish between a big-class regime in which the dimensionality of the inequality space is small and a micro-class regime in which the dimensionality of the inequality space is large. Although Marx (1894) argued that the inequality space in the early industrial period was becoming increasingly consistent with a two-class solution (in which privileged capitalists were juxtaposed to disadvantaged workers), some contemporary class analysts emphasize, to the contrary, that the forces of market differentiation have generated a micro-class regime in which the independence assumption holds not at the big-class level but only within quite detailed occupations (for example, Weeden and Grusky 2005). There is much ongoing debate among inequality scholars on the dimensionality of the contemporary inequality space and, in particular, on whether the dimensionality of that space has been increasing or diminishing.

The foregoing implies that one may usefully distinguish between big-class regimes with few classes and micro-class regimes with many classes. Additionally, one might distinguish inequality regimes not on the basis of how many classes there are but on the basis of how the classes differ from one another. In a purely 'vertical' class system, one can readily order classes on a single scale from 'low' to 'high', with low classes being systematically disadvantaged on all variables and high classes being systematically advantaged on all variables. This organization of the inequality space implies a stark form of inequality in which privilege on one dimension implies very reliably privilege on another. Alternatively, a class system that is (partly) horizontal will embody compensating forms of advantage and disadvantage, meaning that at least some classes are formed by combining high values on one dimension with low values on another. There is, again, much debate among class analysts as to whether the inequality space is becoming more or less vertically organized.

It is of course possible that the inequality space is organized in ways that are largely inconsistent with the class principle. Two types of non-class solutions, as reviewed below, may be usefully distinguished.

Extreme Disorganization

First, one can imagine an inequality space in which the underlying variables don't covary at all, hence yielding a one-class solution or, equivalently, a non-class regime. To be sure, there would be much inequality under this hypothetical constellation of data, yet it would take a uniquely structureless form in which the independence assumption holds throughout the inequality space, not just within a given class. It is unlikely that such extreme disorganization would ever be realized, but some postmodernists (for example, Pakulski 2005) have argued that we are moving gradually toward this form. If they are correct, it means that the growth in income inequality is at least counterbalanced by a decline in the association between income and other valued goods. As with the horizontal class regime described above, here again we have a form of inequality that embodies much in the way of compensating differentials, although such differentials are not in this case packaged into institutionalized classes.

Individuals as Classes

The second main type of non-class solution arises when the variables constituting the inequality space are related to one another in perfectly linear fashion. When the data are configured in this way, it is no longer possible to identify a set of classes within which independence holds, as the underlying inequality variables continue to covary with one another no matter how much one disaggregates. We are left with an extreme micro-class solution in which the data thin out to the point where each individual becomes a class unto himself or herself. This solution is consistent, for example, with the claim that income is a master variable, that it perfectly signals all other individual-level measures of inequality, and that no higher-level class organization therefore appears. Obviously, this ideal type would never be empirically realized in such extreme form, but it is nonetheless important to ask whether it comes closer to being realized in some societies or time periods than in others.

The 'Class Effect' Rationale

We have to this point represented the class principle as a hypothesis about the clustering of

observations in the inequality space. As an alternative motivation for the class hypothesis, it is sometimes claimed that classes are social contexts that affect attitudes, behaviour, and individual action of many kinds. When this motivation is adopted, classes are not typically construed as information-rich social containers that capture many life conditions of interest, but rather as analytic categories that single out a particular social context that is presumed to be very consequential in defining interests. Under such a formulation, a class analyst will therefore typically nominate a single variable (for example, authority, ownership) as especially useful in understanding the sources of social behaviour, with the class categories then defined so as to capture differences across workers on that underlying variable of presumed consequence. The Marxian model, for example, famously embodies the claim that classes are best defined in terms of employment status alone, with the rationale for this definition being that employment status putatively defines interests and hence attitudes and behaviour (Marx 1894). In contemporary labour markets, the class of employed workers is of course very heterogeneous, thus motivating class analysts to introduce further distinctions within that class that are presumed to be consequential in defining interests and action. There is no shortage of such elaborated class models (Wright 2005).

When a class model is motivated by presumed class effects, it is important to establish that such effects are indeed truly causal. If, for example, one finds that seeming differences in the politics of professionals, managers, craft workers and other social classes disappear when income is controlled, then presumably one can refer only to an income effect on politics, not a true class effect. Why might net effects of class be detected even with rigorous controls? In addressing this question, what must first be stressed is that, even when classes are *defined* in terms of a single analytic variable, the resulting classes are nonetheless often organic packages of conditions; and the constituents of these packages may combine and interact in ways that lead to an emergent logic of the situation. The underclass, for instance, may be understood as a combination of negative conditions (intermittent labour force participation, limited education, low income) that, taken together, engender a sense of futility, despondency, or learned helplessness that is more profound than what would be expected from a model that simply allows for independent effects of each constituent class condition. To be sure, a committed reductionist might counter that, when modelling behaviour, one merely needs to include the appropriate set of interactions between the constituent variables. In so far as classes define the relevant packages of interacting conditions, such an approach just becomes an unduly complicated way of sidestepping the reality of classes.

This emergent logic of the situation may well be undergirded by a class culture. At one extreme, class cultures may be understood as nothing more than 'rules of thumb' that encode optimizing behavioural responses to prevailing environmental conditions, rules that allow class members to forgo optimizing calculations themselves and rely instead on cultural prescriptions that provide reliable short cuts to the right decision. In this vein, Goldthorpe (2000) argues that working-class culture is disparaging of educational investments not because of some maladaptive oppositional culture but because such investments expose the working class, more so than other classes, to a real risk of downward mobility. Typically, working-class children lack insurance in the form of substantial family income or wealth, meaning that they cannot easily recover from an educational investment gone awry (in the form of dropping out); and those who nonetheless undertake such an investment therefore face the real possibility of substantial downward mobility. The emergence, then, of a working-class culture that regards educational investments as frivolous may be understood as encoding that conclusion and thus allowing working-class children to undertake optimizing behaviours without explicitly engaging in decision- tree calculations. The behaviours that a rule-of-thumb culture encourages are, then, deeply adaptive because they take into account the endowments and institutional realities that class situations encompass.

The foregoing example may be understood as one in which a class-specific culture instructs recipients about the best means for achieving ends that

are widely pursued by *all* classes. Indeed, the prior rule-of-thumb account assumes that members of the working class share the conventional interest in maximizing labour market outcomes, with their class-specific culture merely instructing them about the approach that is best pursued in achieving that conventional objective. At the other extreme, one finds class-analytic formulations that represent class cultures as more overarching world views, ones that instruct not merely about the proper means to achieve ends but additionally about the proper valuation of the ends themselves. For example, some class cultures (such as aristocratic ones) place an especially high valuation on leisure, with market work disparaged as 'common' or 'polluting'. This orientation presumably translates into a high reservation wage within the aristocratic class. Similarly, oppositional cultures within the underclass may be understood as world views that place an especially high valuation on preserving respect and dignity for class members, with of course the further prescription that these ends are best achieved by (*a*) withdrawing from and opposing conventional aspirations, (*b*) representing conventional mobility mechanisms (for example, higher education) as tailor-made for the middle class and, by contrast, unworkable for the underclass, and (*c*) pursuing dignity and respect through other means, most notably total withdrawal from and disparagement of mainstream pursuits. This is a culture, then, that gives respect and dignity an especially prominent place in the utility function and that further specifies how respect and dignity might be achieved.

Whatever the mechanism that underlies class cultures and class effects, the common assumption is that classes are meaningful social contexts, just as neighbourhoods are likewise understood within the 'neighbourhood effects' literature as meaningful social contexts. These contexts are expected in both cases to have causal effects that are not reducible to mere selective processes. Again, we have to stress that such a 'class effects' rationale for class models is best treated as a hypothesis, as there is little in the way of substantiating evidence at this point (cf. Weeden and Grusky 2005).

It is altogether possible that such class effects are weak or at least weakening. The relevant postmodernist position in this regard is that social class has lost much of the power it once had because (*a*) other cross-cutting social cleavages (such as race or gender) have squeezed out class-based identities and interests, (*b*) identity formation in the postmodern world is so atomized and individualized that all structural bases of social behaviour have become less relevant, (*c*) the institutions that once represented class interests (for example, political parties, unions) have developed into new forms that are less class-based, or (*d*) the forces of the market work to gradually eliminate pockets of rent-generating social action. Regardless of the particular form of the argument, the expectation in all cases is that emergent effects of classes have, during the last several decades, become less prominent.

Conclusions

It should by now be clear that sociologists operating within the class-analytic tradition have adopted very strong assumptions about how inequality and poverty are structured. As was noted, the class concept may be motivated in two main ways, by claiming either that the inequality space has a (low) dimensionality equalling the number of social classes, or that the class locations of individuals have a true causal effect on behaviours or attitudes of interest. The foregoing claims have been unstated articles of faith among class analysts in particular and sociologists more generally. In this sense, class analysts have behaved rather like stereotypical economists, the latter frequently being criticized (and parodied) for their willingness to assume almost anything provided that it leads to an elegant model.

This critique of class analysis is, however, increasingly less justifiable. Indeed, the class-analytic status quo has come under much criticism of late, with many scholars now feeling sufficiently emboldened to argue that the concept of class should be abandoned altogether (for example, Kingston 2000; Pakulski 2005). Although the resulting debate has sometimes been unproductive, it has clearly precipitated an increasing interest in assessing the empirical foundations of class models.

Classical Distribution Theories

Massimo Pivetti

Abstract

Classical distribution theories distinguish between that part of the annual product which is necessary for its reproduction (including necessary subsistence for workers and replacement of the means of production) and the remainder (the 'surplus'), and seek to explain the size of the surplus and its distribution among classes. They do not view the real wage rate and the rate of profit as determined by the relative scarcity of labour and capital; rather, one of the two distributive variables is explained independently from both the social product and the other distributive variable, and the other is determined as a residual.

The terms 'classical economists' and 'classical political economy' were first used by Marx, whose monumental survey of economic theory from the middle of the 17th century up to the early 1860s was contained in the manuscript written between January 1862 and July 1863 which the author called *Theorien über den Mehrwert*. Marx used the terms to describe 'the critical economists', 'the economic investigators . . . like the Physiocrats, Adam Smith and Ricardo' whose 'urge' was 'to grasp the inner connection of the phenomena'; he also referred to Ricardo as 'the last great representative' of classical political economy (Marx 1862–3, vol. 3, pp. 453, 500 and 502; 1873, p. 24).

Marx's description implies that not only authors like Senior, Bastiat, Wilhelm Roscher and John Elliot Cairnes are extraneous to classical political economy, but also such faithful Ricardians as James Mill, McCulloch and John Stuart Mill do not properly fit into it. This can only be understood if one bears in mind that the ranking of the various authors in *Theorien über den Mehrwert* is centred upon the nature of their contributions to the related subjects of distribution and value: the explanation of profit and the

formation of a normal or general rate of profit; the relation between wages and profits, the difficulties in the theory of value that arise in connection with the wage–profit relationship and the formation of a general rate of profit are the chief theoretical questions in the light of which the various authors are surveyed.

Thus a first discriminating factor in Marx's critical survey is provided by each author's attitude towards the main analytical difficulties: whether this or that author shows himself to be aware of their presence and tries to solve them, albeit at the cost of falling into further difficulties and contradictions, or rather tends to present the theory as a fully satisfactory body of propositions by denying the difficulties and 'immediately adapting the concrete to the abstract' (Marx 1862–3, vol. 3, p. 87). This factor explains why Marx is inclined to treat both Torrens (1815, 1821) and Malthus (in particular, 1827) as classical economists, while regarding James Mill as the beginner of the 'disintegration' of the Ricardian theory.

A second factor is the *weight* of the 'vulgar' element present in the contributions of the various authors – meaning by this the tendency to confine one's attention to the 'superficial appearance of the phenomena' *versus* 'the urge to grasp [their] inner connection'. As an important example of this factor one may refer to the increasing tendency, after Ricardo, to explain distribution by competition and 'the [changing] state of supply and demand' (J. Mill 1844, p. 42; see also J.S. Mill 1848, p. 337, and Cairnes 1874, pp. 168–74) – thereby gradually abandoning the classical conception according to which demand and supply can only determine the oscillations of distribution and prices either above or below their 'natural' values. A third discriminating factor is the 'vulgar' element represented by the mere apology for the existing state of affairs (Marx 1962–63, vol. 3, p. 168), or, as Cannan was later to put it, by the 'desire to strengthen the position of the capitalist against the labourer' (Cannan 1917, p. 206). Finally, a fourth factor may be indicated in the tendency to deny the existence of economic laws altogether, and to substitute shallow empiricism for theoretical analysis (think of the so-called Historical School of German political economy).

The theoretical approach to distribution and value 'of the old classical economists from Adam Smith to Ricardo has been submerged and forgotten since the advent of the "marginal" method' (Sraffa 1960, p. v). A contribution to this effect certainly came from the fact that *Theorien über den Mehrwert* remained largely unknown among economists. (It was only in the early 1950s that some sections of the 1905–10 Kautsky edition were translated into English, whilst the complete English translation from the edition based on the original manuscript was made in 1963–71.) In what follows, we shall take 'classical theory of distribution' to mean the main elements which can be regarded as characterizing the approach to the problem of the division of the national product among classes followed by the English classical economists from Adam Smith to David Ricardo, later by Karl Marx, and, more recently, by Piero Sraffa – this century's greatest exponent of the 'classical' approach to distribution.

The classical method of approaching the problem of distribution is based upon a distinction between two parts in the annual product of society: that part which is necessary for its reproduction (which includes the necessary subsistence of the workers employed in the economy) and that part which can be 'freely' disposed of by the society and which constitutes its 'net product' or 'surplus' – what remains of the social product after deducting the necessary subsistence of the workers and the replacement of the means of production. It is the aim of the classical theory to explain the circumstances governing the size of the surplus and its distribution among classes: 'To determine the laws which regulate this distribution, is', according to Ricardo, 'the principal problem in Political Economy' (Ricardo 1821, p. 5). In the course of his work he succeeded in 'getting rid of rent', so as to concentrate on the problem of the distribution between capitalists and workers; in what follows rent will be left entirely out of account – one may suppose that fertile lands abound – and the essential features of the surplus approach to distribution will be illustrated with

reference to the determination of wages and profits.

Contrary to the supply-and-demand approach, which has been the dominant method over the last hundred years, in the theoretical approach to distribution of the classical economists and of Marx, the real wage rate and the rate of profit are not symmetrically and simultaneously determined on the basis of the relative scarcity of labour and capital. Within the classical approach, one of the two distributive variables is explained independently from both the social product and the other distributive variable, and the other one is determined as a residual.

Both the classical economists and Marx considered the real wage as constituting the independent or 'given magnitude' in the relation between the two distributive variables, maintaining that its normal level is determined by 'subsistence'. Normal profits, reckoned gross of interest, are determined as a residual, on the basis of the dominant techniques of production. Given the dominant techniques, the level of the wage rate is thus the only circumstance upon which the normal rate of profit depends and no increase in the latter can be conceived of but through a fall in the former.

Wages and Profits

It is in the context of this relation between wages and profits that the problem of value arises within the classical theory. All the surplus product of the annual labour of the economy, exceeding the portion absorbed by labour itself in the form of wages, must be divided among the individual capitalists according to the capitals they have employed in production. It is the very task of relative prices ('natural prices' or 'prices or production') to ensure such proportional division of the profit share of the surplus, and in order to perform their task relative prices are bound to change in the face of any increase or fall in the quantities of the various commodities accruing to the labourers as wages. This change in relative prices, and in the value of the social product, which must necessarily take place whenever nothing changes but distribution, makes it difficult to determine the effect on profits of a rise and fall in wages; it obscures the inverse relationship between wages and profits which would be apparent if output and its means of production were the same in kind, or if their values remained unaffected by changes in the division of the product. Hence Ricardo's search for a measure of value which would be invariant to changes in wages (Ricardo 1821, ch. I, sections IV, V and VI; Sraffa 1951, pp. xlviii–xlix); hence also, Marx's determination of the general rate of profit *before and independently from* the 'prices of production', on the basis of magnitudes (the quantities of labour bestowed in the production of the relevant heterogeneous aggregates of commodities) invariant to changes in the division of the product (Marx 1894, ch. 9).

Only recently was a solution provided (Sraffa 1960) to the difficulties inherent in the theory of value that were left unresolved by Ricardo and Marx. The picture outlined above, however, points to a clear subordination of the problem of value to the determination of distribution. This contrasts sharply with the dominant supply-and-demand approach, where the theory of value – the conception of equilibrium prices as allocators of given factor endowments and their determination simultaneously with normal outputs and the equilibrium prices of factor services (distribution) – comes almost to coincide with economics itself.

As mentioned above, the real wage rate is explained by the classical authors in terms of 'subsistence'. They included in this notion 'not only the commodities which are indispensably necessary for the support of life, but whatever the custom of the country renders it indecent for creditable people, even of the lowest order, to be without', and 'the want of which would be supposed to denote that disgraceful degree of poverty, which no body can well fall into without extreme bad conduct' (Smith 1776, vol. 2, p. 399). Their conception, in other words, was that the normal wage rate 'depends not merely upon the physical, but also upon the historically developed social needs, which become second nature. But in every country, at a given time, this regulating average wage is a given magnitude' (Marx 1894, p. 859; cf. also Torrens 1815, pp. 62–3).

The classical authors also ascribed to the conditions of competition on the labour market the possibility of influencing real wages for fairly long periods of time, and hence of causing shifts away from the normal distribution of income between capitalists and workers. Smith referred to the possibility that under certain circumstances, connected with the pace of accumulation and the growth in productivity of labour, 'the scarcity of hands' or a 'scarcity of employment' may move the wage above or below the normal average level (Smith 1776, vol. 1, pp. 77 and 80). Starting from Smith's analysis, Marx went on to consider the movements of wages in the periodic alternations of the industrial cycle as regulated ' by the varying proportions in which the working-class is divided into active and reserve army, ... , by the extent to which it is now absorbed, now set free' (Marx 1883, p. 596).

Normal wages having been explained in terms of subsistence, the normal rate of profit must be determined as a residual on the basis of the dominant techniques of production. Those firms which, within each sphere of production, employ more backward or more advanced techniques than the dominant ones, earn profits that are respectively smaller or greater than normal.

In this conception, the conditions of competition amongst capitalists do not have any role to play as regulator of the normal distribution of income between wages and profits. It is easy to see on the basis of Sraffa's price equations (Sraffa 1960, paras 1–4) that, given the wage in terms of specified necessaries and the methods of production, if there is a surplus product in the economy then the system necessarily determines, together with prices, also a positive general rate of profit which no competition whatsoever among capitalists can eliminate or change. If real wages, in other words, determined by historical and social conditions independently from prices and from the rate of profit, absorb only a part of the net product of the economy, it is simply impossible for competition, however intense it may be, to determine prices such as to render nil or 'as low as possible' what remains of the value of the product after the means of production have been reintegrated and the wages paid.

It is true that the competition amongst the owners of capital plays an important role Smith's theory: he makes the level of the 'natural' rate of profit depend on it. But this is precisely where the basic contradiction in Smith's theory may be seen. On the one hand he considers the real wage to be determined by subsistence; on the other he maintains that the rate of profit is determined by competition amongst capitalists, which, by growing more intense as accumulation proceeds, would make 'the ordinary rate of profit as low as possible' (Smith 1776, vol. 1, p. 106). In short, his reasoning proceeds as if *both* distributive variables could be determined independently from each other.

Leaving aside Smith's contradiction, it can be affirmed that in classical and Marxian theory competition is envisaged essentially as the mechanism whereby, in each sphere of production, a single price tends to be established: the price that enables the means of production to be reintegrated on the basis of the dominant production techniques, and wages and profits to be paid at their normal rates. These latter must be explained independently from competition, and, as Marx puts it, it is they that regulate competition, rather than being regulated by it (Marx 1894, p. 865). The competition amongst firms within each sphere of production and the free transferability of capital from one sphere to another – hence the process whereby profit rates gravitate towards their respective normal levels – may be impeded by the presence of monopoly elements in this or that sphere of production. This however will affect the division of profits amongst the particular stocks making up social capital, but not the normal distribution of net output between wages and profits (Marx 1894, p. 861).

Interest and Profits

Profits on capital employed in production normally include, according to the classical economists, besides interest, also a remuneration for the 'risk and trouble' of productively employing it, or what may be termed a normal profit of enterprise. Production and accumulation would not continue,

Ricardo argues, if the profits of the farmers and the manufacturers were 'so low as not to afford an adequate compensation for their trouble and the risk which they must necessarily encounter in employing their capital productively' (Ricardo 1821, p. 122). Such 'adequate compensation' will be different in the various employments of capital, according to 'any real or fancied advantage which one employment may posses over another' (Ricardo 1821, p. 90). On the basis of this conception, natural prices will have to be such as to ensure that, in each sphere of production, what remains of the value of the product after deducting wages and the replacement of the means of production, is sufficient to 'adequately' remunerate the 'risk and trouble' and pay interest at an uniform rate. It can thus be said that interest and profit of enterprise are conceived in the classical analysis as the two magnitudes into which normal profits – determined by real wages and production techniques – resolve themselves.

The money rate of interest emerges from this picture as a magnitude subordinate to the normal rate of profit, being ultimately determined by those real forces, the real wage rate and production techniques, which explain the course of the normal rate of profit. But what if actual experience did not validate the conception of the money rate of interest as a subordinate phenomenon? A few significant modifications would be called for within the classical–Marxian approach to distribution, if it had to be acknowledged that the level of the rate of interest in any one country is strongly influenced by circumstances which have nothing to do with the real forces regarded by the classical economists as governing the rate of profit. These modifications, as will be apparent from the determination of distribution outlined below, would lead to a view of the real wage as the residual rather than the independent or 'given' variable in the relation between profits and wages.

It is important to notice that the replacement of the wage by the rate of profit as the independent distributive variable is fully compatible with the surplus approach to distribution (cf. Garegnani 1984, pp. 320–2). The concept of profits as surplus product is not under discussion when asking which of the two distributive variables should be regarded as 'given' in the present reality of the capitalist economy. The question is whether the relations that workers and capitalists establish with one another tend *primarily* to act upon the real wage or upon the rate of profit, once the view is abandoned that real wages consist of the necessary subsistence of the workers and the possibility of variations in the division of the social surplus is admitted.

Actual experience seems in fact to validate the conception of an autonomous determination of the money rate of interest – autonomous in the sense that interest rates *do* experience lasting changes which are very reasonably explainable without any need to refer to a *primum movens* represented by changes in the normal profit rate. Interest rates in any one country depend directly on monetary policy; interest rate policy decisions, however, are taken under a wide range of constraints having different weights both amongst the various countries and for the same country at different times: external constraints, monetary and fiscal constraints, distributive constraints. The important point is that interest rate policies, both in the short and in the long run, do not appear to be constrained by a predetermined normal profitability of capital. Once this point is acknowledged, then, given the necessary (and generally admitted) long-run connection between the rate of interest and the rate of profit, it will also be acknowledged that it is the former which 'sets the pace' and that the latter will have to adapt itself. On this basis, one can proceed to discover the actual mechanism whereby the causation occurs and to study its implications (see Pivetti 1985).

The actual mechanism whereby lasting changes in interest rates are susceptible of causing corresponding changes in normal profit rates, can be understood by following a three-stage line of reasoning. The first stage simply consists in regarding competition as the mechanism by which prices tend to be equated to normal costs. The second stage of the reasoning consists in looking at the rate of interest as a determinant of production costs, together with money wages and production techniques. Thus, lasting changes in interest rates *constitute* changes in normal costs,

which, *ceteris paribus*, will result in corresponding changes of the price level. The third stage of the reasoning comes about as a consequence of the first two: by the competition amongst firms within each industry, a lasting change in interest rates causes a change in the same direction in the level of prices in relation to the level of money wages, thereby generating changes in income distribution.

