However, and more importantly large FURs offer a concentration of and accessibility to R&D in companies, R&D institutes, and research universities, etc., as well as various arenas for knowledge diffusion and knowledge exchange. They also offer a high accessibility to knowledge generated in other large FURs by means of air travel, intra-company networks in large multinational firms, and networks of university researchers, which implies that they are well positioned to follow the knowledge developments in other FURs. Thus, large FURs offer advantages to high-tech entrepreneurs and firms in terms of a high potential to benefit from various and rich knowledge flows. This is particularly important when the knowledge is complex and tacit in nature (Jaffe et al. 1993). Generally, a form of informational externality accrues to new high-tech entrepreneurs from observing established firms that produces successfully in large FURs. For example, there are large potentials for product and production knowledge to spill over in large, dense FURs. Thus, the start-up frequency for any high-tech sector should increase with the existing density of firms in the actual sector. A final reason for advantages of large FURs for high-tech entrepreneurs arises from reductions in transaction costs (Quigley 1998). Search costs for customers, suppliers, services, and knowledge are lower in larger FURs. This implies that economies of information flows (Acs et al. 1992) on both the demand and the supply side are greater in large FURs than in smaller FURs. Thus, new high-tech firms are most likely to be started where the spillovers are greatest, and hence high-tech clusters are much more likely to emerge in large FURs than in small FURs.

In high-tech industries, a high share of the new ventures is started by former employees from incumbent firms using some of the technological know-how from their former employer (Klepper 2001). This implies, that existing high-tech firms characterised by a high level of technological know-how and continuous innovation provide a training ground for future high-tech entrepreneurs (Franco and Filson 2000). With mechanisms like this a high-tech cluster can secure renewal as well as continued growth for an extended period.

Media Clusters

One sector known for a strong tendency to cluster in large FURs is the media sector. There is today a growing literature dealing with media clusters and in particular with large media clusters, sometimes characterized as ‘global media cities’ (Krätke 2003). There are several obvious reasons to why media firms tend to cluster (Karlsson and Picard 2011). One reason is that many of products from the media sector, like films, are produced in the form of projects, which run for limited periods of time. Each such project needs to engage a large number of different specialists on a temporary basis. Only a relatively large cluster will offer a diverse enough supply of specialists to make such projects economically feasible. Another reason why media sector firms cluster is that many media industries are creative industries within or closely related to the cultural sector. The tendency of media and creative cultural industries to cluster has been documented often in the literature in recent decades (Karlsson and Rouchy 2015).

A parallel process to the emergence of large media clusters in large FURs has been the marked trend towards the globalization of several large media firms (Pratt 2000). The growth of media firms, not least through mergers and acquisitions has led to the formation of very large media groups, which not only occupy a prominent position in the cultural sector in individual countries, but also create increasingly global networks of branch offices and subsidiaries with presence in

many large media clusters (Krätke 2003). These large media groups tend to pursue a strategy that involves the integration and recombination of the media value chains at both the national and the global level. Another crucial strategy is the ambition to take advantage of diversification, i.e. the simultaneous or almost simultaneous distribution and exploitation of the same 'content' via different media, e.g. the print media, television programs and internet services. Furthermore, the globalization of media firms is related to the increased importance of intellectual property rights and copyrights. Copyrights provide the mean for controlling information and entertainment products and ensuring that they can be exclusively exploited in a national market (Bettig 1996).

In recent decades, the media sector has been strongly affected by technological changes. We can today observe that the developments within information and communication technologies (ICT) are stimulating the birth of new media services including the creation, manipulation and distribution of digital content (Gillespie et al. 2001). An interesting characteristic of these new services, which include software, databases, electronic libraries, new media, videos, broadcasting, etc., is that they do not just embody knowledge – they are knowledge and behave as such (Arrow 1962). These new services represent what Quah (1999) calls 'the weightless economy', i.e., an economy whose products are non-excludable, infinitely replicable and electronically transportable costless through space, like knowledge (Arrow 1962). This observation might lead to the conclusion that the location of the production of media products is a non-issue, since there are no raw materials that should be transported to the producer and no physical goods that should be distributed from producer to customers. Media firms could locate anywhere and the FURs would no longer host any clusters of media firms. So why do media firms continue to cluster in large FURs?

At the same time, as 'the weightless economy' develops, we can also observe tendencies of technology-related industrial convergence (Dosi 1988) in the emerging digital economy but also a breakup of old value chains (Ewans and Wurster 1997) followed by a new structuring of value chains, where takeovers and strategic alliances play a significant role (Hagel III and Singer 1999). There are today numerous claims that industries like telecommunications, computing and entertainment are converging and one day might evolve into one huge multimedia industry. This convergence might even have been increasing in recent years with the emergence of the Internet and with the increasing capability of existing networks to carry both telecommunications and broadcasting services (Knieps 2003). Developments in digital technologies and software are creating a large technological innovation potential for the production, distribution and consumption of information services. Convergence, characterised as the ability of different network platforms to carry essentially similar kinds of services, may have very different faces: telecommunications operators may offer audio-visual programming over their networks; broadcasters may provide data services over their networks, cable operators may provide a range of telecommunication services, etc.

In the 1980s and early 1990s, some cyber prophets and technological optimists predicted that the emergence of the digital economy would kill distance and make clustering in large FURs superfluous (Cairncross 1997) and at the same time eliminate the scale disadvantages of smaller and more peripheral FURs. The basic idea was that the spread of the use of ICT has the potential to replace face-to-face activities that formerly occurred in central FUR locations, which would strongly reduce or even eliminate agglomeration economies and hence make economic activities totally 'foot-loose'. At the beginning of the 21st century, however, it has become clear that this picture is at least single-sided. New technologies are likely to remain grounded in existing FURs, implying that these regions will keep their locational attractiveness and that media clusters will remain or even grow. Thus, the ICT has not rendered work and organisation 'space less' (Neff 2005).

There is also increasing evidence that the digital revolution reinforces the position of leading FURs (Castells 1996). So why do media firms

cluster, when the technological opportunities have seemingly reduced the necessity of proximity in operations between inter-linked firms? It seems as if the clustering tendencies are even more dominant in media industries than in many traditional industries. Ogawa (2000) shows, for example, that ICT development may not necessarily encourage the dispersal of economic activities due to the network effects and the technology effects of ICT infrastructure supply. FURs are a means of reducing the fixed travel costs involved in face-to-face interactions. Even if in principle improvements in ICT could eliminate the demand for face-to-face interactions and make large FURs obsolete, empirical results point in the direction that telecommunications are mainly a complement to face-to-face interactions (Gaspar and Glaeser 1998).

A major effect of the rapid diffusion of ICT is a dramatic reduction in transport and communication costs, which will alter the incentives for clustering of media industries and firms. It is too early to observe the results of the diffusion of ICT but it is possible to identify some possible effects (Venables 2001), since ICT reduces

- the search and matching costs in product markets but closeness by customers may still be essential, for products with rich and fluent characteristics
- the direct shipping costs since many products can be delivered in digital form,
- the control and management costs for geographically and organisationally fragmented operations
- the cost of time in transit, i.e. the shipping to and communication with distant locations
- the costs of personal interactions and stimulates knowledge spillovers
- the costs of commuting and of travelling in agglomerations
- the costs of replicating products, and
- the costs of relocation

These effects are not specific for the media sector. However, due to the character of the media sector's products, ICT might have stronger effects on the media sector than on other sectors. It is by no means clear how these factors will affect clustering in the media sector even if it is obvious that the ICT revolution makes it possible for media firms to go from a physical to a virtual value chain as well as to eliminate stages in the value chain (Ghosh 1998). This implies that it is an empirical issue to find out how the clustering in the media sector as well as its different industries is affected by the ICT revolution.

Financial Clusters

The financial services industry has as its primary function to intermediate between savers and borrowers in an economy. Its secondary function includes financial management, risk pooling and facilitation of payments and the transfer of money. Concerning the location of financial services, it is fundamental to make a distinction between retail and wholesale financial services. Retail financial services offer services such as payment systems, savings accounts and loans to the general public and to small and medium-sized firms. Even if these services increasingly are handled over the Internet, the location of retail financial services offices tend to follow the spatial distribution of population and small and medium-sized firms, i.e. the customers of these services.

Wholesale financial services include issuing of bonds and equities, support to mergers and acquisitions, and sophisticated products for managing risks, such as financial derivatives and these services are offered to large companies not least multinational companies and governments. Wholesale financial services have always been concentrated in major cities. Europe's first bankers in the late middle ages located their operations in the major trading centres. The leading commercial centres also developed into centres for banking, insurance and other financial services. During the industrial age growing industrial production and international trade stimulated the concentration of wholesale financial activities to cities with a strategic location in the global networks, i.e. gateways, such as London, New York and Tokyo (Kindleberger 1974; Andersson 2000; McCann and Acs 2011). In recent decades, the wholesale financial services industry has consolidated by means of mergers and acquisitions

(Amel et al. 2004) at the same time as the wholesale financial markets have become global after the deregulation of financial markets in many countries (Slager 2006).

In the developed part of the world, we can today observe that wholesale financial services are concentrated in financial clusters in a small number of metropolitan functional regions (FURS) (Bindemann 1999; Poon 2003). A financial cluster can be described as "the grouping together, in a given urban space, of a certain number of financial services" or as "the place where financial intermediates coordinate transactions and arrange the settlement of payments" (Cassis 2006, 5). This clustering of wholesale financial firms has been driven by a most radical transformation of the global economy in terms of a rapid growth and international transactions in currencies, shares, bonds and other types of securities. This transformation has been made possible through the development of efficient international communication networks that have been expanding to ever-increasing capacities through digitalization and the Internet. Households, pension funds and other financial investors have experienced an increasing international accessibility to different financial markets coupled with increasing economic efficiency and generally lower transaction costs. By increasing the international diversification of portfolios, it has been possible for investors to increase the returns on their investments while keeping the risks constant.

Begg (1992) has developed a typology of such wholesale financial services clusters that can be a useful starting point for a discussion:

1. The first-order clusters consist of three global financial clusters that play in a class of their own: London, New York and Tokyo. These diversified clusters are where the headquarters of major financial services firms and institutions are located and they offer a wide range of financial services (Andersson 2000).
2. The second-order clusters are also diversified but they serve not the whole global economy but supra-regional parts of the global economy. These clusters include Hong Kong, Frankfurt, Paris, Sidney and Singapore.
3. The third-order clusters are specialist or niche international clusters such as Amsterdam, Edinburgh, Luxembourg, Boston, San Francisco, Washington DC, Toronto, Geneva and Zurich.
4. The fourth-order clusters are mainly national centres with more limited involvement in international business and include cities like Stockholm, Rome, Milan, Hamburg, Dublin and Barcelona.

Which are then the general centripetal forces that can be supposed to stimulate the emergence, growth and concentration of large financial services clusters? We can identify a number of such forces (Abraham et al. 1994; Pandit et al. 2008):

- Capitalization and high liquidity
- Macroeconomic conditions
- Opportunities to co-locate near competitors and a variety and critical mass of complementary firms and related services, including financial consultants and other advisers, business journalists, rating offices, analysts, traders, corporate financial officers, bankers and financial regulators,
- Access large pool of skilled and flexible labour,
- A large market size in terms of size and scope,
- Access to financial infrastructure and a highly developed financial market from a technological point of view,
- Access to physical infrastructure, in particular, office space, telecommunications networks and international transport links with enough capacity, not least for the interaction with customers that are external to the cluster,
- Access to localized information, knowledge and technology spillovers with a potential to generate financial innovations.
- A political organization and tradition with 'thick' supportive institutional structures, including regulatory solutions and tax system,
- Low transaction costs,
- The 'right' initial conditions including a financial tradition.

Financial clusters tend to have a very central location in the core of a metropolitan FUR. This

agglomeration of financial activities is explained by the critical role of external economies of scale in financial markets. Not least are there substantial economies of scale in the gathering and analysis of information about scientific and applied R&D and product development in R&D-intensive and high-tech industries and firms. Of course, it is impossible for most financial investors to gather and professionally analyse such information. Instead there has been a steady growth of consultancy firms and units within investment banks and other financial actors specializing in the analysis of such information. The specialists working with information gathering and analysis are dependent upon frequent participation in scientific conferences, informal discussions with scientists, patent engineers and other experts on scientific and high-tech innovation and diffusion. Economies of scale in the analysis of information and knowledge related to R&D and innovation are becoming an increasingly important factor for the efficiency of financial clusters. The critical role of economies of scale in wholesale financial activities is clearly illustrated by the fact that even the largest countries only host a handful of financial centres. The efficiency of a financial cluster depends on its internal connectivity, its capacity to communicate internally and globally and the knowledge base of the regional financial network.

In terms of location, i seems as if the specific address within this central location is important for the wholesale financial services firms. To be considered a serious player in the financial market it is important to have the right address, since such an address signals a strong brand. Personal contacts and opportunities to interact frequently face-to-face within walking distance are of critical importance for the functioning of a financial cluster, since face-to-face meetings involving many persons have the advantage that more complex information can be transferred as well as non-verbal signals indicating the degree to which different partners are happy with the agreement discussed. Also, the opportunity to have face-to-face meetings with regulators is important for wholesale financial services firms in a financial cluster. The customers demanding advanced financial services on their side appreciate the opportunity to find many suppliers of similar and related financial services in large financial clusters and value the opportunities to compare the products and prices of many suppliers of financial services concentrated in a limited geographical area. Customers of advanced financial services look for high quality suppliers and react to market signals such as the reputation of different financial clusters and different wholesale financial services firms.

Labour with financial skills are attracted to large financial clusters because the size of the market offers higher chances of continuous employment. A larger market also gives incentives for people to develop highly specialised financial skills. Furthermore, the movement of people between the financial firms in the cluster helps to develop a network of contacts and facilitates the diffusion of information and knowledge spillovers.

Cluster Policies

Cluster policies are currently a hot topic. Policy makers in many countries at both the national and the regional level have come to believe that supporting and creating clusters is the major industrial policy option to be competitive and to be a winner in the globalisation race (Lundvall 2002). Certainly, there is a strong need for a thorough discussion of cluster policies and not least the rationale for cluster policies. At different levels in many countries, cluster development has become **the** solution to economic development. However, in many cases, cluster development policies seem to be based on no or very limited analysis. Clusters are found and identified without any clear objective criteria. When criteria are used, they are often very simple, such as location quotients. Still worse, there is often very little analysis of what factors that gave rise to the emergence of different clusters, the factors keeping them together, the long-term prospects of the clusters, the fundamental reasons motivating political intervention, and the problems of applying cluster policies (Karlsson 2008b).

Existing clusters can possibly but without certainty be supported by policies. Stimulating the emergence of new clusters is substantially more complicated. Having witnessed the success of a limited number of successful high-tech clusters, many regions want to initiate and nurture their own high-tech clusters. This is often done with little and mostly superficial analysis. Often the initiatives to create new clusters are based upon rather simple imitation strategies, which severely underestimate the difficulties of launching new clusters. The difficulties are real since research has rather little help to offer to identify the necessary and sufficient conditions for successful launching of new clusters.

Clusters contribute positively to real income levels in FURs. This has important implications for regional development polices. However, it is not obvious what the implications are and how cluster policies should be designed (Karlsson and Stough 2002). What type of regional cluster policy to apply depends on

1. the types of cluster(s)
2. the actual degree of cluster formation in the FUR, and
3. the information and knowledge about existing clusters and potential cluster policies possessed by relevant political authorities.

In the ideal case, policy measures should be directed towards the causes of the problem to be solved. It is important to realise that externalities, which stimulate cluster formation is a sign of what is called a market failure. This holds irrespective of whether the externalities are pecuniary or non-pecuniary. In traditional economic welfare theory, the existence of market failures has generally been taken as a motivation for political interference. However, this view has become more nuanced in recent decades. Political interference is associated with its own costs and these costs must be weighed against the benefits from removed or reduced market failures.

In the case of non-pecuniary externalities, market failure is obvious. The individual firm has no incentives in its calculations to consider the positive (negative) effects for other firms in the cluster of its own activities. This condition implies, for example, that private firms in a cluster regularly under-invest in R&D, because they do not consider the value for other firms of its knowledge creation.

Pecuniary externalities on the other hand are market failures connected with scale economies or imperfect competition. The utilization of scale economies, the supply of products, and the degree of competition are all limited by the size of the accessible market potential. If more customers enter the market or if suppliers can have better access to distant markets, the scale limitation is reduced and socio-economic benefits accrue through lower unit costs, coupled with a wider supply of products and/or increased competition. Thus, it is not the pecuniary externalities as such, which represent market failure. It is just a symptom of a market failure, which comes from the production conditions (scale economies) or the market form (imperfect competition).

Certain market failures due to externalities can be avoided if the effects are internalised, e.g. if the firms in a cluster decide to coordinate their activities through a common ownership or through contractual arrangements. Cluster firms can also organise themselves and work jointly to get more firms and/or households to locate in the FUR to increase its market potential, if the size of the market potential is too small for all potential positive pecuniary externalities to be realised. There are, in fact, plenty of examples of the role that private sector leadership can play for cluster initiation and cluster development (Stimson et al. 2002). However, if the number of economic actors is large it might be impossible to achieve internalisation or to organise a private sector leadership. There are also limitations to what cluster firms can achieve on their own. Many important policy issues, such as the building up of material and non-material infrastructures, in most countries reside within the public sector. Obviously, there are two cases when public sector cluster policies might be considered under assumptions of perfect information. The first case concerns private sector coordination failures, where private sector coordination might be substituted with public sector coordination. The second case concerns

sub-optimal market potentials in FURs with clusters, where public sector infrastructure investments can contribute to increased market potentials by means of the geographical extension of FURs and/or better access to external markets. Coordination failures and/or under-optimal market potentials can result in clusters operating under suboptimal scale or that potential profitable clusters are not established.

As a cluster consist of those firms, which best can take advantage of the market potential in a FUR and its durable resources, cluster policies at the FUR level if anything should primarily focus on supporting and developing existing clusters. Due to the existence of positive externalities, the existing clusters in a FUR will normally not achieve an optimal scale spontaneously. However, to the extent that existing clusters are not capable of driving the economic development in a FUR, it might be natural to raise questions about new clusters and thus the possibilities for structural change in a FUR through cluster substitution (Venables 2001).

Even if there might exist basic welfare arguments for cluster policies, there is still the underlying problem that the relevant authorities in a FUR often lack the necessary information and knowledge about

- the character of the cluster benefits
- what the exact causes of the cluster benefits are
- which clusters that generate particularly strong cluster benefits
- what constitutes the coordination problem, and
- the role of intra- and interregional market potentials for clusters

Furthermore, there are other problems related to cluster policies, such as the risks for manipulation and lobbying, and the existence of asymmetric information.

Another problem related to cluster policies is that different economic processes work at different time scales. Product markets, for example, normally change through relatively rapid processes, which generate demands that durable regional characteristics, such as the labour force with its pertinent skills, real capital, infrastructure capital, and so on, should be adjusted. As dynamic competition drives many relatively rapid processes, there is a constant need to upgrade the economic milieu in FURs with clusters. The problem is that such capacity and quality adjustments are a much slower and above all a more sluggish process than the processes in the product markets (Johansson and Karlsson 2001). If the lags in the development of labour supply, environment and infrastructure are large, the growth of clusters may be retarded and rapidly turn into a negative phase. The possibilities to counteract lags in the capacity and quality adjustments and to create conditions for a sustainable cluster growth rests in long-term and credible cluster policies in a FUR that can reduce uncertainty among economic actors about the future growth prospects of the different clusters.

According to the modern theory of endogenous, regional growth, cluster growth is something that grow out of internal regional conditions that are susceptible to change (Johansson et al. 2001). In line with this view, cluster policies deal with conditions, which essentially must be developed and implemented with region-specific knowledge as a base. Thus, cluster policies if they shall be implemented must be implemented at the FUR level even if a more comprehensive view and financial support might come from the national level.

Internal economies of scale mainly rest outside the domain of economic policies. However, policies, which lead to lower fixed costs for labour and capital, reduce the dependence of firms on the size of the market potential in a FUR. Moreover, to get new and growing clusters running, it is important to create optimal conditions for start-ups, spin-offs, spin-outs, and firm growth. It is also important to create a clear vision and strong image for new clusters by means of a conscious and profiled marketing.

The geographical transaction costs are partly determined by the infrastructure and transport policies, which in many countries are determined at the national level. Lower geographical transaction costs extends the borders of FURs and increases their market potential, which creates scope for the development and growth of more industries and clusters and of firms with internal economies of scale. Transport costs are becoming an increasingly

important factor for the development of clusters as other costs connected to international trade decrease. It is important to observe that the profitability of investments in infrastructure is larger in FURs with clusters than in FURs without clusters. Normally cost-benefit calculations of infrastructure investments use to disregard this.

Large parts of the knowledge generation in a FUR is characterised by collective characteristics. Knowledge developed by one firm tends over time to diffuse to other firms in the FUR. This generates increasing returns in the FUR economy i.e. the growth of the FUR economy can be influenced by investments in knowledge, R&D, and human capital. Even if there is no one-to-one-relationship between knowledge-intensity and profitable clusters, there are still strong reasons to believe that clusters are more common in knowledge-intensive industries than in other industries. This implies that if a FUR wants to stimulate cluster growth and cluster formation, there are strong reasons for public investments in higher education and R&D. However, it is important to notice that precision in this case is more important than volume. The investments in higher education and R&D must be cluster relevant.

Coalitions

Myrna Wooders and Frank H. Page Jr.

Abstract

Coalitions appear in an incredible diversity of economic and game-theoretic situations, ranging from marriages, social coalitions and clubs to unions of nations. We discuss some of the major approaches to coalition theory, including models treating why and how coalitions form, equilibrium (or solution) concepts for predicting outcomes of models allowing coalition formation, and current trends in research on coalitions. We omit a number of related topics covered elsewhere in this dictionary, such as matching and bargaining.

The traditional notion of a coalition is a group of players who can realize some set of outcomes for its own membership. How to define this set of outcomes is a fundamental question and its definition is typically either avoided, by assuming that the set of outcomes is given, or treated simultaneously with a solution concept. Alternatively, some process may be given that plays a role in determining the set of outcomes that are achievable by each coalition.

How to define a coalition is an even more fundamental question. Typically a coalition is taken as a subset of players of a game. Yet we often perceive that individuals belong to overlapping coalitions. For example, an individual may belong to the Citizens Coalition for Responsible Media, Immunization Action Coalition and the Democratic Party. We also perceive that coalitions may be *temporary* alliances of groups of people, factions, parties, or nations. For most of this article, however, we view a coalition as simply a subset of players of a game.

When both the concepts of a coalition and its attainable set of outcomes have been defined, the question arises of how the gains from coalitional activities are to be allocated among the members of any coalition that might form, bringing us to the notion of a solution concept. A solution concept is a rule which must be satisfied by any allocation or attainable outcome that is viewed as stable or as an equilibrium. Given a description of the primitives of a situation (a game, economy, or social situation, for example) a solution concept may be viewed as predicting which outcome(s) will emerge. Implicitly, a solution concept involves assumptions about the behaviour of individuals or groups of individuals. Even in situations where a particular solution concept seems compelling, however, there may be no attainable outcomes satisfying the requirements of the solution concept. This problem, and the fact that no single solution concept seems to fit all situations, means that there are competing notions of solution concepts.

In this article we discuss issues of coalitions, the outcomes attainable by coalitions and the division of the benefits of coalition formation among the members of a coalition. Many of the fundamental questions that still intrigue researchers have their roots in the early literature of game theory. We will sketch some of the main concepts in the literature on coalitions, going back to von Neumann and Morgenstern's celebrated volume, with its notion of dominance, and also sketch some of the current approaches to questions of coalitional activities. We conclude by noting some new approaches to what a coalition might be and do and directions that research may be taking.

Domination

What a coalition can achieve, or, even more fundamentally, what a coalition can improve upon for its own membership is a fundamental question. This was realized already by von Neumann and Morgenstern (1953), who introduced the notion of domination. An imputation x (or payoff vector, listing a payoff for each participant in the society) *dominates* another imputation y with respect to a coalition S if the members of S are convinced or can be convinced that they have a positive motive for bringing about y and believe that they can do so. The coalition S is called *effective* (for x). Note that it is possible there is another payoff vector y', a coalition S' that is effective for y', and y' dominates y with respect to S' (but not with respect to S)

and in general, the relation 'dominates' may not be transitive.

Solution Concepts

A number of solution concepts based on notions of domination and effectiveness of coalitions have been defined. Three especially prominent concepts are the von Neumann–Morgenstern stable set, the Shapley value, and the core. A set V of payoff vectors, where each vector is a listing of payoffs to players in a game, is a *von Neumann–Morgenstern stable set* if (*a*) no payoff vector in V is dominated by another payoff vector in V and (*b*) every payoff vector not in V is dominated by some vector in V. The *core*, introduced in Gillies and Shapley in 1953 (see the Logistics Research Project 1957, which contains descriptions of the presentations of D. Gillies and L.S. Shapley, where the core was introduced), consists of those payoff vectors x that are feasible and undominated. The formulation of Gillies (1959) of the core of an abstract game can be widely applied. An *abstract game* consists of a set of alternatives for each coalition and a dominance relationship. The *Shapley value*, introduced in Shapley (1953), assigns to each player his *expected* marginal contribution to coalitions and is also used in numerous applications. Alternative notions of the core and of the value include the *Owen value* (Owen 1977), the τ-*value* (Tijs 1981), the *inner core* (Myerson 1995; Qin 1994; and references therein), and the *partnered core* (Albers 1979; Bennett 1983; Reny and Wooders 1996a).

Let us consider a simple example. Let $N = \{1, 2, 3\}$ be the player set. Suppose that any one player can earn zero, any two players can earn one dollar and the three players together can earn $M \geq 0$ dollars. Suppose $M = 1$; then the von Neumann–Morgenstern stable set consists of the payoff vectors $\left(\frac{1}{2}, \frac{1}{2}, 0\right)$, $\left(\frac{1}{2}, 0, \frac{1}{2}\right)$, and $\left(0, \frac{1}{2}, \frac{1}{2}\right)$. Any payoff vector (z_1, z_2, z_3) is in the core if $z_i \geq 0$ for all i A N and $z_i + z_j \geq 1$ for every pair i, j. This implies that, unless $M \geq \frac{3}{2}$, the core is empty. The Shapley value is defined for *superadditive games*, games with the property that the set of payoff vectors achievable by any union of disjoint coalitions is at least as large as the set of payoff vectors achievable by the coalitions independently.

Superadditivity, for our example, implies that $M \geq 1$, in which case the Shapley value consists of the payoff vector $(\frac{M}{3}, \frac{M}{3}, \frac{M}{3})$.

The bargaining set, introduced by Aumann and Maschler (1964), is based on threats and counter-threats. A payoff vector x is in the *bargaining set* if for every credible objection there is a credible counter-objection. That is, if there is a payoff vector y that dominates x with respect to a coalition S then there is another payoff vector y' and coalition S' that is effective for y' and y' is at least as good as x for the members of S' who are not in S and at least as good as y for members of both S and S'. There are a number of related concepts. The *kernel*, introduced in Davis and Maschler (1965), requires that objections and counter-objections have equal strengths. For our example above, the point $(\frac{M}{3}, \frac{M}{3}, \frac{M}{3})$ is also in the bargaining set and in the kernel. Recent research on concepts of the bargaining set has been spurred by the *Mas-Colell bargaining set* (Mas-Colell 1989) which adapts the bargaining set to economies with a continuum of agents and proves equivalence of the outcomes of the bargaining set and the core in an exchange economy.

Another interesting notion is the *admissible set*, introduced in Kalai and Schmeidler (1977). (See also references therein and Shenoy 1980.) Take as given a set of feasible alternatives, denoted by S, a dominance relation M and the transitive closure of M, denoted by $\widehat{M}$. The *admissible set* is the set $A(S; M) = \{x \in S : y \in S \text{ and } y \widehat{M} x \text{ imply } x \widehat{M} y\}$. The admissible set describes those outcomes that are likely to be reached by any dynamic process that respects preferences. Note that the admissible set concept can be applied to a host of game-theoretic situations, ranging from non-cooperative games, where a coalition consists of an individual player, to fully cooperative games, where any coalition can be allowed to form. As shown by Kalai and Schmeidler, under certain conditions the

admissible set coincides with the set of Nash equilibria and, for cooperative games, the admissible set coincides with the core. More recently, it has been shown that the admissible set consists of the union of basins of attraction, and a von Neumann–Morgenstern set consists of one member of each basin (Page and Wooders 2006).

Behaviour of Coalition Members

What a coalition can achieve also depends on the *behaviour of the members of the coalition*. For example, potential coalition members may bargain over the distribution of the gains to coalition formation and outcomes in the core may not be achievable as equilibria of non-cooperative bargaining processes (an important point made by John Nash 1953, leading to the *Nash program*). Chatterjee et al. (1993) demonstrate this point very well for transferable utility (TU) games, which describe what a coalition can achieve by simply a number, in interpretation, an amount of money, for example.

As stressed by Xue (1998), it may matter whether players are farsighted or myopic in their thinking about forming coalitions. Myopic players take as given the actions of others and behave accordingly. In choosing their actions, farsighted players, in contrast, take into account the reactions of other players to their actions and thus the eventual consequences of their actions. See also Diamantoudi and Xue (2003) who study the far-sighted core of a hedonic game – a game where, instead of payoff sets for coalitions, preferences are given for each individual over all coalitions in which he is contained – and Mauleon and Vannetelbosch (2004) who both allow 'spillovers' between coalitions and farsightedness of players, and demonstrate sufficient conditions for there to exist stable outcomes. (Two important papers in the game theoretic literature studying farsightedness, but not coalition formation, are Chwe 1994, and Harsanyi 1974.)

Players may also take into account 'asymmetric dependencies' within coalitions. A solution displays an asymmetric dependency if one player needs the presence of a second player to realize his payoff in the solution, but the second player does not need the presence of the first. When a player i is dependent on another player j in this sense, but j is not dependent on i, then j is in a position to attempt to obtain a larger share of the surplus from i. Consider, for example, a two-person divide-the-dollar bargaining game. Any division giving the entire dollar to one participant displays an asymmetric dependency; the player receiving the dollar is dependent on the player receiving zero. The player receiving zero is not compelled to join the two-person coalition to receive his part of the payoff. In contrast, to achieve the payoff of 50 cents for each player the two-person coalition is compelled to form – the players are partnered. The partnered core, introduced in Albers (1979) and Bennett (1983) for TU games and in Reny and Wooders (1996a) for non-transferable utility games (where the set of payoffs achievable by a coalition are described by vectors listing a payoff for each member of the coalition) consists of those outcomes in the core with the property that, to achieve his payoff, no individual needs another individual who does not need him. Even in well-behaved exchange economies there may be no outcomes in the core that are not partnered; that is, all outcomes in the core may be vulnerable to the threat of secession by some coalition of players. Page and Wooders (1996) provide an example.

Behaviour of Non-Coalition Members

In many situations, what a coalition can achieve depends on assumptions about the *behaviour of non-coalition members* (sometimes called the 'complementary coalition', although there is no requirement that the complementary coalition actually forms an alliance); for example, individuals may steal, or drop garbage in the backyards of others, or there may be widespread pollution. Two alternative definitions of the core, from Aumann and Peleg (1960), highlight the dependence of the core on the assumptions made about what outcomes are perceived as feasible by coalitions: the α-core, consisting of those outcomes that a coalition can guarantee for its membership, and the β-core, consisting of those outcomes that a coalition cannot be prevented from achieving for

its membership. In some situations, such as private goods economies without externalities or in some recent models of economies with clubs or local public goods, these two notions are equivalent, but, as noted by Shapley and Shubik (1969a), in the presence of externalities between coalitions these concepts may yield different outcomes.

Members of a coalition may also be directly affected by the structure of alliances among non-members of the coalition. This consideration underlies the Lucas and Thrall (1963) concept of *a partition function form game*, where the attainable total payoff to a coalition depend on the structure of coalitions formed by the complementary player set.

In the approach of Chander and Tulkens (1995; 1997), to predict the set of outcomes that it can achieve, a coalition presumes that the outside players will adopt their individually best reply strategies, leading to their notion of the gamma core. In the sense that the non-coalition members are treated as forming one-person coalitions, the Chander–Tulkens approach is more restrictive than that of Lucas and Thrall. When it is assumed that coalitions can freely merge or break apart and are farsighted, however, Chander (2007) demonstrates that, subsequent to a deviation by a coalition, the non-members will have incentives to break apart into singletons, thus providing a justification for the Chander–Tulkens approach.

Other approaches to the question of what a coalition can achieve for its membership have also appeared in the literature. Some recent contributions allow theft or pillage by non-coalition members; see, for example, Jordan (2006), where the payoffs attainable by a coalition are determined endogenously, and references therein.

In application, questions of the behaviour of the non-coalition members have been especially important in industrial organization and environmental economics; see, for example, Yi (1997) and Bloch (1996); see Bloch (2005) and Carraro (2005) for discussions of relevant literature.

Information Sharing Within Coalitions

When players have private information new and difficult issues arise. Chief among these is the issue of *information sharing within coalitions*. How can members of a coalition be induced to share their private information truthfully? Or, if it is not shared truthfully, how much information will be shared and how much of it will be believed? In his seminal paper, Wilson (1978) introduced two notions of the core for situations with private information, namely, the coarse core and the fine core; later Yannelis (1991) introduced the private core. Each of these core notions corresponds to assumptions about the extent to which private information of individual players is shared within coalitions. These issues are further addressed in Allen (2006), who treated core concepts in exchange economies, and Page (1997), who extended Allen's results to infinite dimensional commodity spaces. There is also the question of what informational time frame should be used in defining a solution concept. Following the informational distinctions introduced by Holmstrom and Myerson (1983) in extending the notion of Pareto efficiency to economies with private information, we can ask whether the solution concept should be *ex ante* (that is, defined relative to *ex ante* probability beliefs concerning the future information state of the economy – and therefore before players know their private information), whether it should be interim in nature (that is, defined relative to each possible profile of players' private information – and therefore after each player knows his private information but before players know the information of others), or whether it should be *ex post* (that is, defined relative to each possible information state of the economy – and therefore after each player knows the information state of the economy).

Following a mechanism design approach, Forges et al. (2002) address the issue of honest information revelation within coalitions by focusing on coalitionally incentive-compatible direct mechanisms. A coalitional direct mechanism is a mapping from the set of information profiles of coalition members into coalitional allocations. A coalitional direct mechanism is *incentive compatible* if no coalition member has an incentive to lie about his private information –on the assumption that other coalition members report their private information truthfully (that is, truthful

reporting is a Nash equilibrium of the coalitional revelation game induced by the mechanism). Formulating the coalitional mechanism design game as a TU game in characteristic function form, they demonstrate non-emptiness of the incentive compatible '*ex ante* core'. Other contributions which analyse interim core notions include Ichiishi and Idzik (1996), Hahn and Yannelis (1997), Vohra (1999), Volij (2000), Demange and Guesnerie (2001), Dutta and Vohra (2005) and Myerson (2007). See Forges et al. (2002) for a survey.

The core with incomplete information is gaining prominence in applications, such as political economy (see, for example, Serrano and Vohra 2006).

Coalition Formation

Other important questions are *how coalitions form and how coalition structures influence the behaviour of individuals within coalitions*. Several approaches are possible. Coalition formation and individual behaviour can be viewed as outcomes of market mechanisms or as outcomes of assumed cooperation within groups that may form. Alternatively, coalition formation and individual behaviour can be viewed as outcomes induced from non-cooperative behaviour. More recently coalition formation and individual behaviour within coalitions have been modelled in network settings.

The Market/Cooperative Game Approach

As suggested by Tiebout (1956) and Buchanan (1965), individuals may take as given prices for membership in coalitions (clubs, firms, jurisdictions, and so on). Tiebout conjectured that if public goods are 'local' (that is, public goods are subject to congestion and individuals can be excluded from the public goods provided in jurisdictions in which they are non-members), then the possibility of individuals moving to the jurisdictions where their wants are best satisfied subject to their budget constraints and to taxes creates a competitive 'market-like' outcome. A part of the outcome is a partition of individuals into jurisdictions. Buchanan (1965) stressed the importance of collective activities in a model of clubs with optimal club size; to illustrate, considering our example above where any two players can earn one dollar, if $M < \frac{3}{2}$, then two is the optimal club size. One way to formulate the Tiebout hypothesis (Pauly 1970; Wooders 1978; 1980) is to model the economy as one where individuals pay prices to join coalitions/clubs/jurisdictions and to demonstrate equivalence of the core and the set of outcomes of price-taking equilibrium. The results of these early papers have been greatly extended and refined; see, for example, Conley and Wooders (2001); Ellickson et al. (2001) and, for a survey, Conley and Smith (2005). The spirit of the main results is that, whenever *small group effectiveness* holds – that is, whenever all or almost all externalities can be internalized within relatively small groups of individuals (clubs, jurisdictions, firms, trading coalitions, and so on) or, in other words, whenever all or almost all gains to collective activities can be realized with some partition of the total player set into relatively small coalitions – then economies with many participants are 'market like' in the sense that price-taking economic equilibrium exists and the set of equilibrium outcomes is equivalent to the core of the economy.

The results for models of economies with local public goods and clubs suggest results for cooperative games with endogenous coalition structures. Under small group effectiveness, cooperative games with many players are 'market games' (as defined in Shapley and Shubik 1969b) and thus can be represented as economies where all individuals have concave, continuous utility functions (Wooders 1994a, b). (That the conditions of Wooders 1983, imply that games with many players are market games was first noted by Shubik and Wooders 1982, and the concavity of the limiting per capita payoff function was first explicitly noted in 1987 by Robert Aumann in his entry game theory in the first edition of this dictionary, which is reproduced in the present edition).

A simple example may provide some intuition. Suppose any two players can earn $1.00, as in our earlier example, but now suppose that there are n players in total. If n is odd, then the core is

empty, but for large n each player can receive nearly \$0.50 so certain approximate cores are non-empty and the approximation is 'close'. In defining an appropriate approximate core concept the modeller can either suppose that there are some costs to coalition formation, which can be allowed to go to zero as n instead that the payoff to a coalition with m members is a real number $v(m)$. Suppose the game is becomes large, or that a relatively small set of players can be ignored. Now, more generally, suppose essentially superadditive – the total payoff achievable by $m + m'$ players is greater than or equal to $v(m) + v(m')$. Then the only condition required to ensure non-emptiness of approximate cores of games with many players is that there is a bound K such that $\frac{v(m)}{m} \leq K$ for all m, which implies small group effectiveness. The limiting concave utility function alluded to above is $u(n) = \sup \frac{v(m)}{m} n$. See also Robert Aumann's discussion of Wooders's (1983) result in game theory.

Some other market properties of a game with many participants are that: Outcomes in the core or approximate cores treat most similar players nearly equally (Wooders 1983; Shubik and Wooders 1982; and for the most recent results, Kovalenkov and Wooders 2001a). The Shapley value is in an approximate core (Wooders and Zame 1987). A 'law of scarcity' holds; that is, increasing the abundance of one type of player leads to a decrease in the core payoffs to individual players of the same of similar types (Scotchmer and Wooders 1988; and, for recent results and references, Kovalenkov and Wooders 2005b; 2006). The law of scarcity is in the spirit of the law of demand and law of supply of private goods economies but differs in that an additional player in a game creates both creates additional demand (for the cooperation of others) and additional supply (of players of the same type).

To illustrate further the intimate relationships between markets and economies with group activities such as clubs and/or local public goods, we will discuss Owen (1975), who treats a production economy where individuals are endowed with resources that may be used in production. Rather than selling their resources to firms, individuals form coalitions and use the resources owned by the coalition to produce output which can then be sold at given prices. Owen places conditions on the model – specifically linear production functions – that ensure non-emptiness of the core of the derived game, whose coalitions consist of owners of resources. From the fundamental theorem of linear programming, associated with any point in the core of the game there is a price vector for resources, which is analogous to a competitive equilibrium price vector for resources except that the budget constraint need not be satisfied by individuals but instead only by coalitions. Owen demonstrates that, when the economy is replicated, the core converges to the set of Owen equilibrium prices. The Owen set and the Owen equilibrium prices have been studied in a number of papers – for example, Kalai and Zemel (1982), Samet and Zemel (1984), Granot (1986) and Gellekom et al. (2000). (There is also some relationship to the literature on oligopoly and cost-sharing; see, for example, Sharkey 1990; Tauman et al. 1997.)

It is easy to interpret the resources in Owen's model as attributes of individuals, such as their intelligence, skill level, wealth, ability to dance the tango, and so on. (Of course, labour is typically an input into a production process.) We can also easily interpret a coalition that forms as a club. For example, the club may be a dinner club, where each person brings himself – his personality, his gender, and so on – and also perhaps contributes a dish for the meal. The benefits to membership in a club depend on the attributes of its members – whether they are charming, whether they are good cooks. A difficulty in applying Owen's model to economies with clubs, jurisdictions, or any sort of essential group activity is that his results require linearity of the production function. However, as Owen remarks, concavity of preferences and production possibilities, as in Debreu and Scarf (1963), suffices for all his results except uniqueness of Owen equilibrium prices. But the concavity of limiting per capita payoff functions under the conditions of essential superadditivity and small group effectiveness of Wooders (1983; 1994a, b) implies that in large games with clubs or coalitional activities the economy is representable as a market economy where

individuals have concave preferences. Essential superadditivity simply allows a set of players to partition itself and achieve the outcomes achievable by the collective activities of the members of each element of the partition. Finiteness of the supremum of per capita payoffs (per capita boundedness) rules out average (per individual player) payoff from becoming infinitely large. Recent research investigates the relationship between club economies and games in more detail (see, for recent surveys, Wooders 1994b; Kovalenkov and Wooders 2005a; Conley and Smith 2005).

Closely related in important ways to the market approach are approaches that assume cooperative behaviour on the part of members of the coalitions that form. As in the market approach, what a coalition can achieve is taken as defined, a solution concept assumed (which in some cases includes a partition of the set of players into groups that can achieve their part of the outcome), and the existence and properties of outcomes satisfying the requirements of the solution concept are examined. Classic contributions to this literature, besides those mentioned above, include Aumann and Maschler (1964), Aumann and Shapley (1974), Shapley (1971), and Hart and Kurz (1983). More recent contributions include, among others, Demange (1994), Bogomolnaia and Jackson (2002), Banerjee et al. (2001), Le Breton et al. (2006), and Bogomolnaia et al. (2007). These interesting works deepen insight into the question of conditions on models ensuring there is some outcome satisfying the requirements of solutions having desirable properties, especially the core.

Necessary and sufficient conditions for non-emptiness of cores are demonstrated by Bondareva (1963) and Shapley (1967) for games with transferable utility and, most recently, by Predtetchinski and Herings (2004) and Bonnisseau and Iehle (2007) for non-transferable utility games.

A small but growing literature, initiated by the assignment games of Gale and Shapley (1962), Shapley and Shubik (1972) and Aumann and Drèze (1974), addresses the question of what conditions on permissible coalition structures will ensure that a game has a non-empty cores, independently of the sets of attainable outcomes of the game. Early papers providing such conditions are Kaneko and Wooders (1982) and Le Breton et al. (1992). Recent papers have treated sufficient conditions for non-emptiness of the core of a hedonic game, where preferences are defined directly over coalitions (Bogomolnaia and Jackson 2002; Banerjee et al. 2001; Papai 2004) while Iehle (2006) provides necessary and sufficient conditions. Demange (2004) demonstrates that imposing a hierarchical structure on the set of players, limiting the coalitions that can form, will ensure existence of an efficient outcome that is stable in the sense that no admissible coalition, called a team, could improve upon the outcome for its members. A hierarchical structure is represented by a pyramidal network. A team is a group of individuals who can communicate through the channels created by the hierarchical structure.

A related branch of literature focuses on conditions ensuring that groups of agents do not break away from a coalition. Le Breton and Weber (2001), Haimanko et al. (2004), and Drèze et al. (2006) investigate models with heterogeneous individuals and conditions ensuring existence of secession-proof outcomes, that is, outcomes that are immune to breakaways by subgroups of individuals and are thus in the core. For a different approach motivated by the idea that if a group secedes from a larger group then it does not necessarily stand alone, see Reny and Wooders (1996b), who use the solution concept of the partnered core. See also Alesina and Spolaore (1997) who demonstrate that, in a model of public good provision with a continuum of consumers who are differentiated by their preferred location for a facility and voting within each community, in equilibrium there are too many coalitions (nations).

Non-cooperative Game Approach

Coalitions can arise as equilibrium outcomes of either static or dynamic non-cooperative games. In the non-cooperative literature on clubs or local public goods, it may be assumed that there is a fixed set of jurisdictions, each providing some

level of a public good for its residents. Individuals who move to a jurisdiction pay the average cost of public good provision. Alternatively, individuals may be required to pay a proportion of their income towards financing the public good produced by the jurisdiction. Individuals each chose a jurisdiction in which to live. The main questions are whether a non-cooperative equilibrium (Nash equilibrium in pure strategies) exists and its properties, such as whether, in equilibrium, members of the same jurisdiction have similar wealths. Contributions to this literature include Greenberg and Weber (1986), Demange (1994), Konishi et al. (1997; 1998), Gravel and Thoron (2007). See also Demange (2005), who discusses literature involving both cooperative and non-cooperative approaches. Based on the concept of coalition-proofness (Bernheim et al. 1987) Conley and Konishi (2002) obtain existence of an efficient, migration-proof equilibrium for local public good (club) economies with many but a finite number of players. Casella (1992) and Casella and Feinstein (2002) consider the effects of the possibilities of trade in private goods in the formation of clubs/jurisdictions.

In a number of papers on dynamic games of coalition formation, a payoff set is given for each coalition. Suppose for simplicity that, for each coalition S, there is a unique attainable payoff vector $\{x^i(S) : i \in S\}$. If players are randomly ordered and if according to the ordering each player lists those players he would like as members of his coalition, then one possible solution to such a game of non-cooperative coalition formation would be a partition of the total player set into coalitions where for each coalition S in the partition the members of S all choose S and each player i A S receives the payoff $x^i(S)$. If player i belongs to no such coalition, then he receives some default payoff $x^i(\{i\})$. This sort of approach was introduced in Selten (1981). Perry and Reny (1994) provide a non-cooperative implementation of the core for TU games. In the Perry–Reny model proposed, time is continuous. This ensures that there is always time to reject a non-core proposal before it is consummated. Which coalitions will form typically depends crucially on the rules of the game. The Perry–Reny implementation is meant to reflect the standard motivation for the core as closely as possible. Hart and Mas-Colell (1996) implement the *consistent value* (Maschler and Owen 1992) for NTU games, which, for TU games, is equivalent to the Shapley value. Bloch (1996) treats games where, as in the Lucas–Thrall model, the payoff achievable by a group of players may depend on the entire coalition structure of the remaining players. Ray and Vohra (1997; 1999) study coalitional agreements and coalitional bargaining in partition function games. See Bandyopadhyay and Chatterjee (2006) for a survey of coalition formation based on non-cooperative bargaining. See also Myerson (1995), Seidmann and Winter (1998), Mauleon and Vannetelbosch (2004), among others.

Networks and Coalition Formation

Because networks allow for a detailed specification of interactions between individuals and between coalitions, abstract games over networks have a greater potential to capture the subtleties of bargaining and negotiation than do the abstract coalitional form games of von Neumann–Morgenstern and Gillies and Shapley. A seminal contribution to this line of research is the paper by Myerson (1977). Myerson begins by assuming that the worth of each possible coalition depends on the structure of cooperation between individuals as given by a graph where nodes represent individuals and links between nodes represent interactions between individuals. As in much of the subsequent literature Myerson imposes an allocation rule, a rule specifying how the worth of a coalition is to be shared among its members. The worth of any connected (linked) set of players is divided according to the rule. The specific rule chosen by Myerson is a variant of the Shapley value, now known as the Myerson value. As Myerson shows, this is the only rule satisfying both component efficiency (in sum, the members of each component of the network receive the worth of that component as a coalition) and a fairness property that requires any two players to benefit equally from the formation of a link. Aumann and Myerson (1988) work with extensive form games, where players choose links strategically and allow players to look ahead

and to take into account the end effects of their actions. In their model, once a link is formed, it cannot be broken. The equilibrium concept is non-cooperative subgame perfection. Once players have formed links, the payoffs to players are determined by the Myerson value.

Jackson and Wolinsky (1996) also treat link formation between individual players. A network satisfies their pairwise stability condition if no two players could benefit by creating a link between them and no one player could benefit by cutting a link with another player. Based on the Jackson–Wolinsky model, numerous papers have now looked at costs and benefits of link formation between players and equilibrium outcomes; see Dutta, van den Nouweland, and Tijs (1998) for example, and van den Nouweland (2005) for some recent results and a review. Herings et al. (2006) introduce notions of pairwise farsighted stability. Jackson and van den Nouweland (2005) introduce the concept of a strongly stable network. A network is strongly stable if no coalition could benefit by making changes (additions or deletions) to the links of coalition members. As Jackson and van den Nouweland show, the existence of strongly stable networks is equivalent to non-emptiness of the core in a derived cooperative game. See also Jackson and Watts (2002), who use linking networks and stochastic dynamics to study the evolution of networks.

Other recent works addressing questions of coalition formation in networks make assumptions concerning what a coalition believes it can achieve. These contributions include Watts (2001), who assumes that dominance must be direct, in the sense that a coalition will act to change a network from g to g' only if it perceives an immediate gain. In contrast, Page et al. (2005) consider indirect dominance where a network g dominates another network g' if there is a coalition S that believes it can trigger a series of changes beginning with the network g and ending with the network g' that is preferred by all members of S. Whether dominance is direct or indirect is of crucial importance, as illustrated in Diamantoudi and Xue (2003) and Page and Wooders (2007), among others. Consider, for example, a situation with two jurisdictions, say J_1 and J_2 and seven people. Each person would like to live in the jurisdiction with the fewest residents. With direct dominance, any partition of the people between the two jurisdictions with three people in one jurisdiction and four in the other is stable. In contrast, with indirect dominance, the situation changes; players can be more optimistic. Suppose that initially there are four people in jurisdiction J_1 and three in J_2. Two people in J_1 may move into J_2 in the belief that, since J_2 has become so crowded, three people will leave J_2 and move to J_1, with the result that the two initial movers will be better off.

Using supernetworks, introduced in Page et al. (2005), where nodes represent networks and directed arcs represent coalitional moves and coalitional preferences, networks can also provide a simple representation of the rules of network formation and hence the rules of coalition formation. Network formation rules play a crucial role in determining coalitional outcomes. To illustrate, in the literature on markets and on cooperative games, it is assumed that coalitions can exclude individuals. It may be, however, that groups (or coalitions) are subject to 'free entry' – any group of players can freely join another group without the consent of those being joined. This has long been important in the literature on economies with clubs/local public goods; compare, for example, the models of Konishi et al. (1998) and Demange (1994) with that of Conley and Wooders (2001). As a special case, networks can also accommodate a systematic analysis of coalition formation and payoff division when there are potential irreversibilities. For example, given the informational environment, it may be that the only coalitions which can form are sub-coalitions of existing coalitions. Or the rules of network formation may not allow cycles.

How to Define a Coalition

The traditional approach of cooperative game theory models a coalition as an alliance of players who take as given a well-defined set of possible outcomes or payoffs. The alliance, when considering whether to 'block' a proposed outcome, is

faced with the alternative of standing alone. In reality, however, we observe that individuals belong to multiple, possibly overlapping alliances. This fact has received remarkably little attention in the literature. Some papers in the club literature allow individuals to belong to multiple clubs for the purposes of local public good provision and private good production within each club, including Shubik and Wooders (1982), Ellickson et al. (2001) and Allouch and Wooders (2006). Roughly, if there is only a finite set of sorts of clubs, bounded in size, (Ellickson et al.) or if 'per capita payoffs' are bounded (Allouch and Wooders), then in large economies the core and the set of price taking equilibrium outcomes are equivalent. An interesting application of the idea of overlapping coalitions is developed in Conconi and Perroni (2002), who assume that a country can enter into different alliances, where each alliance to which it belongs is concerned with a different issue.

The definition of a coalition also becomes an issue when the total player set is an atomless continuum. There are two approaches. One approach, introduced in Aumann (1964), is to model a coalition as a subset of positive measure. Major theorems using this approach and relating to coalitions demonstrate equivalence of the core and outcomes of price-taking equilibrium of models of economies Another approach is to describe a coalition as a finite set of players, as in Keiding (1976). This has the advantage that individuals may interact with other individuals, and permits matching or marriage models, for example. An obvious difficulty with such an approach is that, at the heart of economics, is the problem of relative scarcities. Think of the diamond–water paradox; even though water is essential for life itself, it is abundant and thus inexpensive, while diamonds are relatively inessential but scarce and thus expensive.

To see the difficulty in retaining relative scarcities while allowing finite coalitions, suppose, for example, that the points in the interval [0,2] represent boys and the points in the interval [3,4] represent girls so that there are 'twice' as many boys as girls. Suppose the only effective coalitions consist of either boy, girls pairs (i, j) where $i \in [0; 2]$ and $j \in =3; 4]$, or singletons – a matching model. Consider the set of coalitions $(i; j) : j = 3 + \frac{1}{2}i$; this set describes a partition of the total player set and marries each boy to a girl; clearly this partition is not consistent with the relative scarcities given by Lebesgue measure. Indeed, since there are one-to-one mappings of a set of positive measure onto a set of measure zero, it is even possible to have partitions of the total player set into boy–girl pairs and singletons that match each boy to a girl while leaving a set of girls of measure 1 unmatched! A solution to this problem was proposed by Kaneko and Wooders (1986) with the introduction of *measurement-consistent* partitions. A simple formulation of measurement consistency has recently been provided (Allouch et al. 2006), and we use it here. Define an *index set* for a partition of a continuum of players as one member from each element of the partition. A partition of players into finite coalitions is 'measurement-consistent' if every index set for the partition has the same measure. The partition given above is not measurement-consistent while the partition $\{(i; j) : j = 3\ )\ i; i \in [0, 1] \cup \{\{i\} : i \in (1; 2]\}\}$ is measurement-consistent. While in models of exchange economies, the core with finite coalitions (the *f*-core) and the Aumann core yield equivalent outcomes, in the presence of widespread externalities, such as global pollution, the *f*-core coincides with the set of competitive equilibrium prices while the Aumann core may be empty and, even if non-empty, may have an empty intersection with the set of equilibrium outcomes; the concepts of the Aumann core and the *f*-core are distinct with the *f*-core apparently most closely related to the set of competitive equilibrium prices (Kaneko and Wooders 1986; Hammond, Kaneko and Wooders 1989; Kaneko and Wooders 1994). Other works using the ore approach include Berliant and Edwards (2004) and Legros and Newman (1996, 2002). These papers illustrate the advantage of the *f*-core approach in that it enables analysis of activities within groups (firms or clubs, or other organizations) that may contain any finite number of individuals but are negligible relative to the entire economy.

An interesting difference between the Aumann-core and the *f*-core is that, while the Aumann-core has been axiomatized by Dubey and Neyman (1984), the authors stress that the axiomatization is completely different than axiomatizations for the core in cooperative games with only a finite number of players. In contrast, Winter and Wooders (1994) provide an axiomatization for the core of a game with finite coalitions that applies whether the player set is finite or an atomless continuum.

Conclusions

This article began with some of the first works on coalitions in the literature of game theory and concluded with recent work on coalitions and networks. It becomes apparent that the concepts of early works underlie much of even the most recent research. We see at least a part of the future of coalition theory in network modelling of socio-economic coalitions and in more behavioural approaches to coalition theory, involving 'implicit' and 'tacit' coalitions. Language and the ability to communicate well are clearly involved; see multilingualism and references there. Instead of being bound together by commitments and contracts, members of an implicit coalition may be bound together by common language, culture, objectives or by common group memberships and, even though there may be no explicit agreement, members of an implicit coalition might act together, as if they were a coalition. This raises questions of to what extent individuals, who share common group memberships as in Durlauf (2002) for example, are an implicit coalition and whether such individuals have tendencies to form more explicit coalitions. While much has been done on coalitions, there remains much to do.

Coase Theorem

Francesco Parisi

Abstract

The Coase Theorem holds that, regardless of the initial allocation of property rights and choice of remedial protection, the market will

determine ultimate allocations of legal entitlements, based on their relative value to different parties. Coase's assertion has occasioned intense debate. This article provides an intellectual history of Coase's fundamental theorem and surveys the legal and economic literature that has developed around it. It appraises the most notable attacks to the Coase Theorem, and examines its methodological implications and normative and practical significance in legal and policy settings.

Mutuality of advantage from voluntary exchange is one of the most fundamental concepts in economics. The well-known proposition of Ronald H. Coase (1960) – generally known as the Coase theorem – builds on this simple and yet fundamental insight. The law creates many rights and legal entitlements, establishing the initial allocation of rights and liabilities. Whenever there are no legal or factual impediments to exchange, the dynamic of the market will determine the final allocation of such rights.

In this context, Coase suggests that the transferability of rights in a free economy leads toward their best use and an efficient final allocation. Whenever the initial allocation is not optimal, the owners of the rights will have an incentive to transfer them to other individuals who value them more. Such an exchange will continue until there is no further potential for reciprocal profit, which will not be exhausted until each right is in the hands of the highest-valuing individual. The Coase theorem predicts that, in a competitive market environment without legal or factual impediments to exchange, the final allocation of rights will be efficient.

This article discusses the pervasive methodological implications of Ronald Coase's idea to the field of law.

A Brief Intellectual History

Coase's assertion that an initial assignment of property rights is often irrelevant to overall welfare has occasioned one of the most intense and fascinating debates in the history of legal and economic thought. Private property is often explained as the unavoidable by-product of scarcity in a world where common pool losses outweigh the sum of contracting costs and enforcement of exclusive property rights. At the turn of the 20th century, the underlying assumption in the economic literature was that private property emerged out of a spontaneous evolutionary process because of the desirable features of private property regimes in the creation of incentives for constrained optimization.

This understanding of the relationship between scarcity and emergence of legal entitlements characterized mainstream property right theory when Coase entered the academic world. Coase began his undergraduate studies at the London School of Economics in 1929, as a candidate for a Bachelor Degree in Commerce. In those years, one of Coase's teachers, Sir Arnold Plant, was re-examining the theme of property rights from a novel perspective. According to Plant, the traditional justification for private property – scarcity – was incapable of serving as the sole intellectual foundation for this institution. Plant showed that incentives, rather than scarcity, lay at the core of the property right problem (Plant 1974).

Coase's use of legal rules as an object of economic research in his analysis of incentive structure and alternative final resource allocations reveals a remarkable technical affinity with the

work of his undergraduate teacher. In his Nobel memorial lecture, Coase acknowledges the importance of his encounter with Plant as a 'great stroke of luck' that cultivated his interest in property rights theory (Coase 1992, p. 715). For Coase, Plant's teaching that '[t]he normal economic system works itself' (Salter 1921, pp. 16–17) and that prices in a competitive market lead resources to their highest valuing uses was a revelation into the dynamic of the economic system: 'I was then 21 years of age, and the sun never ceased to shine. I could never have imagined that these ideas would become some 60 years later a major justification for the award of a Nobel Prize. And it is a strange experience to be praised in my eighties for work *I* did in my twenties' (Coase 1992, p. 716).

The experience of the following years at the London School of Economics laid the methodological foundations of what would later become Coase's theorem on the problem of social costs. All the ingredients of his revolutionary analysis on the debated theme of social cost had been profiled during his LSE years (see Williamson and Winter 1991, pp. 34–5). But it is not until the late 1950s that Coase verbalized such a simple and yet ingenious idea. He had first expounded the core of his later theorem in an article published in 1959. In those pages, one grasps what would later become the central theme of Coase's celebrated argument:

> Whether a newly discovered cave belongs to the man who discovered it, the man on whose land the entrance to the cave is located, or the man who owns the surface under which the cave is situated is no doubt dependent on the law of property. But the law merely determines the person with whom it is necessary to make a contract to obtain the use of the cave. Whether the cave is used for storing bank records, as a natural gas reservoir, or for growing mushrooms depends, not on the law of property, but on whether the bank, the natural gas corporation, or the mushroom concern will pay the most in order to be able to use the cave. (1959, p. 25)

The discussion of the rationale of property rights under Coase's highest bidder framework obviously contained an attack on the Pigouvian approach (Pigou 1920) to the problem. The point was rather self-evident to Coase, but not so for some of the Chicago economists. George Stigler was among Coase's early critics:

> Ronald Coase criticized Pigou's theory rather casually, in the course of a masterly analysis of the regulatory philosophy underlying the Federal Communication Commission's [FCC] work. Chicago economists could not understand how so fine an economist as Coase would make so obvious a mistake. Since he persisted, we invited Coase (he was then at the University of Virginia) to come and give a talk on it. Some twenty economists from Chicago and Ronald Coase assembled one evening at the home of Aaron Director. . . . In the course of two hours of argument the vote went from twenty against and one for Coase to twenty-one for Coase. What an exhilarating event! (Stigler 1988, pp. 75–6)

According to Coase, the objections to his FCC paper are at the origin of his later 1960 article on the problem of social costs. Coase recalls that he was urged to omit that section of his FCC article, something he refused to do. In retrospect, Coase believes that had it not been for the Chicago economists' attacks his full-fledged idea would have never been formulated (1993, p. 250).

The Positive Coase Theorem

The arguments that were refined in the course of such debate were later put together in the form of an article for the *Journal of Law and Economics* in 1960, titled 'The Problem of Social Cost'. This article – later known as the Coase theorem – soon became a milestone in legal and economic literature. In the course of his austere discussion, Coase does not reveal any sign of anticipated realization of the revolutionary power of his insight. Indeed, Coase insists that he never intended to convey his thoughts in the precise and analytical form of a theorem (1988, p. 157).

A few years after the publication of 'The Problem of Social Cost', a sizeable number of commentaries and theoretical elaborations were developed on Coase's newly presented theme. The unpretentious style of Coase's article had thus been crowned by a notoriety rarely attained by legal writings of any sort (Shapiro 1985, p. 1540). Part of the uproar is explained by the fact that the article challenged an established

principle of public finance (see Manne 1975, pp. 123–6). Before 'The Problem of Social Cost', very little attention had been given to the possibility that the problem of externalities could be resolved through free market exchanges.