The rate of interest thus emerges from our picture as the regulator of the ratio of prices to money wages. The reader will note the main difference between this view and the so-called post-Keynesian theory of distribution: whilst in that theory changes in the level of prices in relation to the level of money wages are determined by changes in aggregate demand, according to the present explanation of distribution they are determined by lasting changes in interest rates.

By taking into consideration also the excess of profit over interest, or profit of enterprise, our conception of the rate of interest as the regulator of the ratio of prices to money wages requires us to assume that lasting changes in the rate of interest do not tend, and are not likely, to be associated with opposite changes in the normal profit of enterprise. This assumption is largely consistent with classical conceptions as regards the normal excess of profit over interest: if profit *does* normally exceed interest (if competition, that is, does not tend to equalize profit and interest), then the excess of the former over the latter must cover objective elements of 'risk and trouble' or elements which are regarded as objective by the majority of the investing public. By taking into account all such elements, we can say that the normal rate of profit in each particular production sphere will be arrived at by adding up *two* autonomous components: the long-term rate of interest or 'pure' remuneration of capital, plus the normal profit of enterprise or the remuneration for the 'risk and trouble' of productively employing capital in that sphere of production. Provided this remuneration is a sufficiently stable magnitude, lasting changes in the rate of interest will cause corresponding changes in profit rates, and inverse changes in the real wage.

Real Wages as a Residue

As we saw above, interest and profit of enterprise are conceived by the classical economists as the two magnitudes into which normal profits resolve themselves, whereas, according to our view, the same two magnitudes should rather be regarded as the *determinants* of the rate of profit. Given the money wage, the real wage appears here as a residue on the basis of the price level reflecting the dominant techniques in the different spheres of production and the normal profit rate determined in each sphere in the way we have just indicated. From this determination of distribution, quite different views from the classical ones may be developed concerning the role of competition amongst capitalists.

Since in our view the real wage constitutes the residual variable, the presence of monopoly elements in this or that sphere of production may affect not only the division of profits amongst the different employments of capital, but also the distribution between profits and wages. Given in fact the money wage, the possibility for some commodities to obtain a monopoly price which rises above the 'price of production' will translate into a ratio price-level/money wage which will be higher than it would be if there were no monopoly elements, and hence into a lower real wage. Assuming the long-term rate of interest to be unaffected by the presence of monopoly elements, it follows that lasting effects of the conditions of competition on distribution may only be obtained in one direction: higher profits than normal. For the long-term interest rate and the normal remuneration of 'risk and trouble' establish, in each sphere of production, the minimum or necessary level below which the profit rate cannot go, over the long run, however intense one may suppose the forces of competition to be.

The possibility must also be admitted that the conditions of competition influence the normal profit rate via the long-term interest rate. At the root of this possible influence of competition there is the fact that the level of the real wage constitutes *in any case* an important constraint on the freedom of monetary policy to establish the level of interest rates. To acknowledge that lasting variations in

the rate of interest determine variations in the normal distribution between profits and wages is not to concede that the real wage may move to any level whatsoever. In each concrete situation, it would be hard to carry on the productive process in an orderly manner if the real wage were lower than certain levels reflecting institutional and historical as well as economic circumstances. Thus, if the conditions of competition have a negative effect on wages – via the levels of profits of enterprise or the methods of production adopted – then beyond certain limits, which will vary from one situation to another, a compensatory effect will have to be sought in the level of interest rates.

According to our view, then, the money rate of interest should be looked on as the magnitude on which the respective powers of capitalists and workers discharge themselves *in the first place.* Wage bargaining and monetary policy are regarded as the main channels through which class relations act in determining distribution, and those relations are seen as tending to primarily act upon the profit rate, via the monetary rate of interest, rather than upon the real wage rate as maintained by both the classical economists and Marx. The level of the real wage prevailing in any given situation is the *final* result of the whole process by which distribution of income between workers and capitalists is actually arrived at.

It seems to us that in the conditions of modern capitalism it is difficult to conceive of the real wage rate as the independent or given variable in the relationship between wages and profits – the difficulty, as we see it, arising from the fact that the direct outcome of wage bargaining is a certain level of the money wage, while the price level cannot be determined before and independently from money wages. Given distribution between profits and wages, and given the methods of production, the level of prices simply depends on the level of money wages. Thus, in our picture, the long-term rate of interest enters into the determination of the price level because it contributes to regulating the ratio of the latter to the money wage – that is, distribution between profits and wages.

If instead the real wage is taken as given, the ratio of prices to money wages will be determined by the condition that it must be such as to ensure the given level of the real wage; and on this basis wage bargaining, in determining money wages, can be thought of as determining also the price level. In such a picture monetary policy plays a purely passive role – the level of the rate of interest having to accommodate to lasting changes in the ratio of prices to money wages, rather than governing that ratio. Now what we are ultimately facing here is a conception of the ratio of prices to money wages as being determined by a magnitude, the real wage rate, which is not actually known before that ratio is known. This explains in our opinion why of the two alternative propositions – that the ratio of prices to money wages depends on the real wage rate, or that the real wage rate depends on the ratio of prices to the money wage – the latter is easier to digest: in actual fact, there are no circumstances determining real wages as distinct from those acting through money wages, the level of prices and the ratio of prices to money wages.

Classical Economics and Economic Growth

Gavin Cameron

Abstract

The classical economists dealt with many of the issues now addressed by modern growth theories, albeit with different theoretical tools and with different perspectives. Classical analyses of the division of labour, population growth, and the difficulties when factors are in fixed supply, continue to have modern applications. However, the models they developed ran into difficulties after the 'marginalist revolution', when it became apparent that sustained technical change, abstinence and thrift by the labouring classes, and factor substitution might forestall the arrival of the stationary state.

The analysis of economic growth was an important feature of the writings of the great classical economists, including Adam Smith, Thomas Malthus, David Ricardo, John Stuart Mill and Karl Marx.

To place them in their historical context is straightforward if economic history is simplified into three distinct epochs. In the first, which spanned most of human history and still obtains in some unfortunate regions, Malthusian conditions prevailed: living standards were static even though there was some population growth. In the second, which began in the middle of the eighteenth century in England, living standards showed some upward tendency and there was a demographic change as fertility rates rose and mortality rates fell, resulting in a substantial rise in population. In the third epoch, characteristic of England from the 1820s perhaps, the move to sustained economic growth provoked a shift from quantity to quality in child-rearing, and all the appurtenances of modern growth began to appear, such as human capital, professional R&D, and technical innovation.

There is much scope for discussion about what factors triggered, propagated, and enhanced such changes, and about when such changes began and whether they were smooth or discrete. For example, Mokyr (2005) argues that living standards in England rose gently between the 17th and

18th centuries due to the spread of world trade, commercialism and the rise of institutions less hostile to consumers and the industrious – nicely, this is sometimes called 'Smithian' growth. Somewhat in contrast, Allen (2001) argues that real wages did not rise significantly over that period in England, but that, since they were falling across most of Europe, the real question is what would have happened in the absence of the Industrial Revolution.

Mokyr also points out that many of the inventions associated with the eighteenth century Industrial Revolution were developed in northwest Europe, but successfully applied in England. It is not surprising that the classical economists were fascinated. Adam Smith was born in 1723, within the Malthusian growth regime, whereas Ricardo, Malthus and Jean-Baptiste Say were well placed to observe the demographic change in England and the beginnings of industry, even though England was still predominantly a rural society in the early nineteenth century. Unsurprisingly, Mill and Marx found it increasingly hard to defend Ricardian doctrines as the modern growth regime began to emerge across Europe and its offshoots in the middle of the nineteenth century.

Being products of the Enlightenment, the classical economists shared a concern for human progress that would do credit to a modern policymaker. One purpose of their analysis was to identify the forces in society that promoted or hindered progress and to provide a basis for policy and action in a time of considerable political innovation in England (including land enclosures, franchise reform, tariff reform, and the abolition of the slave trade) and revolution abroad (including land reform, the continental system, and the tumbrils). This background motivated Ricardo's campaign against the Corn Laws, as it did Malthus's concern with population growth, Smith's attacks on mercantilism, and Marx's analyses of social class.

The classical economists' work was grounded in the economic conditions of their times, and not in the abstract mathematical reasoning that appeared in economics during the marginalist revolution of the 1870s and after, popularized by Ysidro Edgeworth, William Stanley Jevons and Alfred Marshall. In contrast to more recent economic thought, the classical economists saw discussions of economic growth as being inextricably linked with discussions of the theory of value and the theory of distribution. Since their concerns were largely those of educated gentlemen of those times, they wanted to be able simultaneously to explain trade cycles, inflation and other short-run phenomena, as well as real wages and population growth and other long-run phenomena. While it is easy to see the current gap between short-run and long-run macroeconomic models as a lacuna (for example, see Solow 2005), the classical economists tended to run into problems when treating both at the same time.

> The characteristic features of what is commonly meant by industrial progress, resolve themselves mainly into three, increase of capital, increase of population, and improvements in production; understanding the last expression in its widest sense, to include the process of procuring commodities from a distance, as well as producing them. (Mill 1848, Book IV, ch. 3)

The classical economists also worried about the consumption of luxuries and the distinction between productive and unproductive labour. As Brewer (1997) discusses, this is particularly true of Adam Smith, who displays a good deal of ambivalence about luxuries:

> That portion of his revenue that a rich man annually spends is in most cases consumed by idle guests and menial servants, who leave nothing behind them in return for their consumption. That portion which he annually saves, for the sake of the profit it is immediately employed as a capital, is consumed in the same manner, and nearly the same time too, but by a different set of people, by labourers, manufacturers and artificers, who reproduce with a profit the value of their annual consumption. (Smith 1776, Book II, ch. 3)

Smith's view contrasts somewhat with that of his predecessor David Hume, whose mild approval of luxuries was based on the notion that they might encourage economic and political development. Although such notions still figure in modern debates (Greenhalgh 2005), this preoccupation with luxuries and unproductive labour turns out to be not very useful for modelling purposes, unless it is simply be taken to mean that different economic groups have different

propensities to save, which is a truism. However, even if the classical economists did not always approve of certain kinds of consumption, Smith's contention that consumption is the sole end and purpose of all production was a vast improvement on the mercantilist doctrine.

Clearly, the classical economists cannot be written off as growth theorists manqué. The technical core of modern growth theory rests upon technical change, specialization, factor substitution, and factor accumulation, with various recent theorists emphasizing the effects on these of trade, institutions, inequality, political economy, geography and population size and growth. All these issues were concerns of the classical economists, even if they used a different vocabulary.

Nonetheless, it would be fair to say that the classical economists have had only a limited direct impact on recent growth theorists. Adam Smith receives seven references in the current two-volume *Handbook of Economic Growth* (Aghion and Durlauf 2005). Malthus a very respectable 13, while of the other classical economists only Ricardo merits a single mention. Interestingly, an even older economist, William Petty from the seventeenth century, is often quoted in writing about the effect of population size on inventiveness in the scale effect literature (see Jones 2005).

The Stationary State

The classical economists saw all around them the effects of the development of the capitalist system, most importantly, of course, the accumulation of capital, but also the introduction of new techniques. Smith analysed in great detail the process of the division of labour, but more generally the classical economists did not attempt to deal with the relationship between capital accumulation and technical change (although Marx did highlight the issue). In addition to these basic forces of economic growth, they were also interested in the increase in the supply of labour through population growth. In the case of Thomas Malthus, this interest was quite morbid.

> The power of population is so superior to the power in the earth to produce subsistence for man that premature death must in some shape or other visit the human race. (Malthus 1798)

The classical economists' analysis of the process by which capital, technology and labour grow over time led them to a common conclusion, motivated by different causes – that the process of economic growth was gradually self-attenuating and ended in a state of stagnation (the 'stationary state'):

> When the stocks of many merchants are turned into the same trade, their mutual competition naturally tends to lower its profit; and when there is a like increase of stock in all the different trades carried on in the same society; the same competition must produce the same effect in them all. (Smith 1776, Book I, ch. 4)

The principal way in which Smith envisaged a stationary state as obtaining was that the rate of profit would fall as capital accumulated in the long run due to increased competition. Smith associated this stationary state with the position of China, which he described as being one of the most fertile and industrious countries, but also as having low wages and having been long stationary. There is tension in the Wealth of Nations between three separate points: first, his worries about the falling rate of profit; second, his worries that wages could fall to a subsistence level; and third, his description of net saving creating higher levels of output. This shows that although the economic system he describes is very complex, it tends to neglect both the feedback between profits and saving, and substitution between capital and labour.

Some controversy exists about the origin of the idea of 'diminishing returns', although it certainly appears in the writings of Jacques Turgot in the eighteenth century. The early nineteenth-century English economists certainly saw the idea in action with the expansion of cultivated land in England during the Napoleonic Wars. Subsequently, the idea comes to life in Ricardo's 'corn' model. Modern presentations of this model are plentiful (see for example, Kaldor 1956; Pasinetti 1960; Samuelson 1978;

discussions in Glyn 2004). The presentation here follows Bhaduri and Harris (1987).

Suppose that there is a single product, 'corn', produced in a capitalist agricultural economy. Land differs in its fertility and labour is applied in fixed proportions to land of diminishing fertility. The supply of labour is perfectly elastic at some fixed real wage equal to 'subsistence' (this is clearly an extreme form of the Malthusian hypothesis; see for example, in Samuelson 1978, and discussion in Brezis and Young 2003). Total output is distributed between rent paid to landlords, profits to capitalists, and wages. The level of land rent can then be shown to be determined by the difference between the average and marginal product of labour at the prevailing level of employment, and profits are the residual after rent and wages are paid (equal to the marginal product of labour minus the wage, times employment). Although there is a variety of Ricardian schemes for the determination of saving (and hence capital accumulation in a closed economy with no consumption loans), a typical presentation takes saving to be a constant proportion of profits, so the rate of accumulation is uniquely dependent upon the profit rate.

However, as employment growth proceeds, the marginal product of labour falls and so must the profit rate. The system asymptotically approaches a stationary state when the profit rate is so low that accumulation ceases (the 'minimum acceptable rate of profit'). What happens is that capitalists find themselves squeezed between the diminishing product of labour and the need to pay the going wage rate, and paying out an increasing share of output as rent to landlords. There is thus a conflict between landlords and capitalists.

In the absence of technical change, the possibility that landlords or workers could themselves become savers, or substitution away from that resource, any other fixed resource would play the same role. Samuelson (1978) notes that neither Ricardo nor Marx was so naive as to believe literally in fixed proportions between capital goods and labour, but their models were unable fully to reflect this complexity.

Mill provides both a summary and a synthesis of previous writers, drawing particularly on Ricardo:

> On the whole, therefore, we may assume that in a country such as England, if the present annual amount of savings were to continue, without any of the counteracting circumstances which now keep in check the natural influences of those savings in reducing profit, the rate of profit would speedily attain the minimum, and all further accumulation of capital would for the present cease. (Mill 1848, Book IV, ch. 4)

Mill contradicts Smith's assertion that competition is the cause of the falling profit rate and proposes instead a form of diminishing returns to capital, provided by limits to the 'field of employment' of capital. He then explicitly links capital accumulation with saving and notes that there is some minimum rate of profit, below which capital accumulation cannot take place. However, he does propose four mechanisms by which the stationary state may be overcome: first, that capital may be wasted during speculative booms; second, through improvements in production; third, through an expansion of foreign trade, and fourth, through the export of capital to other countries.

The second is the one that resonates with modern growth theory, although Mill muddies the waters with a contradictory passage about why an improvement in the production of luxuries (such as lace and velvet) will affect capital accumulation through a different mechanism.

Marx was also a firm believer in this movement towards a stationary state, exemplified by what he called the falling tendency of the rate of profit (FTRP). In the Marxian scheme, the FTRP is one of the main sources of crises under capitalism. Writers in this tradition usually understate the ability of technical progress to reliably prevent such crises and overstate the role of the business cycle in long-run development. Not every slump or financial crash heralds the end of capitalism. But on the former point, Marx was writing at an early stage of the sustained growth era, largely before the existence of large-scale industrial processes and certainly before professional R&D laboratories (see Glyn 2006, for a discussion of whether the entry of China and India into the global economy might

presage a return to a Marxian era of growth). In such an era, technical innovation may well have appeared more uncertain and less widespread than it would later appear, or, to use Harberger's analogy, more like mushrooms popping up here and there than like yeast leavening the entire economic process (Harley 2003).

It can be seen that the classical economists were much more concerned about the stationary state than if it just represented an equilibrating tendency in a long-run growth model à la Solow where capital deepening slows in the absence of technical change (this is clear from Sweezy 1942, ch. 9). Nonetheless, in the idea of the stationary state (and from Mill's view that he was considering the 'dynamics' of the economy, having dealt with the 'statics'), it is possible to see the seed-corn of the Solow model, once economists such as Marshall, Frank Ramsey, Charles Cobb, and Paul Douglas had laid further foundations.

In contrast, classical theories of growth qua theories of growth became increasingly marginal as the nineteenth century wore on (although of course, Marxian and Marxist analysis remained influential for much longer). The Swedish unemployment of the early 1920s prompted Knut Wicksell to write three articles from a neo- Malthusian standpoint, one of which, entitled 'Ricardo on Machinery and the Present Unemployment', he submitted to the *Economic Journal*. John Maynard Keynes, the editor of the journal, rejected the paper, arguing 'that any treatment of this topic at the present day ought to bring in various modern conceptions for handling the problem and the time has gone by for a criticism of Ricardo on purely Ricardian lines' (J.M. Keynes, quoted in Jonung 1981). In the end, even Piero Sraffa's remarkable work, *Production of Commodities by Means of Commodities* (1960), was not enough to revive Ricardian analysis, although some still see neoclassical economics as its direct descendant (Hollander 1995).

Conclusion

Classical economists are often regarded as 'pessimistic' in their forecasts of the future development of the economy, and came in for heavy criticism from the unlikeliest of sources, the Romantic poets and literary critics such as Ruskin. This kind of trahison des clercs of poets and authors against a changing social order and increasing commercialization is familiar to a modern reader of tracts against global capitalism, and equally well grounded in theory and evidence.

The classical economists' search for a 'theory of value' and a 'theory of distribution' was an attempt to understand the significant economic, political, and social changes of their times, as well as an attempt to understand what would happen in the long run in those economies. There is much to be learnt from their analyses, both as an indicator of the conditions of the times (that is, the importance of land as a factor of production) and also as a precursor to the future development of the theory of economic growth. Without the analytical apparatus that arose during the marginalist revolution (such as production functions and utility functions), their analyses were hampered, but a number of the features that drive modern models of growth made their first appearance in the writings of the classical economists. For example, the importance of the division of labour, technical progress and the role of population growth, as well as the idea of diminishing returns, all feature prominently in modern models.

What is lacking from the classical accounts is the notion of a balanced growth path. The classical economists largely concluded that, in the long run, economies would tend towards a stationary, stagnant state. They emphasized the ability of population growth to keep wages at subsistence level, the notion that capital could only be accumulated out of profits, and the central role of land as a factor of production. In this sense, their analytical scheme is flawed. Economic progress has shown that the possibility of investment in human capital can lead to a demographic shift whereby households choose 'quality' over 'quantity' in their reproductive choices; that saving by workers can be an important source of capital accumulation; and that factor substitution tends to prevent the inexorable rise in the price of any factor, even if it is in fixed supply.

Classical Growth Model

Donald J. Harris

Abstract

The classical economists provided an account of the broad forces that influence economic growth and of the mechanisms underlying the growth process, stressing accumulation and productive investment of a part of the social surplus in the form of profits. Changes in the rate of profit were decisive for analysis of the long-term evolution of the economy. The analysis indicated that in a closed economy there is an inevitable tendency for the rate of profit to fall. In this article, the essential features of the classical analysis of the accumulation process are presented and formalized in terms of a simple model.

Analysis of the process of economic growth was a central feature of the work of the English classical economists, as represented chiefly by Adam Smith, Thomas Malthus and David Ricardo. Despite the speculations of others before them, they must be regarded as the main precursors of modern growth theory. The ideas of this school reached their highest level of development in the works of Ricardo.

The interest of these economists in problems of economic growth was rooted in the concrete conditions of their time. Specifically, they were confronted with the facts of economic and social changes taking place in contemporary British society as well as in previous historical periods. Living in the 18th and 19th centuries, on the eve or in the full throes of the Industrial Revolution, they could hardly help but be impressed by such changes. They undertook their investigations against the background of the emergence of what was to be regarded as a new economic system – the system of industrial capitalism. Political economy represented a conscious effort on their part to develop a scientific explanation of the forces governing the operation of the economic system, of the actual processes involved in the observed changes that were going on, and of the long-run tendencies and outcomes to which they were leading.

The interest of the classical economists in economic growth derived also from a philosophical concern with the possibilities of 'progress' an essential condition of which was seen to be the development of the material basis of society. Accordingly, it was felt that the purpose of analysis was to identify the forces in society that promoted or hindered this development, and hence progress, and consequently to provide a basis for policy and action to influence those forces. Ricardo's campaign against the Corn Laws must obviously be seen in this light, as also Malthus's concern with the problem of population growth and Smith's attacks against the monopoly privileges associated with mercantilism.

Of course, for these economists, Smith especially, progress was seen from the point of view of the growth of national wealth. Hence, the principle of national advantage was regarded as an essential criterion of economic policy. Progress was conceived also within the framework of a need to preserve private property and hence the interests of the property-owning class. From this perspective, they endeavoured to show that the exercise of individual initiative under freely competitive conditions to promote individual ends would produce results beneficial to society as a whole. Conflicting economic interests of different groups could be reconciled by the operation of competitive market forces and by the limited activity of 'responsible' government.

As a result of their work in economic analysis the classical economists were able to provide an account of the broad forces that influence economic growth and of the mechanisms underlying the growth process. An important achievement was their recognition that the accumulation and productive investment of a part of the social product is the main driving force behind economic growth and that, under capitalism, this takes the form mainly of the reinvestment of profits. Armed with this recognition, their critique of feudal society was based on the observation, among others, that a large part of the social product was not so invested but was consumed unproductively.

The explanation of the forces underlying the accumulation process was seen as the heart of the problem of economic growth. Associated with accumulation is technical change as expressed in the division of labour and changes in methods of production. Smith, in particular, placed heavy

emphasis on the process of extension of division of labour, but there is, in general, no systematic treatment of the relation between capital accumulation and technical change in the work of the classical economists. It later becomes a pivotal theme in the work of Marx and is subjected there to detailed analysis (see, for instance, Marx 1867, part 4). To these basic forces in economic growth they added the increase in the supply of labour available for production through growth of population. Their analysis of the operation of these forces led them to the common view, though they quite clearly differed about the particular causes, that the process of economic growth under the conditions they identified raises obstacles in its own path and is ultimately retarded, ending in a state of stagnation – the 'stationary state'.

The conception of the stationary state as the ultimate end of the process of economic growth is often interpreted as a 'prediction' of the actual course of economic development in 19th-century England. There is no doubt that it was for a time so regarded by some, if not all, of the economists and their contemporaries, though the weight that was assigned to this particular aspect of the conception by Ricardo himself is a matter of some dispute. What is more significant, however, is that this conception served to point to a particular social group, the landlord class, who benefited from the social product without contributing either to its formation or to 'progress' and who, by their support of the Corn Laws and associated restrictions on foreign trade, acted as an obstacle to the only effective escape from the path to a stationary state, that is, through foreign trade.

In examining the work of the classical economists we find also that problems of economic growth were analysed through the application of general economic principles, viewing the economic system as a whole, rather than in terms of a separate theory of economic growth as such. These principles were such as to recognize basic patterns of interdependence in the economic system and interrelatedness of the phenomena of production, exchange, distribution and accumulation. In sum, what we find in classical economic analysis is a necessary interconnection between the analysis of value, distribution and growth. Because of these interconnections it was by no means possible to draw a sharp dividing line between the inquiry into economic growth and that into other areas of political economy. As Meek (1967, p. 187) notes:

> To Smith and Ricardo, the macroeconomic problem of the 'laws of motion' of capitalism appeared as the primary problem on the agenda, and it seemed necessary that the whole of economic analysis – including the basic theories of value and distribution – should be deliberately oriented towards its solution.

Distribution of the social product was seen to be connected in a definite way with the performance of labour in production and with the pattern of ownership of the means of production. In this regard, labour, land, and capital were distinguished as social categories corresponding to the prevailing class relationships among individuals in contemporary society: the class of labourers consisted of those who performed labour services, landlords were those who owned titles or property in land, and capitalists were those who owned property in capital consisting of the sum of exchangeable value tied up in means of production and in the 'advances' which go to maintain the labourers during the production period. Each class received income or a share in the product according to specified rules: for the owners, the rule was based on the total amount of property which they owned – so much rent per unit of land, so much profit per unit of capital (and, for the class of finance capitalists or 'rentiers' who lent money at interest, so much interest per unit of money lent). For labourers it was based on the quantity of labour services performed: so much wages per hour.

Accumulation and distribution were seen to be interconnected through the use that was made by different social classes of their share in the product. Basic to this view was a conception, taken over from the Physiocrats, of the social surplus as that part of the social product which remained after deducting the 'necessary costs' of production consisting of the means of production used up and the wage goods required to sustain the labourers employed in producing the social product. This

surplus was distributed as profits, interest and rent to the corresponding classes of property owners. For the classical economists, the possibility of accumulation was governed by the size and mode of utilization of this surplus. Accordingly, their analysis placed emphasis upon those aspects of distribution and of the associated class behaviour which had a direct connection with the disposal of the surplus and therefore with growth. In particular, it was assumed that, typically, workers consumed their wages for subsistence, capitalists reinvested their profits and landlords spent their rents on 'riotous living'. On the other side, accumulation would also influence the distribution of income as the economy expanded over time.

It was this absolutely strategic role of the size and use of the surplus, viewed from the perspective of the economy as a whole and of its process of expansion, which dictated the significance of the distribution of income for classical economic analysis. Thus, for Ricardo especially, investigation of the laws governing distribution became the focus of analysis. In a letter to Malthus, Ricardo wrote (*Works*, VIII, pp. 278–9): 'Political Economy you think is an inquiry into the nature and causes of wealth; I think it should rather be called an inquiry into the laws which determine the division of the produce of industry among the classes which occur in its formation.' What was of crucial significance in this connection was the rate of profits because of its connection with accumulation, both as the source of investment funds and as the stimulus to further investment.

Having 'got rid of rent' as the difference between the product on marginal land and that on intra-marginal units, the Ricardian analysis focused on profits as the residual component of the surplus. Under the simplifying conditions on which the analysis was constructed, there emerged a very clear and simple relationship between the wage rate and the overall rate of profits, determined within a single sector of the economy – the corn-producing sector. The special feature of corn as a commodity was that it could serve both as capital good (seed corn) in its own production and as wage good to be advanced to the workers. With the wage rate fixed in terms of corn, the rate of profit in corn production is uniquely determined as the ratio of net output of corn per man minus the wage to the sum of capital per man consisting of seed corn and the fund of corn as wage good. Competition ensures that the same rate of profit enters into the price of all other commodities that are produced with indirect labour. The overall rate of profits, determined in this way, varies inversely with the corn wage. But, as soon as it is recognized that the wage and/or the capital goods employed in corn production consist of other commodities besides corn, the rate of profits can no longer be determined in this way. For the magnitude of the wage and of the total capital then depends on the prices of those commodities, and these prices incorporate the rate of profit. Attention then has to be directed to explaining the rate of profit by taking account of the whole system of prices. For this purpose the theory of value is called upon to provide a solution and Ricardo struggled with this problem until the end of his life. An elegant solution has been worked out by Sraffa (1960) which shows that, in a system of many produced commodities, with the real wage rate given at a specified level, the rate of profit is determined by the given wage and the conditions of production of the commodities that are 'basics'. It so happens that Ricardo's case of corn is just such a 'basic' commodity in the strict sense that it enters directly and indirectly into the production of every commodity including itself.

The core idea that competition among firms under capitalist conditions tends to produce uniformity of profit rates across all markets remains problematical, especially in the dynamic real-world context of changing technology with various forms of factor immobility and barriers to entry (Harris 1988).

Given the perceived centrality of the rate of profit in a capitalist economy, for classical political economy it becomes a crucial problem in the theory of economic growth to account for movements in the rate of profit associated with the process of capital accumulation and development of the economy. Such movements are a decisive reference point for understanding the long-term evolution of the economy. The classical answer to this problem, as worked out most coherently by

Ricardo, is that in a closed economy there is an inevitable tendency for the rate of profit to fall in the course of the accumulation process and, hence, that the accumulation process itself is brought to a halt by its own logic.

Marx was later to propose this falling tendency of the rate of profit (FTRP) as a *law*. He considered it to be 'the most important law of modern political economy' (1973, p. 748; 1894, part 3). He was, of course, following in the tradition of the classical economists in which the same idea had been firmly entrenched, though supported on different grounds. But, interestingly enough, it is also the case that there exists a distinct conception of a FTRP within neoclassical theory (Harris 1978, ch. 9; 1981). In Keynes, as well, the idea is embodied in his projection of the long-term prospects for capitalism resulting in the 'euthanasia of the rentier' (1936, pp. 375–6). In Schumpeter (1934), it occurs in the form of the idea that the profitability of innovations tends inevitably to be eroded so that the economy settles back to the conditions of the 'circular flow' in the absence of new innovations. Though it is based in each case on quite different foundations, this conception is one of the most striking and persistent uniformities across different schools of economic thought. (For a discussion of the long history of the idea of a falling rate of profit, see Tucker 1960.)

A Model of Accumulation

The essential features of the classical argument regarding the accumulation process can be exhibited with a simple model adapted from Kaldor (1956) and Pasinetti (1960). This model formalizes the Ricardian conception of an agricultural economy producing a single product, 'corn', under capitalist conditions. Land is of differing fertility and labour is applied in fixed proportion to less and less fertile land. Accordingly, the average and marginal product of labour falls as the margin of cultivation is extended through capital accumulation and increase of employment on the land. The system may indifferently be assumed to expand on the extensive or intensive margins of available land. Also, it does not matter for this analysis that there exists any production outside agriculture. It would turn out, in any case, that the overall average rate of profit for the economy as a whole is determined by the agricultural rate of profit or, in the general case, by the conditions of production of 'basics' (see Sraffa 1960; Pasinetti 1977). Of course, in a system with many produced commodities, it is not possible to define 'less fertile land' independently of the rate of profit (Sraffa 1960). However, the problem does not arise in this simplified model of a corn-producing economy. We deliberately abstract from complications associated with the Malthusian population dynamics. This is perhaps the most problematic feature of the classical conception and we return to it below. Meanwhile, it is simply assumed, as in Lewis (1954), that a labour force is in perfectly elastic supply at some conventionally fixed real wage rate equal to 'subsistence'.

Let the production function relating output Y to labour input L be

$$Y = F(L) \quad \begin{array}{l} F(0) \geqq 0 \\ F' > w^* > 0 \\ F'' < 0 \end{array} \tag{1}$$

which satisfies the law of diminishing returns and allows for the existence of a surplus product above the 'subsistence' wage-rate w^*. Total capital K consists entirely of wages W (the 'wage fund') advanced at the beginning of the production period to hire labour. Thus

$$K = W = wL. \tag{2}$$

We are here, for simplicity, neglecting capital as seed-corn, and inputs of fixed capital are ignored. Total output is distributed between payment of rent R to landlords, profits P to capitalists, and replacement of the wage fund:

$$Y = R + P + W. \tag{3}$$

Given the margin of cultivation reached at any time, the level of land rent is determined as the difference between the average and marginal product of labour at the prevailing level of employment:

$$R = \left(\frac{F(L)}{L} - F'\right)L. \tag{4}$$

Profit emerges as the residual

$$P = (F' - w^*)L. \tag{5}$$

It follows that the rate of profit r is determined from

$$r = \frac{P}{W} = \frac{F'}{w^*} - 1. \tag{6}$$

It is the dynamics of the wage fund which represents the process of accumulation in this model. Accumulation of capital consists of the growth of the wage fund with a corresponding increase of employment. Additions to the wage fund come entirely from investment of capitalists' profits since the spendthrift landlords consume their share of the surplus. If the capitalists invest a proportion of profits equal to α, then

$$\Delta W = \alpha P \quad 0 < \alpha < 1. \tag{7}$$

The proportion α need not be a constant. It could vary in a manner dependent on the rate of profit as suggested by Ricardo's idea that

> [the capitalists'] motive for accumulation will diminish with every diminution of profit, and will cease altogether when their profits are so low as not to afford them an adequate compensation for their trouble and the risk which they must necessarily encounter in employing their capital productively. (*Works*, I, p. 122)

In that case we have

$$\alpha = \alpha(r) \quad \alpha' > 0 \alpha(r^*) = 0 \tag{8}$$

where r^* is the capitalists' minimum acceptable rate of profit. By definition the rate of capital accumulation is $g = \Delta W/W$, and from (6), (7), and (8) it follows that

$$g = \alpha(r) \cdot r. \tag{9}$$

Thus, the rate of accumulation is uniquely dependent on the profit rate.

The movement in the profit rate as accumulation proceeds can be derived from (6). Evidently, as employment increases the marginal product of labour falls. The rate of profit must therefore fall. It continues to fall as long as there is any increment to the wage fund so as to employ extra labour on the available land. The process comes to a halt when the profit rate is so low that accumulation ceases. The economy is then at the stationary state.

In this model, the capitalists are caught between, on the one hand, the diminishing productivity of labour as the margin of cultivation is extended and, on the other, the need to pay the ongoing wage rate in order to secure labour for employment. As the productivity of labour falls on the marginal land the pressure of land rent increases for the existing intra-marginal units. The capitalists must therefore pay out an increasing share of the surplus to the landlords. In this way they gradually lose command over the investible surplus of the economy to the landlord class. This distributional conflict between the landlord class and the capitalists constitutes a central feature of the process that drives the economy towards its ultimate stationarity. The impenetrable barrier in the process is the diminishing fertility of the soil. More generally, it is the limitation of natural resources, in this case land, which brings the process to a halt. In this respect the classical model is a particular case of resource-limited growth. Any other limited resource would have the same effect, through increasing 'rents' for that resource. At the same time, this consequence is also the product of the capitalists' own actions in relentlessly seeking to expand the size of their capital.

The underlying dynamic process which expresses this conflictive evolution of capitalist accumulation has usually been assumed in the literature to converge towards the stationary state (see Pasinetti 1960; Samuelson 1978). Some reservation on this question of convergence was originally expressed by Hicks and Hollander (1977) and followed up by Gordon (1983). Subsequent discussion by Casarosa (1978), Caravale and Tosato (1980) and Caravale (1985) further emphasized the problematic nature of the

convergence process. Much of the complexity of this process arises from the intertwined dynamics of distributional change and population growth typical of the Ricardian system. Day (1983) has shown that characterization of the population dynamics by itself may be sufficient to generate extremely erratic or 'chaotic' motions. Bhaduri and Harris (1987) analyse the essential dynamics of the Ricardian system as it is governed solely by the interplay of distribution and accumulation in a model similar to the present one. They find that the model can generate very complex 'chaotic' movements instead of any smooth and gradual convergence to the stationary state. The possibility of such behaviour is shown to depend uniquely on the initial configuration of parameters. This result should lead one to question the presumption that the Ricardian system necessarily converges to a stationary state.

The Malthusian Population Dynamics

A crucial role is played in the classical analysis by the population dynamics deriving from the Malthusian law of population growth. In particular this law requires that population grows in response to a rise of wages above subsistence. This response mechanism is supposed to provide the labour requirements for expansion and thereby hold wages in check. But this is evidently a highly implausible principle on which to base an account of the process of capitalist expansion. If capitalism had to depend for its labour supply entirely upon such a demographic–biological response, it seems doubtful that sustained high rates of accumulation could continue for long or even that accumulation could ever get started. This is because, first, there must exist a biological upper limit to population expansion. Accumulation at rates above this limit would drive up the wage to such a level as to reduce or perhaps choke off the possibility of continued accumulation. For the classical labour supply principle to work, it must be presumed arbitrarily that this limit is sufficiently far out or, equivalently, that the supply curve is sufficiently elastic over a wide range.

Even if it is granted that population growth is significantly responsive to the level of wages, it is still the case that the adjustment of population is inherently a long drawn-out process having only a negligible effect on the actual labour supply in any short period of time. In the interim, any sizeable spurt of accumulation must then cause wages to be bid up, eat into profits, and bring accumulation itself, to a halt. From the start, therefore, accumulation could never get going in such a system. Even if it did, its continuation would always be in jeopardy because the mechanism of adjustment of labour supply is an inherently unreliable one, fraught with the possibility that at any time wages may rise to eat up the profits that are the wellspring of accumulation.

This feature of classical analysis was soundly criticized and rejected by Marx (1867, pp. 637–9). In its place, he sought to introduce a principle that was internal to the accumulation process, which would account for the continuing generation of a supply of labour to meet the needs of accumulation from within the accumulation process itself. This was the principle of the reserve army of labour or the 'law of relative surplus population' (1897, ch. 25, Sections 3 and 4). The reserve army results from a process of 'recycling' of labour through its displacement from existing employment due to mechanization and structural changes in production. In addition to this pool of labour there are other possible sources of increased labour supply to feed the accumulation process. These originate, for instance, in increased labour force participation rates among existing workers, in labour migration, and in the erosion of household work and other forms of non-capitalist production. Capital export to other regions can play the same role. These sources have been observed historically to be more or less significant at various times and places. It appears, therefore, that there is considerable flexibility of labour supply, and hence of accumulation, even without taking account of population growth. The existence of population growth certainly adds to the pool of available labour, as is now widely recognized. But the singular and unique role attributed to it by the Malthusian theory has by now been discredited and abandoned.

Conclusion

The classical economists are often regarded as 'pessimistic' in their prognosis for economic growth. It is said that they constituted economics as the 'dismal science'. Still, there is much to be learned, that is of contemporary relevance, from a close examination of their analytical system. What emerges from such an examination is a complex structure of ideas expressing a deep understanding of the nature of capitalism as an economic system, the sources of its expansionary drive, and the barriers or limits to its expansion. Their ideas were essentially limited, however, to the conditions of a predominantly agrarian economy, without significant change in methods of production, in which, because of the limited quantity and diminishing fertility of the soil, growth is arrested by increasing costs of production of agricultural commodities. Their analysis underestimated the far-reaching character of technological change as a powerful and continuing force in transforming the conditions of productivity both in agriculture and in industry. While they clearly perceived the possibilities opened up by international trade and foreign investment, they failed to incorporate these elements as integral components of a systematic theory of the growth process. It remained for Marx to pinpoint some of the major limitations and deficiencies of the classical analysis and to develop an analysis of the capitalist accumulation process that went beyond that of the classical economists in many respects while also leaving many unresolved questions. Subsequent work has continued to address the issues with limited success. Still today, the theory of growth of capitalist economies continues to be one of the most fascinating and still unresolved areas of economic theory.

Classical Growth Models

Donald J. Harris

Analysis of the process of economic growth was a central feature of the work of the English classical economists, as represented chiefly by Adam Smith, Thomas Malthus and David Ricardo. Despite the speculations of others before them, they must be regarded as the main precursors of modern growth theory. The ideas of this school reached their highest level of development in the works of Ricardo.

The interest of these economists in problems of economic growth was rooted in the concrete conditions of their time. Specifically, they were confronted with the facts of economic and social changes taking place in contemporary English society as well as in previous historical periods. Living in the 18th and 19th centuries, on the eve or in the full throes of the industrial revolution, they could hardly help but be impressed by such changes. They undertook their investigations against the background of the emergence of what was to be regarded as a new economic system – the system of industrial capitalism. Political economy represented a conscious effort on their part to develop a scientific explanation of the forces governing the operation of the economic system, of the actual processes involved in the observed changes that were going on, and of the long-run tendencies and outcomes to which they were leading.

The interest of the classical economists in economic growth derived also from a philosophical concern with the possibilities of 'progress', an essential condition of which was seen to be the development of the material basis of society. Accordingly, it was felt that the purpose of analysis was to identify the forces in society that promoted or hindered this development, and hence progress, and consequently to provide a basis for policy and action to influence those forces. Ricardo's campaign against the Corn Laws must obviously be seen in this light, as also Malthus's concern with the problem of population growth and Smith's attacks against the monopoly privileges associated with mercantilism.

Of course, for these economists, Smith especially, progress was seen from the point of view of the growth of national wealth. Hence, the principle of national advantage was regarded as an essential criterion of economic policy. Progress was conceived also within the framework of a need to preserve private property and hence the interests of the property-owning class. From this perspective, they endeavoured to show that the exercise of individual initiative under freely competitive conditions to promote individual ends would produce results beneficial to society as a whole. Conflicting economic interests of different groups could be reconciled by the operation of competitive market forces and by the limited activity of 'responsible' government.

As a result of their work in economic analysis the classical economists were able to provide an account of the broad forces that influence economic growth and of the mechanisms underlying the growth process. An important achievement was their recognition that the accumulation and productive investment of a part of the social product is the main driving force behind economic growth and that, under capitalism, this takes the form mainly of the reinvestment of profits. Armed with this recognition, their critique of feudal society was based on the observation among others,

Owing to an error on the part of Springer the content of this chapter has been published twice. This duplicate has been retracted.

that a large part of the social product was not so invested but was consumed unproductively.

The explanation of the forces underlying the accumulation process was seen as the heart of the problem of economic growth. Associated with accumulation is technical change as expressed in the division of labour and changes in methods of production. Smith, in particular, placed heavy emphasis on the process of extension of division of labour, but there is, in general, no systematic treatment of the relation between capital accumulation and technical change in the work of the classical economists. It later becomes a pivotal theme in the work of Marx and is subjected there to detailed analysis (see, for instance, *Capital,* I, part 4). To these basic forces in economic growth they added the increase in the supply of labour available for production through growth of population. Their analysis of the operation of these forces led them to the common view, though they quite clearly differed about the particular causes, that the process of economic growth under the conditions they identified raises obstacles in its own path and is ultimately retarded, ending in a state of stagnation – the 'stationary state'.

The conception of the stationary state as the ultimate end of the process of economic growth is often interpreted as a 'prediction' of the actual course of economic development in 19th-century England. There is no doubt that it was for a time so regarded by some, if not all, of the economists and their contemporaries, though the weight that was assigned to this particular aspect of the conception by Ricardo himself is a matter of some dispute. What is more significant, however, is that this conception served to point to a particular social group, the landlord class, who benefited from the social product without contributing either to its formation or to 'progress' and who, by their support of the corn laws and associated restrictions on foreign trade, acted as an obstacle to the only effective escape from the path to a stationary state, that is, through foreign trade.

In examining the work of the classical economists we find also that problems of economic growth were analysed through the application of general economic principles, viewing the economic system as a whole, rather than in terms of a separate theory of economic growth as such. These principles were such as to recognize basic patterns of interdependence in the economic system and interrelatedness of the phenomena of production, exchange, distribution, and accumulation. In sum, what we find in classical economic analysis is a necessary interconnection between the analysis of value, distribution, and growth. Because of these interconnections it was by no means possible to draw a sharp dividing line between the inquiry into economic growth and that into other areas of political economy. As Meek (1967, p. 187) notes:

> To Smith and Ricardo, the macroeconomic problem of the 'laws of motion' of capitalism appeared as the primary problem on the agenda, and it seemed necessary that the whole of economic analysis – including the basic theories of value and distribution – should be deliberately oriented towards its solution.

Distribution of the social product was seen to be connected in a definite way with the performance of labour in production and with the pattern of ownership of the means of production. In this regard, Labour, Land, and Capital were distinguished as social categories corresponding to the prevailing class relationships among individuals in contemporary society: the class of labourers consisted of those who performed labour services, landlords were those who owned titles or property in land, and capitalists were those who owned property in capital consisting of the sum of exchangeable value tied up in means of production and in the 'advances' which go to maintain the labourers during the production period. Each class received income or a share in the product according to specified rules: for the owners, the rule was based on the total amount of property which they owned – so much rent per unit of land, so much profit per unit of capital (and, for the class of finance capitalists or 'rentiers' who lent money at interest, so much interest per unit of money lent). For labourers it was based on the quantity of labour services performed: so much wages per hour.

Accumulation and distribution were seen to be interconnected through the use that was made by

different social classes of their share in the product. Basic to this view was a conception, taken over from the Physiocrats, of the social surplus as that part of the social product which remained after deducting the 'necessary costs' of production consisting of the means of production used up and the wage goods required to sustain the labourers employed in producing the social product. This surplus was distributed as profits, interest, and rent to the corresponding classes of property owners. For the classical economists, the possibility of accumulation was governed by the size and mode of utilization of this surplus. Accordingly, their analysis placed emphasis upon those aspects of distribution and of the associated class behaviour which had a direct connection with the disposal of the surplus and therefore with growth. In particular, it was assumed that, typically, workers consumed their wages for subsistence, capitalists reinvested their profits and landlords spent their rents on 'riotous living'. On the other side, accumulation would also influence the distribution of income as the economy expanded over time.

It was this absolutely strategic role of the size and use of the surplus, viewed from the perspective of the economy as a whole and of its process of expansion, which dictated the significance of the distribution of income for classical economic analysis. Thus, for Ricardo especially, investigation of the laws governing distribution became the focus of analysis. In a letter to Malthus, Ricardo wrote (*Works,* VIII, pp. 278–9): 'Political Economy you think is an inquiry into the nature and causes of wealth; I think it should rather be called an inquiry into the laws which determine the division of the produce of industry among the classes which occur in its formation.' What was of crucial significance in this connection was the rate of profits because of its connection with accumulation, both as the source of investment funds and as the stimulus to further investment.

Having 'got rid of rent' as the difference between the product on marginal land and that on intra-marginal units, the Ricardian analysis focused on profits as the residual component of the surplus. Under the simplifying conditions on which the analysis was constructed, there emerged a very clear and simple relationship between the wage rate and the overall rate of profits, determined within a single sector of the economy – the corn-producing sector. The special feature of corn as a commodity was that it could serve both as capital good (seed corn) in its own production and as wage good to be advanced to the workers. With the wage rate fixed in terms of corn, the rate of profit in corn production is uniquely determined as the ratio of net output of corn per man minus the wage to the sum of capital per man consisting of seed corn and the fund of corn as wage good. Competition ensures that the same rate of profit enters into the price of all other commodities that are produced with indirect labour. The overall rate of profits, determined in this way, varies inversely with the corn wage. But, as soon as it is recognized that the wage and/or the capital goods employed in corn production consist of other commodities besides corn, the rate of profits can no longer be determined in this way. For the magnitude of the wage and of the total capital then depends on the prices of those commodities, and these prices incorporate the rate of profit. Attention then has to be directed to explaining the rate of profit by taking account of the whole system of prices. For this purpose the theory of value is called upon to provide a solution and Ricardo struggled with this problem until the end of his life. An elegant solution has now been worked out by Sraffa (1960) which shows that, in a system of many produced commodities, with the real wage rate given at a specified level, the rate of profit is determined by the given wage and the conditions of production of the commodities that are 'basics'. It so happens that Ricardo's case of corn is just such a 'basic' commodity in the strict sense that it enters directly and indirectly into the production of every commodity including itself.