Coase boldly attacked the conclusions reached by the Pigouvian tradition by suggesting its influence was in part due to the lack of clarity in its exposition (1960, p. 39). Coase departs from the Pigouvian approach by demonstrating that, in the absence of transaction costs, generators and victims of externalities will negotiate an efficient allocation of resources, independent of the initial assignment of rights among them. In confuting the conclusions of the Pigouvian tradition, Coase gave life to a model with the potential for the evaluation of an unlimited number of legal and social issues.

George Stigler was the first scholar to restate Coase's model in the form of a theorem: '[U]nder perfect competition private and social costs will be equal' (1966, p. 113). Demsetz (1967, p. 349) defined the theorem in the following terms: 'There are two striking implications of this process that are true in a world of zero transaction costs. The output mix that results when the exchange of property rights is allowed is efficient and the mix is independent of who is assigned ownership (except that different wealth distributions may result in different demands)'. Soon thereafter, Guido Calabresi stated the same principle more descriptively: 'Thus, if one assumes rationality, no transaction costs, and no legal impediments to bargaining, all misallocations of resources would be fully cured in the market by bargains' (Calabresi 1968, p. 68).

The implicit premise of Coase's analysis draws upon a fundamental postulate of microeconomic theory: the free exchange of goods in the market moves goods towards their optimal allocation. The voluntary transfer of individual rights in the marketplace, thus, will cure a non-optimal allocation of legal entitlements.

The Coasean Methodological Revolution

Coase's article constitutes, according to many commentators, the first example of an economic analysis of law in North American literature. The novelty of his approach inspired an entire generation of scholars – pioneers in this new branch of applied economics. Only a few months prior to receiving the Nobel Prize for economics, in occasion of the First Annual Meeting of the American Law and Economics Association, Ronald H. Coase was recognized, together with Guido Calabresi, Henry G. Manne and Richard A. Posner, as a founding father of Law and Economics. This recognition follows many years of challenging debate. Many of the writings that developed around 'The Problem of Social Cost' tested the premises of Coase's model, seeking to undermine the conditions of his model and stressing the lack of practical reach of his analysis.

Further criticisms pertained to three fundamental points. One group of critics observed that the Coase Theorem disregarded the inter-industrial long-term effects of the system (Calabresi 1965; Wellisz 1964). These critics argued that Coase ignored the possible disequilibria which may occur after the negotiation and the likely dynamic changes in the initial equilibrium. In the context of Coase's well-known example, if the right has been assigned to the ranchers, the farmer will have to pay local ranchers until they all relinquish their right of pasture. The entire cost will, thus, burden the farming industry. Farmers will either have to bear the burden of the injury caused by the livestock or agree to pay the price demanded by the ranchers, whichever is less, on the assumption that negotiation is costless. Under this liability rule, the cost of ranching will not reflect the cost imposed on the farmers. The transfer of rights and liability from one group to another will, therefore, result in a shift in the relative wealth and costs associated with the two industries. The criticism claims that, in the long run, every shift of wealth will lead to an inter-industrial disequilibrium.

In 1968, Calabresi, one of the initial proponents of this criticism, reconsidered it, noting that in the presence of determined conditions the conclusions of Coase remain as true in the long run as in the short term (1968, p. 67). Calabresi's later analysis re-established the authority of the Coase Theorem, at least on this point. It became clear that Coase did not ignore the long-term

effects of his model. Perhaps not explicitly, he had considered them to their logical extreme. Calabresi observes: 'The reason is simply that (on the given assumptions) the same type of transactions which cured the short run misallocation would also occur to cure the long run ones. . . . This process would continue until no bargain could improve the allocation of resources' (1967, pp. 67–8).

In 1972, Harold Demsetz joined this debate, demonstrating with a more systematic analysis that the conclusions reached by Coase are not corroded by the long-term effects of a change in the assignment of property rights. Demsetz's reasoning finds its basis in the principle that the process of allocation of scarce resources among alternative uses is analogous to the process of constrained optimization of the single owner of two conflicting activities.

An additional critique, formulated by Calabresi (1965) and Wellisz (1964), suggests that strategic behaviour in the bargaining process risks compromising Coase's results. These authors observe that the change in the rule of law creates the conditions for possible extortion on the part of the right holders against the other individuals who are bound by the rule. The argument is that individuals are likely to threaten the use of their own rights in a measure which exceeds the optimal level, in order to maximize the gain from the release of their own legal entitlements. By introducing the possibility of strategic behaviour in the negotiation, the result may differ from the optimal equilibrium. Demsetz (1972, p. 21) supplied a convincing answer to this criticism. According to Demsetz, the possibility of strategic behaviour in the negotiations does not alter the efficiency in the final allocation of resources between the two activities. Strategies will be capable of altering the internal distribution of the contractual surplus between the parties, but not the final outcome of the negotiation.

It should be noted, however, that the entire analysis presupposes that the so-called income effect can be ignored. In general, a different allocation of property rights implies a different distribution of wealth between the individuals involved. Different initial endowments generate different final allocations, notwithstanding an equal level of efficiency. In order for the final allocations to be identical, it is necessary that the utility functions of the individuals involved are almost linear. The absence of the income effects implies, in this sense, that the demand functions for the good are independent of the income level.

It should be further observed that the credibility of the threat made in the course of strategic bargaining finds its limits in the market structure in which the Coasean negotiation takes place. In general, the competitive structure of the market eliminates much of the advantage that can be obtained through strategic behavior in the negotiation process. Inasmuch as the market of resources is competitive, strategic bargaining is not capable of bringing about any abnormal return.

The criticism, however, appears to be on the mark when it argues that, in some marginal situations, the curing role of the free exchange may still be impeded. For example, consider reversing the assignment of property rights between the rancher and the farmer. In such a situation, the farmer is likely not to have an equally large number of alternatives. The transfer of a farm from one place to another is costly, and farming unavoidably requires the undertaking of location-specific investments. Since some capital investment is irreversibly locked in that specific location, the farmer has less opportunity to relocate than the rancher. The rancher, consequently, finds himself in a position of local monopoly in the sale of his property right. Demsetz considers the monopoly that affects this feature of the Coasean exchange identical to the standard monopoly of microeconomic analysis (1972, p. 24). According to Demsetz, the concerns for possible monopolistic structures in the market of rights considered by Coase must not, however, be used to raise again the already resolved problem of the initial allocation of rights, since reversing the rule of liability would simply result in the farmer now having monopoly power (1972, pp. 24–5).

A second group of critics concentrated on the distributive effects of the model (Regan 1972; Nutter 1968). They argued that a final efficient allocation of resources requires transfers of wealth

induced by the changed legal rule. Further, these critics observed that, even if one disregards the distributive effects of the rule, a different assignment of the right could in some cases create the conditions for strategic behaviour in negotiation capable of disturbing the efficiency of the final allocation.

A third group of authors focused on the scarce realism of the no-transaction-cost assumption (see Cooter 1987, p. 457). According to this criticism, the true Achilles' heel of Coase's analysis was in the unrealistic assumption of absence of costs in the process of negotiation and transfer of the right. These authors observed that the idea of a transaction without cost is a logical fiction cloaking a mere tautology.

The Normative Coase Theorem

The utility of models predicting behaviour in a zero transaction-cost world is that they guide the law – whose object is to develop rules which approximate the zero transaction-cost world as closely as possible – in responding to legal problems arising in a positive transaction-cost environment (Epstein 1993). The vast literature that developed around Coase's theorem formulated important normative corollaries of it, based on the evaluation of the relative costs of alternative assignments of rights.

According to the positive Coase theorem, absent transaction costs, the final allocation of scarce resources would coincide with the use that an individual who is the single owner of different activities would make of his endowments, regardless of the initial assignment of rights and choice of remedial protection. When transaction costs are present, however, an exchange will be pursued only to the point at which its marginal benefit equals the marginal cost of the transaction. If transaction costs exceed the benefits of a contract, no exchange will take place in the market. For a right to be exchanged it is necessary that transaction costs be less than the difference between the demand and supply prices. If this condition is not met, the Coasean bargaining will not be carried out, and both initial assignment of rights and choice of remedies will affect final allocations.

The Relevance of Transaction Costs and the Simple Normative Coase Theorem

The notion of transaction costs has acquired particular importance in law and economics as the absence of transaction costs represents a fundamental condition for the applicability of the positive Coase theorem. Although at first impression transaction costs play a role analogous to transportation costs in international trade or, more generally, to the contracting costs in the economics of exchange (Demsetz 1972, p. 20), in Coase's world the role of transaction costs has much greater normative implications.

For purposes of the theorem, the notion of transactions costs should include not only bargaining costs associated with the negotiation and conclusion of the contract but also all costs associated with the strategic behaviour of the parties and the execution and enforcement of the transaction. The notion of transaction costs should thus include *ex ante* costs due to asymmetric information, adverse selection, free riding, and hold-up strategies, as well as *ex post* costs associated with monitoring and enforcing the contracts.

Strategic behaviour may be an important source of transaction costs in a Coasean setting. In Coase's various examples, the property rights which are exchanged are private goods, characterized by their excludability. Difficulties arise when the object of the Coasean bargaining is an entitlement which has the nature of a public good (see Cheung 1970, pp. 49–70). Due to the well-known problems associated with the supply of public goods, the Coasean bargaining solution may fail to cure a non-optimal allocation of rights that falls within this category. Consider a scenario in which the object of the Coasean negotiation consists of a non-excludable right (for example, the right to enjoy pollution-free air in a residential environment). As well known, individuals will not reveal their own preferences for public goods through the price system, placing public goods among those cases that are most resistant to the Coasean antidote.

A first simple normative reformulation of the Coase theorem focuses on transaction costs and the role that legal systems may play in reducing these impediments to voluntary bargaining. Legal rules can lower obstacles to private bargaining, such as by reducing transaction costs and minimizing other costs associated with transfer (strategic, legal, and so on). For this reason, transactional cost considerations should be fundamental to any analysis of legal regimes and the design of contracting processes, governance mechanisms and institutions.

The Complex Normative Coase Theorem

The first original formulation of Coase's proposition can be restated as a normative theorem: in the presence of positive transaction costs, the efficiency of the final allocation is not independent of the choice of the legal rule, and that the preferable initial assignment of rights is that which minimizes the effects of such transaction costs. The various normative restatements of the Coase Theorem aim at identifying legal rules and remedies that replicate the outcomes of a hypothetical Coasean bargaining or to mimic the solution that would be chosen by the single owner of interfering resources.

Important normative reformulations of the Coase Theorem focus on two important elements: relevance of initial assignment of rights and relevance of remedial protection. Demsetz (1972) and Calabresi and Melamed (1972) were among the first to discuss systematically the problems resulting from lifting the assumption of zero transaction costs. Articulating the normative core of the Coase theorem, Demsetz observes that the introduction of significant transaction costs into the choice of liability rule analysis does affect resource allocation. One liability rule may be superior to another because the difficulty of avoiding costly interactions is usually different for the interacting parties. Accordingly, the normative predicament indicates that the rule of liability should be based on which party can avoid the costly interaction at the lowest cost.

When two or more parties have conflicting interests in the same resource, the law must decide which party shall prevail, that is, which party shall receive the entitlement. Once the entitlement decision is made, the law must decide how the entitlement is to be protected and whether it may be transferred. Articulating a concept of entitlements protected by property, liability or inalienability rules, Calabresi and Melamed (1972) develop a framework that integrates the approaches of property and tort. Entitlements can be protected by property rules (transfer of the entitlement involves a voluntary sale by its holder), liability rules (the entitlement may be destroyed by another party if he is willing to pay an objectively determined value for it), or rules of inalienability (transfer of the entitlement is not permitted, even between a willing seller and a willing buyer). Calabresi and Melamed allow for a wide range of concerns to be balanced through the assignment of a particular entitlement. Calabresi and Melamed outline how, given the reality of transaction costs, an economic efficiency approach selects one allocation of entitlements over another. Entitlements cannot be enforced solely through property rules because, even if the transfer would benefit all parties, high transaction costs (especially the hold-up problem) may prevent an efficient reallocation. Calabresi and Melamed demonstrate how liability rules often achieve a combination of efficiency and distributive results that would be difficult to achieve under a property rule. Calabresi points out that Coase's analysis offers invaluable instruments for the identification of the areas in which public intervention becomes desirable (Calabresi 1968, pp. 72–3). In its normative version, the theorem indicates that legal rules that minimize the effects of such costs are to be preferred for being relatively more efficient (Polinksy 1989, p. 14). In its more complex formulation, the Coase theorem provides, indeed, a guide for such a choice.

The following is a classic illustration (Polinsky 1989, pp. 11–14). The smoke of a factory soils laundry which is line drying on five neighbouring properties. The losses amount to $150 for each neighbour, for a total of $750. The damage could be eliminated through the installation of a purifying filter on the industrial smokestack or through the acquisition of electric dryers on the part of each one of the neighbouring owners. The cost

of the filter would amount to $300, while the dryers would impose a cost of $100 per household, for a total of $500. The first solution is obviously more efficient, since the acquisition of five dryers would require a greater expenditure than the single filter. The Coase theorem predicts that in the absence of transaction costs the efficient solution will be chosen independently of the initial assignment of property rights. Even if we assume an initial allocation of polluting right to the industry (that is, fully legalizing industrial emissions), the landowners would jointly offer to buy the industrial filter at their expense. Sharing the cost of the filter in equal parts, each owner would face a cost of only $60, with a relative saving of $40 compared with the otherwise necessary acquisition of a personal dryer.

If we relax the initial assumption of no transaction costs, the initial allocation of property rights no longer is immaterial. Imagine that each owner has to face a cost of $120 in order to negotiate the contract with his neighbours and with the owner of the industrial plant. If the right is assigned to the industry, each landowner will have to choose whether to bear the loss of his soiled laundry for $150, to acquire the electric dryer for $100, or, finally, to undertake the negotiation process for a total pro-rata cost of $180. Considering these alternatives, each rational landowner would choose to acquire his own dryer, generating a socially non-optimal outcome. However, the assignment of property rights to the neighbouring residents rather than to the polluting industry would minimize the effect of positive transaction costs, since the industry would have incentives to install the filter, without any need for Coasean bargaining with the neighbours.

Two impediments to bargaining (that is, sources of transaction costs) take the form of externalities and hold-up, which Epstein (1993) shows stand in inverse relationship to each other. He defines the optimal legal rule as that which minimizes the sum of these externality and holdout costs in any particular institutional setting. Epstein demonstrates, through examples in property, restitution and tort, how Coase's transaction costs model plays the central organizing role in developing legal responses to many private law problems. Notwithstanding the obvious measurement and information problems, Epstein (1993) stresses the importance of the 'single owner test': where resources are under the command of two or more persons, the legal arrangement should attempt to induce all the parties to behave in the same way that a single owner would. Epstein concludes that, where the single owner test yields a unique result, that result should be adopted as the legal rule. Where the single owner test does not yield clear results, however, no corollary principle will provide a decisive answer to the particular problem.

Further exploring the choice between property and liability rules suggested by Calabresi and Melamed, Kaplow and Shavell (1996) address several factors casting doubt on the equivalence of these alternatives in low transaction-cost environments. Their analysis considers several objections to Coasean costless bargaining, including the inability of a party to ascertain what the other is willing to pay or accept, victims' ability to mitigate harm, the problem posed by one party being judgment proof, and administrative costs. Kaplow and Shavell find a presumption in favour of liability rules over property rules in the context of harmful externalities, but that this may be overcome as a result of one of more of the factors they describe. After considering some of the proffered justifications for the use of property rules to protect possessory interests, the authors find a strong theoretical case for the protection of these interests using property rules. The normative Coase theorem thus underlies the choice of the optimal system to ensure the protection of various types of property rights.

Also bridging the gap between Coase, where liability rules and property rules are equally efficient, and Calabresi and Melamed, where high transaction costs lead to a preference for liability rules, is the work by Ayres and Talley (1995) on private information as a transaction cost. The inefficiency occurs when parties misrepresent their own valuations to gain strategic advantage in the bargaining process. Focusing on the effect of splitting an entitlement between two rivalrous users rather than among buyers or among sellers, these authors find that, when two parties have

private information about how much they value an entitlement, endowing each party with a partial claim to the entitlement can reduce the incentive to behave strategically during bargaining by inducing greater disclosure. A bargainer has two Coasean alternatives: buy the other party's claim or sell one's own claim. The normative formulation of Ayres and Talley is that a liability rule regime is preferable because it allows a party's decision to pursue one of these alternative transactions to function as a credible signal of a low or high valuation, thereby encouraging more efficient trade.

Building upon the literature on property fragmentation (Heller 1998; Buchanan and Yoon 2000), Parisi (2002) and Schulz et al. (2002) suggest that property is subject to a fundamental law of entropy. In the property context, entropy induces a one-directional bias. This bias is driven by asymmetric transaction costs – it is often harder to reunite separated property bundles than to break them apart. Parisi hypothesizes that courts and legislators account for the presence of asymmetric transaction costs and correct for problem through the selective use of remedies and by selecting default rules designed to minimize the total deadweight losses of property fragmentation. Parisi (2006) offers a reformulation of the normative Coase theorem in situations characterized by asymmetric transaction and strategic costs, such as when complementary fragments of property are attributed to different owners. The asymmetry arises from the fact that it is often harder to reunite separated property bundles than to break them apart. This variant of the Coase theorem turns on (*a*) an initial allocation of entitlements that minimizes the effects of the positive transaction costs, and (*b*) the selection of legal rules that reduce social welfare losses by facilitating optimal levels of reunification.

The Coase Theorem and Its Legacy in Law and Economics

In 1960 Coase entrusted legal and economic scholars with the challenging task of deriving the implications of his theorem in their areas of research. Coase's invitation was taken up by a number of economists and lawyers who experimented with the unparalleled analytical potential of Coase's theorem in their research. According to Coase, economists in the Pigouvian tradition fail to consider the possible reciprocity of the effects of individual choices. By labelling one agent as injurer and the other as victim, the Pigouvian tradition presumes an initial allocation of rights (Cornes and Sandler 1986, p. 59). In such a manner this approach falls into a serious methodological error, notwithstanding empirical psychological studies suggesting otherwise (see Kahneman et al. 1990, pp. 1325–48). By taxing the generator of the externality in a measure corresponding to the difference between the private cost and the social cost of his own activity, the followers of Pigou fail to consider the effects of potential victims' behaviour. If the social cost of the industrial emissions is calculated by aggregating the economic disadvantages of the residents who are negatively affected by the smoke, the figure will vary with the number of individuals who fix their residence in that area. If the Pigouvian tax is imposed on the industrial activity only, there will be less incentive for each resident to consider moving into a different neighbourhood. New individuals may actually locate their residence in that area, without considering the potential increase in the costs imposed on the industrial activity.

Through these arguments, Coase's analysis demonstrates the incapacity of the Pigouvian approach to consider the interdependence of the harmful effects generated by individual choices. Coase's analysis occasioned a paradigmatic shift in legal and economic analysis, and, as Henry Manne once observed, 'it is hard to imagine law ever again being free of the influence of the techniques and findings of objective economic analysis' (1993, p. 4). His theorem, short of providing a simplistic formula for the social cost problem, suggests an alternative approach based on the evaluation of the relative costs of alternative assignments of rights and legal protection.

Coase, Ronald Harry (Born 1910)

Steven G. Medema

Abstract

Ronald Coase made seminal contributions to law and economics and to the theory of the firm, for which he received the 1991 Nobel Prize. The importance of understanding the

role of transaction costs in economic activity and the influence of alternative institutional structures on economic performance are hallmarks of Coase's scholarship, and both the economic analysis of law and the new institutional economics are outgrowths of his work. Coase occupies a significant although somewhat controversial place in the history of the Chicago School of economics.

Ronald Harry Coase was born on 29 December 1910 in the London suburb of Willesden. He received the BSc in Commerce from the London School of Economics in 1932 and while there was greatly influenced by Arnold Plant, who, as Coase has said, taught him many of the lessons that later came to be associated with the Chicago School. Interestingly, Coase did not take a single economics course while he was at the LSE, which he suggests gave him 'a freedom in thinking about economic problems which [he] might not otherwise have had' (1990, p. 3).

Upon completing his studies at the LSE, Coase took up a position at the Dundee School of Economics and Commerce, where he taught with his friend and public choice pioneer Duncan Black from 1932 to 34. Coase moved on to the University of Liverpool in 1934–35 before returning to the LSE, where he remained from 1935 until 1951. His time at the LSE was interrupted by the Second World War, during which he served as a statistician at the Forestry Commission (1940–41) and in the Central Statistical Office, Offices of the War Cabinet (1941–46). Coase left the LSE for the US and the University of Buffalo in 1951, remaining there until 1958. Following a year spent at the Center for Advanced Study in the Behavioral Sciences at Stanford, he accepted an appointment at the University of Virginia in 1959.

Although Coase is most closely associated with the Chicago School, his two most influential works – 'The Nature of the Firm' (1937) and 'The Problem of Social Cost' (1960) – were written before he arrived at Chicago, in 1964, to teach at the Law School and to join Aaron Director in editing the *Journal of Law and Economics.* Coase retired from the University of Chicago in 1981 and was awarded the Nobel Prize in Economics in 1991.

Scholarly Work

While most economists identify Coase with his two classic articles on the firm and social costs, his published output is very extensive and ranges across topics such as accounting, advertising, public goods, consumer surplus, public utility pricing, monopoly theory, blackmail, the economic role of government, and the history of economic thought. Several themes appear throughout Coase's work: the important role played by institutions – in particular the firm, the market and the law – in determining economic structure and performance, the role of transaction costs in economic activity, the need for a comparative institutional approach to economic policy, and a distaste for abstract theorizing. These themes come through unmistakably in *The Firm, the Market and the Law* (1988) and *Essays on Economics and Economists* (1994), which, together, collect many of Coase's most significant writings.

The lion's share of Coase's work during the first part of his career dealt, in one way or another, with firm behaviour and organization. His earliest contributions analysed the formation of

producers' expectations (for example, Coase and Fowler 1935), using the pig cycle as the case study. The conventional cobweb theorem explanation for these cycles was that producers expected current prices and costs to continue into the future. The adjustments in supply that resulted then gave rise to disequilibrium cycles. Coase and Fowler found that this explanation was incorrect – that producers did in fact adjust their expectations of prices and costs very quickly, and that the prediction errors arose from the difficulty of predicting variations in demand and in foreign supply. This work was later cited by J.F. Muth (1961, p. 21) in one of his classic papers on rational expectations. Coase also collaborated with Fowler and Ronald Edwards on a series of pieces dealing with the interrelations between accounting and economics (for example, Coase 1938; Coase et al. 1938). These writings, which were very much in the LSE cost tradition, demonstrated that traditional accounting practices do not adequately capture the true (opportunity) nature of costs and also pointed to the problematic nature of designing workable accounting methods to do so.

Coase also wrote a number of articles dealing with monopoly and imperfect competition, a few of which bear mention of here. Two of his theoretical pieces are of particular import. 'Durability and Monopoly' (1972) demonstrated that a monopoly firm which produces a good that is infinitely durable will be forced to sell the good at the competitive price, unless it can decrease the durability of the good or make contractual arrangements through which it promises to limit its production – a result which has come to be known as 'the Coase conjecture'. 'The Marginal Cost Controversy' (1946) is Coase's most significant work on monopoly and deals with public utility pricing and regulation. Abba Lerner and others had claimed that marginal cost pricing accompanied by a government subsidy is the efficient pricing policy for public utilities. Against this, Coase argued that marginal cost pricing is inferior to a system of multi-part pricing and may in fact be inferior to *average* cost pricing. This paper, and three related papers that followed it, are illustrative of one of the central themes in Coase's work – that, in assessing the efficiency of economic outcomes, one must focus broadly, rather than narrowly, on benefits, costs, and incentives.

Coase's work on public utilities also has an historical strand. Articles on the British Post Office discuss the rise of the penny postage in Great Britain under Rowland Hill and the attempts by the Post Office to enforce its monopoly against incursions by private entrepreneurs, including the messenger companies (for example, 1955). His study of British broadcasting analyses the development of wireless and wire radio broadcasting, as well as of television broadcasting and the rise of the BBC as the monopoly supplier of all of the above (1950, 1954). His interest in the government's role in broadcasting carried over to the United States and an analysis of the role of the Federal Communications Commission (1959, 1966) in the allocation of broadcast frequencies. In fact, it was from this study that 'The Problem of Social Cost' came to be written.

While the foregoing gives a sense for the breadth of Coase's contributions, it is unquestionable that his most influential work is contained in two papers – 'The Nature of the Firm' (1937) and 'The Problem of Social Cost' (1960), the two works cited by the Royal Swedish Academy in awarding Coase the Nobel Prize. In the former, Coase set out to explain why firms exist and what determines the extent of a firm's activities. He found the answer in a concept to which most economists had until recently paid scant attention – transaction costs. Coase suggested that we tend to see firms emerge when the cost of internal organization is lower than the cost of transacting in the market, and that the limit of a firm's activities (or, the extent of internal organization) comes at the point where the cost of organizing another transaction internally exceeds the cost of transacting through the market. Although published in 1937, 'The Nature of the Firm' attracted little attention until the early 1970s, when Oliver Williamson, Armen Alchian, Harold Demsetz and others began to build on or take off from Coase's contribution to bring transaction costs, the contracting process, and firm organization to the fore in economic analysis.

'The Problem of Social Cost' took the transaction-cost paradigm in a different direction –

the legal-economic arena and situations of conflicts over rights. Although 'The Problem of Social Cost' is one of the most cited articles in all of the economics and legal literatures, it has also been widely misunderstood. From this paper comes the now-famous Coase theorem – actually codified as such by George Stigler (1966) – which says that when transaction costs are zero and rights are fully specified, parties to a dispute will bargain to an efficient outcome, regardless of the initial assignment of rights. But Coase recognized that the transaction costs are pervasive and will generally preclude the working of this bargaining mechanism. Coase thus concludes that legal decision-makers should assign rights so as to maximize the value of output in society – a concept that lies at the heart of the modern law and economics movement (Medema 1999; Medema and Zerbe 2000).

The crux of 'The Problem of Social Cost,' however, is Coase's attempt to demolish the Pigovian tradition of social cost theory (Pigou 1932). The analysis that came to be known as the Coase theorem was used to demonstrate that, under standard neoclassical assumptions, Pigovian remedies for externalities are unnecessary: costlessly functioning markets, like the costlessly functioning governments of Pigovian welfare theory, will generate efficient outcomes. The problem, as Coase pointed out, is that neither markets nor governments function costlessly, and thus neither will generate optimal solutions. This leaves policymakers with a choice among imperfect alternatives, and Coase advocates a close examination of the benefits and costs associated with the alternative policy options, in order to facilitate the adoption of policies (including doing nothing at all) which maximize the value of output.

That government failure is at least as pervasive as market failure, and that economists are too quick to advocate tax, subsidy, and regulatory solutions without a careful examination of the situation, are recurring themes in Coase's work. His analyses of social cost issues, public utility pricing, and his classic article on role of the lighthouse in public goods theory as against the actual history of private lighthouse provision in Great Britain (1974) are excellent examples of Coase's position here. When Coase looks at government, he sees agencies captured by special interests, making policies that usually make matters worse rather than better, and operating in virtual ignorance of the virtues of the market. Yet a careful reading of Coase suggests that he is not 'anti-government' but, rather, an advocate for economic theorizing and policymaking which recognizes that policy choices are always among imperfect alternatives.

These criticisms are part of Coase's more general concern about the way that economists practice their trade (1994). He is suspicious of consumer theory as a whole and of the way in which mathematical and quantitative techniques have been used in modern economics. His own writings evidence some graphs and some technical intuitive analysis, but, reflecting Coase's lifelong distaste for using mathematics in his work, there is not an equation to be found. Coase believes that economists are obsessed with what he calls ' blackboard economics', an economics where curves are shifted and equations are manipulated on the blackboard, with little attention to the correspondence (or lack thereof) between these models and the real-world economic system. This, he says, has manifested itself in economists' ignorance of the role played by transaction costs and economic institutions generally, and in an approach to public policy that fails to examine in any kind of depth the consequences of alternative policy actions.

Coase and Chicago

Coase's critical attitude toward the practice of economics does not stop at the doors of the University of Chicago. Indeed, his close association with the Chicago School belies a degree of tension in the relationship and highlights the risks involved in thinking in terms of a homogeneous Chicago school. In spite of his position as a founding father of law and economics and, by extension, the expansion of the boundaries of economics so closely associated with Chicago, Coase has been critical of economic imperialism

generally and of the economic analysis of law in particular (Coase 1977, 1993). Coase's interest is not the economic analysis of law, but rather the study of how the legal system impacts the economic system – old-style Chicago law and economics of the sort being published in the *Journal of Law and Economics* in the 1960s and 1970s. As such, his interest and intellectual commonalities lie much more with the older Chicago school of Frank Knight and Jacob Viner than with the Becker–Stigler–Posner generation, and he has a much greater interest in the new institutional economics (of which he is also regarded as a founding father) than in the modern economic analysis of law movement à la Richard Posner. Coase has been chastised by Posner (1993) on this and other counts, but he remains unapologetic. That Coase has a place within the Chicago tradition goes without saying, but he has also remained his own man – dissenting from the received doctrine when it did not fit with his views.

Cobb–Douglas Functions

Murray Brown

Abstract

Perhaps the most common form of production function in economics, the Cobb–Douglas function has a range of attractive properties. The input demand and supply of output functions have the property of continuous differentiability everywhere on their respective domains; and the form has a function coefficient that is identical to its degree of homogeneity, calculated by summing the factor production elasticities. Its restrictions have made it an object of disdain for some. But the Cobb–Douglas form is remarkably robust in a vast variety of applications and is therefore very likely to endure.

The Cobb–Douglas function is perhaps the most ubiquitous form in economics, owing its popularity to the exceptional ease with which it can be manipulated and to the fact that it possesses the minimal properties that economists consider desirable. It appeared early (at least by 1916; see Wicksell 1958, p. 133), notably in the theory of distribution where it was used to prove the adding-up theorem of factor shares when the production elasticities sum to unity. It is the first form that many embryonic mathematical economists squeeze and buffet to obtain nice expressions for marginal products and utilities. It has been applied econometrically countless times, still surprising people that it can explain the data so well (Mairesse 1974). It forces itself into relatively new areas such as frontier production functions (see Førsund et al. 1980). And it has been used both as a utility and production function in analyses of growth, development, macroeconomics, public finance, labour and just about any other applied area in economics. Yet it possesses restrictive properties and perhaps for that reason it has become for some an object of disdain, often regarded as a child's toy in the world of real economics. But for others, the Cobb–Douglas is at least a venerable form and, effectively, it and its putative inventor are regarded fondly.

In its unrestricted form, the Cobb–Douglas can be written as $f(x) = A\prod_{i=1} x_i^{ai}$, where A is an efficiency parameter, a_i is the elasticity of $f(x)$ with respect to x_i , and $\mathbf{x}$ is confined to $R^n{}_{++}$. Defining the x_i as goods consumed, it has been used as a utility function; defining them as inputs in the production process, it is a production function; as normalized prices, it is an indirect utility function; and so on. We focus here on its use as a production function for a single output.

A large part of the appeal of the form stems basically from the fact that if $0 < a_i < 1$, $f(\mathbf{x})$ is strongly pseudo-concave on its domain. That entails that if the firm is a profit maximizer and factor supply and product demand functions are continuously differentiable on their domains, then the input demand and supply of output functions have the immensely useful property of continuous differentiability everywhere on their respective domains. Also, if $\sum_i a_i \leq 1$ and if factor supply and product demand functions are well-behaved, the input demand functions are downward sloping with respect to own price and the output supply

function does not slope downward with regard to product price. What could be better and, moreover, it is all so simple to demonstrate.