Given the perceived centrality of the rate of profit in a capitalist economy, for classical political economy it becomes a crucial problem in the theory of economic growth to account for movements in the rate of profit associated with the process of capital accumulation and development of the economy. Such movements are a decisive reference point for understanding the long-term evolution of the economy. The classical answer to this problem, as worked out most coherently by

Ricardo, is that in a closed economy there is an inevitable tendency for the rate of profit to fall in the course of the accumulation process and, hence, that the accumulation process itself is brought to a halt by its own logic.

Marx was later to propose this falling tendency of the rate of profit (FTRP) as a *law.* He considered it to be 'the most important law of modern political economy' (*Grundrisse,* p. 748; *Capital,* III, part 3). He was, of course, following in the tradition of the classical economists in which the same idea had been firmly entrenched, though supported on different grounds. But, interestingly enough, it is also the case that there exists a distinct conception of a FTRP within neoclassical theory (see Harris 1978, ch. 9; 1981). In Keynes, as well, the idea is embodied in his projection of the long-term prospects for capitalism resulting in the 'euthanasia of the rentier' (1936, pp. 375–6). In Schumpeter (1934), it occurs in the form of the idea that the profitability of innovations tends inevitably to be eroded so that the economy settles back to the conditions of the 'circular flow' in the absence of new innovations. Though it is based in each case on quite different foundations, this conception is one of the most striking and persistent uniformities across different schools of economic thought. (For a discussion of the long history of the idea of a falling rate of profit, see Tucker 1960).

A Model of Accumulation

The essential features of the classical argument regarding the accumulation process can be exhibited with a simple model adapted from Kaldor (1956) and Pasinetti (1960). This model formalizes the Ricardian conception of an agricultural economy producing a single product, 'corn', under capitalist conditions. Land is of differing fertility and labour is applied in fixed proportion to less and less fertile land. Accordingly, the average and marginal product of labour falls as the margin of cultivation is extended through capital accumulation and increase of employment on the land. The system may indifferently be assumed to expand on the extensive or intensive margins of available land. Also, it does not matter for this analysis that there exists any production outside agriculture. It would turn out, in any case, that the overall average rate of profit for the economy as a whole is determined by the agricultural rate of profit or, in the general case, by the conditions of production of 'basics' (cf. Sraffa 1960; Pasinetti 1977). Of course, in a system with many produced commodities, it is not possible to define 'less fertile land' independently of the rate of profit (Sraffa 1960). However, this problem does not arise in this simplified model of a corn-producing economy. We deliberately abstract from complications associated with the Malthusian population dynamics. This is perhaps the most problematic feature of the classical conception and we return to it below. Meanwhile, it is simply assumed, as in Lewis (1954), that a labour force is in perfectly elastic supply at some conventionally fixed real wage rate equal to 'subsistence'.

Let the production function relating output Y to labour input L be

$$\begin{aligned} Y = F(L) \qquad & F(0) \geqq 0 \\ & F' > w^* > 0 \\ & F'' < 0 \end{aligned} \tag{1}$$

which satisfies the law of diminishing returns and allows for the existence of a surplus product above the 'subsistence' wage-rate w^*. Total capital K consists entirely of wages W (the 'wage fund') advanced at the beginning of the production period to hire labour. Thus

$$K = W = wL \tag{2}$$

We are here, for simplicity, neglecting capital as seed-corn and inputs of fixed capital are ignored. Total output is distributed between payment of rent R to landlords, profits P to capitalists, and replacement of the wage fund:

$$Y = R + P + W \tag{3}$$

Given the margin of cultivation reached at any time, the level of land rent is determined as the difference between the average and marginal

product of labour at the prevailing level of employment:

$$R = \left(\frac{F(L)}{L} - F'\right)L \tag{4}$$

Profit emerges as the residual

$$P = (F' - w^*)L \tag{5}$$

It follows that the rate of profit r is determined from

$$r = \frac{P}{W} = \frac{F'}{w^*} - 1 \tag{6}$$

It is the dynamics of the wage fund which represents the process of accumulation in this model. Accumulation of capital consists of the growth of the wage fund with a corresponding increase of employment. Additions to the wage fund come entirely from investment of capitalists' profits since the spend-thrift landlords consume their share of the surplus. If the capitalists invest a proportion of profits equal to a, then

$$\Delta W = \alpha P \qquad 0 < \alpha < 1 \tag{7}$$

The proportion α need not be a constant. It could vary in a manner dependent on the rate of profit as suggested by Ricardo's idea that

[the capitalists'] motive for accumulation will diminish with every diminution of profit, and will cease altogether when their profits are so low as not to afford them an adequate compensation for their trouble and the risk which they must necessarily encounter in employing their capital productively (*Works,* I, p. 122).

In that case we have

$$\begin{aligned} \alpha &= \alpha(r) \qquad \alpha' > 0 \\ \alpha(r^*) &= 0 \end{aligned} \tag{8}$$

where r^* is the capitalists' minimum acceptable rate of profit. By definition the rate of capital accumulation is $g = \Delta W/W$, and from (6), (7), and (8) it follows that

$$g = \alpha(r) \cdot r \tag{9}$$

Thus, the rate of accumulation is uniquely dependent on the profit rate.

The movement in the profit rate as accumulation proceeds can be derived from (6). Evidently, as employment increases the marginal product of labour falls. The rate of profit must therefore fall. It continues to fall as long as there is any increment to the wage fund so as to employ extra labour on the available land. The process comes to a half when the profit rate is so low that accumulation ceases. The economy is then at the stationary state.

In this model, the capitalists are caught between, on the one hand, the diminishing productivity of labour as the margin of cultivation is extended and, on the other, the need to pay the ongoing wage rate in order to secure labour for employment. As the productivity of labour falls on the marginal land the pressure of land rent increases for the existing intra-marginal units. The capitalists must therefore pay out an increasing share of the surplus to the landlords. In this way they gradually lose command over the investible surplus of the economy to the landlord class. This distributional conflict between the landlord class and the capitalists constitutes a central feature of the process that drives the economy towards its ultimate stationarity. The impenetrable barrier in the process is the diminishing fertility of the soil. More generally, it is the limitation of natural resources, in this case land, which brings the process to a halt. In this respect the classical model is a particular case of resource-limited growth. Any other limited resource would have the same effect, through increasing 'rents' for that resource. At the same time, this consequence is also the product of the capitalists' own actions in relentlessly seeking to expand the size of their capital.

The underlying dynamic process which expresses this conflictive evolution of capitalist accumulation has usually been assumed in the literature to converge towards the stationary state (cf. Pasinetti 1960; Samuelson 1978). Some reservation on this question of convergence was originally expressed by Hicks and Hollander

(1977) and followed up by Gordon (1983). Subsequent discussion by Casarosa (1978), Caravale and Tosato (1980) and Caravale (1985) further emphasized the problematic nature of the convergence process. Much of the complexity of this process arises from the intertwined dynamics of distributional change and population growth typical of the Ricardian system. Day (1983) has shown that characterization of the population dynamics by itself may be sufficient to generate extremely erratic or 'chaotic' motions. In a recent paper, Bhaduri and Harris (1986) analyse the essential dynamics of the Ricardian system as it is governed solely by the interplay of distribution and accumulation in a model similar to the present one. They find that the model can generate very complex 'chaotic' movements instead of any smooth and gradual convergence to the stationary state. The possibility of such behaviour is shown to depend uniquely on the initial configuration of parameters. This result should lead one to question the presumption that the Ricardian system necessarily converges to a stationary state.

The Malthusian Population Dynamics

A crucial role is played in the classical analysis by the population dynamics deriving from the Malthusian Law of Population Growth. In particular this law requires that population grows in response to a rise of wages above subsistence. This response mechanism is supposed to provide the labour requirements for expansion and thereby hold wages in check. But this is evidently a highly implausible principle on which to base an account of the process of capitalist expansion. If capitalism had to depend for its labour supply entirely upon such a demographic-biological response, it seems doubtful that sustained high rates of accumulation could continue for long or even that accumulation could ever get started. This is because, first, there must exist a biological upper limit to population expansion. Accumulation at rates above this limit would drive up the wage to such a level as to reduce or perhaps choke off the possibility of continued accumulation. For the classical labour supply principle to work it must be presumed arbitrarily that this limit is sufficiently far out or, equivalently, that the supply curve is sufficiently elastic over a wide range.

Even if it is granted that population growth is significantly responsive to the level of wages, it is still the case that the adjustment of population is inherently a long drawn-out process having only a negligible effect on the actual labour supply in any short period of time. In the interim, any sizeable spurt of accumulation must then cause wages to be bid up, eat into profits, and bring accumulation itself, to a halt. From the start, therefore, accumulation could never get going in such a system. Even if it did, its continuation would always be in jeopardy because the mechanism of adjustment of labour supply is an inherently unreliable one, fraught with the possibility that at any time wages may rise to eat up the profits that are the wellspring of accumulation.

This feature of classical analysis was soundly criticized and rejected by Marx (*Capital*, I, pp. 637–9). In its place, he sought to introduce a principle that was internal to the accumulation process, that would account for the continuing generation of a supply of labour to meet the needs of accumulation from within the accumulation process itself. This was the principle of the reserve army of labour or the 'law of relative surplus population' (*Capital,* I, ch. 25, sections 3 and 4). The reserve army results from a process of 'recycling' of labour through its displacement from existing employment due to mechanization and structural changes in production. In addition to this pool of labour there are other possible sources of increased labour supply to feed the accumulation process. These originate, for instance, in increased labour force participation rates among existing workers, in labour migration, and in the erosion of household work and other forms of non-capitalist production. Capital export to other regions can play the same role. These sources have been observed historically to be more or less significant at various times and places. It appears, therefore, that there is considerable flexibility of labour supply, and hence of accumulation, even without taking account of

population growth. The existence of population growth certainly adds to the pool of available labour, as is now widely recognized. But the singular and unique role attributed to it by the Malthusian theory has by now been discredited and abandoned.

Conclusion

The Classical economists are often regarded as 'pessimistic' in their prognosis for economic growth. It is said that they constituted economics as the 'dismal science'. Still, there is much to be learned, that is of contemporary relevance, from a close examination of their analytical system. What emerges from such an examination is a complex structure of ideas expressing a deep understanding of the nature of capitalism as an economic system, the sources of its expansionary drive, and the barriers or limits to its expansion. Their ideas were essentially limited, however, to the conditions of a predominantly agrarian economy, without significant change in methods of production, in which, because of the limited quantity and diminishing fertility of the soil, growth is arrested by increasing costs of production of agricultural commodities. Their analysis underestimated the far-reaching character of technological change as a powerful and continuing force in transforming the conditions of productivity both in agriculture and in industry. While they clearly perceived the possibilities opened up by international trade and foreign investment, they failed to incorporate these elements as integral components of a systematic theory of the growth process. It remained for Marx to pinpoint some of the major limitations and deficiencies of the classical analysis and to develop an analysis of the capitalist accumulation process that went beyond that of the classical economists in many respects while also leaving many unresolved questions. Subsequent work has continued to address the issues with limited success. Until today, the theory of growth of capitalist economies continues to be one of the most fascinating and still unresolved areas of economic theory.

A theory of production cannot be said to have existed before the middle of the 18th century. The very word production was previously used in its narrow etymological sense (from the Latin *producere*, to bring forth) of giving birth to new material objects; and it was therefore normally confined to the fruits of the earth. 'When we speak of it', writes Daniel Defoe, 'as the Effect of Nature 'tis *Product* or Produce; when as the Effect of Labour 'tis *Manufacture*' (1728, p. 1).

It is with the writings of the French *économistes* that the term receives a precise technical meaning. At first sight, the Physiocratic terminology is not particularly novel: the words production, productivity, and so on are carefully reserved for agriculture; manufacture, as a mere transforming activity, is considered as eminently sterile. But Quesnay's fundamental innovation lies in the theory behind the terminology: it is not (or not so much) because of some physical property that agriculture is said to be productive, but because it is the only activity capable of generating a net revenue (rent). The way was, however, paved for the recognition of the productivity of non-agricultural activities, provided that the peculiar assumption of rent as the only possible net revenue was dropped (that is, that profit was accepted as a legitimate form of net revenue). This step was taken, a few years later, by Adam Smith.

In the following decades, production became one of the main topics of political economy; this was later sanctioned by the standard structure adopted by economic textbooks, whose first section typically came to be devoted to production. The first English example of this arrangement is given by the *Elements of Political Economy* published by James Mill in 1821 (following in this respect in Say's steps), the same year in which Robert Torrens brought out his *Essay on the Production of Wealth*. Eventually, in Marxian economics, production analysis achieved the status of a cornerstone of the whole theory of social change.

In the second half of the 19th century, as a consequence of the so-called marginalist revolution, the focus of economic theory tended to shift from the sphere of production to that of exchange. Production theory was squeezed into the general framework of the optimal allocation of scarce resources: a framework originally developed to deal with the problem of pure exchange. The theory originally devised by Quesnay seemed, about one century after its birth, to conclude its own theoretical lifetime.

François Quesnay was the first to analyse the system of production and consumption as a single complex process. He looked for the 'natural laws' by which it was regulated, laws which were

independent of the will of man but discoverable by the light of reason. The attempt to present the interplay of these laws in an abstract and manageable way originated the first theoretical model of the history of economic analysis.

The Physiocratic doctrine presents, though often under a misleading feudal disguise, most of the leading ideas of the classical theory of capitalist production. First and foremost, the picture of the system of production and consumption as a circular process: no one will ever deny that consumption is the ultimate end of production, but it is essential to bear in mind the simple fact that past production determines present consumption, and that consumption in turn is nothing but the necessary condition for future production.

The idea of production as a circular process immediately suggests the notion of surplus: if the economy produces more than the minimum necessary for the process to be repeated, then there is a surplus. Its value was called 'net product' by Quesnay: this is the strategic variable for economic activity. The nations' prosperity can be assessed according to the size of their annual net product.

The answers given by the Physiocrats to the fundamental questions of the origins and destination of the net product account for their peculiar class analysis. They assumed that a net product was yielded exclusively by land-using activities; that is, that revenues could be higher than costs only in agriculture, and therefore rent was the only conceivable net revenue. The class of those engaged in agriculture (farmers, the labourers being equated to cattle) was thus called 'productive', in contrast to the 'sterile' class of those engaged in manufacture (artisans); the class of landowners got the whole net product, under the form of rent.

Since the process of production takes time (the agricultural year) it requires advances: for instance, the labourers' subsistence must be available before the harvest. Quesnay distinguishes between annual advances (working capital: seed, subsistence), which are wholly used up in the course of the production process, and original advances (fixed capital, for which a depreciation is allowed), which are not. It is perhaps worth noticing that the word capital was commonly in use in the economic literature of the 18th century. Quesnay's unusual terminology was presumably due to his intention of stressing the physical nature of the advances required by the production process, as opposed to the current meaning of capital as a sum of money employed in trade.

The characteristic agricultural bias of the Physiocrats is shown not only by their doctrine of the sterility of manufacture, but also by the essentially static nature of their models. If the economy is organized according to the natural order, that is according to the 'evident' laws discovered by the economists, it will rapidly attain the maximum level of output consistent with the country's amount of arable land and with the state of technology. Indeed, the *Tableaux* depict this prosperous and stationary situation.

Both these aspects are definitely abandoned by Adam Smith. Precisely because production takes time, and wages, materials and equipment have to be anticipated, the owners of these advances, the capitalists, are naturally entitled to a part of the net revenue, the profits. The advances are consumed by productive workers or used up as raw materials and wear and tear of equipment; the return, in manufacture as well as in agriculture, will normally cover their cost with an addition, which constitutes the profit.

The Smithian capitalist is thrifty and industrious; his profits are well above subsistence, and he will normally save most of them and employ these savings as capital, in order to obtain an additional profit in the future. As a result of these decisions, the capital of the nation as a whole, the fund that sets productive labour to work for the purpose of profit, naturally tends to increase each year in the course of economic progress.

In this way, Smith gave a clear-cut answer to an old dilemma. In his century, two traditional ideas coexisted unreconciled side by side: on the one hand, by analogy with the behaviour of a good husband, thriftiness was praised as a social virtue; on the other hand, it was maintained that a buoyant consumption stimulated trade. In Smith's view, every frugal man is a benefactor, every prodigal man a 'public enemy'.

The progressive state of the economy – it is written in the *Wealth of Nations* – 'is in reality the chearful and the hearty state to all the different orders of the society. The stationary is dull; the declining, melancholy' (Smith 1776, p. 99). The analysis is here primarily concerned with the process of capital accumulation and is therefore necessarily dynamic.

The analysis of the accumulation of wealth inevitably involved the question of the final outcome of the process. It was a common belief – among classical economists – that the economy would eventually tend towards a stationary state. This could be seen optimistically as 'a full complement of riches' (Smith) or, on the contrary, as a sad motionless state (Ricardo); still, it could be considered as relatively far ahead in the future (Smith and, with a suitable economic policy, Ricardo) or just round the corner (J.S. Mill).

An interesting technical feature of the theory of production can be introduced in connection with this question. The advances of every industry are normally composed of commodities that are not produced by that industry. In other words, each industry must exchange part of its output on the market with the necessary inputs to start the production process again. These transactions, dictated by the technology in use, were clearly described by the *Tableau:* in this highly aggregate picture, the two activities considered, productive and sterile, are both essential to reproduction. But, in a more detailed framework, we can distinguish between those commodities which play a productive role as inputs, and those which do not ('luxuries'). The growth potential of the economy is affected only by the conditions of production of the first type of commodities ('basics' according to modern terminology).

Since every line of production requires labour, and workers consume food, foodstuffs are basics par excellence. Food production in turn requires land, a non-reproducible resource; the scarcity of land becomes therefore the limiting factor to accumulation. Land is essential, and is fixed in supply, so the eventual outcome of the growth process is the stationary state. (One might think that in this way we are back with the original Physiocratic perspective, but now attention is focused on the dynamic process rather than on its static outcome.)

David Ricardo presented a sophisticated version of this argument, in which the result that the growth process ends in a stationary state is analytically restated via his theory of profits. In evaluating this kind of argument, one must remember the vital *ceteris paribus* assumption, especially with regard to technology. Of course, the process of exhaustion of natural resources can be checked by improvements which affect agriculture. Ricardo has often been criticized for his allegedly cursory treatment of technical progress: one instance can be found in *The Logic of Political Economy* written a quarter of a century later (1844) by his follower Thomas de Quincey.

With Karl Marx, the concept of production acquires new and wider meanings; in a sense it leaves the narrow field of economic theory to become the cornerstone of a general theory of social systems and of history (the development of material production, notes Marx in the first book of *Capital*, is) 'the basis of any social life and of any true history'). The starting point of the analysis is the notion of production in its elementary form: men produce the necessaries for their existence; their productive activity is labour, which materializes into products. In other words, men produce the conditions for their material life. What men are is then determined by production; more specifically, by what is produced and by the way in which it is produced.

Production is essentially a social process: there are no 'natural laws' to be investigated, but social relations which are historically determined. These relations constitute the structure of society and determine its material and intellectual way of life. The evolution of religion, ethics, art and government is an ultimate consequences of the evolution of the social relations of production.

In his justly famous preface to the *Critique of Political Economy*, Marx has left a very effective summary statement of this approach:

> In the social production which men carry on they enter into definite relations that are independent of their will; these relations of production correspond to a definite stage of development of their material powers of production. The sum total of these

> relations of production constitutes the economic structure of society – the real foundation on which rise the legal and political superstructures and to which correspond definite forms of social consciousness. The mode of production in material life determines the general character of the social, political, and spiritual processes of life. It is not the consciousness of men that determines their existence, but, on the contrary, their social existence determines their consciousness. (Marx 1859, p. 100)

Production, distribution, exchange and consumption cannot be grasped in their essence but as successive moments of a unique circular process, thoroughly determined by the social conditions of production. Marx reproaches political economy for having arbitrarily separated the sphere of production, regulated by allegedly universal laws, from that of distribution, where we can take account of the social environment.

The search for universal laws of production has in turn led the economist to concentrate upon the trivial aspects of the phenomenon and to overlook the questions that are truly essential in investigating the present mode of production. For example, having defined as capital the set of the means of production, and having observed the obvious fact that men have always needed some kind of instrument to produce, the economists are ready to attribute a universal and ahistorical validity to the notion of capital. In this way, they have simply swept aside the key question: what is the socially determined relationship which turns an instrument used in production into 'capital'?

The formation of classical political economy historically coincided with the development of the factory system in manufacture. An early description of an integrated production process is offered by William Petty (1683) with reference to the watch trade. Another obvious reference is the famous pin factory described by Adam Smith in the first chapter of the *Wealth of Nations* (1776). In both cases, the division of labour is presented as the main virtue of the new form of productive organization: provided that the extent of the market is sufficient, it is maintained that output can be expanded more than proportionately with the labour employed in manufacture (increasing returns to scale).

Marx used these two examples to draw a distinction between the 'heterogeneous' manufacture (exemplified by Petty's watch-making activity) in which the final output is obtained by simple assemblage of 'partial and independent products', and the more sophisticated 'organic' manufacture (exemplified by Smith's pin factory) in which a series of successive operations gradually transforms the original raw material into the finished product.

Smith referred to three arguments in favour of the technical superiority of an ever increasing division of labour:

> first, to the increase of dexterity in every particular workman; secondly, to the saving of the time which is commonly lost in passing from one species of work to another; and lastly, to the invention of a great number of machines which facilitate and abridge labour, and enable one man to do the work of many. (Smith 1776, p. 17)

It has been observed that these arguments are not truly convincing. The importance attributed to increased dexterity conflicts with the relatively low level of skills required in contemporary factories (witness the common use of child labour). Time saving does not imply specialization by individuals: in principle, it could equally be attained by a suitable reorganization of the activity of a single artisan. And the introduction of machines does not seem to exhibit any necessary relation to the increasing division of tasks.

In fact the new organization of labour associated with the factory system did go along with the process of technical change associated with the Industrial Revolution. But its original role was primarily to discipline the manner in which the work was performed and to give the capitalist the power of controlling the production process in every single detail.

The introduction of machinery came after labour specialization and reinforced the need for a thorough organization of production. The effects of the introduction of the steam-engine and other complex machines were eventually studied by two scholars who possessed the necessary technical background, Charles Babbage (1832) and William Ure (1835); their tracts were very popular at the time and were widely used by the economists

(for example, by John Stuart Mill and Marx). They conceived of the control and management of a factory as that of a single complex machine, under the full control of the capitalist and with manual work brought to a minimum.

It is worth noticing that these speculations about the rational management of a highly mechanized factory were easily extended to society as a whole. At the turn of the century, Mikhail Tugan-Baranovsky (1905) dreamed of an economy in which machines were automatically produced by machines, and where the labour force was paradoxically reduced to one worker alone. In a similar vein, especially in Germany after the First World War, we find many suggestions for a 'rational' organization of the economy as if it were a giant *Konzern* (as an extreme example, see the 'natural economy' proposed by Otto Neurath (1921) for the ephemeral Bavarian republic).

Classroom Peer Effects

Jane Cooley

Abstract

A central objective of studies of peer effects in education production is to determine whether certain groupings of students can improve academic achievement. This article describes the challenges associated with identifying peer effects in education production and some solutions offered by the literature. We then review some of the existing evidence on peer spillovers and avenues for future research.

Introduction

A central objective of studies of peer effects in education production is to determine whether certain groupings of students can improve academic achievement. For instance, do students benefit from being grouped with students of similar ability (academic tracking)? Do tracking policies

benefit higher ability students at the expense of lower ability students? Do mixed ability classrooms benefit lower ability students at the expense of those of higher ability? Do single-sex classrooms improve achievement for boys and girls? Does racial or socioeconomic integration improve achievement of traditionally disadvantaged students? Is racial integration more effective than socioeconomic integration at narrowing racial achievement gaps? What classroom groupings are most efficient?

Research that seeks to inform these policies can broadly be divided into two classes: event studies and achievement production studies. Event studies consider, for instance, actual events of desegregation (e.g. Guryan 2004; Harris 2007) or contrast academic tracking with mixed ability settings either internationally or across schools (see Gamoran 2009, for a recent overview). A key challenge for these studies is to separate a peer effect from disparities in difficult-to-measure resource inputs across settings. In the case of desegregation, black students may face lower resources or teacher quality prior to desegregation than in the integrated setting. In the case of tracking, teachers may teach differently in mixed ability than in tracked classes, or higher quality teachers may be assigned to higher ability tracks. Separating the effect of resources from peers can be important because it is possible, at least in principle, to reallocate resources without manipulating peer groups.

Another class of studies uses an achievement production framework and exploits variation in the composition of students across a set of classrooms, year groups, or schools to determine how different peer groupings affect student outcomes. In this case, instead of directly examining the policy, such as tracking or desegregation, these studies consider how higher percentages of nonwhite or higherachieving peers affect student performance. Like the event studies described above, achievement production studies also face the identification problem of separating peer effects from resources that may be correlated with observed student groupings. However, the key advantage of these studies is to begin to separate different sources of peer effects. For instance, if mixed ability classrooms are also more racially diverse, is it the ability of students or their racial composition that drives improvements in achievement? The attempt to disentangle channels of peer influence is fraught with its own set of challenges, as discussed below (see Cooley 2009).

As the literature on peer effects is extensive, evidence from only a small sample of recent studies is discussed. In particular, the focus is on achievement production types of studies. These are becoming increasingly common, particularly given new panel data sources on student achievement and peer groups, such as the state administrative data sets in the USA. We describe the identification challenges for these studies in more detail, some solutions offered in the literature, and the potential of these studies to inform policy.

Identification Challenges

Studies of peer effects in education production often take as a starting point a linearin-means production function. This provides a simple context to describe the basic challenges for identifying peer effects. Let Y_{igt} denote student i's achievement in peer group g at time period t. X_{it} denotes observed individual characteristics, which often include parental education, race, sex, and some measure of income. K_{gt} captures observed classroom inputs, such as teacher experience or expenditure, and μ_{gt} captures unobserved inputs, such as unobserved teacher quality. Achievement production is then

$$Y_{igt} = X_{it}\gamma_x + \overline{X}_{-igt}\gamma_{\overline{x}} + K_{gt}\gamma_k + \overline{Y}_{-igt}\gamma_{\overline{y}} + \mu_{gt} + \varepsilon_{igt}, \quad (1)$$

where peer spillovers derive from both mean peer characteristics $\overline{X}_{-igt}$ (contextual or exogenous effects) and mean peer achievement $\overline{Y}_{-igt}$ (the endogenous effect), using the language of Manski (1993). Often these specifications are estimated as valueadded models, conditioning on a student's lagged peer achievement to help control for prior inputs to achievement.

There are several challenges with identifying a causal effect of peers. First, unobservable shared effects (μ_{gt}) may be correlated with peer characteristics. This could occur through selection (nonrandom assignment) into classrooms or schools. It could also be the case that these unobservables vary systematically with the composition of the peer group if, for instance, teachers teach differently with different sets of students. Random assignment to peer groups would not eliminate the latter effect, and most peer effect studies implicitly attribute these types of reallocations in teacher effort to peers.

In this setting, random assignment is sufficient to recover a reduced form effect of peer characteristics. To see this, solve for average peer achievement and substitute back into equation (1). Then we have the reduced form equation for peer achievement:

$$Y_{igt} = \pi_0 + X_{it}\pi_x + \overline{X}_{-igt}\pi_{\bar{x}} + K_{gt}\pi_k + \pi_\mu \mu_{gt} + \zeta_{igt}, \quad (2)$$

where $\frac{\pi_{\bar{x}}=\gamma_{\bar{x}}(N-1)+(N-2)\gamma_{\bar{x}}\gamma_{\bar{y}}+\gamma_x\gamma_{\bar{y}}+\gamma_{\bar{x}}(N-2)}{(N-1)-(N-2)\gamma_{\bar{y}}-(N-1)\gamma_{\bar{y}}^2}$. Random assignment helps ensure that $\overline{X}$ is independent of μ_{gt}, which would permit the identification of the reduced form effect of peer characteristics, $\pi_{\bar{x}}$, given $E(\zeta_{igt}|X_{it}, \overline{X}_{-igt}, K_{gt}) = 0$. Using Manski (1993)'s terminology, $\pi_{\bar{x}} \neq 0$ means that *social effects* exist, in that either $\gamma_{\bar{x}} \neq 0$ and/or $\gamma_{\bar{y}} \neq 0$.

Second, even if students are randomly assigned to classrooms and peer characteristics satisfy some sort of independence with unobserved shared group inputs, there still exists the challenge of determining the causal mechanism of the peer effect. For instance, if ability is unobservable and correlated with observed characteristics X, it may not be possible to separate out an effect of the observed characteristic from unobservable ability.

Furthermore, it may not be possible to separate contextual ($\gamma_{\bar{x}}$) from endogenous ($\gamma_{\bar{y}}$) peer effects because of the simultaneity problem. Moffitt (2001) points out that what makes this simultaneity problem particularly difficult is the lack of compelling exclusion restrictions, a policy that shifts one student's achievement independently of his peers. Brock and Durlauf (2001a, b) make the important point that the identification challenge stems from the particularly restrictive functional form chosen in the linear-in-means model. In a more general nonlinear model, such as simply focusing on median rather than mean peer achievement, $\gamma_{\bar{y}}$ is identified (at least in a random assignment setting absent correlated unobserved shared inputs).

As discussed by Manski (1993) and others, endogenous and exogenous peer effects have quite different implications for policy, so addressing the simultaneity problem may be important. In particular, endogenous effects entail *social multipliers*, whereas exogenous effects do not. A social multiplier occurs when the improvement to one student's achievement leads to improvements in their peers. This would multiply any redistribution of resources among students. To consider an example, suppose there are only spillovers from peer ability. If all students benefit from higher peer ability, switching from tracked to mixed-ability classrooms leads to improvements for lower-ability students at the expense of higher-ability students. In contrast, if social multiplier effects exist, the losses (gains) to higher- (lower-) ability students from lower- (higher-) ability peers are partially offset by improvements (losses) in the achievement of their lower- (higher-) ability peers through the social multiplier.

Evidence of Social Effects

The vast majority of achievement peer effect studies focus on determining the social effect of peers. This reduced form estimate of peer effects is intuitively appealing, as many assignment policies are based directly on student observable Xs, as described in the above model. The actual mechanism of peer influence (endogenous or exogenous effects) may not be important. Similarly, whether the peer effect derives directly from the observable characteristic or correlated unobservable characteristics of the students may be a secondary concern. For instance, if the policy question is racial integration, it may not matter whether the

peer effect derives from race or other unobservables correlated with race.

Given that the objective is to determine the existence of a peer effect based on observable attributes of the students, selection of students into peer groups is the key challenge for these studies. While studies have found evidence of peer effects in the college setting using random assignment (See Carrell et al. 2008; Sacerdote 2001; Zimmerman 2003), random assignment to peer groups is much rarer in elementary and secondary school settings. Tennessee's Student Teacher Achievement Ratio project (Project STAR) is a notable exception. In this experiment, elementary students were randomly assigned to classrooms within schools. Graham (2008) and Boozer and Cacciola (2001) exploit the random assignment along with random variation in class size and find evidence of significant effects of being grouped with higher ability peers on student achievement.

Similar in spirit, quasi-experimental designs often exploit longitudinal data on student achievement to isolate plausibly random variation in peer groups to identify peer effects. For instance, Hoxby (2000) and Hanushek et al. (2009) attempt to isolate idiosyncratic variation in year-group-level peer composition across cohorts within schools to identify peer effects using Texas public school administrative data. The basic intuition is that while students may be systematically assigned to classrooms within a school, the year-group-level peer groups in a given year vary only for random reasons, such as differences in the birth cohort. In other settings, Lavy and Schlosser (2007) and Lavy et al. (2008) consider peer effects in Israeli schools; Ammermueller and Pischke (2009) provide interesting across country comparisons, relying on random assignment within schools.

While most studies focus on observable peer characteristics, Arcidiacono et al. (2010) develop an innovative, iterative approach to recovering spillovers from unobservable peer "ability", recovered as a persistent component of peer achievement (See Burke and Sass 2006, for an application in the elementary setting).

Behavioural Spillovers

While the above-mentioned studies provide important and compelling evidence of the existence of peer effects, they do not distinguish between spillovers deriving from peer characteristics and endogenous peer effects that would arise through behavioural spillovers among students within peer groups. Increasingly, evidence suggests that behavioural spillovers in the classroom exist.

Kinsler (2010) and Figlio (2007) show that having disruptive peers negatively affects student achievement. Lavy et al. (2008) find that having a higher proportion of repeaters has negative consequences on the classroom environment (as measured through survey questions). In related work, Lavy and Schlosser (2007) find that having more girls improves the classroom environment. Bishop et al. (2003) use unique survey data on high school students and find that peer pressure is a significant determinant of student effort and achievement at school. Fryer and Torelli (2005) find racial disparities in how academic achievement affects popularity, positing that black students face different social pressures than white students. Cipollone and Rosolia (2007), Gaviria and Raphael (2001), Nakajima (2007), Krauth (2005) find evidence that peers affect the decision to drop out of high school, and other behaviours, such as alcohol consumption, smoking or drug abuse, that may affect school achievement.

The evidence above strongly suggests that peer behaviour may affect students' behaviours in various ways. Absent direct measures of these behaviours, the achievement production framework captures these in peer achievement. For instance, harder-working, better-behaved students are higher-achieving. Students may benefit simply because the classroom learning environment with harder working (higherachieving) peers is more productive (e.g. Lazear 2001). Students could also benefit if they work harder because their peers are working harder, as implied by the other types of behavioural spillovers discussed above (See Bishop 2006; Akerlof and Kranton 2002).

Yet, because of the difficult simultaneity and the lack of clear exclusion restrictions, there is

little evidence regarding the effect of contemporaneous peer achievement on a student's achievement. Cooley (2010) illustrates potential sources of exclusion restrictions in the achievement production context. For instance, Cooley (2010) uses a policy that has differential effects on student incentives within the same classroom to address the simultaneity problem in achievement and finds evidence of large endogenous peer effects. This strategy is similar in spirit to strategies used in studies of behavioral peer effects in other settings, such as Cipollone and Rosolia (2007).

An alternative potential source of instruments is offered by partially overlapping peer groups, as discussed in Bramoulle et al. (2009), Giorgi et al. (2010), Cohen-Cole (2006) and others. The intuition (in its most basic form) is that if students A and B are grouped together in one setting, students B and C in another setting and A and C are never grouped together, then A provides an exclusion for determining the effect of B on C. This follows because A only affects C through his affect on B.

Nonlinearities

A well-known limitation of the linear-in-means model of achievement production with peer spillovers is that average achievement remains unchanged regardless of the grouping; the benefits to one group are perfectly offset by the losses to another. The literature recognizes this shortcoming and generally pays considerable attention to potential heterogeneity in peer effects. Studies find evidence of heterogeneity by race, gender and student ability (e.g. Hanushek et al. 2009; Gibbons and Telhaj 2006; Cooley 2010; Hoxby and Weingarth 2005; Lavy et al. 2008). In perhaps the most systematic investigation of nonlinearities in peer effects, Hoxby and Weingarth (2005) investigate a variety of potential models of peer effects and find that accurately accounting for nonlinearities in spillovers from lagged peer achievement (rather than just focusing on averages) eliminates much of the apparent spillovers from other observable peer characteristics.

Policy Implications

In contrast to the event studies described above, a limitation of the peer effects in achievement production studies is that generally the parameters estimated in these models are not directly applicable to reassignment policies. For instance, estimates of the effect of racial composition conditional on socioeconomic status may be interesting in principle, but not a feasible policy to implement in practice if race is correlated with SES. Furthermore, while studies generally find that achievement is negatively affected by higher percentages of nonwhite students (see, for instance, Hanushek et al. 2009), it would not be possible to lower the nonwhite percentage for all students. Put differently, these parameters can only be interpreted in a partial equilibrium sense.

In part, this limitation of the achievement production framework can be overcome by simulating the effect of different assignment policies by, for instance, randomly assigning students to classrooms and predicting the resulting achievement using the achievement production parameter estimates, as in Cooley (2010). Of course, the related challenge with moving to this type of general equilibrium context is that students cannot simply be sorted at will by policy makers. Thus, ultimately incorporating peer effect estimates into some of the existing general equilibrium locational sorting frameworks (e.g. Bayer et al. 2007; Ferreyra 2007; Nechyba 2000) is likely to be a useful way forward.

Graham et al. (2008) offer an innovative approach to this problem, moving beyond the achievement production framework to focus on estimating policyrelevant parameters. They directly characterize the effect of reallocations of students on the distribution of outcomes, particularly focusing on a model with two types of student (e.g. white and nonwhite). An appealing feature of this method is that it does not rely on distinguishing between the different micromechanisms of peer influence.

While this is a very useful approach, Cooley (2009) shows that when endogenous peer effects are heterogeneous (implying heterogeneous social multipliers) and there is sorting in the data, reduced

form estimates of the social effect of peers are often not sufficient to determine the effects of reallocations. Intuitively this follows because reassignment of students to classrooms also, by necessity, reallocates the unobserved group input (such as teacher quality) among students. This creates social multipliers that the reduced form estimator, even if estimated very flexibly, generally cannot predict when there is heterogeneity in student responses to peers. Evidence in the literature on exogenous peer effects and behavioural spillovers discussed above is strongly suggestive of heterogeneous endogenous peer effects. However, whether this is quantitatively important for understanding distributional consequences of reallocations remains to be determined.

Another important area of future research is likely to be the dynamics of peer effects, i.e. how peer effects vary with student age and over time. Vigdor and Nechyba (2007) and Carrell et al. (2008) find evidence that the effect of peers may persist over time. Studies, such as those by Todd and Wolpin (2003) and Cunha and Heckman (2007), show that the schooling dynamics generally are important for understanding human capital accumulation. The logic in these studies may extend to peer effects in important ways. Research on how the history of peer inputs determines achievement and the nature of social interactions in the classroom may further help inform school policy related to the age at which school choice policies, desegregation or academic tracking should be implemented.

In conclusion, it is worth noting that a better understanding of the role of peers in education production has implications far beyond the types of policies described above that are directly aimed at regrouping students. Many policies also indirectly affect student groupings. Most notably, various school choice mechanisms may have big effects on the composition of schools and classrooms. Evidence of peer effects also helps inform policies that are not directly targeted at schools. For instance, given that school composition is often closely tied to residential location, peer effects are important for understanding the broader implications of changes in property taxes or other policies that affect residential sorting patterns.

Cliffe Leslie, Thomas Edward (1827–1882)

J. Maloney

T.E. Cliffe Leslie was both the pioneer (with J.K. Ingram) and the most radical member of the English Historical School. Born in Co. Wexford, he was educated at King William's College, Isle of Man, and at Trinity College, Dublin. In 1853 he became professor of jurisprudence and political economy at Queen's College, Belfast. His inaugural lecture 'The Military Systems of Europe Economically Considered' was published in

1856 and set the empirical, comparative tone that informed all his work. It was, however, Leslie's Irish context that did most to sharpen his onslaught on orthodox economics. To the Irish tenant-farmers, lacking either security of tenure or the right to be compensated for improvements they had made, liberal economists offered only free trade and the assurance that no good could come from specific legislation for Ireland. Thus Robert Lowe (shortly to become Gladstone's Chancellor) in 1868 urged Parliament to oppose land reform 'with the principles of political economy'. That Mill dissented, supporting what eventually became the Irish Land Act of 1870, was perhaps the crucial episode in Leslie's becoming a self-proclaimed disciple of Mill.

In 1870 Leslie published a volume of essays entitled *Land Systems and the Industrial Economy of Ireland, England and Continental Countries*. Highly praised by Mill in the *Fortnightly Review*, it was the last and most important of his works directly on the Irish question. In the same year he fired his opening salvo in the English *Methodenstreit* with 'The Political Economy of Adam Smith' (1888). Here Leslie lauded Smith as an inductive, historically minded economist whose brand of economics should never have been supplanted by the grotesque abstractions and unbalanced methodology of Ricardo. In 'On the Philosophical Method of Political Economy' (1888), Leslie reiterated that man was not, as the classical economists had assumed, a being whose 'great variety of different and heterogeneous motives' could be compounded into a homogenous desire for wealth when deductive analysis was required. He went on to attack orthodox political economy for its failure – inability, indeed, as it stood constituted – to go behind the individual economic agent and weigh up the social and historical forces moulding his actions and preferences. But perhaps his most radical paper, and certainly the one which strikes the strongest chord today, is 'The Known and the Unknown in Economics' (1888), in which the limits of the economist's information – and the blithe unconcern of many economists about the fact that these limits exist – are laid sharply bare. Here, again, historical relativism is the mainspring, Leslie arguing that only in a primitive village economy, with predictable 'reproduction' of economic activities and prices set by custom, can the economist have something approaching complete knowledge. When prices are set in a competitive market, when credit and default weaken certainty and trust, when technical change accelerates to the point where products rapidly become obsolete, then universalist economic 'laws' represent little more than an (unwitting) confession of ignorance as to the really important features of any particular episode until it can be written up from a historian's perspective.

Leslie's intended *magnum opus*, a work on the economic and legal history of England, had only reached manuscript stage when he lost it in France in 1872. For the remaining ten years of his life, his contribution was more critical than constructive. However, in the 1870s, radical criticism of deductive economics was badly needed, as both Marshall and John Neville Keynes were later to admit.

Climate Change, Economics of

Lawrence H. Goulder and William A. Pizer

Abstract

Climate-change economics attends to the various threats posed by global climate change by offering theoretical and empirical insights relevant to the design of policies to reduce, avoid,

or adapt to such change. This economic analysis has yielded new estimates of mitigation benefits, improved assessments of policy costs in the presence of various market distortions or imperfections, better tools for making policy choices under uncertainty, and alternative mechanisms for allowing flexibility in policy responses. These contributions have influenced the formulation and implementation of a range of climate-change policies at domestic and international levels.

Q54

The prospect of global climate change has emerged as a major scientific and public policy issue. Scientific studies indicate that human-caused increases in atmospheric concentrations of carbon dioxide (largely from fossil-fuel burning) and of other greenhouse gases are leading to warmer global surface temperatures. Possible current-century consequences of this temperature increase include increased frequency of extreme temperature events (such as heat waves), heightened storm intensity, altered precipitation patterns, sea-level rise, and reversal of ocean currents. These changes, in turn, can have significant impacts on the functioning of ecosystems, the viability of wildlife and the well-being of humans.

There is considerable disagreement within and among nations as to what policies, if any, should be introduced to mitigate and perhaps prevent climate change and its various impacts. Despite the disagreements, in recent years we have witnessed the gradual emergence of a range of international and domestic climate- change policies, including emission-trading programmes, emission taxes, performance standards, and technology-promoting programmes.

Beginning with William Nordhaus's 'How fast should we graze the global commons?' (Nordhaus 1982), climate-change economics has focused on diagnosing the economic underpinnings of climate change and offering positive and normative analyses of policies to confront the problem. While overlapping with other areas of environmental economics, it has a unique focus because of distinctive features of the climate problem – including the long time-scale, the extent and nature of uncertainties, the international scope of the issue, and the uneven distribution of policy benefits and costs across space and time.

In our discussion of the economics of climate change, we begin with a brief account of alternative economic approaches to measuring the benefits and costs associated with reducing greenhouse gas emissions, followed by a discussion of uncertainties and their consequences. We then present issues related to policy design, including instrument choice, flexibility, and international coordination. The final section offers general conclusions.

Assessing the Benefits and Costs of Climate Change Mitigation

Climate Change Damages and Mitigation Benefits

As noted, the potential consequences of climate change include increased average temperatures, greater frequency of extreme temperature events, altered precipitation patterns, and sea-level rise. These biophysical changes affect human welfare. While the distinction is imperfect, economists divide the (often negative) welfare impacts into two main categories: *market* and *non-market* damages.

Market Damages As the name suggests, market damages are the welfare impacts stemming from

changes in prices or quantities of marketed goods. Changes in productivity typically underlie these impacts. Often researchers have employed climate-dependent production functions to model these changes, specifying wheat production, for example, as a function of climate variables such as temperature and precipitation. In addition to agriculture, this approach has been applied in other industries including forestry, energy services, water utilities and coastal flooding from sea-level rise (see, for example, Smith and Tirpak 1989; Yohe et al. 1996; Mansur et al. 2005).

The production function approach tends to ignore possibilities for substitution across products, which motivates an alternative, hedonic approach (see, for example, Mendelsohn et al. 1994; Schlenker et al. 2005). Applied to agriculture, the hedonic approach aims to embrace a wider range of substitution options, employing cross-section data to examine how geographical, physical, and climate variables are related to the prices of agricultural land. On the assumption that crops are chosen to maximize rents, that rents reflect the productivity of a given plot of land relative to that of marginal land, and that land prices are the present value of land rents, the impact of climate variables on land prices is an indicator of their impact on productivity after crop-substitution is allowed for.

Non-market Damages Non-market damages include the direct utility loss stemming from a less hospitable climate, as well as welfare costs attributable to lost ecosystem services or lost biodiversity. For these damages, revealed-preference methods face major challenges because non-market impacts may not leave a 'behavioural trail' of induced changes in prices or quantities that can be used to determine welfare changes. The loss of biodiversity, for example, does not have any obvious connection with price changes or observable demands. Partly because of the difficulties of revealed-preference approaches in this context, researchers often employ stated-preference or interview techniques – most notably the contingent valuation method – to assess the willingness to pay to avoid non-market damages (see, for example, Smith 2004).

Cost Assessment

The costs of avoiding emissions of carbon dioxide, the principal greenhouse gas, depend on substitution possibilities on several margins: the ability to substitute across different fuels (which release different amounts of carbon dioxide per unit of energy), to substitute away from energy in general in production, and to shift away from energy-intensive goods. The greater the potential for substitution, the lower are the costs of meeting a given emission-reduction target.

Applied models have taken two main approaches to assessing substitution options and costs. One approach employs 'bottom-up' energy technology models with considerable detail on the technologies of specific energy processes or products (for example, Barretto and Kypreos 2004). The models tend to concentrate on one sector or a small group of sectors, and offer less information on abilities to substitute from energy in general or on how changes in the prices of energy-intensive goods affect intermediate and final demands for those goods.

The other approach employs 'top down' economy-wide models, which include, but are not limited to, computable general equilibrium (CGE) models (see, for example, Jorgenson and Wilcoxen 1996; Conrad 2002). An attraction of these models is their ability to trace relationships between fuel costs, production methods, and consumer choices throughout the economy in an internally consistent way. However, they tend to include much less detail on specific energy processes or products. Substitution across fuels is generally captured through smooth production functions rather than through explicit attention to alternative discrete processes. In recent years, attempts have been made to reduce the gap between the two types of models. Bottom-up models have gained scope, and top-down models have incorporated greater detail (see, for example, McFarland et al. 2004).