Another attractive property of the form is that it has a function coefficient that is identical to its degree of homogeneity, calculated by summing the factor production elasticities. Thus, $\sum_i a_i \lessgtr 1$ for all i easily and succinctly characterizes decreasing, constant and increasing returns to scale, respectively. This characteristic also has important implications for the cost, profit and revenue duals of the production function. For example, the cost function of a price-taking firm which has a Cobb–Douglas technology decomposes into two parts, one a linear homogeneous function of factor prices and the other a function of output q, that is $C(q, \mathbf{w}) = B\prod_{i=1} w_i^{ci} q^{co}$, where B is a positive constant, $\mathbf{w}$ is a (positive) price vector of the inputs, $c_i = a_i/\sum_i a_i$ and $c_0 = 1/\sum_i a_i$.

The list of attractive properties extends to the aggregation problem since the Cobb–Douglas is homogeneous and weakly separable. First consider the question of aggregation across inputs. Suppose one can write a generalized Cobb–Douglas function as follows:

$$q = \prod_{s=1} \left(\prod_{j=1} x_{sj}^{b_{sj}} \right)^{Y_s},$$

where $b_{sj} = a_{sj}/\sum_j a_{sj}$, $Y_s = \sum_j a_{sj}$, J_s is the number of factors in the sth group, S is the number of groups, $s = 1, 2,..., S$, and $j = 1, 2,. . ., J_s$. Notice that $\sum_j b_{sj} = 1$. Since each expression in the parentheses is homogeneous of degree one for each s, the profit maximization procedure can be decomposed into two stages and there exist quantity and price indexes (call them x_s and W_s, respectively) such that the expenditure on the sth group is $W_s x_s$ for s = 1, 2, ..., S.

With respect to aggregation across firms, suppose the rth firm's production function were

$$q_r = A_r x_{1r}^{c_{1r}} x_{2r}^{c_{2r}}, ..., x_{nr}^{c_{nr}},$$

where $\sum_i c_{ir} = 1$ and $i = 1, 2, ..., R$. It is evident that the expansion paths for all firms are straight lines through their respective origins. Then under the extremely restrictive conditions that the expansion paths for each firm are parallel (i.e. if $c_{ir} = c_{it} = c_i$ for each i and for all r and t), and that the first order conditions are satisfied, the R functions consistently aggregate to

$$q = x_1^{c_1} x_2^{c_2}, ..., x_n^{c_n},$$

a nicely behaved aggregate production function.

There is another way to look at the aggregation-across-firms problem that involves the Cobb–Douglas function. Suppose that factors in each firm are used in fixed proportions with the Leontief coefficients being distributed across all firms according to a Pareto distribution. Then a surprising result by Houthakker (see Sato 1975) is that the aggregate production function of the industry is a Cobb–Douglas form.

Of course, there is a price for these desirable implications and most of it is owing to the fact that the Cobb–Douglas technology entails that the elasticity of substitution takes on the knife-edge value of unity. If there is no technological change, a unit substitution elasticity implies that the income shares of all factors of production remain constant in the face of changes in things that are deemed germane such as saving, the rate of growth of the economy and relative factor supplies. Only the state of the technology matters in this instance, a highly disputable outcome. When technological change is allowed to proceed in a Cobb–Douglas world, it is a fact that Hicks-, Solow- and Harrod-neutral technological change are equivalent, thus blurring these distinctions. Another implication of the unit substitution elasticity of the (linear homogeneous) Cobb–Douglas form is that, used in growth models, it guarantees the existence and stability of equilibrium growth, again obscuring an important problem in economics.

Furthermore, it is a fact that the Cobb–Douglas form requires that each factor of production be essential in the sense that no factor may be completely substituted for another. Hence the domain of the function must be confined to the set of strictly positive real numbers. This is not particularly disturbing for situations in which the factors can be taken to be large aggregates but it does limit the analysis in other contexts.

Technological change is represented in the Cobb–Douglas by changes in the efficiency parameter A which are Hicks neutral, by changes in the scale of the factor inputs which are factor augmenting and also Hicks neutral, and by changes in the elasticities of production which may be Hicks non-neutral. However, the unit elasticity of substitution is restrictive in still another way: it cannot represent a technological advance that results in a change in the ease of substitution among factors of production.

What is the form's provenance? It is generally attributed to Paul Douglas and although he gracefully acknowledged (Douglas 1967) that Wicksteed and Walras were cognizant of it, he neglected to add Wicksell's name to the list. Be that as it may, Douglas relates in his gentle comments that in 1927 he asked a professor of mathematics, Charles Cobb, to devise a formula that could be used to measure the comparative effect of each of two factors of production upon the total product to satisfy a linear log–log relationship in his input and output data. His work encountered a host of theoretical concerns (see Brown 1966 for a discussion) aside from the capital, output and labour measures for which he was faulted. But the production form remained in spite (or perhaps because) of its restrictive properties.

Subsequent work has demonstrated that the Cobb–Douglas is a special case of a variety of forms and approaches. The constant elasticity of substitution (CES) production function is perhaps the most well known of the forms that yield the Cobb–Douglas as a special case, either by using L'Hôpital's rule when the elasticity of substitution goes to unity or it can be derived from certain expressions used in deriving the CES function (see Brown and De Cani 1963). Parenthetically, the CES, itself, is known to mathematicians as a mean of order t [i.e. $\left(\sum_{i=1} a_i x_i^t\right)^{\frac{1}{t}}$ for $t \neq 0$] so that, if one takes the limit as $t \rightarrow 0$, of course, the Cobb–Douglas emerges. Also, it can be derived from the translog production form (Christensen et al. 1973) and many others, besides, by judiciously restricting certain parameters. A different approach to the derivation of the Cobb–Douglas form has been taken by P. Zarembka (1987), who specifies each variable as $z(\lambda) = (z^{\lambda} - 1)/\lambda$ for $\lambda \neq 0$ and $z(\lambda) = \ln z$ for $\lambda = 0$. Then, applying this transformation to the production function, we would have $z_0 = q$ and $z_i = x_i$ for all i. Thus, if the z_k ($k = 0, 1, ..., n$) are related linearly, the transformation turns out to be a useful procedure in econometrics to treat the general problem of functional form, an important special case of which is the Cobb–Douglas.

In sum, though it is restrictive and sometimes regarded as an economic toy, the Cobb–Douglas form is remarkably robust in a vast variety of applications and that it will endure is hardly in question.

Cobbett, William (1763–1835)

N. W. Thompson

William Cobbett was born, appropriately, at the 'Jolly Farmer' in Farnham, Surrey, in 1763. He was by turns soldier, clerk, teacher, journalist and political agitator but whether in his early literary career as an anti-Jacobin pamphleteer or later in his role as combative radical his voice was that of the small farmer threatened by the forces of economic and social change which characterized the early phases of Britain's industrial revolution.

Cobbett's acerbic castigation of its major theorists shows he had little time for political economy and he would certainly have greeted with a wry guffaw his inclusion in a dictionary of economic thought. Nevertheless it was the case that much of his writing in the *Twopenny Register* (1816–20) and works such as *Paper against Gold* (1815) was given over to a discussion of economic questions and in particular the economic difficulties that confronted Britain in the post-Napoleonic war period, and even in his *Rural Rides* (1830) few opportunities were lost of discoursing on matters economic.

For Cobbett material impoverishment was a consequence of the political decisions affecting taxation, the Debt, the convertibility of the currency etc., which emanated from a Parliament corrupted by the influence of tax-gatherers, 'Change Alley men, sinecurists, placemen, Jews and Borough-tyrants. Crucial here was the passage of the Bank Restriction Act of 1797, which in suspending cash payments by the Bank of England had created a 'Paper money system' that robbed the 'industrious' of their 'earnings' producing 'that monster in civil society, starvation in the midst of abundance'. This paper money system was seen in itself as a means of appropriating the product of labour but most importantly, with the return to cash payments in 1819, it created a situation where the nation was compelled to pay in an appreciated medium of exchange debts contracted in a depreciated paper currency. The industrious were therefore forced to pay in gold what had been contracted in paper. Thus both the inflation of the Revolutionary and Napoleonic wars and the deflation that followed were seen by Cobbett as redistributing wealth in favour of the idle generally and the fundholders and bankers in particular. Justice demanded, therefore, that there should be an equitable adjustment in the level of taxation to take account of the appreciation in the value of money. For this, parliamentary reform and an end to political corruption were necessary prerequisites.

Under the undifferentiated heading of 'The Thing', Cobbett sought to attack all those who jeopardized his vision of a stable, hierarchically structured, rural economy and society, dominated by the independent yeoman farmer and free from 'the all-devouring Jew and tax-eater'. Specifically, he condemned 'the Funding and Manufacturing and Commercial and Taxing System' for their tendency to draw 'wealth into great masses . . . [and] man also into great masses', like 'the Great Wen' [London], which both corrupted its inhabitants and impoverished the country as a whole.

Cobbett's was an anti-industrial, anti-commercial, anti-urban and anti-City political economy with its ideological roots in the political radicalism of the eighteenth century and with Paine's *Decline and Fall of the English System of Finance* (1797) as its basic text. Yet if, with the growth of industrial capitalism, this 'old corruption' critique became increasingly irrelevant and inadequate; if by the 1830s it was being supplanted in the working-class press by anti-capitalist and socialist analysis of contemporary ills which deployed to critical effect the tools and concepts of political economy, this should not obscure the remarkable longevity of Cobbettian ideas. Thus even a superficial survey of Chartist literature will show just how indelible was the mark left by the *Twopenny Register* upon a generation of political radicals. In a sense too Cobbett's vision of a pastoral England peopled

by free-born, hearty independent cultivators will remain indestructible, drawing sustenance as it does from an ineradicable human craving for the permanence, the certainty, the order and the stability which rural self-sufficiency seems to offer.

Cobden led the campaign that repealed the Corn Laws in 1846, after which there was free trade in grain. The son of a Middlesex farmer, he sought his fortune in Manchester, became an owner of a mill that employed 2,000 workers and was noted for excellence of its calicoes. At 35, he was a rich man.

His calling, however, was politics. After taking part in the successful effort to incorporate Manchester, he entered the movement against the Corn Laws in 1838. Until then it had been conducted by middle class radicals and various business interests, among them the Manchester Chamber of Commerce. Cobden, John Bright, and others like them wanted to enlarge the movement, make it bold and uncompromising. They were exasperated by the businessmen who so wanted to look respectable that they could not see where their interest lay. Thomas Tooke had said the same about the London merchants, when on their behalf he drafted the celebrated petition of 1820 for free trade and they were reluctant to sign it.

The militants of Manchester formed the National Anti-Corn Law League and agitated for free trade up and down the country. They become known as the Manchester School of Economics and were celebrated as arch advocates of laissez-faire. Actually they were a coalition of diverse interests that agreed on only one issue – repeal of the Corn Laws – and each did so for its particular reasons.

Cobden's reason was peace. He believed free trade would break down national barriers and give everyone a material interest in avoiding war. This was not an argument gotten up for the occasion but the expression of a view he had long held. When young he wrote two long tracts on foreign policy which denounced alliances among nations and political engagements of all kinds, decried the idea of a balance of power, was especially disapproving of colonies, then went on to extol

free trade as the way to peace and its guarantor. Years later, after he and Bright had brought down the Corn Laws, he told him, 'I have always had an instinctive monomania against the system of foreign interference, protocolling, diplomatising, etc.'

That scarcely expressed the horror he had of violent action, even the suggestion of it. When the southern states of America seceded, he thought Lincoln was wrong in bringing the issue to battle although he had no sympathy with them (except their fondness for free trade). He was shocked by the massacres in India and was opposed to wars of independence and to revolution. He thought duelling was barbarous, was against capital punishment, objected to boxing, couldn't stand brass bands, and asked the Pope to prohibit bull fighting in Spain. He favoured free trade so long as its effect was peaceful, as he believed it usually was, but when he believed it was not he quickly put it aside. He opposed the sale of foreign bonds in the London market if the proceeds were to be used to buy arms. 'No free trade in cutting throats', he said.

Pacifism, not laissez-faire, was Cobden's guiding principle; and he applied laissez-faire less to domestic than to foreign markets. He did not care for the Factory Acts but only spoke, never voted, against them. He approved of increasing the monopoly powers of the Bank of England and of regulating aspects of railway construction. He had no use for the New Poor Law, of which most economists of the day approved, and spoke derisively of McCulloch's 'usual dogmatism'. But he carefully read the latter's edition of the *Wealth of Nations* and wrote in the margins of the chapters that moved him. His notes are especially lively where Smith condemns the colonial policy of Great Britain. However, where he describes the operation of the invisible hand, the margins are quite untouched.

Cobweb Theorem

B. Peter Pashigian

Abstract

The cobweb theorem purports to explain persistent fluctuations of prices in selected agricultural markets. It was first developed in the 1930s under static price expectations where the predicted price equalled actual price in the last period. Muth's rational expectations hypothesis posited that forecast errors will not be serially correlated and the pattern of past forecast errors cannot be used to improve the accuracy of the forecasts. The fundamental question of whether observed price cycles are better explained by systematic errors in price forecasts or by the cumulative impact of unpredictable shocks has not as yet been definitively addressed.

The persistent fluctuations of prices in selected agricultural markets have attracted the attention of economists from time to time, and the theory of the cobweb was developed to explain them. The theory is applicable to those markets where production takes time, where the quantity produced depends on the price anticipated at the time of sale, and where supply at time of sale determines the actual market price.

One strand of the cobweb literature (the term was coined by Kaldor 1934) concentrates on how expectations are formed and the effect of the price expectations mechanism on the stability of equilibrium. Cobweb theory was first developed under static price expectations where the predicted price equalled actual price in the last period. The cobweb theorem proved that the market price would (not) converge to (long-run) equilibrium price if the absolute value of the price elasticity of demand was greater (smaller) than the price elasticity of supply. This stability condition was modified later as more sophisticated expectations models were adopted. Early articles by Tinbergen, Ricci and Schultz appeared in 1930 in German (see Waugh 1964, for a review of this literature). Ezekiel's important article (1938) spells out in greater detail the conditions for convergence, divergence or perpetual oscillation and shows how cycles of different lengths could be generated under static expectations.

Why the theory was developed in the 1930s and not earlier is a bit of mystery, for recurring price cycles for some agricultural products had been reported by agricultural economists for some time. Economists may have been attracted to the cobweb theory in the 1930s because of the events of the Depression. A theory that explained both oscillation and long departures from stationary equilibrium was more attractive after the events of the Depression. The fact that Ezekiel's paper was reprinted in the 1944 American Economic Association volume on business cycles lends credence to this view.

The impression left by Ezekiel and subsequent contributors is that the cobweb theory is a valuable tool for explaining price cycles. Ezekiel was aware of the simplicity of static expectations and not unmindful of the importance of shocks on the demand and the supply sides of the market in causing aberrant price fluctuations (for example, weather and the randomness of yields). Even so, agriculture economists, who were presumably more familiar with price fluctuations in agricultural markets, have been more prone to accept the theory, while other theorists have given the theory more of a mixed reception.

The price expectations mechanism has undergone many refinements over the years. In 1958 Nerlove proposed the use of adaptive expectations. This suggestion is motivated by the findings of econometric studies which showed the price elasticity of demand to be less than the price elasticity of supply for many agricultural goods. Under these conditions the static expectations version of the cobweb model predicts a price cycle of increasing amplitude. However, the observed price cycles in agricultural markets showed no sign of being explosive. Nerlove attempted to reconcile theory with evidence and to show that convergence is possible under a broader set of conditions provided expectations are adaptive. During the 1930s the attractiveness of the cobweb model seemed to be in its ability to explain persistent or even explosive price cycles. By the late 1950s these were no longer attractive features, and Nerlove felt compelled to offer an explanation of why price cycles of increasing amplitude are not observed even when demand elasticities are smaller than supply elasticities. Waugh (1964) took a different tack and attempted to reconcile the theory with the evidence of stable price cycles by suggesting that the price elasticity of supply becomes smaller (larger) than the price elasticity of demand at prices well above (below) the long-run equilibrium price. Under this assumption, a stable price cycle will eventually be reached.

The length of the cobweb price cycle is determined by the length of the production process. If it takes one year to bring a fattened hug to the market, then the complete price cycle should take two years. At first, little attention and superficial explanations were given to explain why the predicted length is often shorter than the actual length of the price cycle. It was left to the critics to point out these discrepancies.

The critics are responsible for the other strand of the literature. They appeared early but were not very influential at first although their criticisms were ultimately given more weight. The critics questioned the rationality of using an arbitrary expectations mechanism by otherwise profit-maximizing agents, and pointed out that the theory implies that producers would expect to lose wealth if they entered and remained in an industry with a cobweb price cycle. In a perceptive article on the pig cycle in England, Coase and Fowler (1935) questioned the realism of static expectations. They showed that the price of a bacon (mature) pig less the cost of feeding for the next five months and less the cost of a feeder (*y*oung) pig, which would be stable in a competitive market if farmers had static expectations, fluctuated over time. Hence the empirical evidence contradicted the assumption of static expectations. They presented evidence that pig breeders reacted quickly to a change in expected profits, and this implied that the pig price cycle should be only two years instead of the observed four-year period. The fluctuation in the profits per pig was attributed to the difficulty of predicting both demand and foreign imports. The Coase-Fowler paper advanced, if only in faint outline, the essence of the rational expectations hypothesis which was to blossom some 35 years later. They hinted that anticipated prices would not be formed in a mechanistic way because profits would be higher the more accurate are the forecasts. Prediction errors were due to the difficulty of predicting shifts in demand and in foreign supply.

Buchanan's paper (1939) criticized the cobweb model because it implied that producers suffer aggregate losses over the price cycle when output is determined by the long-run supply curve. He pointed out that the theory was based on the dubious assumption of a continued supply of entrepreneurs standing ready to dissipate their capital. The critics were also disturbed by the ambiguity of whether the supply curve is of the short-or long-run variety, and the failure to clarify how the adjustment from the short-run to the long-run supply curve is made. These early criticisms and ambiguities aside, references to the cobweb theory continued to appear in textbooks.

Nerlove's paper (1958) briefly rekindled the controversy. His purpose was to resurrect the theory and show that it could explain price behaviour if adaptive expectations were employed. Mills (1961) criticized the use of adaptive and other autoregressive expectations mechanisms in the deterministic model because they implied a simple pattern of forecast errors that producers could detect, incorporate into their forecasts and thereby improve the accuracy of their price forecasts. While Nerlove's suggestion did rectify one limitation of the cobweb theory, it did not address the critical issue of why producers relied on any particular forecasting mechanism. Muth (1961) developed the implications of rational expectations for cobweb theory in his now famous paper. Muth postulated that expectations were the predictions of the economic structure of the market and incorporated all available information. Under certain conditions the predicted price equals the conditional expectation of price, given currently available information. Adaptive expectations can be rational only under special conditions, and the coefficient of adaptation is determined by the values of the slopes of the demand and supply curves.

The rational expectations formulation has powerful implications for cobweb theory. If the price forecasts incorporate all available information and are on average correct, then forecast errors will not be serially correlated and the pattern of past forecast errors cannot be used to improve the accuracy of the forecasts. Moreover, what is then left of the supposed ability of the cobweb theory to explain the cyclical behaviour of prices? Price fluctuations would have to be explained either by the cyclical pattern of exogenous variables or by the summation of random shocks (Slutsky 1937). Muth's paper represents a

frontal attack on the traditional cobweb model. He notes that the traditional model tends to predict a shorter price cycle than is observed and indicates that the rational expectations version predicts a longer price cycle.

Interest in the cobweb model has ebbed in recent years and few articles on it have appeared in the major journals. Economists have found it more rewarding to apply the rational expectations hypothesis to areas like monetary or business-cycle theory than to the study of particular markets, even though the analysis of markets with inventories raises issues that are just as difficult and subtle. The question of whether the cobweb does or does not explain price cycles has not really been resolved. Freeman (1971) has suggested that the traditional cobweb model explains cycles in the markets for lawyers, physicists and engineers. Tests of the rational expectations hypothesis have been suggested by Pashigian (1970) when expectations data are available and by Hoffman and Schmidt (1981) when expectations data are unavailable. So the methodology exists for distinguishing between the competing hypotheses. Few econometric tests have been made of the rational expectations hypothesis in markets where the assumptions of the cobweb model apply. The fundamental question of whether observed price cycles are better explained by systematic errors in price forecasts or by the cumulative impact of unpredictable shocks has not as yet been definitively addressed.

Coddington, Alan (1941–1982)

Victoria Chick

Born in Doncaster, Yorkshire, Coddington began his academic career with a degree in physics at Leeds University. After a year teaching mathematics in a school in York, he returned to university in that city for his D.Phil. in Economics. On taking his degree in 1966 he was appointed Assistant Lecturer in Economics at Queen Mary College, London, where he rose steadily to become Professor in 1980.

His theoretical work has three main strands: an early interest in the theory of bargaining, resulting in several articles and a much-respected book (1968); various aspects of environmental economics; and, continuing throughout his career, methodology and the history of 20th-century economic thought.

It is this last area which one immediately associates with Coddington's name. From his work on interpretations of Keynes, his characterizations of the 'neoclassical synthesis' of the textbooks as 'hydraulic Keynesianism' and of the 'fundamentalists' as 'Chapter 12 Keynesians' (referring to the chapter of the *General Theory* which discusses the precariousness of long-term expectations) have entered economists' everyday language.

His coverage of modern economic thought included not only Keynes, but also Hicks, Shackle, Friedman, Hahn, Malinvaud, Clower and Leijonhufvud. His article on Hicks (1979) and much of his work of Keynes, with an invaluable new chapter ('The Keynesian Dichotomy') were reworked into his posthumously published book, *Keynesian Economics: The Search for First Principles*, to which every reviewer responded first with enthusiasm, then with regret that they had been deprived by Coddington's suicide of the intellectual stimulus of debating with him.

Codetermination and Profit-Sharing

D. M. Nuti

The contract regulating labour employment by capitalist firms usually embodies three basic elements: a fixed money wage rate per unit of time, the subjection of workers to the employer's authority in the workplace and the short-term nature of the hiring commitment. Explicit or implicit departures from this standard can be observed; they are the result of individual or collective negotiations in the labour market, which balance out their advantages and disadvantages for each party, either directly or through accompanying changes in other parameters of the labour contract. Government legislation and economic policy set limits or fix actual values for some of these parameters and stipulations; within these bounds the market determines the rest.

Long tenure, i.e. the employee's option on continued employment, like all options has a value (for the employee) and a cost (for the employer), which is matched by correspondingly lower pay than that associated with shorter-term contracts. The partial and delayed indexation of money wages to a consumer price index for the period between successive rounds of wage negotiations favours employees when inflation decelerates and employers when it accelerates. Piece-rates, i.e. wages related to *individual* performance, give employees a short term reward (penalty) for effort supply higher (lower) than that which otherwise could be contractually fixed, as well as automatic participation in productivity gains due to learning by doing, subject to a ratchet effect on the determination of subsequent rates; employers save on the costs of recruitment, supervision, and contractual enforcement, lose short term productivity gains but can use more fully their contractual power in exacting effort and speeding up progress when rates are reviewed. Government policy influences directly or indirectly market

choice, in the pursuit of policy targets such as distributive fairness, employment, price stability, efficiency and growth.

The same combination of private interest and government policy determines the degree of workers' participation in decision-making processes (codetermination) and in the performance (profit-sharing) of enterprises (for a bibliographical survey, see Bartlett and Uvalic 1985).

Codetermination

Employee participation in enterprise decision-making in cooperatives amounts to full entrepreneurship through participation in assemblies, the election of representative organs and involvement in the appointment of managers. In other enterprises it takes the form of access to information and right to consultation, participation in decisions on conditions and organization of work and on internal social questions, through a workers' council or similar organ; right up to the minority (or even parity) participation and vote in the board of directors of a joint-stock company (as in German *Mitbestimmung*; see Nutzinger 1983) with a possibility of influencing decisions about employment, the level and structure of investment and other crucial factors were the other board members to be sufficiently divided.

The effects of codetermination are three-fold:

(i) The reduction in labour disutility obtainable when workers have a say in the division of labour and work organization, since enterprises may neglect workers' preferences about the specific uses to which their labour is put or at any rate respond to the needs of a hypothetical average worker: if the number of enterprises is not large enough, workers' control is necessary to reduce disutility and alienation. The effect of workers' control on productivity has an indeterminate sign (Pagano 1984).

(ii) The reduction of the number and intensity of conflicts in the workplace in general and, in particular, the more likely acceptance by workers of unpopular decisions by management, when workers receive detailed and credible information and participate in decision making, identifying themselves partly with the enterprise and above all lengthening their time horizon in view of continued participation in decision-making (Aoki 1984; Cable 1984; Fitzroy and Mueller 1984). Of course conflicts within the firm are made more tractable by the *introduction* of codetermination but *afterwards* are bound to reappear over time (Furobotn 1985); also there remains a basic conflict between employed and unemployed workers which may even be exacerbated by the employment protection policies conceivably encouraged by those already employed in their exercise of codetermination.

(iii) The greater correspondence between workers' powers and responsibilities, codetermination being the counterpart of workers' exposure to enterprise risks. The very fact that workers, unlike capitalists, cannot diversify between different enterprises when selling their services exposes them to an employment and income risk which induces them to make a claim to control; a claim which up to a point the employer may prefer to accept instead of granting higher wages or longer tenure.

Profit-Sharing

In pre-capitalist systems workers' participation in the results of their enterprise took the forms – now little used – of sharecropping in agriculture and of sliding scales (indexing wage rates to the price of the product), for instance, in English coalmines. In modern capitalism such participation – for which 'profit-sharing' is a shorthand label – takes the form of cooperatives' net revenue sharing, production prizes based on group or overall performance, participation in gross/net revenue/profit, share options, participation in investment funds and pay increases graded according to productivity growth.

The effects of an element of profit-sharing in labour earnings are three-fold:

(i) An expected increase in labour productivity. This is not due to workers gaining from the product of *individual* extra-effort (as in the case of piece-rates) since each of n workers employed will only get at most $1/n$ of the product of his own extra-effort (Samuelson 1977) and on the contrary may *reduce* effort if he can, being exposed to at most only $1/n$ of the output loss from his own lower effort. The productivity gain can be expected from workers, costlessly to themselves, gaining from intelligent and effective use of any given individual level of effort, from cooperating with other workers and management and from monitoring and supervising each other's effort, efficiency and cooperation (Reich and Devine 1981; Fitzroy and Kraft 1985).

(ii) Cyclical flexibility of labour earnings and therefore greater stability of profit levels and rates. Employment will not be stabilized during the cycle by labour earnings flexibility obtained through profit-sharing because the marginal cost of labour to firms – i.e. the fixed component of pay – does not vary automatically. Workers, who are normally risk-averse, will prefer a fixed sum of money to a profit-sharing formula of equivalent amount while employers, who are normally risk-lovers, may or may not prefer greater stability of profit rates (according to their actual attitude to risk and the alternative cost of reducing risk through diversification) to the point of granting higher average earnings on a profit-sharing formula than a fixed wage to mutual advantage. Therefore profit-sharing is favoured primarily in risky ventures; otherwise on this ground alone profit-sharing would be favoured by firms only in a recession (when workers would only accept it as an alternative to a permanent wage cut) and by workers only during a boom (when firms would only accept it as an alternative to a permanent wage increase).

(iii) Higher level of labour employment, for a given level of labour earnings with respect to a fixed wage regime, due to the lower marginal cost of labour to profit-sharing firms. Vanek finds that higher employment will be associated with higher aggregate income, lower prices (because of higher output), higher export volume and domestic import substitution (with undetermined effects on the balance of payments depending on price and income elasticities), lower after-tax and after-labour-share profits and higher labour-share in national income (Vanek 1965).

Rediscovering Vanek's macroeconomic benefits from profit-sharing (though not its impact on net profits and relative income shares), Weitzman claims that these benefits are neglected by individual firms, as in other instances of 'public goods', 'externalities' and 'market failures', therefore necessitating public policy measures (Weitzman 1983, 1984). However, there is no reason why a firm should object to granting a given increase in earnings under the guise of a profit-share instead of an equivalent fixed amount unless that represents forced insurance against profit variability; and why workers – at least at the level of nation-wide collective bargaining – should not take into account the potential employment and price stability benefits of this formula and offset them against the greater variability of their earnings in between negotiations, due to both cyclical factors and random factors affecting their firm's performance.

Contrary to Weitzman's belief, in fact, profit-sharing is not absolutely superior to wage contracts. For workers, profit-sharing transforms the probability distribution of uncertain employment at a fixed and certain income into a probability distribution of employment with a higher mean (because of lower marginal cost of labour) but no less variable over the cycle, at a more variable income (both over the cycle and for other factors affecting dispersion of enterprise performance) and at a higher (real) mean. For firms it transforms a more into a less variable probability distribution of money profit rates around the same mean (or a lower mean if workers are protected from actual losses; the effect on real profit rates depending on accounting conventions and choice of *numéraire*). In the pursuit of greater employment and price

stability of course a government may grant tax relief to shared profits, just as effectively and with just as much reason as it may subsidize the marginal cost of labour to firms under a wage regime. Otherwise there is no reason why profit-sharing should be forced upon unwilling workers and firms by well-meaning reformers, beyond the extent they are prepared to consider in their market transactions. These propositions are developed further below (see also Nuti 1985, 1986).

Interdependence Between Codetermination and Profit-Sharing

The respective effects of codetermination and of profit-sharing are not independent. The productivity increase expected from profit-sharing can be raised by workers having collective discretion over the organization of labour; or the productivity fall which might derive from workers' control over labour organization might be tempered by profit-sharing. Greater variability of earnings – during the cycle and across firms – strengthens under profit-sharing the case for codetermination already present in workers' exposure to employment risk in the wage régime. The income premium required by risk-averse workers to replace some of their fixed wage with a variable profit-share can be reduced by their involvement in the decisions which expose them to income variability in the first place. The reduction in conflict frequency and intensity expected from codetermination is enhanced by profit-sharing because for each worker it partly internalizes the conflict between 'us' and 'them' otherwise manifested and enacted externally; in any case it is a requirement of any effective incentive system that power and responsibility should not be separated.

The quantification of degrees of 'codetermination' and to a lesser extent of 'profit-sharing' raises conceptual and practical difficulties (though see Cable 1985). By and large we can observe a certain correlation between the two: both codetermination and profit-sharing are zero in the pure capitalist enterprises and unity in cooperatives and other forms of partnerships of capital and labour; minor forms of codetermination (or conversely of profit-sharing) tend to go hand in hand with minor forms of profit-sharing (or of codetermination); a high degree of one without the other is virtually unknown.