Because climate depends on the atmospheric stock of greenhouse gases, and because for most gases the residence times in the atmosphere are hundreds (and in some cases, thousands) of years,

climate change is an inherently long-term problem and assumptions about technological change are particularly important. The modelling of technological change has advanced significantly beyond the early tradition that treated technological change as exogenous. Several recent models allow the rate or direction of technological progress to respond endogenously to policy interventions. Some models focus on *R&D-based* technological change, incorporating connections between policy interventions, incentives to research and development, and advances in knowledge (see, for example, Goulder and Schneider 1999; Nordhaus 2002; Buonanno et al. 2003; Popp 2004). Others emphasize *learning-by-doing-based* technological change where production cost falls with cumulative output, in keeping with the idea that cumulative output is associated with learning (for example, Manne and Richels 2004). Allowing for policy-induced technological change tends to yield lower (and sometimes significantly lower) assessments of the costs of reaching given emission-reduction targets than do models in which technological change is exogenous.

Integrated Assessment

While the cost models described above are useful for evaluating the cost- effectiveness of alternative policies to achieve a given emissions target, the desire to relate costs to mitigation benefits (avoided damages) has spawned the development of *integrated assessment models.* These models link greenhouse gas emissions, greenhouse gas concentrations, and changes in temperature or precipitation, and they consider how these changes feed back on production and utility. Many of the integrated assessment models are optimization models that solve for the emissions time-path that maximizes net benefits, in some cases under constraints on temperature or concentration (see, for example, Nordhaus 1994).

Dealing with Uncertainty

The uncertainties about both the costs and the benefits from reduced climate change are vast. In a recent meta-analysis examining 28 studies' estimated benefits from reduced climate change (Tol 2005), the 90% confidence interval for the benefit estimates ranged from − $10 to + $350 per ton of carbon, with a mode of $1.50 per ton. On the cost side, a separate study found marginal costs of between $10 and $212 per ton of carbon for a ten per cent reduction in 2010 (Weyant and Hill 1999).

Uncertainty and the Stringency of Climate Policy

Increasingly sophisticated numerical models have attempted to deal explicitly with these substantial uncertainties regarding costs and benefits. Some provide an uncertainty analysis using Monte Carlo simulation, in which the model is solved repeatedly, each time using a different set of parameter values that are randomly drawn from pre-assigned probability distributions. This approach produces a probability distribution for policy outcomes that sheds light on appropriate policy design in the face of uncertainty. Other models incorporate uncertainty more directly by explicitly optimizing over uncertain outcomes. These models typically call for a more aggressive climate policy than would emerge from a deterministic analysis. Nordhaus (1994) employs an integrated climate-economy model to compare the optimal carbon tax in a framework with uncertain parameter values with the optimal tax when parameters are set at their central values. In this application, an uncertainty premium arises: the optimal tax is more than twice as high in the former case as in the latter, and the optimal amount of abatement is correspondingly much greater. The higher optimal tax could in principle be due to uncertainty about any parameter whose relationship with damages is convex, thus yielding large downside risks relative to upside risks. In the Nordhaus model, the higher optimal tax stems primarily from uncertainty about the discount rate (Pizer 1999).

The Choice of Discount Rate Under Uncertainty

The importance of the discount rate arises because greenhouse gases persist in the atmosphere for a century or more, and therefore mitigation benefits

must be measured on dramatically different timescales from those of ordinary environmental problems. A prescriptive approach links the discount rate to subjective judgements about intergenerational equity as indicated by a pure social rate of time preference (see, for example, Arrow et al. 1996). A descriptive approach relates the discount rate to future market interest rates. Under both approaches, significant uncertainties surround the discount rates. Recent work by Weitzman (1998) points out that a rate lower than the expected value should be employed in the presence of such uncertainty, a reflection of the relationships among the discount *factor*, the discount *rate*, and the time interval over which discounting applies. Put simply, the discount factor e^{-rt} is an increasingly convex function of the interest rate r as the period of discounting t increases. This implies that in the presence of uncertainty the certainty- equivalent discount rate is lower than the expected value of the discount rate: that is, $ln(\mathrm{E}[e^{-rt}])/t < \mathrm{E}[r]$. The difference between the appropriate, certainty-equivalent rate and the expected value of the discount rate widens the longer the time horizon is. While Weitzman focuses on a single uncertain rate, Newell and Pizer (2003a) show that, under reasonable specifications of uncertainty about the evolution of future market rates, this approach doubles the expected marginal benefits from future climate change mitigation compared with the estimated benefits from an analysis that uses only the current rate.

Act Today or Wait for Better Information?

In addition to concerns about convexity and valuation, uncertainty raises important questions about whether and how much to embark on mitigation activities now as opposed to waiting until at least some uncertainty is resolved. Economic theory suggests that, in the absence of fixed costs and irreversibilities, society should mitigate (today) to the point where expected marginal costs and benefits are equal. Yet climate change inherently involves fixed costs and irreversible decisions both on the cost side, in terms of investments in carbon-free technologies, and on the benefit side, in terms of accumulated emissions. These features can lead to more intensive action or to inaction, depending on the magnitude of their respective sunk values (Pindyck 2000). Despite the ambiguous theory, empirically calibrated analytical and numerical models tend to recommend initiating reductions in emissions in the present, reflecting initially negligible marginal cost and non-negligible environmental benefits (Manne and Richels 2004; Kolstad 1996).

The Choice of Instrument for Climate-Change Policy

Policymakers can consider a range of potential instruments for promoting reductions in emissions of greenhouse gases. Alternatives include emissions taxes, abatement subsidies, emission quotas, tradable emission allowances, and performance standards. Policymakers also can choose whether to apply a given instrument to emissions directly (as with an emission-trading programme) or instead to pollution-related goods or services (as with a fuel tax or technology subsidy).

Initial economic analyses of climate-change policy tended to focus on a carbon tax because it was relatively easy to model and implement. This is a tax on fossil fuels – oil, coal, and natural gas – in proportion to their carbon content. Because combustion of fossil fuels or their refined fuel products leads to carbon dioxide (CO_2) emissions proportional to carbon content, a carbon tax is effectively a tax on CO_2 emissions. In the simplest analysis, a carbon tax set equal to the marginal climate-related damage from carbon combustion would be efficiency-maximizing. However, in more complex analyses – where additional dimensions such as uncertainty, other market failures, and distributional impacts are taken into account – the superiority of such a carbon tax is no longer assured. We now consider these other dimensions and their implications for instrument choice.

Prices (Taxes) vs. Quantities (Tradable Allowances) in the Presence of Uncertainty

Theoretical and empirical work by Kolstad (1996) and Newell and Pizer (2003b) suggests that the

marginal benefit (avoided damage) schedule for emissions reductions is relatively flat. Weitzman's (1974) seminal analysis indicates that under these circumstances expected welfare losses are smaller from a price-based instrument like a carbon tax than from a quantity-based instrument like emission quotas or a system of tradable emission allowances. That is, it is preferable to let levels of emissions remain uncertain (which is the result under a tax) than to let the marginal price of emission reductions remain uncertain (which is the result under a quota). Despite these economic welfare arguments, and recent work on hybrid approaches (Pizer 2002), many environmental advocates prefer the quantity-based approach precisely because it removes uncertainty about the level of emissions.

Fiscal Impacts and Instrument Choice

A second issue stems from the potential for policies such as carbon taxes and auctioned permits to generate revenues. A number of studies show that using such revenues to finance reductions in pre-existing distortionary taxes on income, sales, or payroll can achieve given environmental targets at lower cost – perhaps substantially lower cost – than other policies (see, for example, Goulder et al. 1999; Parry et al. 1999; Parry and Oates 2000). Therefore, carbon taxes and auctioned permit programmes that employ their revenues this way will lower the excess burden from prior taxes, giving them a significant cost-advantage. Correspondingly, subsidies to emission reductions or to new, 'clean' technologies will have a cost disadvantage associated with the need to raise distortionary taxes to finance these policies.

Distributional Considerations

Despite these attractions of revenue-raising policies such as carbon taxes and auctioned tradable allowance systems, trading programmes with freely distributed permits have achieved greater popularity among policymakers. In New Zealand, for example, industry opposition led the government to drop its proposed carbon tax in 2005. At the same time, the European Union has, and Canada is planning, trading programmes where tradable permits are freely distributed, in line with virtually all conventional pollution trading programmes in the United States.

The politics may reflect differences between systems of freely allocated allowances and systems with auctioned allowances (or carbon taxes) in terms of the distribution of the regulatory burden. Under both types of emission-permit system, profit-maximizing firms will find it in their interest to raise output prices based on the new, non-zero cost associated with carbon emissions. If the allowances are given out free, firms can retain rents associated with the higher output prices, and this offsets other compliance costs. In contrast, if the allowances are auctioned, firms do not capture these rents. Thus, firms bear a considerably smaller share of the regulatory burden in the case of freely allocated permits. Indeed, Bovenberg and Goulder (2001) show that freely allocating all carbon permits to US fossil fuel suppliers generally will cause those firms to enjoy *higher* profits than in the absence of a permit system; and freely allocating less than a fifth of the permits may be sufficient to keep profits from falling. These considerations reveal a potential trade-off between efficiency and political feasibility: the revenue-raising policies (taxes and auctioned permits) are the most cost-effective, while the non-revenue-raising policies (freely distributed permits) have distributional consequences that may reduce political resistance.

Emissions Instruments vs. Technology Instruments

As noted in the cost discussion, the long-term nature of the climate-change problem makes technological change a central issue in policy considerations. Economic analysis suggests that both 'direct emissions policies' and 'technology-push policies' are justified on efficiency grounds to correct two distinct market failures. Direct emissions policies (emission trading or taxes) gain support from the fact that combustion of fossil fuels and other greenhouse-gas-producing activities generate negative externalities in the form of climate change-related damages. Technology-push policies (technology and R&D incentives)

gain support from the fact that not all of the social benefits from the invention of a new technology can be appropriated by the inventor. The latter argument applies to research and development more generally, and is especially salient if the first market failure is not fully corrected (Fischer 2004a). Numerical assessments reveal substantial cost-savings from combining the two types of policy (Fischer and Newell 2005; Schneider and Goulder 1997).

Policy Designs to Enhance Flexibility

The previous discussion indicates that no single instrument is best along all important policy dimensions, including cost uncertainty, fiscal interactions, distribution and technology development. A further issue in policy choice is how to give regulated firms or nations the flexibility to seek out mitigation opportunities wherever and whenever they are cheapest. For both price- and quantity-based policies, flexibility is enhanced through broad coverage: specifically, by including in the programme as many emissions sources as possible and by providing opportunities for regulated sources to offset their obligations through relevant activities outside the programme. For quantity-based programmes, flexibility can also be promoted through provisions allowing trading of allowances across gases, time, and national boundaries. Such flexibility is automatically provided by price-based programmes simply because they involve no quantitative emissions limits. Importantly, as quantity-based programmes provide these additional dimensions of flexibility, they reduce the efficiency arguments for price-based policies in the face of uncertainty voiced in the preceding section by providing opportunities to adjust to idiosyncratic cost shocks across time, space and industry (Jacoby and Ellerman 2004).

Flexibility Over Gases and Sequestration

So far we have focused almost exclusively on emissions of carbon dioxide from the burning of fossil fuels as both the cause of human-induced climate change and the object of any mitigation policy. Yet emissions of a number of other gases (as well as non-energy-related emissions of carbon dioxide) contribute to the problem and possibly the solution, particularly in the short run. Models suggest that half of the reductions achievable at costs of $5–$10 per ton of carbon dioxide equivalent arise from gases other than carbon dioxide. In addition, carbon sequestration can be part of the solution. Biological sequestration (for example, through afforestation) has been cited as a particularly inexpensive response to climate change (Sedjo 1995; Richards and Stavins 2005). Geological sequestration (for example, injection into depleted oil or gas reservoirs) represents a very expensive proposition now, but could be an important component of a long-term policy solution if costs decline (Newell and Anderson 2004).

Four issues can complicate the inclusion of these activities: monitoring, baselines, comparability and, in some cases, liability. First, some of these sources are fugitive emissions that are difficult to monitor at any point in the product cycle. Second, some activities, especially those involving fugitive emissions, are often left unregulated but allowed to enter as ‘offsets’, requiring a counterfactual baseline against which actual emissions levels can be measured. Fischer (2004b) evaluates various approaches to defining project baselines. Third, a problem of comparability arises with non-CO_2 gases because it is necessary to determine relative prices among greenhouse gases in a market-based programme. As a theoretical matter, the ratio of prices of a ton of current emissions of two different gases should be the ratio of the present value of damages from these emissions (Schmalensee 1993). In practice it is difficult to apply this formula because it requires a great deal of information about the damages and because it calls for time-varying trading ratios (Reilly et al. 2001), which implies significant administrative burdens. Under the Kyoto Protocol and the EU Emissions Trading Scheme, one set of trading ratios is used at all times, and the ratios are calculated by determining the ratio of warming impacts over a 100-year horizon beginning with the present time. Finally, a liability issue arises with regard to sequestration. For both biologically

and geologically sequestered carbon, a key question is who should be held liable for carbon dioxide that is released accidentally or otherwise.

Flexibility Over Time

While price policies naturally allow emissions to rise and fall in response to shocks over time, quantity-based policies must explicitly address the question of whether regulated sources can bank unused allowances for future use or, in some cases, borrow them from future allocations. In the climate change context, merely shifting emissions across time, as opposed to allowing accumulated emissions to vary, holds the environment harmless because climate consequences are generally due to accumulated concentrations, not annual emissions (Roughgarden and Schneider 1999, discuss the possibility of dependence on both accumulated concentrations and the rate of accumulation.) Such shifts across time might reflect either a more efficient choice of timing in response to capital turnover and technological progress (Wigley et al. 1996), or an attempt to ameliorate cost shocks (Williams 2002; Jacoby and Ellerman 2004). The rate of exchange between present and future emissions allowances need not be unity: Kling and Rubin (1997) show that the optimal rate at which banked allowances translate across periods should reflect the expected trend in marginal mitigation benefits, the interest rate, and decay rate of the accumulated gas.

Flexibility Over Location

The defining feature of the climate-change problem may be its intrinsically global nature. Greenhouse gases tend to disperse themselves uniformly around the globe. As a result, the climate consequences of a ton of emissions of a given greenhouse gas do not depend on the location of the source, either within or across national borders, and shifts in emissions across locations do not change global climate impacts. Under these circumstances, economic efficiency calls for making market- based systems as geographically broad as possible. It supports federal over regional policies, and international coordination over idiosyncratic domestic responses.

International Policy Initiatives and Coordination

International coordination is both crucial and exceptionally difficult to achieve. Studies indicate that the economic and social impacts of climate change would be distributed very unevenly across the globe, with the prospect of large damages to several nations in the tropics coupled with the potential for *benefits* to some countries in the temperate zones (see, for example, Tol 2005; Mendelsohn 2003). This uneven distribution makes achieving international coordination especially difficult.

The Kyoto Protocol is the first significant international effort to reduce greenhouse gas emissions. It assigns emission limits to participating industrialized countries for 2008–2012, but offers flexibility in allowing these countries to alter their limits by buying or selling emission allowances from other industrialized countries or by investing in projects that lead to emission reductions in developing countries. The importance of these flexibility mechanisms for dramatically lowering compliance costs in this international setting is well documented (Weyant and Hill 1999).

The Protocol has been criticized on the grounds that it imposes overly stringent emission-reduction targets and lacks a longer-term vision for action. In addition, a core feature of the Protocol – legally-binding emission limits – has been challenged on the grounds that such limits are not self-enforcing, an arguably necessary attribute in a world of sovereign nations (Barrett 2003). Some argue that the Protocol's project-based mechanisms for encouraging (but not requiring) emission reductions in developing countries are highly bureaucratic and cumbersome, consistent with our earlier comments about project-based programmes more generally. These criticisms have led to considerable research considering the Kyoto structure and comparing it with various alternative international approaches. Aldy et al. (2003) summarize more than a dozen alternatives, which include an international carbon tax and international technology standards.

A further major criticism is that the Protocol imposes no mandatory emissions limits on

developing countries, which collectively are expected to match industrialized countries in emissions of greenhouse gases by 2035. The desire to promote greater participation by developing countries, as well as to involve the United States in the international effort, has motivated considerable research examining, within a game-theoretic framework, the requirements for broader participation and for stable international coalitions (see, for example, Carraro 2003; Hoel and Schneider 1997; Tulkens 1998).

Conclusions

Climate-change economics has produced new methods for evaluating environmental benefits, for determining costs in the presence of various market distortions or imperfections, for making policy choices under uncertainty, and for allowing flexibility in policy responses. Although major uncertainties remain, it has helped generate important guidelines for policy choice that remain valid under a wide range of potential empirical conditions. It has also helped focus empirical work by making clear where better information about key parameters would be most valuable.

Clearly, many theoretical and empirical questions remain unanswered. We suggest (with some subjectivity) that there is a particularly strong need for advances in the integration of emissions policy and technology policy, in defining baselines that determine the extent of offset activities outside a regulated system, and in fostering international cooperation.

From 2003 until 2030 the world is poised to invest an estimated $16 trillion in energy infrastructure, with annual carbon dioxide emissions estimated to rise by 60%. How well economists answer important remaining questions about climate change could have a profound impact on the nature and consequences of that investment.

Cliometrics

Robert Whaples

Abstract

Cliometrics (from Clio, the ancient Greek muse of history) studies history by applying the rigour of economic theory and quantitative analysis while simultaneously using the historical record to evaluate and stimulate economic theory and to improve comprehension of long-run economic processes. It thus allows mainstream economists to study economic history using their familiar methods. Since the 1950s, when cliometrics demonstrated that antebellum slave-owning was profitable, it has grown to become the dominant approach to economic history. It is now addressing traditional economic historians' topics like non-market behaviour and embracing methods and findings from disciplines beyond economics.

Cliometrics aspires to enhance the study of the economic past by applying the rigour of economic theory and quantitative analysis, while simultaneously using the historical record to evaluate and stimulate economic theory and to improve comprehension of long-run economic processes (Greif 1997). The term derives from Clio, the ancient Greek muse of history.

The methodology emerged in the United States in the late 1950s among a new generation of neoclassically trained economists who found that many historical writings contained analysis, frequently implicit, that did not conform to the minimum standards of economic literacy and so led to important misinterpretations of the historical record. Pioneering the use of computers in historical research, cliometricians were able to construct extensive macroeconomic time series and also to estimate economic relationships and marginal effects. Instead of imprecise qualitative statements such as 'it is difficult to exaggerate the importance of this', cliometrics tried to provide precise numerical estimates of economic magnitudes and economic relationships.

The potential value of the new approach was convincingly displayed in one of the first cliometric papers, Alfred Conrad and John Meyer's 'The economics of slavery in the Ante Bellum South' (1958). Earlier historians had wanted to compare the profitability of owning slaves with that of other investments, but didn't know how. Conrad and Meyer derived the average capital cost per slave, including the average value of the land, animals and equipment used by a slave. Estimates of gross annual earnings were generated from data on the price of cotton and the physical productivity of slaves. Net earnings were then obtained by subtracting maintenance and supervisory costs. The average length of the stream of net earnings was determined from mortality tables. The computation for female slaves took account of the

number and productivity of offspring, plus maternity and rearing costs. Conrad and Meyer's preliminary findings strongly refuted the dominant historical interpretation that slave owning wasn't profitable. Numerous subsequent refinements confirmed their conclusion, which is now almost universally accepted.

Among the early cliometric studies that transformed historical interpretation, several works stand out, including Douglass North's *The Economic Growth of the United States, 1790–1860* (1961), Robert Fogel's *Railroads and American Economic Growth* (1964), and Fogel and Stanley Engerman's *Time on the Cross*: *The Economics of American Negro Slavery* (1974). Indeed, Fogel and North's research was so influential that in 1993 the Royal Swedish Academy cited them 'for having renewed research in economic history by applying economic theory and quantitative methods in order to explain economic and institutional change', and awarded them the Nobel Memorial Prize in Economics as 'pioneers in … cliometrics' (Royal Swedish Academy of Sciences 1993).

One can gauge the rise of cliometrics by examining the *Journal of Economic History* (*JEH*). In the early 1950s fewer than two per cent of the pages in the *JEH* were devoted to cliometric articles, that is, those using extensive quantification and explicit economic theory. This figure subsequently climbed to ten per cent in the late 1950s, 16 per cent in the early 1960s, 43 per cent in the late 1960s, and 72 per cent in the early 1970s (Whaples 1991). In the late 1950s cliometrics was seen by some as a mere fad, but by the 1970s it was the standard approach for American economic historians. The cliometric tide has not ebbed; rather, the percentage of cliometric pages in the *JEH* rose to 83 per cent in the late 1980s and 90 per cent in 2004. Opening the pages of the *JEH, Explorations in Economic History* or the *European Review of Economic History* is very much like opening the pages of other empirically oriented economics journals, allowing mainstream economists to tackle historical research by familiarizing themselves with historical issues and applying the same methods they would use elsewhere. The overlap between cliometrics and economic history as practised by economists is now almost complete, as cliometrics has become dominant among economists doing historical research outside North America.

Cliometrics is not without critics. Traditional economic historians saw the young cliometricians as outsiders, as economists, not historians or economic historians; they claimed that these upstarts were theorists with little knowledge of the facts and with no sense of history, and that their findings were driven by restrictive theoretical assumptions (Goldin 1995). The economic historian had always been a hybrid, like the mule able to work in a challenging environment because it shared its parents' best traits. The cliometrician, on the other hand, wasn't a hybrid but was akin to a horse (or, worse, a jackass) that was trying to plough a field for which it was unsuited. Many historians found cliometric methods, models and multivariate regressions incomprehensible and could no longer keep up with research in economic history. Perhaps as a result many American history departments discontinued training and hiring specialists in economic history, and departments of economic history disappeared where they had been common outside the United States.

Many cliometricians, led by Douglass North, argued that most early cliometric research was too wedded to static neoclassical theory, which tends to focus analysis on historical episodes and topics for which markets were important but which severely limits the issues that can be examined. The neoclassical approach essentially assumes that the same preferences, technology and endowment lead to a unique economic outcome, implying that history does not affect equilibrium and that institutions other than the market don't matter. As the neoclassical grip was loosened in the 1980s, many cliometricians returned to studying issues traditional to economic historians, such as the nature and role of non-market institutions, culture, entrepreneurship, institutional innovation, politics, social factors, distributional conflicts, and the historical processes of economic growth and decline (Greif 1997). The field has also stretched its boundaries by taking seriously findings and methods from disciplines outside economics, such as the use of anthropometrics (which measures human stature and even skeletal remains) and by reaching

even further into the past, such as by analysing the efficiency of the English economy in the 11th century using data from the Domesday Book.

Clubs

Suzanne Scotchmer

Abstract

The word ‘club’ has a deceptively frivolous connotation, as does the word ‘game’. But, like game theory, club theory has wide reach. By ‘club’ economists mean a small group of people sharing an activity, often in a context where they care about each other’s characteristics. Such activities may include production of goods and services (firms), production of education (schools, academic departments), sharing of private goods in small groups, and community life (churches, charity organizations). The formation of firms, choice of schools, and choice of games to play are all covered by club theory, as are social arrangements like marriage.

Origins

The word ‘club’ entered the economics literature with a seminal (1965) paper of James Buchanan, who used it to describe a group of people sharing a public good. The key idea he introduced was that public goods are often subject to congestion, and in that sense exhibit some of the rival aspect of private goods. As a consequence, it may be more efficient to replicate a public facility for different (small) groups of users rather than to bear the congestion cost imposed by many people using the same facility. As we will see, club theory has subsequently developed to focus more on interactions among the members of a group, in particular, firms, than on the facilities they share, but both aspects are important.