The combination of 100 per cent codetermination (= self-determination) and 100 per cent profit-sharing (= net revenue sharing) obtained in cooperative firms, according to conventional literature, is subject to economic stimuli of a somewhat 'perverse' kind. These are primarily: restrictive employment (= membership) policies; destabilizing and Pareto-inefficient reactions (or at best inelasticities) to price changes and technical progress; a low propensity towards self-financed investment (Ward 1958; Vanek 1970). In empirical studies of cooperative firms there is no incontrovertible evidence of these phenomena, which are probably partly offset by other economic (job security, growth-mindedness, etc.) and non-economic stimuli; but there is a presumption that – albeit in a weak form – the same tendencies and, in particular, employment restrictive policies might be associated with codetermination. We can also presume that workers' eagerness to press and ability to assert demands for codetermination, as in the case of other demands, increase as unemployment diminishes. Hence the employment-generating benefits of profit-sharing can be at least partly offset by the restrictive employment policies possibly associated with codetermination brought about by profit-sharing and by greater proximity to full employment. Recent empirical studies suggest modest but sizeable improvements in economic performance from codetermination and profit-sharing (Cable and Fitzroy 1980; Estrin et al. 1984) when and where they occur but there may have been costs that remained unobserved and, in any case, the improvements cannot be generalized.

Markets and Policy

Degrees of codetermination and profit-sharing may well be regarded as desirable on 'political' (as opposed to 'purely technical') grounds such as

equity and social peace. They may also be the best policy instruments in the pursuit of public objectives such as stability, employment and growth, in the sense of having the least cost in terms of public funds or offering the most attractive trade-offs between alternative targets. Otherwise, as Jensen and Meckling argue for codetermination and one can also argue for profit-sharing, if it is truly beneficial to both stockholders and labour no laws would be needed to force firms to undertake reorganization (1979, p. 474). Yet renewed and insistent calls for public intervention in favour of *profit-sharing without codetermination* have been put forward by M.L. Weitzman in recent writings (1983, 1984, 1985a, b, 1986). The proposal has been enthusiastically received in certain academic and political circles and hailed as a breakthrough in the specialist press.

Weitzman's novelty, the foundation for this renewed fascination with profit-sharing, is the rash assertion of two propositions. First, that long-run full employment equilibrium under profitsharing is associated with permanent but non-inflationary excess demand for labour, which cushions off the economy from contractionary shocks and gives new dignity and status to labour. In adman's language we are told, for instance:

> A share system has the hard-boiled property of excess demand for labour, which turns into a tenacious natural enemy of stagnation and inflation. The share economy possesses a built-in, three-pronged assault on unemployment, stagnant output, and the tendency of prices to rise. This is a hard combination to beat. (Weitzman 1984, p. 144.

Second, that even in the short run the share economy can achieve and maintain full employment. For instance:

> The share system, . . ., has a strong built-in mechanism that automatically stabilizes the economy at full employment, even before the long-run tendencies have had the chance to assert their dominance. . . . a share economy has the direct 'strong force' of positive excess demand for labor . . . pulling it towards full employment. . . . the strong force of the share system will maintain full employment. (Weitzman 1984, p. 97)

Were these claims well founded an enlightened government possessing these truths would be justified in forcing profit-sharing on to a yet unconverted and disbelieving public, thus achieving full employment, price stability and growth at a stroke. Unfortunately miracles exist only for the uninformed and the faithful, but do not bear the weight of sober scrutiny. First, excess demand for labour at full employment cannot be sustained and can only be a temporary disequilibrium. Second, permanent excess demand for labour is inconsistent with lack of codetermination, and when this is introduced restrictive employment policies will alter the picture. Third, and most important, there is no guarantee that full employment can necessarily be achieved. Without these benefits the alleged 'public good' merits of the sharing contract disappear.

Excess Demand for Labour at Full Employment

Suppose that the share economy reaches a state of full employment. Weitzman maintains the presence and persistence of excess demand for labour in long-run equilibrium on the basis of the following argument:

$$\text{labour total pay} = \text{marginal revenue value of labour productivity at full employment} \tag{1}$$

because long-run equilibrium must be full-employment equilibrium and because of the underlying homomorphism of profit-sharing and wage contracts in long-run equilibrium (Weitzman 1983). By definition of profit-sharing

$$\text{labour total pay} = \text{fixed pay} + \text{share of net profits} \tag{2}$$

where fixed pay is greater than or equal to zero, and the share of net profits is greater than zero. It follows from (1) and (2) that:

$$\text{marginal revenue value of labour productivity at full employment} > \text{fixed pay} = \text{marginal cost of labour to firms} \quad (3)$$

i.e. firms will wish to employ more workers than are available. A permanent state of excess demand for labour will exist, which will protect full employment from contractionary shocks, as long as shocks do not reduce the marginal revenue value of labour productivity at full employment below the fixed element of pay, in which case the maintenance of over-full employment requires a reduction of the fixed element without cutting earnings as much as necessary in the wage regime.

There are three grounds for refuting this syllogism. First, firms should be well aware that, whatever their pay formula, they can only attract workers by offering the going rate for labour total pay and should regard this, and not the fixed element of pay, as marginal cost of labour. If firms behave as they should, excess demand for labour disappears.

Second, if firms regard the fixed element of pay as the marginal cost of labour they should find its being lower than the marginal revenue value of labour productivity disquieting enough to experiment with alternative combinations of pay parameters without raising total pay above labour productivity. Risk-averse workers preferring fixed pay to potentially variable earnings of identical mean, risk-neutral or risk-loving employers will reduce their labour cost by raising the fixed element of pay at the expense of workers' profit share; even without taking into account attitude to risk it is plausible to expect managers to experiment with alternative pay parameters and not to rest until they have equalized their marginal cost and marginal value of labour, i.e.

$$\text{marginal revenue value of labour productivity at full employment} = \text{fixed pay} \quad (3')$$

which can only be reconciled with the definition (2) of a profit-sharing contract if the workers' share of net profit is zero: with the sharing component of earnings the 'share economy' also vanishes and reverts to the fixed wage economy without any excess demand for labour.

Third, workers perceiving excess demand for labour are likely to reduce their supply of effort and/or increase turnover – as they do in the only known instances of permanent excess demand for labour, i.e. Soviet-type economies (see Lane 1985) – if not right down to the point where their marginal product equals fixed pay at least as close to that level as they are allowed to get by monitoring and supervising arrangements. This is another mechanism which can reduce and eliminate excess demand for labour if it occurred.

Codetermination and Employment

The lack of codetermination is an explicit precondition of Weitzman's claims (though not of Vanek's, who does not claim full and over-full employment of labour and does not need this restriction). (In the earlier version of his analysis Weitzman takes a sanguine view of the possibility of keeping codetermination in check: '... the bargaining power of labor unions is not a natural right ...' (1984a, p. 109); '... the decisions on output, employment and pricing are essentially made by capitalists' in his model (p. 132); 'I can see no *compelling* reason why a capitalist firm should be more prone to allow increased worker participation in company decision making under one contract form than under another' (p. 133, emphasis added). His latest version is more open-minded: workers' participation in decision-making becomes not only possible but desirable as 'a question of justice and practical politics' as long as it excludes *employment* decisions (1986). It is extremely hard to imagine *any* major decision, in which workers might have a voice, that would *not* directly or indirectly also affect employment. Either this limitation or workers' participation would have to give way.) We know that it is possible to exclude workers from codetermination in the presence of persistent unemployment; such exclusion might be difficult at full employment, and it would certainly be very

difficult with excess demand for labour, but the *persistent* state of excess demand for labour postulated by Weitzman should make the exclusion of codetermination, whether or not employment questions are directly involved, impossible without an authoritarian or military regime. This is not a moral, or legal, or legalistic proposition; it is a question of 'practical politics'.

Once workers have a say on output, employment and pricing and related questions (investment, innovation, etc.) they will try and resist the very possibility of dilution of their own shares just as shareholders usually resist the dilution of share capital; for better or worse they are likely to adopt, or are tempted to adopt, other things being equal, restrictive employment policies in the possibly misguided and self-defeating purpose of raising or maintaining individual earnings. This is not a case *against* profit-sharing, but an argument for not expecting that overfull employment, if achievable, can be sustained necessarily, i.e. an argument against the plausibility of Weitzman's model (see Nuti 1985).

Profit-Sharing and Full Employment

The foundation of Weitzman's claims on behalf of profit-sharing is the assertion that, even in the short run, the share economy 'delivers' full employment of labour. ('Resources are always fully utilised in a share system' (Weitzman 1985b, p. 949); real world frictions, inertias and imperfections are mentioned only to be exorcised, and to reassert the full employment claim at least as a 'natural tendency' (p. 949, p. 952) of the share economy which, we are told, 'delivers full employment' (1986); see also Weitzman 1984, p. 97.)

For a share economy to 'deliver' full employment three necessary conditions must be satisfied simultaneously:

(i) The physical marginal productivity of labour at full employment must be positive;
(ii) The marginal revenue obtained by firms from that physical marginal product of labour must also be positive;
(iii) The fixed element of pay in share contracts must be flexible enough to fall down to the level of the marginal revenue product of labour at full employment, positive as it may be.

The first condition rules out the possibility of *classical* unemployment, i.e. due to lack of equipment, land or other resources in the quantities necessary to employ all workers efficiently. Yet, after over a decade of deep and protracted recession, deindustrialization and decapitalization, even advanced industrialized countries such as Britain of France today cannot be expected to be able to satisfy this condition as a matter of course, not to speak of Italy or, say, Spain, or of less developed countries. In his formal model Weitzman (1985b) postulates constant physical productivity of labour; this is a plausible assumption *up to near-full capacity* but Weitzman gives no reason why the capacity should be constrained by labour instead of other resources.

The second condition rules out the possibility of *Keynesian* unemployment, i.e. aggregate demand constraints making the marginal product of labour valueless before full employment is reached. Even if the first condition was satisfied, imperfect competition – which in all of Weitzman's work provides the environment in which the share contract is to operate – provides an excellent reason why firms might not give to additional physical products a positive value. Weitzman can assert that '... a "pure" sharing system not having any base wage would possess an infinite demand for labor' (1985b, p. 944), which implies positive marginal revenue for any level of output, because of the very special assumption that the elasticity of demand is *greater than unity* (p. 938), which makes demand curves absurdly and indefinitely elastic even for imperfectly competitive firms. The proposition cannot have any claim to general validity.

Even if demand for labour *were* to be infinite in the pure share economy, i.e. with a zero fixed element of pay, it would not necessarily be infinite, or even large enough to reach full employment, for a positive fixed element of pay. Weitzman neglects the determination of the

relative weight of the fixed and variable components of the share contract but recognizes the impossibility of total dependence of pay on profit; yet he takes for granted, for no good reason, that the fixed element of pay can be compressed down to whatever is the full employment marginal revenue product of labour, which we do not even know for sure is positive.

It is a non-controversial feature of the sharing contract, known from Vanek (1965), that the replacement of part of the wage by a profit-share of identical average cost to firms will lead to greater employment, higher output and lower prices – in the absence of large enough adverse feedback on investment (which Weitzman recognizes as a possible short run effect of the introduction of sharing) and in the absence of large enough feedbacks of accompanying codetermination on firms' employment policy. But there is a world of difference between higher employment and full employment and another world of difference between full employment and persistent over-full employment; no serious work can afford to switch indifferently and cavalierly from one to the other.

Share Contracts and Public Good

If the share economy could really guarantee, as general and necessary consequences of its establishment, the achievement and stability of full employment without adverse drawbacks there would be a case for public policy treating the share contract as 'public good' to be pressed on an unenlightened public still largely unaware of potential benefits, as in the case of safe vaccination against infectious disease. The case for the share economy would not be much greater than that for enforced wage flexibility, which would also guarantee full employment and stability under the same circumstances. A downward flexible wage would not deliver excess demand for labour but this is a questionable achievement and would not be necessary to absorb contractionary shocks if wages were flexible; downward flexible wages would also require a greater fall of money earnings to achieve full employment in the short run and may be more likely to bring about adverse effects on aggregate demand; otherwise there is little to choose between the two, except for the lower degree of public resistance that can be expected for share contracts with respect to wage cuts.

In fact if the share contract could really deliver and maintain full employment, while a wage economy could not, the greater variability of workers' earnings associated with profit-sharing over the cycle would disappear and, between firms, could be eliminated by labour freely redeploying itself at will across labour-hungry firms; the variability of employment would also disappear; workers would have de facto free access to a job in any firm of their choice, as in forgotten utopias (Hertzka 1890; Chilosi 1986). Thus it could be said that '... a move towards profit sharing represents an unambiguous improvement for the working class' (Weitzman 1985b, p. 954). But we have seen that profit-sharing cannot guarantee full (let alone over-full) employment. Without full employment, the higher variability of earnings associated with profit-sharing remains and it may or may not be compensated by the higher mean value of employment probability and perhaps real earnings. Outside over-full employment, in fact, the share economy is just as vulnerable to contractionary shocks as the wage economy because, in spite of flexibility of labour earnings in the share regime, the marginal cost of labour to firms (which is the fixed component of workers' pay) remains constant just as does the wage. Thus the higher stability of employment to be found in Japan simply cannot be the result of profit-sharing, as Weitzman firmly believes, seeing that Japan has never known a state of over-full employment; higher employment stability would require workers' shares in GNP instead of their enterprise's profits.

The fact that the adoption of a share contract, without the guarantee of stable full employment, has a cost for workers, eliminates the necessity, but not the possibility, of the share contract having 'public good' features. A vaccine may be somewhat unsafe, its degree of unsafety acceptable to all if vaccination is universal and all benefit from reduced exposure to infection, yet individuals benefit from free-riding strategies and the

enforcement of universal vaccination as 'public good' can still be beneficial to all. If labour contracts were negotiated exclusively at the level of individuals or firms the external beneficial effects of the share contract might be lost from sight; but these external benefits – unlike the case of genuine 'public goods' – are completely internalized in nationwide negotiations between associations of employers and employees. Admittedly the benefits, such as they are, of profit-sharing may be still unknown to the public at large and deserve wider publicity. But it is counterproductive to foist a good medicine on a sceptical public by claiming that it can guarantee longevity or immortality. At the first signs that such excessive claims are unfounded it may be thrown away despite its real lesser benefits.

Coghlan, Timothy (1855–1926)

Colin G. Clark

Coghlan was the son of a poor family in Sydney, and obtained his education through scholarships. Like several other distinguished economists, his

original career was in engineering, in this case civil engineering, which led to his taking an interest in statistics. New South Wales had been established as a penal colony under military rule, and therefore right from the colony's beginning people and governments were accustomed to statistical enumeration much more thorough than in the rest of the world. Coghlan was appointed statistician by the colonial government, and produced over a long period of years a large output of excellent statistical papers.

Before Federation in 1901, there were six separate colonial governments in Australia, often pursuing different objectives. This was particularly the case in the highly controversial matter of free trade or protection. The two most populous colonies were Victoria and New South Wales. Victoria had attracted a large population through the abundance of alluvial gold in its riverbeds. This was soon exhausted; and deep mining fell far short of taking its place. The Victorian Government considered that the only way to provide employment to make up for the decline in mining was to establish manufacturing industries under high tariff protection. New South Wales (which admittedly had not had such a destabilizing gold rush) was determined to adhere to free trade, with the object of promoting agricultural and pastoral production. Some of Coghlan's writings were polemic, strongly stating the free trade case. In the *Wealth and Progress of New South Wales*, in succeeding editions, the available statistics of the colony were assembled, pointing to a superior rate of growth to that of Victoria.

Coghlan was fifty years ahead of his time in making national product estimations for New South Wales. Without any experience in any other country to guide him, he devised methods which would pass muster today. His work however was not followed up. There was no further estimate of Australian national product until the study by Benham in the 1920s, using less precise methods, and then another gap until Sir John Crawford and I prepared a study in 1937.

Coghlan prepared a series of publications on a more extensive basis, *The Seven Colonies of Australasia* (i.e. including New Zealand; it was thought at the time New Zealand might enter the Australian federation).

The free trade case was lost in 1908, when Victoria, with its allies in some other states, persuaded the new federal government to impose highly protective tariffs.

Coghlan was posted to London, where he performed most of the duties (but without the title, which went to the political head) of Agent General for New South Wales. The duties were varied and responsible, including the raising of large sums in loans.

In partial retirement, Coghlan embarked upon a *magnum opus*, *Labour and Industry in Australia*, which was published in England in 1918, giving a most full and detailed account of its subject, but illuminated by stories and anecdotes which make it readable.

Cognitive Ability

William T. Dickens

Abstract

Modern psychological theory views cognitive ability as multidimensional while acknowledging that the many different abilities are themselves positively correlated. This positive correlation across abilities has led most psychometricians to accept the reality of a general cognitive ability that is reflected in the full scale score on major tests of cognitive ability or IQ. This article provides an introduction to the history of cognitive testing and some of its major controversies. Evidence supporting the validity of measures of cognitive ability is presented and the nature and implications of group differences are discussed along with evidence on its malleability.

Some people are obviously and consistently quicker than others to understand new concepts; they solve unfamiliar problems faster, see relationships that others don't and are more knowledgeable about a wider range of topics. We call such people smart, bright, quick, or intelligent. Psychologists have developed tests to measure this trait. Originally called IQ tests (for Intelligence Quotient because the measures were constructed as the ratio of mental age to chronological age multiplied by 100), that name has fallen out of favour. Instead, such tests are now often referred to as tests of cognitive ability. Although the term IQ is still sometimes used to refer to what such tests measure, none constructs a ratio.

History

Spearman (1904) first popularized the observation that individuals who do well at one type of mental task also tend to do well at many others. For example, people who are good at recognizing patterns in sequences of abstract drawings are also good at quickly arranging pictures in order to tell a story, telling what three-dimensional shapes drawn in two dimensions will look like when rotated, tend to have large vocabularies and good reading comprehension, and are quick at arithmetic. This pattern of moderate to strong positive correlations across the whole spectrum of mental abilities led Spearman to hypothesize the existence of a general mental ability similar to the common notion of intelligence. A person's ability with any particular type of task would be equal to the sum of that person's general ability plus considerations unique to that particular task. Thus general ability could be measured by constructing sub-tests of a number of similar items (individual tasks of the same type such as arithmetic problems) of differing complexity. Each sub-test would present items of a different type, and individual scores across sub-tests could be aggregated. Task specific factors would average out leaving the final score as mainly a measure of general ability or 'g'. Using an approach like this Binet (1905) developed the first IQ test as a way of identifying students' academic potential. That test was adapted for use in English by Terman and in 1916 became the Stanford–Binet IQ tests – still one of the most commonly administered tests of cognitive ability.

Spearman's hypothesis of a single general mental ability and many specific abilities was challenged by Thurstone (1935), who popularized

the notion that people had a number of independent primary mental abilities rather than a single general mental ability. Both Spearman and Thurstone made contributions to the development of factor analysis as a way to identify the presence of unobserved variables (abilities) that affect a number of observable variables (sub-test or item scores). Today, the Spearman–Thurstone debate has been resolved with a compromise. The most common view among psychometricians who study cognitive ability is that there are a number of different abilities. Some people are better at solving problems verbally while others are good at solving problems that involve visualization. Some people who are good at both of these things may be only average at tasks that rely heavily on memory. However, there is a tendency for people who perform well in any of these broad areas to perform well in all others as well (Carroll 1993). Most modern tests of cognitive ability provide both a full-scale score that is most reflective of general intelligence, and a number of special-ability specific sub-scores as well.

Validity

Binet's is considered the first successful test of cognitive ability in that it was able to accurately predict teachers' assessments of their students on the basis of a relatively short verbally administered test. Scores on tests of cognitive ability correlate well with common perceptions of how bright or smart someone is. They are also strongly correlated with measures of academic achievement such as achievement test scores, grades and ultimate educational attainment (typically .5 or better). They are less highly correlated (.5 or less) with many important life outcomes including reported annual income and job status. Performance on a wide range of jobs and work tasks is positively related to cognitive test scores with performance on more demanding jobs having higher correlations. Some have claimed that general cognitive ability is responsible for most of this explanatory power (Ree and Earles 1992; Ree et al. 1994). This was a major theme of the controversial best-seller *The Bell Curve* (Herrnstein and Murray 1994). Heckman (1995), in a review of that book, argues that even though g has significant explanatory power, many other factors, both cognitive and non-cognitive, matter as well.

Finally, test scores are correlated with a number of social behaviours including unwed motherhood, criminal activity, and welfare receipt (Jensen 1998, ch. 9). While these correlations are substantial, and cognitive test scores are typically better predictors of most of these outcomes than any other single personal attribute, they still explain less than half the variance.

Individuals' scores on tests of cognitive ability also tend to be strongly correlated over time – much more so for adults than for children. A study of older adults found their full-scale IQ scores to be correlated .92 when tested at two points in time three years apart (Plomin et al. 1994). In contrast, a study of children tested at two points in time roughly two years apart found correlations of only .46 for those who were less than one year old at first testing and .76 for those who were one year old at first testing (Johnson and Bradley-Johnson 2002).

It is common to draw a distinction between tests of achievement and tests of ability. Achievement tests measure how much knowledge the test taker has accumulated in a particular area while ability tests endeavour to measure how quickly a person can solve unfamiliar problems. Typically, scores on the two types of tests are highly correlated. In fact, all tests of ability are, to some degree, tests of achievement as it is impossible to measure ability without also measuring the test taker's reading or verbal comprehension at least. Further, to the extent that the task being tested relies on knowledge of geometry, arithmetic, general knowledge, and so on, the rolls of the achievement test and ability test are confounded.

Cultural bias has been a concern with knowledge-based tests. Some knowledge is more accessible to some people than others. For example, we would expect that a child growing up with upper middle-class parents in New York or Paris to find it easier to learn the distance between the two cities (a general knowledge question that was once on one of the popular IQ tests) than someone from the slums of St. Louis or a tribesman from

the bush in Africa. For this reason a number of tests have been constructed that require a minimal amount of prior knowledge, such as Cattell's culture fair test (Cattell 1960) or Raven's progressive matrices (Raven 1941).

Group Differences

No matter what test is administered, men and women of the same background tend to have very similar average scores on tests of cognitive ability, though they differ slightly in their performance on some sub-tests (Jensen 1998, pp. 531–6). However, there are large differences across ethnic groups and geographic areas. The difference that has generated the most controversy is the difference in average scores of US blacks and whites, which is typically reported to be about one white standard deviation, though this gap has declined some in recent years (Dickens and Flynn 2006). Do these represent real differences in cognitive ability or do they reflect cultural bias in the tests?

Defenders of the tests offer several pieces of evidence suggesting that they are unbiased. Foremost is the evidence of 'external validity' – that the same regression equation that predicts outcomes such as job performance, grades, or educational attainment for one group will typically do a similarly good job for any other group. Also, different groups find the same questions more or less difficult. Members of different groups with similar scores will have similar patterns of right and wrong answers. If some questions are more culturally biased than others, the disadvantaged group should find those items more difficult than the mainstream group does. But researchers looking for such cultural bias have found no evidence of it (an exception occurs when one of the groups being compared is made up of non-native speakers of the language in which the test was administered, in which case scores on questions requiring a better knowledge of the language will be lower). Surprisingly, to the extent that there are black–white differences across test items, blacks do worse on what seem to be some of the least culturally dependent items – those involving abstract or symbolic problem-solving. Differences tend to be smaller on seemingly culturally rich items such as general knowledge. Herrnstein and Murray (1994, Appendix 5) provide a review of the evidence on bias.

The best evidence that tests can be biased in at least some circumstances comes from studies of a phenomenon called stereotype threat. It has been shown that reminding people of their group identity can cause them to perform in ways more consistent with stereotypes of the group's abilities. For example, blacks have been found to perform worse on some particularly difficult vocabulary items when given a questionnaire that asked them to state their race before taking the test or when the test was represented as a test of intelligence as opposed to a test of vocabulary. Women who were told that the difficult math test they were taking generally showed gender differences performed worse than those taking the same test who were told the test showed no differences. Men showed the opposite effect and performed better when told the test showed a gender difference (Steele 1997). However, it has not been demonstrated that stereotype threat produces substantial bias on standard tests in standard test-taking circumstances.

While most evidence is consistent with the view that tests provide a fair measure of the underlying concept of cognitive ability across ethnic groups, it is not conclusive. For example, since tests rarely explain as much as half the variance in the outcomes in studies of external validity, there is always the possibility that the tests underestimate black cognitive ability but that other disadvantages pull down black performance. If true, the validity of the tests as predictors of practical outcomes is an artifact of offsetting biases. This could explain why it is that when regressions of white performance on white test scores fail to predict black performance they tend to predict better performance than is observed. Further, commonsense notions that people from different cultural backgrounds probably have less opportunity to acquire certain types of information or practise certain skills should be given some weight. If studies find that blacks do no worse than similarly scoring whites on highly culturally loaded items, that could indicate that the poorscoring whites

were similarly disadvantaged. If disadvantage is more common for blacks than whites due to discrimination, that disadvantage could still explain some of the score gap. However, the strong correlation of even the culturally reduced tests with performance, and the similar magnitude of the gap on those tests between groups, suggest that much of the measured gap in ability between groups reflects real differences in average developed ability. This conclusion naturally leads to the consideration of the sources of those differences.

The question of whether individual, and particularly group, differences in cognitive ability are due more to nature or to nurture has been enormously controversial for the last century. Dickens (2005) presents a summary of the evidence on the origin of black–white differences and concludes that they are most likely not substantially genetic in origin. Rushton and Jensen (2005) reach the opposite conclusion. Whatever the right answer, whether the black–white gap has genetic origins is probably the wrong question. It seems that people are concerned with the issue mainly because they confuse having a genetic cause with immutability. While genes almost certainly play a large role in explaining individual differences in cognitive ability within ethnic groups raised in similar circumstances, it also seems that developed cognitive ability is highly malleable.

Malleability

A large amount of evidence has accumulated on the role of genes in explaining individual differences in cognitive ability. Several reviews of this literature conclude that differences in genetic endowment explain somewhere between 60 per cent and 80 per cent of the variance in cognitive ability in representative samples of the adult population in developed countries. The percentage for children is lower than for adults, with most estimates placing it around 40 per cent for six-year-olds (Plomin et al. 2001; Neisser et al. 1996). The figure is also estimated to be lower among disadvantaged populations (Turkheimer et al. 2003) though not consistently (Asbury et al. 2005). This figure is referred to as the heritability of cognitive ability. It is estimated by contrasting people with different degrees of relatedness raised in the same home or people with similar relatedness raised in different homes. For example, the correlation of the cognitive ability of identical twins raised in completely independent environments will be equal to the heritability of cognitive ability under the assumptions typically employed to make such estimates. While this evidence establishes that genes play a large role in determining individual differences, little is known about which genes are involved or how they influence cognitive ability (Plomin et al. 2001).

The high heritability of cognitive ability has led some to conclude that people's environments play little role in shaping their ability and that, therefore, individual differences are largely immutable and group differences must be largely due to differences in average genetic endowment. It has been argued that, if all of the observable differences in environment between people produce only 40 per cent or less of the variance in cognitive ability, then the large differences between blacks and whites could not result from the relatively small differences in environment between the average white and the average black. Thus differences in genetic endowment must play a substantial role. A formal version of this argument was first presented by Jensen (1973, pp. 135–9). A similar argument was made by Herrnstein and Murray (1994, pp. 298–9).

Yet despite the high heritability of cognitive ability, it does seem to be quite sensitive to environmental changes. In a review of the effects of early education programmes, Lazar and Darlington (1982, p. 44) noted that 'The conclusion that a well-run cognitively oriented early education program will increase the IQ sores of low-income children by the end of the programs is one of the least disputed results in educational evaluation'. The gains they surveyed were often quite large, though they also tended to decline substantially after children left the programmes. There is also evidence that being in a cognitively demanding environment can increase measured cognitive ability. Ceci (1991) surveys the evidence on the effects of school attendance on measured ability and finds it to be substantial.

Finally, the most profound changes in measured cognitive ability have taken place over time. James Flynn has documented huge gains in cognitive ability – as much as a standard deviation or more a generation – in more than 14 countries. Numerous other authors have found gains on other tests and in other countries (Flynn 1987, 1998, 2006). This phenomenon of large and pervasive gains has been dubbed 'the Flynn Effect'.

How is it that large gains are possible in the face of high heritability estimates? The chief flaw in the argument that high heritability implies a limited role for environment is that it misunderstands what heritability is measuring. It ignores the possibility that genetic and environmental influences might be correlated. In particular, it ignores the possibility that genetic influences on ability are largely the work of environmental advantages that come about due to modest physiological advantages.

Consider a sports analogy. Identical twins raised apart have a shared genetic endowment that tends to make them notably taller than their peers. As such they are both better basketball players. Even though they are raised apart, both are likely to spend more time playing basketball than other children their age. They are good at it and thus enjoy it more than other activities in which they do not naturally excel. Consequently they both get more practice at basketball than their peers, and that makes them better at the game. Being better players than their peers, they are more likely to be picked by coaches for high-school teams and more likely to receive yet more practice and more intensive coaching. If this leads to them playing in college they will both be enormously better players than the average person. A small physiological difference, which would make only a very modest difference in their performance on the court if they were untrained and inexperienced, has mushroomed into a huge difference in performance because it has been reinforced by the environmental influences of practice and coaching.

It is not hard to imagine the same thing happening with cognitive ability. Someone who is slightly quicker or has an emotional disposition amenable to thought and contemplation will be more likely to spend more time in intellectual pursuits. Such a person will likely receive positive reinforcement from teachers and be more likely to be tracked into more demanding classes and to develop friendships with other similarly disposed children. Such a child will have much more opportunity to practise intellectual work and receive more 'coaching' in intellectual pursuits. A small initial physiological difference could mushroom into a large difference in ability through a process whereby the advantage leads to a better environment which improves ability and gives access to even better environments.

If such reciprocal causation is at work in the development of cognitive ability, then small persistent exogenous differences in environment could produce large differences in cognitive ability. Dickens and Flynn (2001) lay out a formal model of such a process. If in a cross section of people in the same ethnic group most exogenous environmental differences are transient, then they will not accumulate through reciprocal causation and will not explain much variance across individuals. However, small persistent differences between groups or generations could cause large differences if they drive the engine of reciprocal causation. Similarly, preschool programmes which enrich children's cognitive environment can have large effects, but once the children are removed from the programme the process can work in reverse and unravel the gains. The exogenous decline in the quality of the environment from the removal of the programme's stimulation sets off a downward spiral of poorer performance leading the child into poorer environments, yet poorer performance and so on.

Conclusion

Modern psychology views cognitive ability as having a number of dimensions, all of which seem to be correlated with one another. Many interpret this correlation as reflecting an underlying general cognitive ability, or g, that is measured by the full-scale scores on the major tests of cognitive ability or IQ. General cognitive ability is an important predictor of a wide range of economic and life outcomes, with similar predictive validity across groups with different average levels of ability. Still, cognitive test scores typically explain

far less than half the variance in life outcomes, so cognitive ability is only one important factor among many that explain success.

Adult differences in cognitive ability within representative samples of ethnic groups raised in similar circumstances are subject to substantial genetic influence, but this does not mean that group differences are genetic in origin. Despite the large role played by genetic differences in explaining adult variance in cognitive ability, there is considerable evidence that intelligence is highly malleable and the life outcomes influenced by intelligence even more so.

Born in The Hague, Cohen Stuart was an engineer who took up the challenge put forward by the famous Dutch economist and politician N.G. Pierson to study the mathematical foundations of what we would call nowadays an optimal tax structure. His thesis (Cohen Stuart 1889) has been reprinted in part (Musgrave and Peacock 1958).

The international attention to Cohen Stuart's exposition is due to the thorough discussion by F.Y. Edgeworth in his article on the pure theory of taxation (Edgeworth 1897). Following a lead by Pierson, Cohen Stuart studied the impact of the principle that each taxpayer should sacrifice an equal proportion of the total utility which he derives from material resources. He proved that it depends on the decrease of marginal utility of income, whether the income taxed above a certain minimum will be progressive, regressive or proportional in relation to the level of income. Cohen Stuart argues that in most practical cases a modest progressive tax rate will emerge.

Although based on old-fashioned concepts of measurable utility, Cohen Stuart's contribution to the analysis of the optimal income tax is part of the modern theory of optimal taxation (Mirrlees 1971) and therefore comparable to Cournot's role in the development of the theory of oligopoly.

Cohen, Ruth Louisa (Born 1906)

Phyllis Deane

Ruth Cohen is one of the select band of leading professional economists whose importance is measured more by her emphatically commonsense influence on colleagues and pupils than by the length of her publications list. Born in 1906, she entered Newnham College, Cambridge, in 1926 to read for the Economics Tripos within a Faculty that contained a galaxy of outstanding individuals and included such stars as Keynes, Pigou, Robertson, Maurice Dobb and Piero Sraffa. She had already developed a research interest in agricultural economics when, after spending a couple of years as Commonwealth Fund Fellow at Stanford and Cornell, she joined the Oxford University Agricultural Economics Research Institute in 1933. For the next six years she pursued that specialization and completed two well-received books – one an analytical and statistical history of milk prices and the other a text on the economics of agriculture which J.M. Keynes invited her to write for the

Cambridge Economic Handbooks, of which he was then editor.

In common with most of the leading British economists of her generation she became a temporary civil servant soon after the outbreak of World War II, serving first at the Ministry of Food and later at the Board of Trade when questions of postwar reconstruction were rising to the top of the economic policy agenda of government. In 1945 she returned to Cambridge as lecturer in the Faculty of Economics and Politics and as Director of Studies in Economics at Newnham College, to which she had been elected a Fellow in 1939 and of which she was to become an active Principal in 1954. Soon after retiring from her university post in 1972 she was elected to the Cambridge City Council, where for a decade and a half she has devoted her formidable energy and talent as an applied economist to local government problems.

Ruth Cohen's reputation among contemporary economists has rested largely on her capacity to offer forceful, direct and perceptive oral comments on issues of current economic debate – theoretical as well as applied. This is the kind of salutary influence on the discipline that is rarely acknowledged in print, except in the occasional footnote. In the event, however, her typically terse intervention in the torrid capital theory debates that raged in the learned journals of the 1950s and 1960s has been duly credited with having triggered off a spate of articles in the capital-switching and capital-reversing phase of the debate – a phase which eventually ended in general agreement that her observation had revealed what some would describe as a fatal flaw, and others an awkward anomaly, in the orthodox neo-classical theory of the production function. To have stimulated this degree of consensus in a theoretical controversy which has carried unusually heavy methodological and ideological undertones is no mean achievement.

Cohn, Gustav (1840–1919)

H. C. Recktenwald

Lecturer (*Privatdozent*) at the University of Heidelberg in 1869, Cohn was appointed professor of economics at the Riga Polytechnic Institute (1869–72). After spending some years in England he was appointed to a chair of economics at the Zürich Polytechnic Institute in 1875 and then in Göttingen in 1884. There he lived up to his death in 1919.

Cohn is noted for his pioneering contributions to the theory and policy of transportation and public finance. In his *Untersuchungen* (1874–75), *Eisenbahnpolitik* (1883) and *System* (1898, vol. 3), utilizing biased materials produced by parliamentary commissions, he strongly recommended railway centralization and government ownership while opposing canal construction; yet he failed to test the efficiency of these policy recommendations. In the field of public finance he is (like Rau, Roscher, von Stein and Wagner) the typical German exponent of Smith's liberal principles (not his moral theory) coupled with his own historical and ethical ideas, which were based on relatively poor analysis and synthesis. Cohn attributed to the state an economic and moral competence which he unquestioningly assumed. Advocating the legitimacy of value judgements (*Werturteile*) and ethical norms in economic science, he dealt with equity in taxation, particularly the controversial subsistence level and progressive taxation. Seligman rightly classes Cohn among the founders of the science of public finance.

His writings on general economics (1885–98, 1886) are distinguished by a philosophical foundation and a brilliant essayistic style which earned him a great reputation among his contemporaries.

Cointegration

Mark W. Watson

Abstract

This article summarizes the mathematical structure of cointegrated time series models and discusses econometric procedures commonly used to analyse cointegrated time series. This discussion is carried out in the context of stochastic trends that follow driftless I(1) or 'unit root' processes. The article concludes with a brief discussion of cointegration in the context of more general stochastic trends.

Cointegration means that two or more time series share common stochastic trends. Thus, while each series exhibits smooth or trending behaviour, a linear combination of the series exhibits no trend. For example, short-term and long-term interest rates are highly serially correlated (so they are smooth and in this sense exhibit a stochastic trend), but the difference between long rates and short rates – the 'term spread' – is far less persistent and shows no evidence of a stochastic trend. Long rates and short rates are cointegrated.

The concept of cointegration was formalized by Clive W.J. Granger in a series of papers in the 1980s (Granger 1981; Granger and Weiss 1983; Granger 1986; Engle and Granger 1987), and in 2003 Granger received the Nobel Prize in Economics for this work. A flurry of research activity followed Granger's original contributions in this area and produced a practical set of econometric procedures for analysing cointegrated time series.

Mathematical Structure of I (1) Cointegrated Models

Let X_t denote a scalar I(1) stochastic process, with moving average representation $X_t = c(L)\varepsilon_t$, where ε_t is a scalar white noise process, and $c(L) = \sum_{i=0}^{\infty} c_i L^i$ is a polynomial in the lag operator L, and where the moving average coefficients, c_i decay sufficiently rapidly so that $\sum_{i=1}^{\infty} i|c_i| < \infty$. The Beveridge–Nelson decomposition (see trend/cycle decomposition) implies that X_t can be represented as $X_t = \tau_t + a_t$, where T_τ is a random walk, so that $\tau_t = \tau_{t-1} + e_t$, where e_t is white noise and a_t has a moving average representation $a_t = d(\mathrm{L})\varepsilon_t$, where

$\sum_{i=1}^{\infty} |d_i| < \infty$. Thus, X_t can be expressed as the sum of a stochastic trend, τ_t, and an I(0) process, a_t.

When X_t is an $n \times 1$ vector of I(1) processes, a similar result implies that $X_t = A\tau_t + a_t$, where A is a matrix of constants, τ_t is a vector of random-walk stochastic trends, and a_t is a vector of I (0) processes. Because X_t contains n elements, the vector τ_t will generally contain n stochastic trends. However, when τ_t contains only $k < n$ stochastic trends, A is $n \times k$, so that $\alpha' A = 0$, for any vector α in the null space of the column space of A. This means that $\alpha' X_t = \alpha' a_t$, so that the linear combination $\alpha' X_t$ does not depend on the stochastic trends. In this case, the time series making up X_t are said to be cointegrated. Any non-zero vector α that satisfies $\alpha' A = 0$ will annihilate the stochastic trend in $\alpha' X_t$, and vectors with this property are called cointegrating vectors. When A has full column rank, the number of linearly independent cointegrating vectors is $r = n - k$, which is called the cointegrating rank of the process.

For example, suppose that X_t contains $n = 3$ series representing interest rates on one-month, three-month and six-month US treasury bills. Suppose that $X_{it} = \tau_t + a_{it}$, for $i = 1, 2, 3$, where τ_t is a common stochastic trend shared by the three interest rates. Then $X_t = A\tau_t + a_t$, where $k = 1$ (there is a single stochastic trend), $A = (1\ 1\ 1)'$ (the trend has an equal effect on each of the interest rates) and $\alpha_1 = (1\ 0\ -1)'$ and $\alpha_2 = (1\ 0\ -1)'$ are two linearly independent cointegrating vectors, so that $r = 2$ and $\alpha_1' X_t$ and $\alpha_2' X_t$ denote the interest rate term spreads.

Vector moving average models (VMAs) and vector autoregressions (VARs) are often used to represent the linear properties of vector stochastic processes. The Granger representation theorem (see Engle and Granger 1987) shows that VMAs and VARs for cointegrated processes have special structures. In general, the VMA for an I(1) vector process is "$X_t = D(\mathrm{L})\varepsilon_t$, where ε_t is white noise with full rank covariance matrix. When X_t is not cointegrated, the $n \times n$ matrix $D(1)$, which contains the sum of the moving average coefficients, has rank n. But, when X_t is cointegrated, $D(1)$ has rank $k < n$, where k denotes the number of stochastic trends. When X_t is not cointegrated, the VAR for X_t can be written in terms of ΔX_t and has the form $\Phi(\mathrm{L})X_t = \varepsilon_t$, where $\Phi(\mathrm{L})$ is a stable lag polynomial (so its roots are outside the unit circle) and ε_t is white noise. When X_t is cointegrated, the VAR has the form Φ (L) $X_t = \beta\alpha' X_{t-1} + \varepsilon_t$, where α is an $n \times r$ matrix with columns that are the linearly independent cointegrating vectors. Thus, the cointegrated VAR expresses the elements of ΔX_t as functions of its own lags, but also includes the r regressors $\alpha' X_{t-1}$ in each of the VAR's n equations. The variables $a' X_{t-1}$ are called 'error-correction terms' and the cointegrated VAR is called a 'vector error correction model' (VECM).

Watson (1994) provides a summary of the algebra linking these various representations of the cointegrated model.

Testing for Cointegration

The time series making up X_t are cointegrated if the linear combinations $\alpha' X_t$ are I(0) random variables. If X_t is not cointegrated, then $\alpha' X_t$ will be I (1) for any non-zero vector α. Tests of cointegration ask whether $\alpha' X_t$ is I(1) or I(0).

Consider the simple case in which there is only one potential cointegrating vector, so that $\alpha' X_t$ is a scalar. Cointegration can then be tested using a unit root test applied to $\alpha' X_t$. The straightforward application of a unit root test requires that α is known, so that the scalar variable $\alpha' X_t$ can be calculated directly from the data. This is possible in many empirical applications (such as the interest rate example described above) where the value of α can be pre-specified.

Thus, suppose that α is known, and consider the competing hypotheses $\mathrm{H}_{\mathrm{I}(1)}$: $\alpha' X_t$ is I(1) and $\mathrm{H}_{\mathrm{I}(0)}$: $\alpha' X_t$ is I(0). The hypothesis $\mathrm{H}_{\mathrm{I}(1)}$ means that the elements of X_t are not cointegrated and the hypothesis $\mathrm{H}_{\mathrm{I}(0)}$ means that the elements are cointegrated. Under $\mathrm{H}_{\mathrm{I}(1)}$ the autoregressive model for $\alpha' X_t$ contains a unit root, while under $\mathrm{H}_{\mathrm{I}(0)}$, the autoregressive model for $\alpha' X_t$ is stable.

The null $\mathrm{H}_{\mathrm{I}(1)}$ can be tested against the alternative $\mathrm{H}_{\mathrm{I}(0)}$ using an augmented Dickey–Fuller

(ADF) unit root test or the modified ADF test developed in Elliott, Rothenberg and Stock (1996). The null $H_{I(0)}$ can be tested against $H_{I(1)}$ using the best local test proposed by Nyblom (1989), modified for serial correlation as described in Kwiatkowski et al. (1992), or a point-optimal test as discussed in Jansson (2004). (There are important practical considerations associated with the choice of the long-run-variance estimator (see heteroskedasticity and autocorrelation corrections) used in tests for the $H_{I(0)}$ null hypothesis because of the high degree of serial correlation under the alternative. See Müller (2005) for discussion.)

When α is not known, the unit root tests described in the last paragraph use $\hat{\alpha}'X_t$ in place of $\alpha'X_t$, where $\hat{\alpha}$ is an estimator of α. For example, Engle and Granger (1987) suggest estimating α by regressing the first element of X_t onto the other elements of X_t using OLS, and carrying out an ADF test using the residuals from this regression. Estimation of α changes the distribution of the ADF test statistic from what it is when α is known, so that critical values for the Engle–Granger test are different than the standard ADF critical values. As described in Phillips and Ouliaris (1990) and Hansen (1992) the correct critical values depend on the number of elements in X and on the properties of the deterministic trends in the model. Stock and Watson (2007) tabulate choices of critical values from the Phillips and Ouliaris (1990) and Hansen (1992) papers that are appropriate for data that follow I(1) processes that may or may not contain drift, and thus serve as conservative critical values. Modifications for tests of the $H_{I(0)}$ null versus the $H_{I(1)}$ alternative are discussed in Shin (1994) and Jansson (2005).

The tests outlined above are useful for testing whether a single series $\alpha'X_t$ is I (0) or I(1), but in many applications there may be more than one potential cointegrating relation ($r > 1$) so that it is useful to have tests for hypothesis that postulate different values of r. That is, it is useful to entertain hypotheses of the form $H_j : r = j$, for $j = 0, 1, \ldots n$. The hypothesis $r = 0$ means that there is no cointegration, $r = 1$ means that there is a single cointegrating vector, and so forth. As discussed in Johansen (1988), these tests are easily formulated and carried out using the VECM model. Recall that the VECM model has the form $\Phi(L)X_t = \beta\alpha' X_{t-1} + \varepsilon_t$. Consider the null and alternative hypotheses $H_o : r = r_o$ *vs.* $H_a : r = r_a$ where $r_a > r_o$, and write the VECM as $\Phi(L)X_t = \beta_o\alpha_0' X_{t-1} + \tilde{\beta}\tilde{a}'X_{t-1} + \varepsilon_t$, where α_o contains the r_o cointegrating vectors under the null and $\tilde{a}$ contains the additional cointegrating vectors under the alternative. Under the null hypothesis, the variables $\tilde{a}'X_{t-1}$ do not enter the VECM, while under the alternative these variables enter the VECM. Thus, the null and alternative can be written as $H_o : \tilde{\beta} = 0$ versus $H_a : \tilde{\beta} \neq 0$. As in the case of $r = 1$, the tests depend on whether the cointegrating vectors are known or unknown. When the cointegrating vectors are known, the regressors $\alpha_o'X_{t-1}$ and $\tilde{\alpha}'X_{t-1}$ can be constructed from the data, and the Wald test for $\tilde{\beta} = 0$ can be constructed using the usual regression formula. When the cointegrating vectors are unknown, the testing problem is more difficult, but Johansen (1988) provides an simple formula for the likelihood ratio test statistic. In either case, the critical values for the test are 'non-standard', that is, they are not based on the χ^2 or F distributions. Critical values for the tests depend on the values of $r_a - r_o$, the number of cointegrating vectors that are known and unknown, and the presence or absence of constants and time trends in the model. The various critical values are tabulated in Horvath and Watson (1995).

Estimating Unknown Cointegrating Coefficients

Unknown coefficients in cointegrating vectors are typically estimated using least squares and Gaussian maximum likelihood estimators (MLEs). The properties of these estimators can be understood by considering a simple bivariate model

$$X_{1t} = \theta X_{2t} + \eta_{1t}$$
$$X_{2t} = X_{2t-1} + \eta_{2t}$$

where $\eta_t = [\eta_{1t}\eta_{2t}]' \sim$ iid N $(0, \Sigma)$. In this example, there is one common trend that coincides with X_{2t}, the cointegrating vector is $\alpha = (1 - \theta)'$ where θ is an unknown parameter, the error correction term is $\alpha' X_t = \eta_{1t}$ which is potentially correlated with the innovation in the common trend, η_{2t}, and the assumption of normality is used to motivate the Gaussian MLE of θ.

The OLS estimator of θ has several interesting properties (Stock 1987). Even though X_{2t} and η_{1t} are correlated, the OLS estimator is consistent; indeed it is 'super-consistent' in the sense that $\hat{\theta}^{OLS} - \theta \sim O_p\left(T^{-1}\right)\hat{\theta}^{OLS}$, so that $\hat{\theta}^{OLS}$ converges to θ faster than the usual $\sqrt{T}$ rate familiar from regressions involving I(0) variables. These results follow because, in the cointegrated model, the regressor X_{2t} is I(1) and therefore is much more variable than an I(0) regressor $\left(\sum_{t=1}^{T} X_{2t}^2 \sim O_p\left(T^{-2}\right)\right.$ in this I(1) regression instead of $O_p(T^{-1})$ in the usual I(0) regression), and the correlation between X_{2t} and η_{1t} is non-zero, but vanishes as the sample size becomes large. (The covariance is constant, but the variance of X_{2t} increases linearly with t, so the correlation vanishes as t increases.)

Despite these intriguing and powerful features, the OLS estimator has two properties that make it unsatisfactory for many uses. First, while OLS is consistent, the correlation between the regressor and error term induces a bias in the large sample distribution of the estimator, and this bias can be severe in sample sizes typically encountered in applied work (Stock 1987). Second, the large-sample distribution of the OLS estimator is non-normal, and this complicates statistical inference. For example, the standard interval $\hat{\theta}^{OLS} \pm 1.96SE\left(\hat{\theta}^{OLS}\right)$ does not provide a 95 per cent confidence set even in large samples. Interestingly, Gaussian maximum likelihood estimators share the super consistency properties of OLS, but do not suffer from these unsatisfactory properties (Johansen 1988; Phillips 1991).

To construct the Gaussian MLE, factor the joint density of $\{X_t\}_{t=1}^{T}$ into the density of $\left\{X_{1t}|\,(X_{2t})_{t=1}^{T}\right\}_{t=1}^{T}$ and the density of $\{X_{2t}\}_{t=1}^{T}$. The density of $\{X_{2t}\}_{t=1}^{T}$ does not depend on θ, and the density of $X_{1t}|(X_{2t})_{t=1}^{T}$ is characterized by the Gaussian linear regression $X_{1t} = \theta X_{2t} + \beta X_{2t} + v_t$, where β is the regression coefficient from the regression of η_{1t} onto η_{2t} $(=\Delta X_{2t})$, v_t is the error in this regression, and $v_t|(X_{2t})_{t=1}^{T} \sim$ iid $\mathrm{N}(0, \sigma_2)$. Simple calculations (Phillips 1991) can then be used to show that $\hat{\theta}^{MLE} - \theta \sim O_p\left(T^{-1}\right)$ and that $\hat{\theta}^{MLE}|(X_{2t})_{t=1}^{T} \sim \mathrm{N}(\theta, V)$, where V depends on $(X_{2t})_{t=1}^{T}$. Thus, $\hat{\theta}^{MLE}$ is consistent, is conditionally normally distributed and unbiased, and $\left(\hat{\theta}^{MLE} - \theta\right)/V^{1/2} \sim \mathrm{N}(0,\ 1)$, so that inference about θ can be carried out using standard methods associated with the Gaussian linear regression model. Thus, for example, $\hat{\theta}^{MLE} \pm 1.96\ SE\left(\hat{\theta}^{MLE}\right)$ provides a valid 95 per cent confidence set for θ, where $SE\left(\hat{\theta}^{MLE}\right)$ is computed using the usual regression formula.

While these results may appear quite special (X_t is bivariate and η_t is normally distributed and serially uncorrelated) they carry over to more general models with minor modifications. For example, X_{1t} and X_{2t} may each be vectors and the regression $X_{1t} = \theta X_{2t} + \beta X_{2t} + v_t$ becomes a multivariate regression. Under weak assumptions on the distribution of η_t, there is sufficient averaging so that $V^{-1/2}\left(\hat{\theta}^{MLE} - \theta\right) \to N(0, I)$, meaning that the assumption of normality for η is not critical (although $\hat{\theta}^{MLE}$ still refers to the MLE computed by maximizing the Gaussian likelihood). Serial correlation in η_t can be handled in a variety of ways. For example, Saikkonen (1991) and Stock and Watson (1993) consider the 'dynamic OLS' (DOLS) regression $X_{1t} = \theta X_{2t} + \Sigma_{i=-k}^{k}\ \beta_i X_{2t-i} + v_t$, which includes enough leads and lags of ΔX_{2t} to insure that v_t is (linearly) independent of $(X_{2t})_{t=1}^{T}$. Phillips and Hansen (1990) and Park (1992) develop adjustments based on long-run covariance matrix estimators, and Johansen (1988) derives the exact Gaussian MLE based on the VECM. Under general assumptions, all of the estimators are asymptotically equivalent.

Alternative Models for the Common Trends

The concept of cointegration involves variables that share common persistent 'trend' components. The statistical analysis outlined above utilized a particular model of the trend component, namely, the driftless unit root process $\tau_t = \tau_{t-1} + e_t$. Analysis of this model highlights many of the key features of cointegrated processes, but more general models are often needed for empirical analysis. For example, constant terms are often added to the model to capture non-zero means of error correction terms or drifts in the trend process. These constant terms change the distribution of test statistics for cointegration in ways familiar from the effect of constants and time trends in Dickey–Fuller unit root tests (see Hamilton 1994). Hansen (1992) and Johansen (1994) contain useful discussion of the key issues. Higher-order integrated processes (for example, I(2) processes) are discussed in Johansen (1995), Granger and Lee (1990), and Stock and Watson (1993). Hylleberg et al. (1990) discuss cointegration at seasonal frequencies. Robinson and Hualde (2003) and the references cited therein discuss cointegration in fractionally integrated models.

Elliott (1998) discusses cointegrated models in which the trend follows a 'nearunit-root' process – an AR process with largest autoregressive root very close to 1.0. (Formally, the asymptotics use a local-to-unity nesting with largest root AR root equal to $1-c/T$, where c is a constant.) Elliott shows that, while the basic cointegrated model remains unchanged in this case, the properties of Gaussian maximum likelihood estimators of unknown cointegrating coefficients change in important ways. In particular, the Gaussian MLEs are no longer conditionally unbiased, and confidence intervals constructed using Gaussian approximations $\left(\text{for example, } \hat{\theta}^{MLE} \pm 1.96SE\left(\hat{\theta}^{MLE}\right)\right)$ can be very misleading. Elliott's critique is important because small deviations from exact unit roots cannot be detected with high probability, and yet small deviations may undermine the validity of statistical inferences constructed using large-sample normal approximation applied to Gaussian MLEs.

Several papers have sought to address the Elliott critique by developing methods with good performance for a range of autoregressive roots close to, but not exactly equal to 1.0. For example, Wright (2000) argues that if θ_0 is the true value of a cointegrating coefficient, then $X_{1t} - \theta_0 X_{2t}$ will be I(0), but if θ_0 is not the true value then $X_{1t} - \theta_0 X_{2t}$ will be highly persistent. He suggests testing that $\theta = \theta_0$ by testing the $H_{I(0)}$ null for the series $X_{1t} - \theta_0 X_{2t}$. Alternative testing procedures in this context are proposed in Stock and Watson (1996) and Jansson and Moreira (2006).

Colbert was born at Reims on 29 August 1619 and died on 6 September 1683. In no way at all could he be called an economist. He was, however, one of the most powerful administrators, known to history, of measures affecting the economic life of a nation, to such an extent and with such lasting influence that his name is preserved in the notion of Colbertism.

He came of a mercantile family which had acquired some public offices. He learned his job as economic administrator by entering the service, in 1651, of a man he was effectively to succeed, Cardinal Mazarin. Once successfully installed in the service of Louis XIV, after Mazarin's death in 1661 his climb to power was rapid. He soon came to hold numerous offices of state: finance, commerce, buildings, the navy, and more besides. His achievements rested in part upon his exercising virtually undisputed power for 22 years as the dominant minister of the grandest of absolute

monarchs, and in part upon his own qualities of character which he brought to bear upon the economic problems of France as he perceived them. Those qualities included energy, tenacity, shrewdness, honesty, a notable ability to deploy the techniques of the courtier, and a wholly remarkable capacity for hard work. His hand was felt in every aspect of French economic life; and everywhere he exercised that passion for order which is so often the hallmark of the bureaucrat. Adam Smith sniffed at him as a 'laborious and plodding man of business ... accustomed to regulate the different departments of public offices' (Smith 1776, p. 627). But he was a lot more than that. Cold, humourless, and devoted, he was the super-servant of a super-king.

Those qualities did not, on the other hand, include any original economic ideas whatever. He had absorbed, with characteristic thoroughness, all the assumptions, maxims, dogmas, and assorted notions about economic matters which circulated in 16th- and 17th-century Europe, and to which the label of mercantilism has become attached. Consequently, by dint of his position and activities, and because a very large volume of his papers have survived for the historian, he has come down to posterity as the embodiment of conventional mercantilism in practice. Non-existent as a theoretical entity, mercantilism has acquired the appearance of a coherent economic policy probably more from Colbert's activities than from any other single historical source. And because it appeared, and was continued after his death, in the grandeur which was France, it was copied or adapted in other aspiring monarchies. French mercantilism or Colbertism thus became a recognizable reality in a way that the English 'mercantile system' did not.

The nature of his economic ideas can often be gathered from the explanatory memoranda which he addressed to Louis XIV (who was not always as interested in such matters as Colbert thought he should be). They have a familiar ring. He wanted money circulating in the kingdom, not because he identified money with wealth, but because it facilitated the payment of taxes and helped to stimulate economic activity; those branches of overseas trade which brought in precious metals were therefore to be especially favoured. Manufacturing industry deserved encouragement because it lessened French dependence on imports, because it was the basis of an export trade which brought in wealth, and because it employed the idle (the Catholic Colbert had the zeal for work and the disapproval of idleness normally thought of as peculiar to Puritanism). In the interest of the economic unification of France, internal trade and transport needed improvement by the removal of tolls and the repair of roads and bridges. Royal support was needed, and was secured, for the construction of canals – of which the most spectacular achievement was the opening in 1681 of the Canal des Deux Mers, providing a waterway between the Atlantic and the Mediterranean.

Colbert shared the pervasive belief in a fixed cake of trade, so that, as he patiently explained to Louis in March 1669, the whole trade of Europe was carried in a fixed number of vessels and therefore 'le commerce cause un combat perpétuel en paix et en guerre entre les nations de l'Europe, à qui on emportera la meilleure partie'. The Dutch, the English and the French were the 'acteurs de ce combat' (*Lettres* VI, p. 266). France's gain was to be secured by Holland's and/or England's loss. It followed that shipbuilding should be encouraged and the French navy and mercantile marine greatly enlarged. France should move in on trades hitherto dominated by her rivals. Hence his setting up in the 1660s of privileged trading companies: a French East India Company, a French West India Company to improve and exploit French colonies, and the Company of the North to tap the Baltic trade. Such views also provided an economic justification for the war which Louis launched against Holland in 1672. Colbert had to find the revenue for these and others of his master's military activities. Consequently, he devoted much time to trying to reform the royal finances. Many of his measures – for example, to improve the collection of taxes or to unify the customs system – were thus again part of a policy designed to improve the performance of the economy so that it could in turn yield more wealth to the greater glory of *le roi soleil.*

How much success attended Colbert's policies has been a matter of debate. Laissez-faire economists and economic historians of similar views have inevitably disparaged them and stressed the rigidities which were built into the French economy in the 18th century. His efforts to unify the chaotic diversity of French fiscal and customs administration were only very partially successful; his overseas trading companies were inadequately financed and generally unprofitable; his comparative neglect of agriculture left the basis of the economy in a poor state. But his work did greatly improve the size and efficiency of the French navy and mercantile marine; stimulate – albeit at a high cost – certain areas of French manufacturing industry; and encourage French merchant enterprise in branches of trade hitherto the preserve of others. Not all of this was evident in his own lifetime. But one thing was: Colbert died a very rich man, ennobled as Marquis de Seignelay, his brothers and sisters and cousins amply provided with lucrative sinecures, his sons as ministers or army officers, and his three daughters married off to dukes. Such were the 17th-century rewards of administering an economy.

Colbertism

D. C. Coleman

Colbertism is a term used to describe the economic policies associated with the French statesman, Jean-Baptiste Colbert; and sometimes, confusingly, as a synonym for mercantilist policies in general.

In the course of his account, and denunciation, of the mercantile system, Adam Smith presented it as something foisted upon governments by conspiring businessmen. Extending this view from England to France, he said of Colbert that he had been 'imposed upon by the sophistry of merchants and manufacturers' (Smith 1776, p. 434). Whatever degree of truth there may be in his account so far as it related to England – and there is some – it wholly misrepresents the mind of Colbert and the nature of Colbertism. Distrusting the self-interest of businessmen as a power for the greater good of society, Colbert believed profoundly that, although their pursuit of profits should be encouraged, the way to ensure that such activities redounded to the greater wealth, and hence power and glory, of France was by regulation and order. So Colbertism was essentially a systematic treatment of economic activities imposed from above by the King through his servant. It could be described as a version of the mercantile system appropriate to an absolutist state. It owed little or nothing to mercantile or manufacturing pressures brought to bear on governments. Although there were some similarities between Colbertism and English mercantilism, both in the ideas which lay behind it and in its outward forms as it affected overseas trade, the creation of Colbertian policies did not in the least resemble the process of bargaining and compromise between Crown and Parliament by which English mercantilism was muddled into existence. For this reason alone the term 'Parliamentary Colbertism', coined by Cunningham and used by him to describe English economic policy, 1689–1776 (Cunningham 1907, II, pp. 403–68), was singularly inappropriate. It was also inapt for the different reason that Colbertism was distinguished by a concern for the direct control of production which was wholly absent from the English version of mercantilist policies.

The quintessence of Colbertism is strikingly illustrated in Colbert's approach to manufactures. Observing that France had great industrial potential, with many and scattered crafts and substantial manpower, he set about the country's industrial

rehabilitation. He used a variety of weapons: subsidies, special tax reductions or exemptions, protection against foreign imports, the encouragement of early marriage and large families, grants of special privileges, and the establishment of *manufactures royales*. Disapproving, for example, of the way in which his countrymen imported and wore the woollen cloth or serges of Holland and England, he set up *manufactures royales* to stimulate their production in France; and in 1667 very sharply increased import duties against the offending English and Dutch imports. Similar techniques were used to promote the making of lace, silk stockings, tapestries, carpets, glassware, tinplate, soap, naval supplies, and cannon. Luxury items and textiles received particular attention. It has been said that 'the greatest industry in France was supplying the wants of the King and his court' (Cole 1939, II, p. 303). In quantitative terms this was probably untrue but its significance was very real; and such a statement could not possibly be made about English industry. Stimulation demanded regulation. So Colbert established a Code of Commerce, promulgated for textiles elaborate controls covering precise lengths, widths and other details of all types of textiles; established an apparatus of industrial inspection; and insisted upon all labour being organized within the guild structure.

Three points need to be stressed about these measures. First, Colbertism was here a continuation and codification, a new ordering of old practices; it was part of an *étatisme* with medieval roots. Second, at the time that Colbert was imposing these measures on the French economy, their English counterparts were withering away; the last legislative attempt at general regulation of the English cloth industry failed in 1678. Third, Colbert's regulative achievements were continued after his death: Colbertism brought many more detailed regulations in the seventy years after 1683.

Colbert's founding of privileged monopolistic trading companies shows a certain resemblance to the prior establishment of their counterparts in Holland and England. Again, however, the special nature of Colbertian mercantilism is evident both in the preponderance of royal and government finance in the early years of these companies because of inadequate mercantile enthusiasm for them; and in the degree of personal control which Colbert himself exercised, especially over the French East India Company. So far from being a product of mercantile pressures Colbertism ran foul of merchants on more than one occasion. Colbert made himself very unpopular with those of Marseilles, for example, when, obsessed by the need to keep money circulating so that taxes could be paid, he tried to prevent them from exporting coin in order to conduct their trade with the Levant. And the highly protective anti-Dutch tariff of 1667 attracted internal opposition because it so obviously invited retaliation.