Buchanan’s idea resonated with an idea of Tiebout (1956), who argued that ‘local public goods’ will be provided optimally if agents are free to choose among jurisdictions. He argued

that, if jurisdictions are relatively small, there should be enough jurisdictions and jurisdictional variety to satisfy most residents.

These papers led to the conjecture, pursued by a long list of scholars (see Scotchmer 2002), that competition should provide for optimal group formation. This was by analogy to other market contexts where demand and supply equilibrate at prices that support an efficient allocation, provided that all the actors, including firms, are small relative to the market. Allowing for group formation is a powerful extension of competitive theory, since groups have features that do not fit easily into the general equilibrium theory of Kenneth Arrow, Gerard Debreu and their successors. Such features include externalities among agents, learning of skills, and shared consumption of private goods, whether through rental markets or informal arrangements.

The research agenda surrounding clubs has only recently produced the modifications to general equilibrium theory that accommodate group formation. Along the way, it has been necessary to sort out competing equilibrium concepts, and the difference between models of pure group formation, for which I use the word 'clubs', and models of group formation where membership in the group is coupled to occupancy of land. For the latter I use the term 'local public goods.'

The distinction between clubs and local public goods is the focus of Scotchmer (2002), so I will not focus on it here. Local public goods economies differ from club economies in that jurisdictions are defined by geographical boundaries, and access to local public goods is intermediated by a land market. The price of land serves two related purposes: it allocates land within each jurisdiction, and in conjunction with capitalization effects, allocates agents among jurisdictions. An important complexity is that land and local public amenities are not generally priced or consumed separately. Instead, they are bundled. Although there are two price systems, local taxes and land prices, these cannot generally be interpreted as separate prices for local public goods and land, due to the bundling and to capitalization. In this environment, there are many possibilities for how to define a commodity space and price system, none entirely satisfying. The possibilities are more limited in the club model, where there is no land market that intermediates access to groups. Nevertheless, there are many nuances in adapting general equilibrium theory to group formation, which I now explore.

Clubs (Groups) in General Equilibrium

There have been two approaches to putting clubs into general equilibrium theory, which I refer to as the EGSSZ approach and the CPPT approach. The EGSSZ approach follows Ellickson et al. (1999, 2001, 2005, referred to here as EGSZ), Scotchmer (2005), Zame (2005), and Scotchmer and Shannon (2007). The CPPT approach follows Cole and Prescott (1997) and Prescott and Townsend (2006).

I begin with the EGSSZ model, and then discuss how it relates to the CPPT model. The commodity space begins with an exogenously given set of *group types*. In a state of the economy, there may be many copies of a given group type. A group type specifies a finite set of memberships, activities that the members engage in, and an input–output vector of private goods. Thus, group types may be interpreted as firms that produce private goods or use private goods as inputs to other activities. The memberships may have qualifications attached to them, such as to be smart or brawny, or to have skills such as the ability to write computer code. These qualifications are called *membership characteristics*. A given membership may or may not be available to an agent in his consumption set and, if it is, his qualification for the membership may be innate or learned.

Using the notation of Scotchmer and Shannon (2007), let $\mathbf{G}$ be a finite set of group types, and for each $g \in \mathbf{G}$, let $\mathbf{M}(g)$ be a set of memberships. Each membership $m \in \mathbf{M}(g)$ has attached to it a membership characteristic. The definition of the group type also specifies the group's activities and an input–output vector, say $h(g) \in \mathbf{R}^N$. Some group types do not require inputs or produce outputs; some require only inputs; and some (firms) may require inputs to produce outputs. Labour in a firm is not modelled as an input but rather as a

group membership for which skills or other characteristics may be required.

It is convenient to assume that a group's required input–output vector is distributed among members of the group. Thus, each group has associated to it an exogenously given transfer function $t_g : \mathbf{M}(g) \rightarrow \mathbf{R}^N$ such that $\Sigma_{m \in \mathbf{M}(g)} t_g(m) = h(g)$. The transfers specify each member's share of h, which may have positive and negative elements. Unless used for incentive purposes as in the papers referenced in section "Unverifiable Characteristics and Games" below, the transfer functions t_g can largely be arbitrary. Any maldistribution can be remedied through membership prices, discussed below, which are endogenous.

There is a continuum of agents, say, $A = [0,1]$. Each agent consumes a bundle of private goods $x \in R^N_+$ and a *list of memberships*, $\ell : \cup_{g \in G} \mathbf{M}(g) \rightarrow \{0, 1\}$. The value $\ell(m) = 1$ means that the agent chooses membership m, hence belongs to a group of type g such that $m \in \mathbf{M}(g)$. A state of the economy is (x_a, ℓ_a), $a \in A$, where $x_a \in \mathbf{R}^N_+$ is agent a's consumption of private goods and ℓ_a is a list of memberships. Each agent $a \in A$ has a utility function u_a, an endowment of private goods, $e_a \in \mathbf{R}^N_+$, and a consumption set. The utility function takes values $u_a(x_a, \ell_a)$, where $x_a \in \mathbf{R}^N_+$ is a consumption of private goods and ℓ_a is a list of memberships.

An agent's consumption set determines which memberships are available to him. For example, an agent's consumption set would presumably not permit both a membership in a sumo wrestling club and a membership in a ballet club, since the qualifications for those memberships cannot coexist in the same agent. Consumption sets play a much larger role in club theory than in private-goods economies. Some memberships may not be available to a given agent at all, regardless of what other memberships he chooses or what private goods he invests.

A state of the economy is feasible if it satisfies material balance in private goods, and if, in addition, membership choices are consistent with each other. Membership choices are *consistent* if there exist non-negative real numbers $\alpha(g)$, $g \in \mathbf{G}$, such that the number (measure) of agents who choose each membership $m \in \mathbf{M}(g)$ is $\alpha(g)$. Thus, $\alpha(g)$represents the number of type-g groups, and consistency implies that there are (almost) no groups that are only partially filled.

Consistency of membership choices presents the main technical difficulty in this model. The fixed point in the EGSZ (1999) proof of existence delivers prices such that membership choices are consistent. There is no analogous consistency condition for private-goods exchange economies, and consistency would typically be impossible if the club economy had a finite number of agents rather than a continuum.

To define equilibrium, we need two sets of prices: private-goods prices $p \in \mathbf{R}^N_+$ and membership prices $q : \cup_{g \in G} \mathbf{M}(g) \rightarrow \mathbf{R}$. The membership prices can be positive or negative. An agent's budget is determined by the value of his endowment and the value of the transfers he receives (or is obligated for) in his memberships, evaluated at the equilibrium private goods prices p. These must generate enough income to pay for his memberships at prices q and for his private goods consumption at prices p.

Stated informally, an equilibrium consists of private goods prices p, membership prices q, and an allocation (x_a, ℓ_a), $a \in A$ such that each agent is optimizing in his budget set; supply equals demand for private goods; the membership choices are consistent; and the membership prices sum to zero in each group type. Thus, the profit in each group is shared among the members – there is no notion of ownership of groups or group types.

Since the membership prices sum to zero within each group, some members pay other members. Intuitively, some members are paid because they create positive externalities or production opportunities for the members who pay. If, for example, there is a membership that relatively few agents are qualified to fill, or if it is costly to acquire the qualification, then that membership may have a negative price – the member is paid to belong to the group.

All the technical difficulties of general equilibrium theory appear here, such as the distinction between quasi-equilibrium and equilibrium. The technical difficulties in going from

C

quasi-equilibrium to equilibrium are exacerbated by group formation, since, for example, the inputs required for the group can exhaust the endowment of the members, who are then in the zero-wealth position. (See Gilles and Scotchmer 1997, example 3.)

I now give two informal examples of how club theory expands the reach of general equilibrium theory. First, let the group type be a firm that uses inputs to produce outputs. The required labour, with its required skills, is modelled through group memberships. The required skills might be innate for some workers, but for others might have to be acquired through investments of private goods or memberships in other group types, such as schools or apprenticeships. The negative elements of the input–output vector $h(g)$ are inputs, and the positive elements are the firm's output. These inputs and outputs are divided up among the workers (members) according to the transfer function t_g, and ultimately bought or sold in the market. The transfers contribute to the members' incomes. However, the income from the firm is further redistibuted through the endogenous prices (wages) q.

Substitution in the production process is modelled by using different firm types. If it is possible, for example, to produce the same input/output vector with many unskilled workers or with fewer skilled workers, those options would be modelled as different firm types. Whether a given firm type is used in equilibrium depends on the prices of private goods and memberships, the opportunity costs of workers (reflected in membership prices), and 'externalities' created within the firm type. Agents might avoid a very profitable technology because they dislike the production process or because they dislike the characteristics required of the other workers. This feature of production economies is not otherwise accommodated in general equilibrium theory.

Firms are perfectly competitive because each firm of a given firm type has measure zero in the economy, and therefore has no market power. Each firm makes zero profit even though there is no concept of linearity in production. The only constant returns to scale is that many copies of a given firm type may form, each producing the same output from the same inputs. However, each copy of the group type is a separate zero-profit entity.

Second, let the group type be a school. Suppose for simplicity that there are no private goods inputs or outputs, hence no internal transfers. Some of the memberships are called 'teacher' , and others are called 'student'. The same person is typically not qualified for both roles. The student memberships may be further differentiated. Some student memberships may be called 'advantaged student' (and require the appropriate qualification) and others 'disadvantaged student'. Which membership a student is qualified for is presumably constrained in his consumption set.

Since the membership fees sum to zero, the teacher will presumably be paid, and the students will pay. However, if advantaged students confer positive externalities on disadvantaged students, it might occur that both teachers and advantaged students are paid by disadvantaged students. Otherwise the advantaged students might prefer schools where all memberships are for advantaged students, where they themselves receive higher externalities.

The model I have described is a delicate amalgam of features inherited from the theory of general equilibrium for exchange economies and features of public goods economies, such as externalities and the sharing of private goods. In general equilibrium theory, the key features of a competitive equilibrium are that (*a*) the commodity space is defined independently of the set of agents, (*b*) the price system is complete with respect to the set of commodities, (*c*) prices are anonymous, and (*d*) agents optimize with respect to the price system, but not by observing other agents' preferences or endowments. Early discussions of price-taking equilibrium for club economies missed various of these requirements. For example, in analyses that use the 'core' equilibrium concept from game theory, following Pauly (1967), the commodity space has been defined as the set of groups (coalitions) that are feasible in the economy, even when the core is decentralized with prices. This idea departs from general equilibrium theory in that the available commodities

(group types) depend on the set of agents. That model has other limitations as well. Since agents can only belong to a single club, it cannot accommodate the notion that an agent may want to belong to several groups, for example, a school where he acquires skills and a firm where he exercises the skills. Further, many of the earlier models also restricted to a single private good (often with transferable utility), and therefore did not allow the important interpretation that groups are firms in a production economy.

In the model I have described, following EGSZ (2005) and Scotchmer and Shannon (2007), characteristics are defined as part of the membership, rather than attached to the agent. An agent can only choose a given membership if he is innately endowed with the characteristic required for it or, alternatively, can acquire it. The earlier models of EGSZ (1999, 2001) made the more restrictive assumption that all characteristics are innate, but the same proofs of existence of equilibrium and related theorems apply to both cases.

Randomized Memberships

In the model described above, agents choose memberships deterministically. However, the premise behind the CPPT branch of the clubs literature is that randomness can be utility enhancing, and randomness will therefore be created by the market. This depends on the premise that utility functions can be interpreted as von Neumann–Morgenstern utility functions (not assumed in the EGSZ model), and is illustrated by the following example.

Suppose there are two firm types, g_1 , $g_2 \in \mathbf{G}$. The firm type g_1 has a single worker and g_2 has a worker and supervisor. The club memberships are $\mathbf{M}(g_1) = \{m_{w1}\}$, $\mathbf{M}(g_2) = \{m_s, m_{w2}\}$. Suppose that each agent can choose a single membership, that a third of the agents have consumption sets that permit supervisor memberships, m_s, and two-thirds of the agents have consumption sets that permit worker memberships, m_{w1} or m_{w2}. There is a single private good, of which each agent has an endowment e. The utility of supervisors is equal to their consumption of the private good, regardless of memberships, and the utility of each worker is the following, where c is his consumption of the private good, and f is positive and increasing.

$$u(c,\ell) = \begin{cases} \frac{1}{2}f(c) & \text{if} \quad \ell = 0 \\ f(c) & \text{if} \quad \ell(m_{w1}) = 1 \\ f(c)+1 & \text{if} \quad \ell(m_{w2}) = 1 \end{cases}.$$

In an EGSZ-type equilibrium, the prices of memberships are $q(m_{w1}) = 0$ and $q(m_s) = -\hat{q}$, together with price $p = 1$ for the private good, where $f(e-\hat{q})+1 = f(e)$. Workers receive utility $f(e) = f(e-\hat{q})+1$ and supervisors receive utility $e+\hat{q}$. The supervisors are paid by the workers because agents who are qualified to be supervisors are relatively scarce and therefore valuable. They facilitate the creation of high value in supervised firms.

The basic idea of the clubs model of Cole and Prescott (1997) can be seen in the example. If the workers' utility function can be interpreted as a von Neumann–Morgenstern utility function, and if f is concave, the EGSZ-type equilibrium is not efficient. The expected utility of workers can be increased without decreasing the utility of supervisors by equalizing the workers' consumption in the two memberships m_{w1}, m_{w2}, and letting them randomize on those two memberships. The equalized consumption is $\hat{c} = (1/2)(2e-\hat{q})$. Then the *ex post* utility of workers who end up in m_{w1} is less than the *ex post* utility of workers who end up with m_{w2}, but their *ex ante* expected utility is the same, namely, $(1/2)f(\hat{c}) + (1/2)(f(\hat{c})+1) = f(\hat{c}) + (1/2)$, and larger than $f(e)$.

Cole and Prescott argue that the randomized outcome can be achieved in two ways. The agents can buy lotteries on club memberships directly, or the agents can buy randomizations on wealth and then choose their club memberships deterministically as in the EGSZ model. In the first implementation, prices are on units of probability placed on different consumption bundles. In the example, consumption bundles would be elements of some finite set $\mathbf{L} = \{(c,m)\}$, where, for mathematical convenience, c is in a finite set of points in $\mathbf{R}_+$ and $m \in \{m_s, m_{w2}, m_{w1}, m_o\}$, where m_o is a null membership that means no group membership is chosen.

The prices are $\{p(c, m) \in \mathbf{R}_+ : (c, m) \in \mathbf{L}\}$. If an agent chooses a consumption bundle (c,m) with probability one, he pays $p(c,m)$. More generally, an agent can choose probabilities (a 'lottery') $\{x(c, m) \in \mathbf{R}_+ : (c; m) \in \mathbf{L} \sum_{(c, m) \in \mathbf{L}} x(c; m) = 1\}$. It is then natural to define the utility function on the vectors x, so that the agent receives utility $u(x)$ and pays $p \cdot x$.

This transformation, also used by Prescott and Townsend (2006), gives the group-formation model a structure that is similar to an exchange economy. However, for analytical tractability some desirable features are given up along the way, such as that the authors assume there is a finite set of preference types, and restrict each agent to a single membership.

Moreover, there is a single profit-maximizing 'intermediary' on the supply side, which offers a combination of lotteries that maximizes profit, and creates firms from the outcome of agents' (independent) randomizations. To do this, the intermediary must serve a continuum of agents. The intermediary is therefore a different type of firm than the group types in the EGSSZ model and the firms of the CPPT model, such as g_1, g_2.

An important role of the intermediary in the CPPT model is to make transfers of value among the groups over which lotteries are offered. In the randomization above, the single membership in the firm type g_1 is coupled with consumption $\hat{c} < e$. The value of the member's consumption in g_1 is less than the value of the endowment, while the value of the members' consumptions in g_2 is more than the value of their endowments. Since the value of consumption must equal the value of endowments in aggregate, there is a transfer of value from g_1 to g_2. The intermediary who creates the lottery absorbs both sides of this transfer.

Scotchmer and Shannon (2007) show how lotteries on memberships can be introduced to the EGSSZ model through *lottery group types*, which are finite and are formally treated the same as ordinary group types. There is no need for a distinguished firm (intermediary) that serves a continuum of agents. A lottery group type is composed of several constituent group types in **G**. A feasible lottery must have the same number of lottery memberships as there are memberships in the constituent group types, since the lottery members will be assigned to the memberships in the constituent group types. The probability distribution is uniform on all assignments that are consistent with the memberships.

In the example, a lottery group type is constructed from one copy of g_1 and one copy of g_2, and has three memberships. Worker memberships to the lottery group type are such that the member can be assigned to m_{w1} or m_{w2}, and a supervisor membership is such that the member can only be assigned to m_s. There are two ways to make this assignment, each with probability one-half. Each worker has probability one-half of being assigned to mw_1 or mw_2, as required. If the lottery group type is defined such that the internal transfer of each worker to the supervisor is $e - \hat{c}$, the equilibrium membership prices q are zero.

With this structure, each lottery is a group type with finite memberships, and, as such, fits directly into the EGSZ model with no modification. Each worker pays the same membership fee for a lottery membership, but receives different *ex post* utility, depending on the outcome of the internal lottery. There are no transfers of value among lottery groups, as required by the zero-profit condition, but there are transfers of value among groups within each lottery group type.

A caveat is that not all lotteries can be accommodated with a finite number of group types. Each lottery group defines fixed probabilities on wealths and memberships. Different probabilities are provided by different lottery groups. Since there are continuously many possible lotteries, a complete lottery space would require a continuum of lottery group types, some very large. Thus, as in the CPPT approach, there is some loss in the technical convenience of restricting to a finite number of group types.

Unverifiable Characteristics and Games

In game theory the game is primitive. An agent either finds himself in the game or he does not, but there is generally no explanation for which game he finds himself in. Club theory allows agents to choose among games. However, to interpret a

game as a finite group type, the theory must accommodate strategies and characteristics that are not verifiable. Such an extension is suggested by Prescott and Townsend (2006), who use the CPPT approach to discuss how the market chooses among firm types that are subject to moral hazard. Equilibrium will weed out the contractual arrangements that are inefficient, where that may depend on the prices at which private goods trade. The same idea is taken up and extended by Zame (2005) and Scotchmer and Shannon (2007). The latter two papers build closely on EGSZ (1999, 2005) but differ in emphasis and in the way group formation is formalized.

Some unverifiable characteristics are chosen, and some are innate. The natural word for an unverifiable characteristic that is chosen is 'strategy', while it is more natural to say 'unverifiable characteristic' when the characteristic is innate but unobservable. Both play the same role in the model. In a normal-form game, for example, the membership might indicate row player or column player, and the strategy might indicate the unverifiable play. In a group type that is a firm, the membership is a job, and the unverifiable job characteristic might be innate proficiency at writing computer code.

When strategies (characteristics) are unverifiable, the groups that materialize from a member's choices will have a random component, namely, the unverifiable characteristics of other members. For random realizations of groups, Scotchmer and Shannon (2007) use the term 'augmented' group types. The agents first choose their verifiable memberships and unverifiable strategies, and are then randomly matched into augmented groups consistent with their choices.

If the unverifiable characteristics can be distinguished according to something verifiable like output, then group types can be defined such that agents screen optimally into groups, just as if the characteristics themselves were verifiable (see example 2 in Scotchmer and Shannon, 2007). No such ploy is available if the unverifiable characteristics affect utility directly.

After being matched into augmented groups, agents choose their consumptions of private goods. Each agent's income and demand for private goods may depend on the unverifiable characteristics in his groups. Since each agent's demand depends on the random matching, there is no conceptual reason to think that private-goods prices should be the same for all matchings, and Scotchmer and Shannon do not assume it. There may be two sources of uncertainty in an agent's consumption of private goods: uncertainty about the augmented groups and uncertainty about the prices of private goods. Both sources of uncertainty affect the *ex ante* demand for group memberships, and the optimizing choices of strategies.

If the set of agents were finite, the augmented groups realized by different agents could not be independent of each other. Duffie and Sun (2004a, b) show that the continuum remedies this problem. In the continuum, each agent's random match can be understood as independent of any other agent's random match, and a law of large numbers applies to demand. The law of large numbers provides an easy way to prove existence of equilibrium despite the randomness caused by unverifiable characteristics. If one assumes that the equilibrium prices must be the same at every random matching, aggregate demand can be treated as constant for all random matchings, and existence of equilibrium follows from EGSZ (1999). But this should not lead us to believe that constant prices are natural. There is no reason that the same equilibrium price vector should be selected at each random matching – constant prices are an assumption, not a conclusion. (This is an important difference between the treatments of Zame 2005, who assumes constant prices, and Scotchmer and Shannon 2007, who explore the consequences when prices can depend on the random matching. Variation in prices may reduce welfare.)

Prescott and Townsend (2006) prove the first welfare theorem for a class of economies with moral hazard. In contrast, Zame (2005) and Scotchmer and Shannon (2007) show many senses in which equilibrium will be inefficient. The difference lies partly in the classes of economies considered, and partly in the definition of 'efficiency', which is only defined relative to the trading opportunities in the economy. For

example, Scotchmer and Shannon point out that inefficiency in teams would vanish if agents could choose a game with a residual claimant. In the model of Prescott and Townsend, that is not an option.

These models have three broad classes of inefficiencies. First, the exogenous set of group types (games) in the economy may not be rich enough to achieve first-best efficiency, as in the teams example. Second, there are belief-driven coordination problems, well known in game theory, that are not solved by embedding games in general equilibrium. There may be multiple equilibria, including efficient ones and inefficient ones, each supported by beliefs that are correct in equilibrium. Third, there are inefficiencies in the trading of private goods. Trades in private goods are always efficient from an *ex post* point of view (conditional on the random matching) but not necessarily from an *ex ante* point of view. Depending on what is observable, the latter inefficiency may be remediable through insurance markets.

Clusters

Charlie Karlsson
Jönköping University, Jonkoping, Sweden

Abstract

It is a fundamental structural characteristic of industrial economies that economic activities tend to co-locate, i.e. cluster in space. The study of clusters and clustering is today an integral part of many undergraduate and post-graduate studies in business administration, economics, economic geography, and urban and regional planning as well as a topic of research in these disciplines. At the same time, we can observe many governments at different levels in industrialized countries that have initiated cluster studies and introduced policies aiming at supporting existing clusters and stimulating the emergence of new clusters. The success of these policies has varied

substantially but cluster policies seem to have become an integral part of the industrial and regional policies in industrialized countries.

Introduction

It is a fundamental structural characteristic of industrial economies that economic activities tend to co-locate, i.e. cluster in space (Karlsson 2008a). The study of clusters and clustering is today an integral part of many undergraduate and postgraduate studies in business administration, economics, economic geography, and urban and regional planning as well as a topic of research in these disciplines. At the same time, we can observe many governments at different levels in industrialized countries that have initiated cluster studies and introduced policies aiming at supporting existing clusters and stimulating the emergence of new clusters. The success of these policies has varied substantially but cluster policies seem to have become an integral part of the industrial and regional policies in industrialized countries. There is currently a strong belief that clusters can be the major vehicle for economic development and growth in three ways: i) by increasing the productivity of the firms located in the cluster through internal and external economies of scale, ii) by increasing the pace of innovation through rapid knowledge exchange, and iii) by stimulating the formation of new firms, i.e. entrepreneurship, and the growth of firms (Huggins 2008).