The vast regulative apparatus built up by Colbert and his successors showed more contempt than understanding of the role of businessmen. French commercial and industrial advance during the 18th century, though owing something to Colbert's initiating stimuli, continued despite, rather than because of, the perpetuation of Colbertism. Indeed, one of the reasons for the final reaction against it was the extent to which the bureaucratic machine had become both corrupt in its operation and irrelevant to the needs of the French economy. It helped the proliferation in 18th-century France of a congerie of fiscal officeholders and a concomitant trade in offices and privileges functioning in and around an overblown court. Such practices certainly existed before Colbert's day; but just as Colbert brought a new administrative zeal to old economic ideas, so Colbertism came to provide a still more fertile soil for the growth of ancient corruptions. Meanwhile, however, it appealed to other states – Prussia and the German principalities, Russia, Austria, Spain – intent on building up or repairing economic bases for the support of absolutist courts, territorial ambitions, or the urge for military glory. The sorts of mercantilism which they adopted all varied a good deal, despite the common name and some common economic ideas. But those of central, eastern and southern Europe were often much nearer in spirit to Colbertism than to the mercantile system which Smith discerned in England or to the particular variety which the Dutch had erected in Holland. Colbertism was in this sense *sui generis*.

Cole, George Douglas Howard (1889–1959)

Anthony Wright

A British socialist intellectual, G.D.H. Cole was born in Cambridge in 1889. He grew up in London and was educated at Balliol College, Oxford. As a young Oxford don, Cole came to prominence during the second decade of the century as a leading advocate of guild socialism (a doctrine of workers' control in industry) and adviser to the labour and trade union movements. After the collapse of guild socialism, Cole continued to be the outstanding socialist theorist and Labour Party intellectual in Britain during the interwar and immediate postwar periods, always combining academic work with political commitment. An encyclopaedist and polymath, Cole's published output was prodigious in both volume and range. He produced over a hundred books, and at different periods held academic posts in three disciplines (philosophy, economics, political theory) and could easily have held posts in at least two others.

Cole's central and lifelong preoccupation was with the advocacy of a decentralized, self-managing and participatory form of socialism. It is against this background that his work in economics has to be seen. Although he immersed himself in economic matters during the interwar period (when he was Reader in Economics at Oxford), he regarded this as a labour of necessity. In a basic sense, he did not *like* economics, and railed against the 'algebraic sterilities' of those economic theorists who divorced the subject both from social values and from the solution of pressing problems in the real world. He was, anyway, not equipped to enter the higher reaches of theoretical economics, and his own economic theory therefore remained essentially derivative. His early guild socialism had been remarkably innocent of any serious economic theory at all.

Yet, instead of confirming Cole as of only minor importance, what this really serves to emphasize is the remarkable nature of his contribution to practical economics between the wars. If his economic theory was derivative, he derived it from sources that enabled him to construct radical policy proposals to combat slump and unemployment. Drawing particularly upon the 'underconsumption' (or 'over-saving') analysis of capitalism developed by J.A. Hobson, Cole mounted a sustained critique of economic orthodoxy in relation to unemployment throughout the 1920s and argued the need for demand stimulation and a bold programme of public works and investment. The great merit of Hobsonian economic theory for a socialist like Cole was that it provided the materials from which capitalism could be both indicted and reformed.

Cole's recovery programme remained substantially the same in the 1930s, but from the early years of that decade he displayed a clearer understanding of how such a programme was to be financed. His policy proposals were already proto-Keynesian, but from the early 1930s (when he worked with Keynes on the Economic Advisory Council) he analysed the economic situation from a recognizably Keynesian perspective. Reviewing Keynes's *General Theory* in the *New Statesman* (the house magazine of the British Left), Cole described it as 'the most important theoretical economic writing since Marx's *Capital*, or, if only classical economics is to considered

as comparable, since Ricardo's *Principles*'. Above all, it provided the theoretical credentials for his own dissenting economics.

However, if Keynes had to be absorbed by the Left, and mobilized for a recovery programme, Cole also took the view that it was necessary to look beyond the conditions of short-term stabilization and towards the development of a 'new' economics of socialism. He therefore emerged as a leading advocate of socialist economic planning in the 1930s, but for the rest of his life (and after the war from the vantage point of the Chichele Chair of Social Political Theory at Oxford) he continued to search for a form of socialist economy consistent with his prior commitment to a form of non-bureaucratic socialist democracy.

Collective Action

Mancur Olson

Abstract

The logic of collective action undermines the assumption that common interests are always promoted by their beneficiaries. Where the number of beneficiaries is large, the benefits of collective action are a public good: beneficiaries will gain whether or not they participate in promoting them, while their individual efforts cannot secure them. Small groups can use selective incentives to ensure that their members contribute to promoting their common interests. This typically results in the paradoxical 'exploitation of the great by the small'. The logic of collective action helps explain many notable examples of economic growth and stagnation since the Middle Ages.

For a long while, economists, like specialists in other fields, often took it for granted that groups of individuals with common interests tended to act to further those common interests, much as individuals might be expected to further their own interests. If a group of rational and self-interested individuals realized that they would gain from political action of a particular kind, they could be expected to engage in such action; if a group of workers would gain from collective bargaining, they could be expected to organize a trade union; if a group of firms in an industry would profit by colluding to achieve a monopoly price, they would tend to do so; if the middle class or any other class in a country had the power to dominate, that class would strive to control the government and run the country in its own interest. The idea that there was some tendency for groups to

act in their common interests was often merely taken for granted, but in some cases it played a central conceptual role, as in some early American theories of labour unions, in the 'group theory' of the 'pluralists' in political science, in J.K. Galbraith's concept of 'countervailing power', and in the Marxian theory of class conflict.

More recently, the explicit analysis of the logic of individual optimization in groups with common interests has led to a dramatically different view of collective action. If the individuals in some group really do share a common interest, the furtherance of that common interest will automatically benefit each individual in the group, whether or not he has borne any of the costs of collective action to further the common interest. Thus the existence of a common interest need not provide any incentive for individual action in the group interest. If the farmers who grow a given crop have a common interest in a tariff that limits the imports and raises the price of that commodity, it does not follow that it is rational for an individual farmer to pay dues to a farm organization working for such a tariff, for the farmer would get the benefit of such a tariff whether he had paid dues to the farm organization or not, and his dues alone would be most unlikely to determine whether or not the tariff passed. The higher price or wage that results from collective action to restrict the supply in a market is similarly available to any firm or worker that remains in that market, whether or not that firm or worker participated in the output restriction or other sacrifices that obtained the higher price or wage. Similarly, any gains to the capitalist class or to the working class from a government that runs a country in the interests of that class, will accrue to an individual in the class in question whether or not that individual has borne the costs of any collective action. This, in combination with the extreme improbability that a given individual's actions will determine whether his group or class wins or loses, entails that a typical individual, if rational and self-interested, would not engage in collective action in the interest of any large group or class.

Analytically speaking, the benefits of collective action in the interest of a group with a common interest are a public or collective good to that group; they are like the public goods of law and order, defence, and pollution abatement in that voluntary and spontaneous market mechanisms will not provide them. The fundamental reality that unifies the theory of public goods with the more general logic of collective action is that ordinary market or voluntary action fails to obtain the objective in question. It fails because the benefits of collective or public goods, whether provided by governments or non-governmental associations, are not subject to exclusion; if they are received by one individual in some group, they automatically also go to the others in that group (Olson 1965).

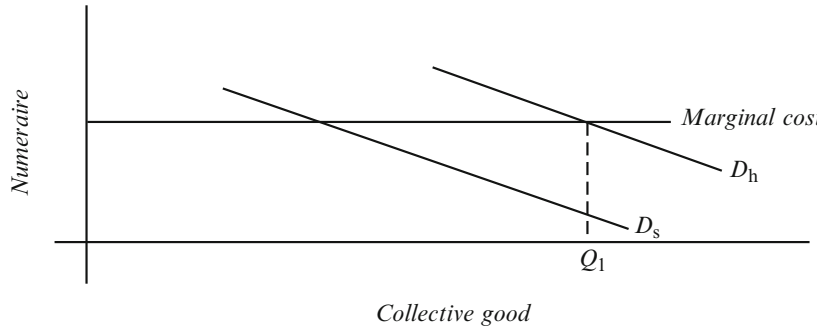
Since many groups with common interests obviously do not have the power to tax or any comparable resource, the foregoing logic leads to the prediction that many groups that would gain from collective action will not in fact be organized to act in their common interests. This prediction is widely supported. Consumers have a common interest in opposing the legislation that gives various producer groups supra-competitive prices, and they would sometimes also have a common interest in buyers' coalitions that would countervail producer monopolies, but there is no major country where most consumers are members of any organization that works predominantly in the interest of consumers. The unemployed similarly share a common interest, but they are nowhere organized for collective action. Neither do most taxpayers, nor most of the poor, belong to organizations that act in their common interest (Austen-Smith 1981; Brock and Magee 1978; Chubb 1983; Hardin 1982; Moe 1980; Olson 1965).

Though some groups can never act collectively in their common interest, certain other groups can, if they have ingenious leadership, overcome the difficulties of collective action, though this usually takes quite some time. There are two conditions either of which is ultimately sufficient to make collective action possible. One condition is that the number of individuals or firms that would need to act collectively to further the common interest is sufficiently small; the other is that the groups should have access to 'selective incentives'.

The way that small numbers can make collective action possible at times is most easily evident on the assumption that the individuals in a group with a common interest are identical. Suppose there are only two large firms in an industry and that each of these firms will gain equally from any government subsidy or tax loophole for the industry, or from any supra-competitive price for its output. Clearly each firm will tend to get the benefit of any lobbying it does on behalf of the industry, and this can provide an incentive for some unilateral action on behalf of the industry. Since each firm's action will have an obvious impact on the profits of the other, the firms will have an incentive to interact strategically with and bargain with one another. There would be an incentive to continue this strategic interaction or bargaining until a joint maximization or 'group optimal' outcome had been achieved. This same logic obviously also applies to collective action in the form of collusion to obtain a supra-competitive price, and thus we obtain the well-known incentive for oligopolistic collusion in concentrated industries whenever there are significant obstacles to or costs of entry. As the number in a group increases, however, the incentive to act collectively diminishes; if there are ten identical members of a group with a common interest, each gets a tenth of the benefit of unilateral action in the common interest of the group, and if there are a million, each gets one millionth. In this last case, even if there were some incentive to act in the common interest, that incentive would cease long before a group-optimal amount of collective action had taken place. Strategic interaction or voluntary bargaining will not occur since no two individuals have an incentive to interact strategically or to bargain with one another. This is because the failure of one individual to support collective action will not them have any perceptible effect on the incentive any other individual faces so there is no incentive for strategic interaction or rational bargaining. Thus we obtain the result that, in time, sufficiently small groups can act collectively, but that this incentive for collective action decreases monotonically as the group gets larger and disappears entirely in sufficiently large or 'latent' groups.

When the parties that would profit from collective action have very different demand curves, the party with the highest absolute demand for collective action will have an incentive to engage in some amount of collective action when no other member of the group has such an interest. This leads to a paradoxical 'exploitation of the great by the small'. This is true to a greater degree and is evident much more simply if income effects are ignored, as in the demand curves for a collective good depicted in the figure below. When the party with the highest demand curve for the collective good, D_h, has obtained the amount of the collective good, Q_1, that is in its interest unilaterally to provide, any and all parties with a lower demand curve, such as D_s, will automatically receive this same amount, and thus have no incentive to provide any amount at all! (Olson 1965). When income effects and certain 'private good' aspects of some collective goods are taken into account the results are less extreme, but a distribution of burdens disproportionality unfavourable to the parties with the absolutely larger demands tends to remain. This disproportion has been evident, for example, in various military alliances and international organizations, in cartels, and in metropolitan areas in which metropolis-wide collective goods are provided by independent municipalities of greatly different size (Olson and Zeckhauser 1966; Sandler 1980) Fig. 1.

The other condition, besides small numbers, that can make collective action possible, is 'selective incentives'. Those large groups that have been organized for collective action for any substantial period of time are regularly found to have worked out special devices, or selective incentives, that are functionally equivalent to the taxes that enable governments to provide public goods (Olson 1965; Hardin 1982). These selective incentives either punish or reward individuals depending on whether or not they have borne a share of the costs of collective action, and thus give the individual an incentive to contribute to collective action that no good that is or would be available to all could provide. The most obvious devices of this kind are the 'closed shop' and picket line arrangements of labour unions, which often make union membership a condition of



Collective Action, Fig. 1

employment and control the supply of labour during strikes (see, for example, McDonald 1969; Gamson 1975). Upon investigation it becomes clear that labour unions are not in this respect fundamentally different from other large organizations for collective action, which regularly have selective incentives that, though usually less conspicuous than the closed shop or the picket line, serve the same function.

Farm organizations in several countries, and quite notably in the United States, obtain most of their membership by deducting the dues in farm organizations from the 'patronage dividends' or rebates of farm cooperatives and insurance companies that are associated with the farm organizations. The professional associations representing such groups as physicians and lawyers characteristically have either relatively discreet forms of compulsion (such as the 'closed bar') or subtle individual rewards to association members, such as access to professional publications, certification, referrals, and insurance. In small groups, and sometimes in large 'federal' groups that are composed of many small groups, social pressure and social rewards are also important sources of selective incentives.

The selective incentives that are needed if large groups are to organize for collective action are less often available to potential entrants or those at the lower levels of the social order than to established and well-placed groups. The unemployed, for example, obviously do not have the option of making membership of an organization working in their interest a condition of employment, nor do they naturally congregate as the employed do at workplaces where picket lines may be established. Those who would profit from entering a cartelized industry or profession are similarly almost always without selective incentives. Experience in a variety of countries also confirms that those with higher levels of education and skill have better access to selective incentives than lower income workers; highly trained professionals such as physicians and attorneys usually come to be well organized before labour unions emerge, and the unions of skilled workers normally emerge before unions representing less skilled workers. The correlation between income and established status and access to selective incentives works in the same direction as the lesser difficulty of collective action of small groups of large firms in relatively concentrated industries explained above. Together these two factors generate a tendency for collective action to have, in the aggregate though not in all cases, a strong anti-egalitarian and pro-establishment impact (Olson 1984).

The study of collective action goes back to the beginnings of economics, but then came to be strangely neglected during most of the rest of the history of the subject. Though this is not generally realized, the study of collective action, admittedly only in an inductive and intuitive way, was a crucial part of Adam Smith's analysis of the inefficiencies and inequities in the economies he observed (Smith 1776). Smith even noted that the main beneficiaries of collective action in his time were by no means the poor or those of average means. He also emphasized the tendency for urban interests to profit from collective action at the expense of rural people, because the

geographical dispersion of agricultural interests areas made it more difficult for them to combine to exert political influence or to fix prices; this emphasis presumably owed something to the poor transportation and communication systems in his day, which presumably obstructed the organization of rural interests more in his time than it does in developed countries now.

The label that Adam Smith gave to the set of public policies, monopolistic combinations, and ideas that he attacked was, after all, 'mercantilism', because the single most important source of the evils was the collective action of merchants, or merchants and 'masters', especially those organized into guilds or 'corporations'. In his discussions of the 'Inequalities Occasioned by the Policy of Europe' and of 'The Rent of Land' (Bk. I, ch. 10, pt. ii and ch. 11), Smith emphasized that 'whenever the legislature attempts to regulate the differences between masters and their workmen, its counsellors are always the Masters'. Similarly,

> it is everywhere much easier for a rich merchant to obtain the privilege of trading in a town corporate, than for a poor artificer to obtain that of working in it . . . Though the interest of the labourer is strictly connected with that of the society . . . his voice is little heard and less regarded.

The rural interests are similarly at a disadvantage, according to Smith, especially as compared with those in 'trade and manufacturers':

> The inhabitants of a town, being collected into one place, can easily combine together. The most insignificant trades carried on in towns have accordingly, in some place or another, been incorporated . . . voluntary associations and agreements prevent that free competition which they cannot prohibit. . . .The trades which employ but a small number of hands run most easily into such combinations. . . . People of the same trade seldom meet together, even for merriment and diversion, but the conversation ends in a conspiracy against the public, or in some contrivance to raise prices.

By contrast, 'the inhabitants of the country, dispersed in distant places, cannot easily combine together'.

These passages, though not in the order they appear in Smith, nonetheless correctly convey his alertness to collective action. Though the handicap that rural interests face in organizing for collective action is far less in developed countries today than it was in Smith's time, even this part of his argument still generally holds true in the developing countries, where transportation and communication in the rural areas are poor, peasants are generally unrepresented, and agricultural commodities normally underpriced (Anderson and Hayami 1986; Schultz 1978; Olson 1985).

Adam Smith's insights into collective action and its consequences were ignored until recent times. Presumably one reason is that most economists in the 19th and early 20th centuries were mainly interested in the logic of the case for competitive markets. The logic of collective action, by contrast, is really a general statement of the logic of market failure; it embodies the central insight of the theories of public goods and externalities, that markets and voluntary market-type arrangements do not generally work in those cases where the beneficiaries of any collective good or benefit cannot be excluded because they have not paid any purchase price or dues (Baumol 1952). It was not until Knut Wicksell's New Principle of Just Taxation' was published in German in 1896 (Musgrave and Peacock 1967) that any economist revealed a clear understanding of the nature of public goods, and only with the publication of Samuelson's articles in the 1950s (Samuelson 1955) that this idea came to be generally understood in the English-speaking world.

A second obstacle to the development of the logic of collective action was that collective action by governments was normally taken for granted. Notwithstanding the difficulties of collective action, anarchy is relatively rare because a government that provides some sort of law and order quickly takes over. This in turn is due to conquerors and the gains they obtain in increased tax revenues from establishing some system of law and order and property rights. In the absence of the provision of these most elemental collective goods, there is not much for a conqueror to take, so the historic first movement of the invisible hand is evident in the incentive conquerors have to establish law and order. Those who lead the governments that succeed conquerors obviously must

maintain a system of law and order if they are to continue collecting significant tax revenues. Since governments providing basic collective goods have been ubiquitous, the classic writers on public goods like Wicksell and Samuelson did not even ask how collective goods emerged in the first place. They focused instead on how to determine what was an appropriate sharing of the tax burdens and on the difficulty of determining what level of provision of public goods was Pareto-optimal. This in turn naturally led to Wicksell's recommendation that only those public expenditures that could, with an approximate allocation of the tax burdens, command approximate unanimity, should normally be permitted, and to Samuelson's and Musgrave's (1959) concern for the non-revelation of preferences for public goods. The difficulties of collective action and public good provision on a voluntary basis therefore naturally did not gain any theoretical attention.

When, as in the new political economy or public choice, the focus is also on the efforts of extra-governmental groups to obtain the gains from lobbying, cartelization, and collusion, and on private action to obtain collective benefits of other kinds, a more general conception becomes natural (Barry and Hardin 1982; Olson 1965; Taylor 1976). It then becomes clear that the likelihood of voluntary collective action depends dramatically on the size of the group that would gain from collective action. When a group is sufficiently small and there is time for the needed bargaining, the desired collective goods will normally be obtained through voluntary cooperation (Frohlich et al. 1971). If there are substantial differences in the demands for the collective good at issue, there will be the aforementioned paradoxical 'exploitation of the great by the small'. When the number of beneficiaries of collective action is very large, voluntary and straightforward collective action is out of the question, and taxes or other selective incentives are indispensable. Selective incentives are available only to a subset of those extra-governmental groups that would gain from collective action. Even those extra-governmental groups that do have the potential of organizing through selective incentives will usually have great difficulty in working out these (often subtle) devices, and will normally succeed in overcoming the great difficulties of collective action only when they have relatively ingenious leadership and favourable circumstances.

If follows that it is only in long-stable societies that many extra-governmental organizations for collective action will exist. In societies where totalitarian repression, revolutionary upheavals, or unconditional defeat have lately destroyed organizations for collective action, few groups will have been able in the time available to have overcome the formidable difficulties of collective action. It has been shown elsewhere (Mueller 1983; Olson 1982), that (unless they are very 'encompassing') organizations for collective action have extraordinarily anti-social incentives; they engage in distributional struggles, even when the excess burden of such struggles is very great, rather than in production. They also will tend to make decisions slowly and thereby retard technological advance and adaptations to macroeconomic and monetary shocks. It follows that societies that have been through catastrophes that have destroyed organizations for collective action, such as Germany, Japan, and Italy, can be expected to enjoy 'economic miracles'. An understanding of collective action also makes it possible to understand how Great Britain, the country that with industrial revolution discovered modern economic growth and had for nearly a century the world's fastest rate of economic growth, could by now have fallen victim to the 'British disease'. The logic of collective action, in combination with other theories, also makes it possible to understand many of the other most notable examples of economic growth and stagnation since the Middle Ages, and also certain features of macroeconomic experience that contradict Keynesian, monetarist, and new classical macroeconomic theories (Balassa and Giersch 1986).

Collective Action (New Perspectives)

David P. Myatt

Abstract

Olson's logic of collective action predicts that public-good provision is most likely to fail when the size of the consumer group is large; his public goods are partially rival, and so the private cost of provision is relatively high. With a pure public good, this logic no longer applies, and so attention turns to producer groups. When provision involves teamwork (so that the collective action succeeds when everyone works together) then coordination problems arise. Modern techniques suggest that 'good' equilibria in which provision is successful are robust only when the costs of provision fall below private rather than social benefits.

In a review conducted on behalf of the UK Government, Stern (2007) concluded that 'climate change is a serious global threat, and demands an urgent global response ... the benefits of strong and early action far outweigh the economic costs of not acting'. The cuts in emissions that he suggested could generate global benefits. However, the costs would be borne individually by those making significant cuts (developed nations) or by those sacrificing future opportunities (rapidly developing nations).

A shared desire to cut greenhouse-gas emissions generates a classic problem of collective action: a group with common interests must rely on voluntary individual optimization for the pursuit of those interests. Stern's 'urgent global response' to a 'serious global threat' requires nations to act. Such sovereign states need respond only to their own incentives; any participation is voluntary. Within each state, the pursuit of national objectives is not automatic; environmental effects stem from the decisions of individual agents. Even if it were in a state's collective interest to support a collective action against climate change, it cannot be assumed that constituents of that state would individually offer their backing.

To economists, the collective-action problem boils down to the private provision of a public good or the private exploitation of a common resource. Law and order, military defence and pollution control are classic textbook examples of public goods: the benefits of provision are non-excludable, and so private providers fail to capture the full impact of their contributions. This market failure leads to inefficient under-provision. On the other hand, the commons exploitation of traffic congestion and commercial fishing yield negative externalities: market failure yields to inefficient overindulgence in these activities. In both cases, individuals fail to pursue efficiently their collective objectives.

The idea that group members will not always pursue their common interests was once not accepted widely. In his article in the first edition of the *New Palgrave*, Mancur Olson (1987) observed that 'economists, like specialists in other fields, often took it for granted that groups of individuals with common interests tended to act to further those common interests, much as individuals might be expected to further their own interests'. He persuasively argued that 'the existence of a common interest need not provide any incentive for an individual action in the group interest'. Hence consumers may fail to campaign for their collective protection, unions may fail to protect all their members, oligopolists may fail to maintain collusive prices, and nations of the world may fail to prevent further climate change.

Olson's point was simple and is now familiar: when contemplating choice, individuals consider only the private impact of their actions. For the classic case of a public good, an individual faces the full marginal cost of provision but fails to account for the benefit spilling over to others; the presence of positive externalities leads to under-provision. If an individual could internalize these externalities, perhaps by excluding the consumption of others and charging them for it, then efficiency could be restored. Alas, pure public goods are non-excludable, and hence this route to efficiency is blocked.

Nevertheless, as long as individuals enjoy some private benefit from voluntary action then we can expect some, albeit too little, provision of public goods. The extent of any inefficiency depends upon the nature of the collective-action problem, the availability of mechanisms to restore efficiency, and the size and nature of the relevant group. Olson (1965) concluded that 'unless the number of individuals in a group is quite small, or unless there is coercion or some other special device to make individuals act in their common interest, rational, self-interested individuals will not act to achieve their common or group interests'. In the context of small groups, when partial provision is deemed possible, he identified 'a surprising tendency for the 'exploitation' of the great by the small'. These claims led to his theory of groups: (*a*) collective actions fail when the groups are large; (*b*) larger factions bear a disproportionate share of any provision; and (*c*) selective incentives are necessary if groups are to succeed. These three claims are considered in turn, before attention turns to a rather different perspective on collective action.

The first claim is Olson's 'group size' hypothesis: private provision should fall as a group

grows larger. Olson (1965) painted a picture of a meeting at which too few people make careful contributions: 'When the number of participants is large, the typical participant will know that his own efforts will probably not make much difference to the outcome, and that he will be affected by the meeting's decision in much the same way no matter how much or how little effort he puts into studying the issues.' More directly, the claim is that the private benefit of any voluntary contribution falls with the group's size; equivalently, the private cost for any particular level of public provision rises with the group size. This claim leans on two implicit assumptions. First, an increase in the number consuming the good leads to an increase in the provision cost, and hence the good is (at least partially) rival; it is an impure public good. Second, the group size corresponds to the number of consumers, and not to the size of the contributor pool.

These two implicit assumptions that underpin the group-size hypothesis are often valid. For instance, the global climate change that worried Stern (2007) corresponds to a 'large group' global collective-action problem (Sandler 2004). Nevertheless, the assumptions often exclude interesting collective-action problems. The first assumption rules out pure public goods. Consider, for instance, the contemporary voluntary provision of open-source software (Raymond 1998; Johnson 2002; Lerner and Tirole 2002). The typical license under which such software is distributed 'requires that the source code ... be made available to everyone, and that the modifications made by its users also be turned back to the community' (Lerner and Tirole 2001). This a modern instance of the 'collective invention' documented by Allen (1983). Open-source software is automatically non-excludable. Of course, software is a classic instance of a non-rival good: consumption by one individual does not hamper the consumption opportunities of others. Hence, an increase in the size of the group consuming the good, while fixing the size of the group able to provide it, has no direct impact on incentives.

Olson's second claim was that provision costs fall on larger members of a group. The idea is that such members consume large shares of the public good, and so face a relatively large private benefit. Once again, this builds upon the assumption that the collective output is rival; for a pure public good, the same logic would predict that those who care most contribute most, and such contributors need not be large in a conventional sense.

Olson's third claim concerned the possible response to the problem of collective action. Such a response requires, according to this claim, selective incentives that are 'functionally equivalent to the taxes that enable governments to provide public goods ... [they] either punish or reward individuals depending on whether or not they have borne a share of the costs of collective action, and thus give the individual an incentive to contribute ...' (Olson 1987). The classic example of selective incentives is the 'closed shop' of labour unions; to enjoy the benefits of collective union bargaining power each worker must be a member, and hence pay the costs of any strike action. Interestingly, when the selective incentive is based on preventing a group member from enjoying the collective output then the implicit assumption is that the public good is at least partially excludable.

In summary, Olson (1965, 1987) forcefully clarified the inescapable logic of collective action: any theory of group behaviour must rely upon the incentives faced by individuals, and not simply assume that groups pursue their common interests. His theory of groups remains relevant for many contemporary problems. However, it steps outside the world of pure public goods by assuming the interdependent consumption of an impure public good, and does not allow for interdependence of production. Put more succinctly, Olson's groups consist of public good consumers rather than public good providers.

Attention now refocuses on collective-action problems in which economic players non-cooperatively choose whether to participate in the private production of a pure public good. Crucially, there can be interdependence of production: the incentive to participate in a collective action depends on the expected participation of others. Decisions become genuinely strategic, and this changes the nature of the collective-action problem.

A little notation proves helpful. Amongst n players, write x_i for the action of player i, and collect the actions of everyone together into a vector x. Payoffs satisfying

$$u_i(x) = G(x) - c_i(x_i) \quad (1)$$

comprise the value $G(x)$ of public good and the private cost $c_i(x_i)$ that player i incurs when contributing to it; the externality imposed on others is captured by $(n-1)G(x)$. The nature of the strategic interaction amongst players depends upon the form taken by $G(x)$. A simple specification is when x_i is a positive real number and $G(x) \equiv \sum_{i=l}^{n} x_i$. A player's decision is strategically independent of others' actions: he simply equates the private marginal benefit of the public good to its private marginal cost via the first-order condition $1 = c'(x_i)$, yielding the usual under-provision problem (Cornes and Sandler 1996).

A second natural specification to consider is where $G(x) \equiv F\left(\sum_{i=l}^{n} x_i\right)$ for some nicely behaved concave production function $F(\cdot)$. This falls within the class of Cournot contributions games (Chamberlin 1974; McGuire 1974; Young 1982; Cornes and Sandler 1985; Bergstrom et al. 1986; Bernheim 1986). Here, strategic interaction is non-trivial since the marginal benefit of increased public good provision depends on the total contributions of all players. Nevertheless, a unique Nash equilibrium involves under-provision. The associated literature concerned itself with the comparative-static properties of such models, including the response of public good output and the burden of provision to the redistribution of income (Warr 1983; Kemp 1984).

These first two examples of eq. (1) simply flesh out the implicit model of Olson (1965). The nature of the collective action problem changes significantly when $G(x)$ takes on more interesting and yet plausible shapes. For instance, $G(\cdot)$ might take a weakest link ($G(x) = \min\{x_i\}$) or best shot ($G(x) = \min\{x_i\}$) form (Hirshleifer 1983, 1985); these are special cases of symmetric but non-additive specifications (Cornes 1993).

Here, however, attention turns to situations in which the success of a collective action (that is, the successful provision of a public good) turns upon either the participation of a critical mass of players, or contributions that exceed a particular threshold. Returning once more to the economics of climate change, a plausible scenario is one in which the ice caps melt unless carbon emissions are pushed down below a critical level. Whereas in a Cournot contributions game the incentive to contribute decreases with the participation of others, here it may increase: a nation may find it worthwhile to chase environmental targets if and only if it expects others to play their part in international agreements.

A central feature of threshold-based scenarios is that an individual's decision depends on aggregate participation. This is easiest to explore in a binary-action game where $x_i \in \{0,1\}$ for each player i; hence $x_i = 1$ can be interpreted as individual participation in a collective action. In many such situations, the incentive to participate depends on the number of others who do so. Hence, writing $\Delta u_i(x)$ for this incentive,

$$\Delta u_i(x) \equiv P(m) \text{ where } m = \sum_{j \neq i} x_j. \quad (2)$$

When $P(m) < 0$ for all m, no players participate; this is an n-player Prisoner's Dilemma. If $P(m)$ decreases with m, then the unique equilibrium entails the participation of m^* players, where $P(m^* - 1) > 0 > P(m^*)$; for the Cournot games considered above the participation m^* might be socially suboptimal. If $P(m)$ increases with m, so that there is a threshold m^* satisfying $P(m^* - 1) < 0 < P(m^*)$, then there are two pure-strategy Nash equilibria, one in which everyone participates, and one in which the collective action fails. This means that the problem of collective action becomes one of coordination.

Games satisfying eq. (2) drew the insightful attention of Schelling (1973, 1978). He opened his analysis by describing the use of protective helmets in ice hockey: players were willing to wear helmets only if others did so too. Other sociological examples are easy to find: members of a crowd will join a protest only if others do so (Berk 1974; Granovetter 1978) and successful consumer boycotts require a critical mass (Innes 2006).