The current large interest in clusters is a culmination of a research tradition that goes back to the late 19th century and is associated with names such as Marshall, Weber, Ohlin, Hotelling, Cristaller and Lösch. Even if these thinkers have contributed to the field over the years, it has been mainly economic geographers that have kept the research tradition running. Mainstream economists have largely ignored spatial issues until the early 1990s, when Krugman (1991) showed that the most striking feature of the geography of economic activity was concentration. It was first with the contributions by Krugman (1991) and Porter (1985) that research on clusters took off. While Porter mainly focuses clusters from a nation state perspective and how they generate competitive advantages, Krugman discusses clusters as something developing at the regional level due to specific centripetal forces that induce firms in individual industries to co-locate. According to Krugman, the geographic concentration of production is evidence for the pervasive influence of increasing returns. Since the early 1990s, a growing number of non-spatial economists have started to pay attention to what is known as "New Economic Geography". Fujita et al.(1999) note the increased theoretical and empirical interest among economists in where economic activities locate, why they concentrate in space and the importance of these processes for core areas in economics such as urban economics, location theory, and international trade theory.

Economic geographers mainly have accepted the economic analysis of clustering processes but stress that social, cultural and institutional factors also play an important role the development, growth and possible decline of clusters (Martin and Sunley 1997). The benefits of co-location are a function of the internal configuration of clusters. These benefits are derived from flexibility, informal networks based on frequent face-to-face interaction, trust-based interconnections among some large and many small firms and their subcontractors, specialized local infrastructures and institutions, a common skilled labour pool, and the rapid diffusion of knowledge and ideas (May et al. 2001). Perhaps the most important benefit of a cluster is information and knowledge advantage due to the potential for frequent face-to-face interaction that co-location generates. The information and knowledge is communicated through the 'industrial atmosphere' in the form of 'noise' and 'buzz'. The face-to-face interaction brings

distinct information including persistent updates, planned and unplanned learning, and the development of similar interpretation schemes, shared understanding of new knowledge and new technologies, which, over time develop shared cultural traditions and habits. However, the benefits do not come for free. Economic agents must establish and invest in links to other economic actors and build the necessary trust (Karlsson et al. 2005). Scott (1998) claims, for example, that clusters can only create new knowledge and new products and continue to grow if they also have linkages with external markets and utilise a mix of local and non-local transactions. Thus, the effects of local interaction and learning are much stronger if they are continuously supported by impulses from other regions and clusters (Bathelt 2005).

What is an industrial cluster and what do different researchers imply when using the concept? Despite substantial research on clusters, there is still much confusion concerning the proper conceptualization of a cluster, except that it is generally conceived as a non-random (Elison and Glaeser 1997) geographical agglomeration of firms, with shared complementary capabilities (Richardson 1972). Inside such clusters, one can identify several forms of intended and unintended interactions. Increasing returns occur when such interactions generate positive economic externalities for firms in the cluster. Gordon and McCann (2000) have offered some help by providing a comprehensive assessment of various theoretical frameworks where industrial clusters have been analysed. They stress that the phenomenon of industrial clustering has attracted researchers from several disciplines and research traditions employing a diverse set of conceptualisations, theoretical frameworks and analytical approaches, which has generated ambiguity. Concepts such as agglomeration, cluster, industrial district, regional economic milieu, and industrial complex have been used interchangeably often with very little concern about how to make them operational. Gordon & McCann identify three analytically distinct forms of spatial industrial clustering, each of them subject to a logic of its own:

- The classical model of pure agglomeration, referring to job matching opportunities and service economies of scale and scope, where externalities arise via the local market and local spill overs
- The industrial-complex model, referring to explicit links of sales and purchases between firms leading to reduced transaction costs
- The club model, also known as the social-network model, which focuses on social ties and trust facilitating cooperation and innovation

Whatever type of cluster, the phenomena of industrial clustering is evidence of the pervasive influence of increasing returns (Krugman 1991). Typical for clusters is the existence of one or several forms of direct and/or indirect interaction between economic agents. Increasing returns are obtained, when such interaction generates positive externalities for the economic agents in the cluster.

The three cluster notions above may coexist since local markets, local transaction links, and local social networks can be integrated in various combinations within functional regions. Thus, even if it is possible to analytically distinguish three "pure" cluster models, it is important to realise that industrial clusters often exhibit rich but complicated and integrated features, many of which may be difficult to create or influence by policy measures. Many industrial clusters are unique and are the result of specific historical circumstances. Cluster models give little guidance for the development of such clusters, since they are the result of specific circumstances, which are impossible to imitate.

The Home of Clusters: The Functional Urban Region

A functional urban region (FUR), characterised by its agglomeration of activities and by its intra-regional transport infrastructure, provides intra-regional proximity and facilitates an intra-regional mobility of people, products, and inputs. The basic characteristic of a FUR is the integrated

labour market, in which intra-regional commuting as well as intra-regional job and labour search is much more intensive than for the inter-regional counterparts (Johansson 1998). The border of a labour market region is a good approximation of the border of a FUR, which normally contains one employment centre but in some cases two or more employment centres.

Porter (2000, 254) defines a cluster as "a geographically proximate group of inter-connected companies and associated institutions in a particular field, linked by commonalities and complementarities. The geographic scope of a cluster can range from a single city or state to a country or even a group of neighbouring countries." One can question this kind of all-embracing definition. The concept of proximity totally loses its meaning due to Porter's fuzziness regarding the spatial boundaries of clusters. We prefer to name such concentrations beyond the functional economic region as industrial networks. The forces keeping such networks together are in several respects different from those keeping a cluster together within a single functional region.

The concept of market potential can be used to describe economic concentration and the opportunities of making contacts within and between such concentrations (Lakshmanan and Hansen 1965). There are strong reasons for making a precise distinction between the internal and the external market potential of a FUR. The geographic delineation of a FUR is in a fundamental way related to the identification of its internal market potential. The internal market potential is a measure of the market opportunities existing inside the borders of a FUR.

It is a common assumption in regional economics that products vary with respect to the contact or interaction intensity associated with their input and/or output transactions (von Thünen 1826). For products with standardised and routine transaction procedures, little or no direct contact between buyer and seller is necessary. Moreover, when the same supplier and customer repeat the same delivery, the interaction between these two actors can be routinized, and hence the contact intensity goes down, causing transaction costs to decline. However, many products are traded under complex (and contact-intensive) transaction conditions, which may involve many transaction phenomena such as inspection, negotiations and contract discussions, legal consultation and documentation of agreements. Such products may themselves be complex and have a rich set of attributes, but the basic thing is that from a transaction point of view, they are not standardised, and the interaction procedures are not routine. A special case of a contact-intensive transaction is when a product is customised and designed according to specifications by the customer in a process of supplier-customer interaction. Thus, we can assume that the contact-intensity associated with selling and delivering different products varies considerably.

Another common assumption is that interaction costs are much lower for transactions within a FUR than between FURs. This implies that contact-intensive products can be claimed to have distance-sensitive transaction costs and that these geographic transaction costs rise sharply when a transaction passes a regional border (Johansson and Karlsson 2001). This also implies that products can be distance-sensitive with respect to input transactions. Similar arguments apply to the labour market in the sense that individuals (firms) search for jobs (labour) mainly inside their FUR. Thus, the interaction frequency associated with distance-sensitive products supplied in each FUR including labour can be assumed to decrease with increasing (time) distance from the region's centre (Holmberg et al. 2003). It is a general result from spatial interaction theory, that the interaction intensity is a decreasing function of the time distance between origin and destination (Sen and Smith 1995).

For each type of product in a FUR, it is possible to divide the total market potential into the internal (intra-regional) and the external (inter-regional) market potential. Firms wanting to supply distance-sensitive products must find a sufficiently large demand for their sales inside their own FUR. When internal economies of scale prevail, the internal market potential must exceed a certain threshold if firms producing distance-sensitive products will be able to make

a positive profit, i.e. "economic density" matters (Ciccone and Hall 1996).

The size of the internal market potential in a FUR is among other things a function of its infrastructure provision. Interaction infrastructure offers high density combined with low transaction costs, i.e. a large accessibility (Johansson 1996). This implies that suppliers have a large accessibility to customers and that producers have a large accessibility to suppliers of specialised inputs and households supplying specialised labour inputs.

Infrastructure has two fundamental roles (Lakshmanan 1989): (i) it influences both the consumption and the production possibilities of societies, and (ii) it is intrinsically a collective good in the sense that it is common to all households and firms. Thus, infrastructure in a basic way influences the size of the internal and external market potential of a FUR by (i) extending its links for interaction trough space, and (ii) creating intra- and inter-regional accessibility. Infrastructure also extends over time through its durability, which creates sustainable conditions for production and consumption for extended time-periods.

The Emergence and Growth of Clusters

The traditional analyses of location and clustering using the resource-based theory of location and clustering (and trade) emphasise the relative abundance of resources "trapped" in a FUR (Ohlin 1933). Critical resources have the character of durable capacities, which on the one hand, include natural resources and on the other hand the supply of infrastructure in the form of facilities and networks, R&D organisations, existing production capacities with specific techniques, and the supply of different semi-immobile labour categories. Modern resource-based models often emphasise the supply of knowledge-intensive labour as a primary location factor. The durable capacities generate comparative advantages in the sense of Ricardo and influence the potential specialisation profile of a FUR. Although these characteristics are exogenously given in the short and medium term, a major part of the durable characteristics (except natural resources) change gradually over time and are created by investment and migration processes.

The resource-based approach has been challenged in recent decades by scale-based models (Dixit and Norman 1980; Krugman 1980; Ethier 1982), even though Ohlin (1933) explicitly refers to the role of scale economies nearly five decades earlier. These models explain location and clustering (and trade) in a context of internal and external economies of scale and local and external market potentials of FURs, where the dynamics of the interdependence between market size and economies of scale is essential. In the short and medium term, the properties of markets are durable phenomena, which create comparative advantages in the pertinent FURs. It is obvious that to understand the emergence and the growth and dynamics of clusters there is a need to bring the two approaches together. One possible approach to do this is to associate (i) the resource-based advantages to the input market potentials of each sector, and (ii) the scale-based advantages to the customer market potentials of each sector (Holmberg et al. 2003).

The realisation of scale economies and the associated potential of division of labour, i.e. decomposition of production, and specialisation are intrinsically related to the size of the accessible market (Stigler 1951). When the decomposition takes place within a firm, the firm takes advantage of internal economies of scale, and when decomposition leads to outsourcing of production, the firm may take advantage of external economies of scale. Internal economies of scale are technological phenomena related to individual firms and imply that productivity increases (the unit cost decreases) as output gets larger. They may be related to the existence of one or several productivity-enhancing indivisibilities (fixed-cost factors), such as indivisible equipment, knowledge resources including patents, brand names, material and non-material networks or set-up costs including learning how to do it (Koopmans 1957), i.e. a "catalyst", which must be present in the production process without being used up (Krugman 1990). It is not the absolute size of the fixed costs that matters. Instead, the

size of the fixed costs should be related to the size of the accessible demand (Chamberlin 1933).

In theories of agglomeration of firms, i.e. of clustering, internal economies of scale and the size of the internal and external market potential of FURs are used as the principal factors explaining the spatial agglomeration of firms. Internal economies of scale are essential components in all models, which emphasize the role of variety of outputs and inputs, respectively. Firms with internal economies of scale search for FURs with a large enough market potential for making it possible to produce with a profit and FURs in which many firms want to locate develop a large internal market potential. Some types of goods and many types of services are associated with large geographical transaction costs, implying that the intra-regional market potential determines whether profitable production is possible in a FUR or not. Thus, it is essential to classify products according to their distance sensitivity in terms of transaction costs. Based on such an approach one can identify specific categories of products with a potential to develop clusters in small, medium-sized and large FURs, respectively.

Industrial clustering cannot be explained solely by internal economies of scale. Of equal importance is the existence of external scale-economies, which are vital for a sustainable development of clusters in FURs. The first type of external economies of scale – localisation economies – is a systems phenomenon, which occurs when several firms, producing similar products, are in the same FUR. Localisation economies are vital for specialisation and clustering processes in small and medium-sized FURs (when they are not resource-based) (Johansson and Karlsson 2001). The second-type of external economies of scale – urbanisation economies – is another type of systems phenomenon, which occurs in large FURs hosting many different and interacting clusters.

The impact of external economies of scale in the form of location economies was emphasised already by Marshall (1920). A firm operating under constant returns to scale can benefit from positive external economies of the output from other firms in the same FUR, i.e. from external economies of scale (Chipman 1970). Localization economies generally play a central role in many models in urban and regional economics as well as in models of spatial product cycles (Mills 1967; Hirsch 1967).

According to Marshall's theoretical scheme, the positive industry-specific effects from clusters, i.e. the co-location of firms, have three sources, namely (1) non-traded local inputs, (2) local skilled-labour supply, and (3) information spillovers. The first category may be considered as distance-sensitive inputs. Due to high geographic transaction costs, these inputs are more expensive when delivered from sources outside the FUR. This implies that proximity becomes an advantage when firms are co-located, since the concentrated demand from the pertinent industry also attracts neighbouring firms, which are input suppliers. These input suppliers have their own internal economies of scale. Thus, it is important for them to have accessibility to a sufficiently large demand, which in this case is provided by the localised firms in the cluster. The desire of specialised input suppliers to be in the same FUR as their customers is determined by a combination of frequent interactions with their customers and distance-sensitive transaction costs.

The second category of localisation economies is related to a firm's labour acquisition costs. In a FUR, where a large share of the labour force already has specialised industry-relevant skills, the costs for a firm to expand its labour force may be lower than otherwise. For example, search and training costs can be assumed lower when the skilled labour pool is large in a FUR. At the same time, a cluster of firms can attract to the FUR a rich variety of labour categories, specialised to suit the industry in question. According to the above arguments, proximity to specialised input suppliers and specialised labour supply will imply that inputs can be acquired at lower total costs for given quality levels. Because of this, the described phenomena belong to the family of pecuniary externalities.

The third category, the information and knowledge available in clusters is a regionally available, semi-public good. This phenomenon has the character of a non-pecuniary externality, since it

brings benefits that are not charged at a price, except in the form of land prices. Information and knowledge are spread without being priced in the intra-regional neighbourhood, because in such an environment with intense face-to-face interaction it becomes prohibitively costly to privatise all information and knowledge. Hence, some of it will spill over, sometimes as the result of a conscious mutual exchange of information. The information and knowledge of importance concerns a wide area, such as information and knowledge about production technique, product attributes, input suppliers, customers, and/or market conditions. The Marshall approach provides an explanation of the sources of co-location economies within an individual industry in a single-industry cluster. Duranton and Puga (2004) describe Marshall's three mechanisms as sharing, matching and learning economies.

Another scheme for analysing agglomeration economies was outlined by Ohlin (1933). In contrast to Marshall, Ohlin focused more on how the individual firm is affected by co-location with other firms. In his classification, agglomeration economies have four origins:

- *Internal economies of scale* associated with the production technique of the individual firm
- *Localization economies*, which affect the individual firm as an influence from the industry to which it belongs
- *Urbanisation economies*, which arise from the size of the FUR and thus are external to the industry and its firms
- *Inter-industry linkages* of input-output type, where proximity to suppliers of intermediate inputs reduces their price.

Both input and customer market potentials tend to vary with the size of the FUR. This makes it possible to combine resource-based and scale-based models to explain the emergence and growth of clusters. We can assume that the larger the FUR, the larger the potential to combine internal and external economies of scale and the larger the economic density. Scale economies imply for large FURs a location advantage regarding all products with a "thin demand" and thus clusters in these industries mainly will be found in such regions. Thus, large FURs can specialise in "cluster diversity" and rely on the double forces of internal and external scale economies. However, scale economies constitute an equally important phenomenon for industrial clustering in FURs of all sizes. Also, smaller regions can develop a specialisation, i.e. a cluster, in a self-organised way, but in this case, the development is limited to a set of closely related products in the same industry with low geographical transaction costs supported by localisation economies.

The location of a firm to small and large FURs, respectively, may release a set of self-reinforcing circular processes, which in an endogenous change process give rise to one or several clusters through what Myrdal (1957) described as "cumulative causation." This form of positive feedbacks is in general constrained by the development of the demand in the FUR and in its external markets, and by the existing capacities in the form of built environment, accessibility based on transportation systems, production capacities, and labour supply. For certain activities, these constraints may not be binding, whereas other activities require adjustments of the durable capacities. The market potentials can be assumed to adjust at a faster time scale than the durable capacities. In a longer time perspective, the capacities and the economic milieu in a FUR will adjust through a system of coupled feed-back linkages. The interaction between scale economies and regional durable characteristics has the same nature both in small and large FURs, although external linkages to other (and larger) FURs are more vital in smaller FURs. For small and medium-sized FURs, the adjustment of durable capacities may be assumed rather specific given the narrow set of sectors, which form the specialisation nucleus of such regions. We may understand how the location of an individual firm may release a clustering process by referring to (i) a firm's customer market potential, (ii) a firm's input market potential, and (iii) a firm's labour-input market potential. In a similar manner, it is possible for the individual household to identify its (i) job market potential, (ii) housing market potential, and (iii) consumption market potential. The interaction

infrastructure will function as a support factor in the clustering process.

Clustering as an Entrepreneurial Process

Clustering processes are located and limited to the FUR where the initial entrepreneur or group of entrepreneurs decided to locate a new firm. The emergence of clusters is often triggered by events that make a natural or social asset of a FUR an important location factor for an industry or that encourage a local entrepreneur or group of entrepreneurs to engage in a specific industry (Feldman and Schreuder 1996). Entrepreneurs function as innovators when they transform new and existing knowledge into marketable products (Karlsson et al. 2014). They are also change agents and at the same time, as they are driven by the possibility to earn an entrepreneurial profit, they influence the conditions for other entrepreneurs to start and develop firms. They do this by changing the demand and supply conditions in the FUR over time and by developing norms and other informal institutions, which form the entrepreneurial climate in the FUR. Due to their co-location, firms are also able to develop trust-based relationships, not only with other firms in the same industry but also with other important economic agents in the FUR, such as suppliers, customers, public authorities, R&D institutions, and so on (Press 2006).

Cluster formation processes are not linear processes but can be described as adaptive, self-organising processes. These processes engage entrepreneurs as well as political decision makers and contribute to the establishment of supporting and governing functions as well as material and non-material infrastructures often with the help of public resources. This implies that the cluster and the regional specialisation created through the activities of entrepreneurs tend to become unique due to its history (Krugman 1991) and thus inherently difficult to copy (Feldman and Martin 2004).

When entrepreneurs during the cluster formation process decide to start new firms, they take advantage of those resources, which have accumulated over time, such as customer market potential, input supply potential, knowledge, and financial and social capital (Westlund 2006). Cluster growth is often driven by the start-up of "breakaway firms" (Jacobs 1969), i.e. firms started by entrepreneurs with experiences from the same industry. Entrepreneurs with experiences from the same industry create the cluster and contribute to its continued growth (Feldman and Romanelli 2006).

To the extent that these entrepreneurs are successful, their activities will further strengthen the economic milieu in the FUR including its knowledge base, institutions and social capital. Likewise, they increase the possibilities to take advantage of internal and external economies of scale and establish new firms. Successful clusters not only create their own resources, institutions, and potentials. They also attract resources, such as financial capital, labour and entrepreneurs from other FURs. However, there is no guarantee that clusters, which have developed well in early stages will continue to grow. There are examples of clusters, which after being successful in early stages start to deteriorate long before the mature stage (Feldman and Francis 2004).

Since entrepreneurs initiate economic activities and build up resources and market potentials, they are a necessary factor in the dynamic cluster formation process. Entrepreneurial processes are mostly localised processes. New firms are to a high extent started in the FUR where the entrepreneur works and has established commercial and social networks and has access to a customer market potential as well as an input supply potential.

Three Important Types of Clusters

The literature contains many empirical cluster studies ranging from case studies to general analyses of clusters within specific industries. Whatever industry we think of from food, textiles, metal manufacturing all the way to cars, ICT, restaurants and financial services we can observe clear tendencies to cluster. Due to the limited space, we here limit the discussion to three types of clusters: high-tech clusters, media clusters and financial clusters.

High-Tech Clusters

When explaining the clustering particularly of high-tech firms, it is natural to make a theoretical distinction between co-location forces working at the demand side (clusters offer a large enough demand for new distance-sensitive high-tech products) and at the supply side (clusters offer better conditions for creative and innovative activities).

Even if most studies of high-tech clustering have concentrated on supply side factors, it is worthwhile also paying interest to demand side factors. It seems clear that there is a strong tendency among high-tech clusters to be located primarily in those large FURs in the rich industrialised countries that often can be characterised as metropolitan regions. These regions offer good conditions for innovative firms developing new products, since they offer a large home market but also a high accessibility to the markets in other large FURs in the home country as well as abroad due to highly developed air traffic networks.

Large FURs are concentrations of company headquarters, company R&D divisions, other advanced industries, research universities, university hospitals, R&D institutes, and high-income earners, i.e. they are concentrations of demanding customers with a high willingness to pay for innovative products fulfilling their specific requirements. Thus, due to their demand structure, these regions are an excellent testing ground for new products. Due to their high internal accessibility, they offer good opportunities for extended periods of interaction with customers during the product development and testing phases. In other words, these regions offer a home market where new innovative products can be tested and nurtured in the first phase before exporting them to other large FURs and in the second phase more generally.

There are general incentives for entrepreneurs to locate their firms in large FURs because they are more likely to be better exposed to customers there. Searching is costly for customers who, *ceteris paribus*, will prefer to minimize search costs by purchasing in areas of concentrated supply. This is particularly relevant in markets with discerning potential customers with specific requirements, who are keen to enquire and search before placing a purchase order (Karlsson and Johansson 2006).

A further advantage of locating high-tech firms in large FURs is the positive information externalities in such regions, through which individual entrepreneurs and firms receive signals about the strength and content of regional demand by observing successful trades of established suppliers. Such observations also inform about varieties of existing products including lack of varieties, and trigger the development of new varieties. Moreover, the fact that a given firm is in a FUR with a successful high-tech cluster provides potential customers with an indication or image of quality.

Like all other entrepreneurs, high-tech entrepreneurs can reduce their risks by locating in large FURs (Mills and Hamilton 1984). To the extent that fluctuations in demand are imperfectly correlated across customers, the demand for products with high geographical transaction costs can be stabilized in such regions.

The concentration of purchasing power and demanding customers in large FURs is a stimulus to entrepreneurs to start imitating successful products and thereby often also improving them to take market shares from incumbents by being localised near them, i.e. in the same FUR (Hotelling 1929). Indeed, when the competition in the product market is imperfect, which is the case in high-technology markets generating many product varieties that are imperfect substitutes, geographical proximity increases competition in the product market (Fujita et al. 1999). The gain of such actions may be short-lived if further high-tech entrepreneurs enter, or if the incumbents in the region react to this unwanted competition. However, this kind of competition is critical to keep a high-tech cluster vital and vibrant, even if many high-tech firms over time may suffer from proximity to other firms and eventually fail.

On the supply side, large FURs offer high-tech entrepreneurs and firms advantages in terms of accessibility to a large pool of well-educated and specialised labour (Marshall 1920), particularly, specialised workers in different technical fields

but also in accounting, law, design, advertising, etc. This reduces the costs for starting, running and expanding new businesses (Krugman 1993). Furthermore, densely populated agglomerations are conducive to a greater provision of non-traded inputs, i.e. their producer service infrastructure is more developed. Such inputs are provided in greater variety, at lower costs and possibly at higher quality in large FURs (Krugman 1991). There also exist physical infrastructure benefits for high-tech entrepreneurs and firms to locate in such regions, in terms of access to highways and airports, and thus better accessibility to suppliers located in other regions at home or abroad.