Political situations can also fit eq. (2). Consider a plurality rule election in which a group wishes to prevent the success of a disliked incumbent candidate. They can do so if and only if a critical number m^* abandon their first-preference candidate and vote for their second choice. Setting $P(m^*-1) > 0$ and $P(m) < 0$ otherwise yields a strategic-voting model (Palfrey 1989; Myerson and Weber 1993; Cox 1994, 1997; Myatt 2007).

In sociology, collective-action games with threshold properties fall under the umbrella of the theory of critical mass (Oliver et al. 1985; Oliver and Marwell 1988; Marwell et al. 1988; Marwell and Oliver 1993). Alas, these sociologists had no theoretical machinery for selecting between multiple equilibria. In economics, multiple equilibria arise in threshold-driven step-level public goods games (Palfrey and Rosenthal 1984). Once again, the problem of coordination boils down to a need to choose amongst multiple equilibria. Fortunately, recent contributions to economics allow some progress to be made on the equilibrium-selection problem.

To explore further, it is instructive to consider a simple world: two individuals (A and B) either participate (Y) or not (N) in a collective action. Participationinvolves a private cost (either c_A or c_B), but may provide a public good to be enjoyed by both players. A natural representation is via a simple 2×2 strategic form game (Fig. 1).

In the 'provision game' a participant produces a public good worth v to everyone. A player's marginal product is strategically independent: the incentive for player A to participate is always $v - c_A$, and hence he does so if and only if $v > c_A$. However, this generates a spillover of v for player B, and hence the social gain is $2v - c_A$. The parameter configuration $2v > c_A > v$ yields the classic under-provision of a public good.

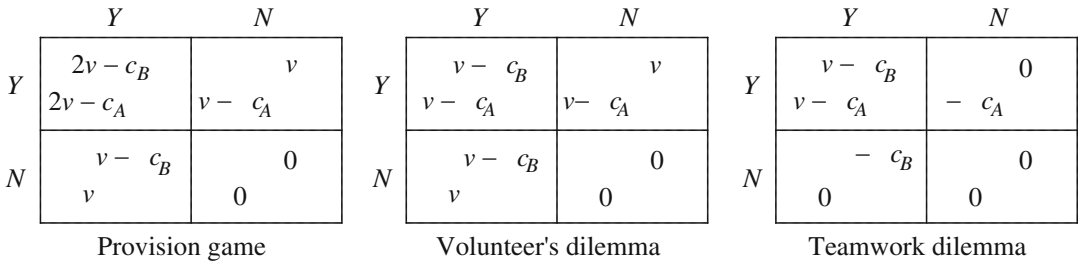
But what if there is strategic interdependence? Suppose that only one player need provide, so that a second participant generates a cost but no additional benefit. This 'volunteer's dilemma' (Diekmann 1985) is a textbook game of 'chicken' (Lipnowski and Maital 1983). If $2v > c_A > v$ and $2v > c_B > v$ then neither player is willing to participate even though it is socially optimal for someone to do so. However, if $v > c_A$ then player A participates so long as player B does not. If $v > c_B$, then there are two pure-strategy Nash equilibria in which a single player provides the public good. But who provides?

One possibility is to use risk dominance (Harsanyi and Selten 1988) as a selection criterion. The risk-dominant equilibrium is that which maximizes the product of players' incentives to remain at the equilibrium. So, in the volunteer's dilemma, the equilibrium in which A provides is risk-dominant if $(v - c_A)c_B > (v - c_B)c_A$, which holds if and only if $c_A < c_B$: the most efficient provider volunteers. Following Olson (1965), the strong (low-cost providers) bear the cost of provision to the benefit of the weak.

A coordination problem also arises in the 'teamwork dilemma' (Fig. 1) where both players are needed for the collective action to succeed. This is an assurance or 'stag hunt' game: as long as $v > c_A$ and $v > c_B$ there is a pure-strategy equilibrium in which both players participate, and a second with no participation in which the collective action fails. The former equilibrium is risk dominant if and only if $(v - c_A)(v - c_B) > c_A c_B$, which boils down to $v > c_A + c_B$; this requires a single private (not social) benefit from the public good to exceed the total private cost of provision. If $2v > c_A + c_B > v$, then the collective action fails even though it would be socially optimal for it to succeed. Once again, this is a return to Olson (1965): success of the collective action relies on private incentives.

All well and good, but can the criterion of risk dominance be justified? In the recent literature two contrasting approaches lead to the same answer.

The theory of global games (Carlsson and Van Damme 1993; Morris and Shin 2003) supposes that players do not share common knowledge of the payoffs of games. Instead, players must rely upon privately observed signals of the game being played. For instance, players may be unsure of the true value v of the public good, and see an estimate of it. Crucially, this estimate allows them to infer not only this value but also the probable signals received by others, and hence their opponents' likely behaviour. When signals become very precise then the play of a simple 2×2 game almost



Collective Action (New Perspectives), Fig. 1 Public-good provision games

always coincides with the risk-dominant Nash equilibrium (Carlsson and Van Damme 1993).

Others have selected equilibria by studying the evolving play. Players (or populations from which players are drawn) may adjust their play over time in the direction of myopic best-reply, but occasionally 'mutate' to a different strategy (Kandori et al. 1993; Young 1993, 1998). As the probability of mutations vanishes, play in the long run focuses on a single stochastically stable equilibrium (Foster and Young 1990). In a symmetric teamwork dilemma, it picks out the risk dominant equilibrium.

Can modern literature say anything about the general case of eq. (1)? Players act as though they are attempting to maximize jointly the single real-valued function

$$\rho(x) \equiv G(x) - \sum_{i=l}^{n} c_i(x_i). \qquad (3)$$

This is a potential function, and yields a potential game (Monderer and Shapley 1996). This function has a natural interpretation: the private benefit that a single individual derives from a public good, minus the total private costs involved in its provision.

Clean results emerge when play of a potential game evolves via a payoff-responsive stochastic strategy-revision process (Blume 1993, 1995, 1997; Brock and Durlauf 2001; Blume and Durlauf 2001, 2003). Over time, players occasionally revise their strategies. When a player does so, his decision is not a myopic best reply to the current play of others, but rather a quantal response (McKelvey and Palfrey 1995): the log odds of choosing one action rather than another is determined by the difference in their payoffs, and so he is more likely to choose better performing strategies. An inspection of eq. (3) reveals that the difference in a player's payoffs is equal to the difference in potential; the potential function captures the essential strategic interaction of the game.

Allowing play to evolve, the strategy-revision process is drawn towards the states-of-play with the highest potential. In the long run, when quantal responses approximate best replies, the process spends almost all time in the state that maximizes $\rho(x)$: evolution leads players to maximize the difference between a single private benefit and total private costs rather than social welfare which would incorporate the full social benefit of $nG(x)$.

This approach can be applied to the teamwork dilemma: the potential of the state-of-play in which neither player participates is zero, and the potential of the equilibrium in which the collective action succeeds is $v - (c_A + c_B)$. The latter equilibrium has positive potential if and only if $v > c_A + c_B$: only if a private individual would be willing to step forward and pay the full cost of provision himself will the collective action succeed. So, whereas it may at first appear that the success of a collective action (the coordinated play of f*Y*,*Y*g in the teamwork dilemma) can follow from the interdependence of team members, evolving play results in failure (the play of f*N*,*N*g in the teamwork dilemma) unless a private individual would be willing to fund the collective action himself.

On reflection, this should be unsurprising. Each step of evolving play (or each step of

reasoning in a global-game argument) is driven by reference to private incentives. So what lesson should be taken away? Even when a group's problem is one of coordination, its members cannot escape Olson's (1965, 1987) fundamental logic of collective action.

Collective Agriculture

Peter Nollan

The socialist countries have generally modelled their rural institutions on those of the USSR in the 1930s. For the most part, means of production were owned by the so-called collective, farmwork was 'collectively' organized, and personal income 'collectively' distributed. At their peak, over one-third of the world's farmers worked under this system.

'Socialist' countries have favoured collectives for the following principal reasons.

Firstly, the leadership in most 'socialist' countries initially was afraid of an economically independent peasantry with ideas shaped by individualistic 'petty commodity production'. As Stalin put it: 'a great deal of work has to be done to remould the collective-farm peasant, to correct his individualistic mentality and to transform him into a real working member of a socialist society' (Stalin 1929, p. 469). Collectives were not intended as independent cooperatives: collectivization was party-led and collectives were subject to considerable external control (see e.g., Davies 1980; Volin 1970; Selden 1982; Unger 1984). Such a rationale is deeply undemocratic, especially given the peasants' numerical dominance in those countries (see, in particular, Cohen 1974, ch. 6).

Second, it was believed that state intervention through party-led collectives would improve rural economic performance (see e.g., Stalin 1929; General Office 1956). Collectives could raise savings and investment rates through reinvesting income and mobilizing 'surplus' labour for capital construction. Unfortunately, success in these respects can damage labour motivation by reducing current returns to collective labour. Collectives also could provide a vehicle for rapidly introducing new technology. However, this applies to bad as well as good technology – examples of the former are legion in 'socialist'

agriculture, including the various programmers in the Soviet Union associated with Lysenko (discussed in Volin 1970) and the ill-fated introduction of the double-wheeled, double-share plough, in China (Kuo 1972, ch. 12).

Third, party-led collectives were viewed as a means to attain high farm marketing rates and an outflow of farm sector savings to finance non-farm investment:

By transferring the disposal of agricultural output from individual peasants to government-supervised collective farm managements, collectivization destroys the basis for the peasants' resistance to the 'siphoning-off' of the economic surplus (Baran 1957, p. 268).

However, without, for example, adequate supplies of appropriately priced industrial commodities, forcibly raising the rate of farm sector marketings can reduce the growth rate of farm output and the future volume of farm marketings. Moreover, it has proved difficult to achieve a net farm savings outflow due, for example, to agriculture's need for industrial incentive goods and farm inputs (increased, insofar as inputs are inefficiently used and collectivization adversely affects livestock holdings, motive power and fertilizer supplies), and the state's inability to control private market prices (Ellman 1975; Ishikawa 1967).

Fourth, it was considered that collectives would prevent 'capitalist' polarization alongside farm modernization, with the majority of peasants becoming wage labourers (Stalin 1929; Mao 1955). Evidence from other developing countries contradicts Stalin and Mao's crude vision of rural class polarization (see, especially, Hayami and Kikuchi 1981). It indicates too that appropriate state policies (e.g. land reform, provision of education and credit, infrastructure construction, progressive taxation) can mitigate rural class inequalities. Class polarization is not the inevitable accompaniment of rural modernization, nor is collectivization the only way to resolve problems of rural class inequality (e.g. Hayami and Kikuchi 1981).

Fifth, Lenin, Stalin and Mao all believed that agriculture was characterized by lumpiness and economies of scale (Lenin 1899; Stalin 1929; Mao 1955). In many farm tasks, large scale is indeed an advantage, for example in research, processing, building and maintaining irrigation facilities. However, many modern farm inputs are divisible. Provided they are appropriately priced, credit is available and they have access to lumpy complementary inputs, all farm strata modernizing areas tend to acquire them (Hayami and Kikuchi 1981). Moreover, in large agricultural units labour supervision is a major problem (Bradley and Clark 1971). If a collective's members trust each other and are motivated to work hard for the group irrespective of relative income then labour supervision is not an issue. However, this is rarely the case (Morawetz 1983) and collective farm managers have had to devise payment systems to motivate farm workers. In certain farm tasks (notably harvesting) it is easy to pay labour according to its product, but for most farm tasks it is more difficult than in industry to devise payment systems that strongly motivate from the work often requires a flexible response from the worker which is difficult to anticipate in the payment system; the final produce takes a long time to produce, with different workers' contributions difficult to isolate; work is physically dispersed and production conditions vary greatly from one part of the production unit to another; the main task specializations are seasonal, and permanent minute sub-division of work into easily measurable segments is not generally possible. These problems have meant that under private agriculture, if labour is relatively abundant and capital relatively expensive, the normal outcome is for land to be rented out beyond a certain farm size, so that a relatively high output per acre can be attained through self-operating, self-motivated, rent-paying farmers, rather than cultivated with large numbers of hired workers. In collective farms, the attempt to supervise large numbers of farm workers has resulted in powerful managerial diseconomies of scale and reduced farm efficiency.

Collective agriculture has not performed well. Collective farms in the USSR in 1929–31 and in China in 1959–61 experienced massive institutionally caused declines in farm output, accompanied by demographic disasters (on the Soviet Union, see Volin 1970, ch. 10; on China, see Ashton et al. 1984). It is indeed, a terrible indictment of collective farming, that the worst famines

of the 20th century have occurred under that system. The USSRs long-term growth of farm output has required colossal capital outlays so that by the 1970s, the agricultural sector was absorbing over one quarter of Soviet new fixed investment (Carey 1976). From the mid-1950s to the later 1970s Chinese farm output per caput was stagnant: 'decollectivization' of agriculture in the early 1980s was accompanied by a huge in farm output (Nolan and Paine 1986).

The 'socialist' countries' poor agricultural performances is in part attributable to shortcomings in the supply of industrial goods (Smith 1981). Part is also due to extensive state intervention in collective farms. However, there are fundamental problems in principle even with relatively independent collective farms. Large units (whether state, collective or private) are necessary to undertake activities exhibiting lumpiness or economies of scale. However, for many farm tasks powerful managerial diseconomies of scale exist, and even given favourable policies in other respects, in most circumstances this would prove a barrier to good performance of collective farms.

Collective bargaining is a term applied to a variety of methods of regulating relationship between employers and their employees. Its distinctive feature is that it clearly acknowledges a role for trade unions. In contrast with, for example, autocratic paternalism or producer cooperatives, the employer who engages in collective bargaining accepts the right of independent representatives of employees, acting as a collectivity, to argue their point of view on matters that affect their interests. Pay and working conditions are the most common subjects of collective bargaining, but it can encompass any aspect of management.

The impact of collective bargaining upon management, and its effectiveness from the point of trade union members, vary enormously between different employment circumstances. They depend ultimately upon the collective strength that can be mobilized by employees within the legislative constraints laid down by the state. Collective bargaining is thus best seen as a political institution. It provides a means of bringing at least temporary reconciliation of divergent interests between employers and employees in circumstances in which each side can, to a greater or lesser extent, inflict damage on the other. It is, however, a political institution that is intimately linked with economic processes. The relative power of the bargaining partners owes much to their respective labour and product markets. At the same time the outcome of their bargaining has a major impact upon both the wages and the productivity of labour.

Theoretical Approaches

This view of collective bargaining as primarily a political rather than an economic institution is relatively recent. Beatrice Webb claimed, according to Marsh (1979), to have originated the expression in 1891 in her study *The Co-operative Movement of Great Britain*. She analysed it further with her husband Sidney Webb in *Industrial Democracy* (1897). Although they did not define it, they saw it as an alternative to individual bargaining, so that the employer, instead of making separate deals with isolated individuals, 'meets with a collective will and settles, in a single agreement, the principles on which, for the time being, all workmen of a particular group, or class, or grade, will be engaged'. They identified it as one of three methods used by trade unions to meet their objectives, the other two being to establish mutual assurance arrangements for their members and to press governments to enact favourable laws. For all the richness of the Webbs' analysis, collective bargaining remained for them essentially an economic institution, imposed upon the employer by a labour cartel whereby workers secured better terms of employment by controlling competition among themselves. A naive version of this view can be seen to underlie much formal analysis of collective bargaining by present-day labour economists.

For the next half century Marsh reports no substantial development of the concept apart from in Leiserson's *Constitutional Government in American Industries* (1922). Then in 1951 Chamberlain, in his book *Collective Bargaining,* argued that there were, in essence, three distinct theories. 'They are that collective bargaining is (1) a means of contracting for the sale of labour, (2) a form of industrial government, and (3) a method of management.' The first, 'marketing' theory was much the same as that of the Webbs. The second, 'governmental' aspect was concerned with the procedural needs of dispute resolution. The third 'managerial' theory referred to the way in which management and unions in practice combined 'in reaching decisions on matters in which both have vital interests'; unions through collective bargaining become not the usurpers of management functions but 'actually *de facto* managers'. At much the same time Harbison (1951) was stressing the very constructive social role that collective bargaining played in resolving industrial conflict and in pushing for the enhancement of the 'dignity, worth and freedom of individuals in their capacity as workers'.

This more complex view of collective bargaining has been refined by Dunlop (1967)

and Kochan (1980) in the United States, but probably the most influential discussion has been Flanders' attempt of 1968 to create a comprehensive theoretical analysis. He argued that the economic associations of the term 'collective bargaining' are misleading. The collective agreement commits no one to either buy or sell labour, but rather ensures that, when labour is bought or sold, the terms of the transaction will accord with the provisions of the agreement. Above all else, collective bargaining is a rule-making process covering many aspects of the employment relationship besides pay and conditions of work. The second characteristic feature of collective bargaining that Flanders stressed is that of the power relationship between the protagonists whose negotiations ('the diplomatic use of power') create the rules. Thus, while there are also technical rules and legal rules regulating work, what distinguishes the legitimacy of those that result from collective bargaining is their authorship. They are jointly determined by the accepted representatives of both employers and employees who consequently share responsibility for both the rules' contents and their observance.

Flanders' analysis has proved fertile in several respects. It has drawn attention to the extent to which collective bargaining is a positive management technique rather than just an impediment to effective management imposed by trade unions. As a result of this shift in emphasis, a major part of academic research into collective bargaining in the 1980s has explored managerial, as opposed to trade union, strategies, and has exposed the extent to which union behaviour is shaped by these management strategies. In addition, what could be seen as the Weberian undercurrent in Flanders' analysis has focused policymakers' attention upon the importance of procedural clarity in conflict resolution, and thereby upon the dangers of ambiguity in the legitimation of agreements. The most obvious example is provided by the influential central recommendation of the British Royal Commission on Trade Unions and Employers' Associations of 1968. The emphasis it placed upon employer initiated procedural reform, rather than legislative constraints on trade unions, owed much to the evidence that Flanders had submitted. Finally, by conceptualizing wages as part of a broader package of regulations and as embodying strongly normative principles, the theory opened the way to a more fruitful understanding of wage determination than is offered simply by the market models of orthodox theory.

Two crucial features of the employment relationship ensure that the process of collective bargaining is fundamentally unlike that of non-labour commercial bargains. They are its open-endedness and its continuity. The labour contract is open-ended because the recruitment of an employee does not ensure the performance of work; the employee has to be motivated, by whatever means, to perform to the required standard. In all but highly oppressive societies such motivational techniques tend to be varied and complex, differing not least in the extent to which they place emphasis upon levels of pay and upon employee participation. Since social comparisons (and especially very local ones) play an important part in the motivation and demotivation of labour, the bureaucratic standardization of terms of employment, which is generally a characteristic of collective agreements, often fits in well with management's preferred personnel techniques. In this way, properly conducted collective bargaining can provide a socially stable working environment which facilitates the employer's prime aim of eliciting labour productivity. In short, the conduct of the bargain affects the quality of the labour bargained over.

The second distinctive feature of the employment relationship is its continuity. Employer and employees are bound together, for better or worse, for an indeterminate duration. Additions to and departures from the workforce generally occur in a piecemeal way. A host of potentially contentious issues feature in the relationship, only a small minority in contention at any one time, and many affecting only a minority of the workforce. Thus a bargain over a particular issue, such as a pay grievance, cannot be evaluated in isolation, but as one fibre in a thick rope of regulations, with many largely implicit trade-offs with respect to other issues, past, present and future.

Characteristics

The definition of collective bargaining as the joint regulation of the employment relationship by employer and employee representatives is one that covers a broad range of processes. It is helpful to analyse these further. An initial distinction has to be made between negotiation and consultation. In a negotiation the discussions are characterized, first, by the awareness of each side of the possibility of one inflicting costs on the other in the absence of an acceptable outcome. Second, a negotiation has to result in some sort of agreement, however informal, to which the two sides are, at least for the time being, committed. Consultation, by contrast, is unaccompanied by either the threat of sanctions or the need to reach binding agreement. Actions taken by management in the light of consultation result from a reappraisal of the facts of the case; those taken after negotiation reflect a compromise which has taken into account the threat (or experience) of sanctions inflicted by either or both sides. Under most collective bargaining arrangements it is felt advisable by both sides to distinguish as far as is possible between negotiations and consultations, at any rate in formal procedures. It is, for example, now normal in large unionized workplaces in Britain to deal with them in specifically different committees, even though the membership of those committees may be much the same.

In practice the distinction is far from clear-cut. The blend of approaches adopted in a particular collective bargaining episode depends very much upon the issue in question and the relationship between the parties involved. In their study *A Behavioral Theory of Labor Negotiations* (1965), Walton and McKersie distinguished four classes of negotiation. First, there were 'distributive' bargains: zero-sum negotiations typified by annual wage bargains and characterized by very formal proceedings. Second were 'integrative' bargains: problem-solving discussions aiming at non-zero-sum gains for both sides and generally much more informal in procedure. Third, was 'attitudinal structuring', an almost didactic form of bargaining dialogue in which one side tries to alter the way in which their opponents perceive the problem and its context. Finally, 'intra-organizational' bargains were aimed at altering positions and attitudes, not on the other side, but within the negotiator's own side.

An important influence upon the way in which bargaining is conducted is the personal 'bargaining relationship' between the two individuals who have to take the lead in representing the two sides. This is a term given to the level of trust and facility of communication that exists between them. However acrimonious the collective dispute over which they are bargaining, the better the bargaining relationship between the individual negotiators, the more efficiently they will be able to assess each other's relative power position and the better the chance of the dispute being settled without recourse to expensive sanctions. In a mature bargaining relationship it is common for the negotiators to protect each other from their own sides by, for example, avoiding the humiliation of a bargaining opponent by helping him to gloss over the magnitude of a defeat and by manipulating public statements from one's own side so as to help in his intra-organizational bargaining with his own.

It is normal to draw a clear distinction between the substantive and procedural aspects of collective bargaining. A substantive agreement sets out the actual pay levels, working conditions, or whatever that have been agreed and will be worked to. A procedural agreement defines the way in which such substantive terms might be altered, added to, or interpreted. An effective procedure for negotiation or grievance settlement will state which agents on each side are entitled to be involved in negotiations, in what sequence different sets of negotiators are entitled to consider the matter, what their precedence is, and possibly also matters such as rights of appeal, time constraints, ratification methods and the form of the substantive outcome.

This distinction is particularly obvious in countries whose labour laws cause collective agreements to be tested in the courts; the substantive agreements tend to be written, detailed, formal, and established for specified duration. There

are other countries where employer preference, or legal opportunity, makes it unusual for the bargaining opponents to use legal sanctions against each other. In these circumstances the great bulk of substantive regulation may be unwritten and in the form of verbal agreements, custom, and tacit understandings. Because of this a greater emphasis is placed upon the rectitude of the procedural agreements (which may still be very informal) whereby this amorphous body of substantive rules is interpreted and altered, not through comprehensive periodic negotiations, but by a constant incremental process of piecemeal adjustment. Although the United States might be described as exemplifying the legalistic extreme, and Great Britain the 'voluntaristic', most bargaining arrangements have elements of each, with the degree of legalism and formality varying by issue and industry, as well as by country.

Bargaining Structure

The structure of bargaining in a country, industry, or enterprise, refers to several different characteristics of collective bargaining. The two most important are the 'bargaining units' and 'bargaining levels' employed. A bargaining unit is a group of employees covered by a particular agreement. Within this basic territory of industrial government there is a coherence of terms of employment, procedures, and trade union representation that is not necessarily to be found between different bargaining units. The level of bargaining refers to the role played by the principal negotiators within their organizations; whether, for example, the employer representative responsible is a factory manager, a company director, or an employers' association representative.

These two characteristics are involved in the single most important decision in the shaping of any bargaining structure which is whether the employers confront the unions singly or in alliance. Single-employer bargaining, resulting in agreements at company-level or lower, is the majority practice in the United States and Japan and now in Britain. Multi-employer bargaining, in which associations of employers conclude industrywide agreements, remains the most important form in most of Continental Europe. In practice there is often some employer collusion in industries where single-employer bargaining dominates, and there is usually room for individual employer discretion in industries with strong employers' associations, but the distinction remains one of fundamental economic, political, and managerial significance.

Two other defining characteristics of bargaining structure are its 'form' and 'scope'. The first refers to the extent to which proceedings and agreements are formalized and codified. As already mentioned, this depends in part upon the labour legislation of the country. The second matter, scope, refers to the range of issues covered by collective bargaining. At its narrowest it may include no more than pay and hours, while elsewhere it may take in issues as diverse as training policy, investment decisions and child-care facilities.

The most comprehensive theory seeking to explain industrial and national differences in bargaining structure is to be found in Clegg's *Trade Unionism under Collective Bargaining* (1976). This sees the strategy adopted by employers as the main determinant of bargaining structure, although changes in strategy may be slow to take effect. The legislative framework of a country is also of crucial importance. It defines the limits of rights to strike, the status of the employment contract, any guarantees of security for trade unions, and the legally responsible agents on each side.

Most countries acquired their principal labour legislation at some historic period of crisis – war, defeat, depression, or extreme industrial unrest – and the institutional arrangements that developed from that have become consolidated in subsequent, more peaceful times. This helps to account for the very great variations in collective bargaining practice to be found in different countries; they often owe their origin to a distant panic measure based upon a fashionable idea (such as, for example, compulsory arbitration in Australia or compulsory conciliation in Canada) to which employers and unions have adjusted so firmly that radical reformation is all but impossible. A recurring experience around the world is of

legislatures finding extreme difficulty in reforming collective bargaining, other than in times of extreme crisis, because of the essential privacy of the bargaining relationship between employers and union.

Most industrialized countries publicly assert a commitment to collective bargaining as a necessary part of a democratic society, and for most it is the normal means of conducting industrial relations in the public sector. Convention 84 (1947) of the International Labour Organization asserts that 'all practical measures shall be taken to assure to trade unions which are representative of the workers concerned the right to conclude collective agreements with employers and employers' associations'. In practice the freedom of collective bargaining in both public and private sectors varies substantially between countries and over time.

No discussion of collective bargaining would be complete without a mention of the debate concerning its relationship with industrial democracy.

One view is that, because collective bargaining is essentially concerned with compromise, trade unions are sucked into collaborating with capitalism and thereby denied the opportunity of uniting the working class in overthrowing existing employers and then instituting true industrial democracy through workers' control. Opposing this is a view that deplores the fact that collective bargaining institutionalizes the opposition of capital and labour: them and us. It considers that the best form of industrial democracy is to be found where workers are brought to perceive an ultimate identity of interest with employers. Between these positions is that most clearly expressed by Clegg in *A New Approach to Industrial Democracy* (1960). This argues that there can never be complete identity of interest between employer and employee, and also that if employee representatives are given managerial responsibilities they will be forced to behave very similarly to the employers they have replaced. Consequently the role of the trade union is best seen as one of constant opposition, acting to modify management actions in the light of members' interests insofar as their organized power permits. Far from undermining the common interests of capital and labour, collective bargaining permits the joint regulation of aspects of employment which would otherwise generate greater disharmony and division.

Collective Choice Experiments

Rick K. Wilson

Abstract

Collective choice experiments examine voting mechanisms that aggregate individual preferences. Two general topics have received the most attention. The first pertains to agents deciding on a single collective outcome or

policy. The second topic covers election mechanisms that govern candidates and voters.

Duncan Black (1948) and Kenneth Arrow (1963) raised the key question of collective choice: if people have different preferences for policy outcomes are there general mechanisms that can (always) aggregate those preferences in consistent and coherent ways? The answer is 'no'. Starting from simple premises involving individual transitivity, aggregate Pareto optimality and non-dictatorship there is no collective choice mechanism that yields a socially transitive outcome. Such a finding is startling given the confidence placed in democratic institutions that rely on voting mechanisms to choose a single outcome from many possible outcomes.

Experimentalists have thoroughly explored different institutions that can be used to aggregate preferences. Political economists who straddle both economics and political science have carried out much of this work. Their concern is with situations where actors who have opposed interests have to settle on a single outcome and with the properties of the institution used to produce an outcome. This article first turns to the institutional mechanisms by which individuals settle on a collective outcome. The second topic turns to electoral mechanisms used in representative democracies.

Spatial Committee Experiments

In the late 1960s theoretical papers by Davis and Hinich (1966) and Plott (1967) described a social choice environment for spatial committees. Those committees consist of a well-defined multidimensional policy space, with actors holding fixed preferences over the dimensions, and policies represented as points in the space. Using rules that mimic many parliamentary systems, these theoretical papers demonstrate that a Condorcet winner (a policy that can defeat all others under pairwise voting) exists only under rare distributions of voters' preferences. Plott (1967) establishes the conditions under which a Condorcet winner will exist and he makes the connection between this and a Nash equilibrium of a spatial committee game. Like others, he concludes that an equilibrium is rare in multidimensional spatial committee games.

Early spatial committee experiments by Berl et al. (1976) and Fiorina and Plott (1978) provide evidence that when a Condorcet winner exists, subjects choose it or outcomes that are close to it. In games where there is no such equilibrium (which is the most common case), subjects select outcomes that scatter in the policy space. These initial empirical findings, coupled with experiments by Laing and Olmsted (1978) and McKelvey et al. (1978), defined the standard for conducting spatial committee experiments. Subsequent experiments have adopted almost identical procedures.

The standard experimental design introduces a two-dimensional policy space. The orthogonal dimensions are arbitrary (X and Y in most settings) and typically range from zero to 200 or more units. Every point in the space characterizes a policy. Preferences over outcomes are induced by assigning each subject a payoff function mapping earnings in dollars to each point in the space. While many payoff functions have been tested, most experimenters have settled on a quadratic loss function, with monetary payoffs decreasing as a function of distance from a subject's ideal point. Usually five subjects are assigned different ideal points in the space, and it is the arrangement of these ideal points that allows the experimenter to manipulate, whether a Condorcet winner exists or not. Subjects are given an initial status quo and then allowed to introduce amendments. Voting takes place following an amendment, with the winner becoming (or remaining) the new status quo. Amending takes place in between votes. A motion to adjourn, passed under a voting rule, constitutes the stopping rule for the committee decision. This serves as the standard institution

for subsequent spatial committee experiments. Changing these basic institutional rules became the way to test theories of collective choice.

Experimental results in the absence of equilibrium are both frustrating and profitable. Frustration arises over the fact that committee choices tend to be clustered in similar regions of the policy space. While there appears to be some pattern to the outcomes, the process by which these outcomes arise has not been fully characterized (but see the attempt by Bianco et al. 2006). Profitably, these empirical results led theorists and experimenters to add agenda control to the structure of the game. This led to a distinction between preference-induced and structure-induced equilibrium. For example, Plott and Levine (1978) showed the effectiveness of agenda control both in the laboratory and in a natural setting. Awarding agenda power created a structure-induced equilibrium and laboratory subjects converged to it. Recent experimental work by Frechette et al. (2003) illustrates that the equilibrium favours agenda setters.

Theoretical work by Buchanan and Tullock (1962) led experimentalists to examine whether changing the proportion of actors needed to pass a policy had any effect. Experiments by Laing and Slotznick (1983) showed that moving from simple majority rule (50 per cent plus 1) to supermajority majority rule (67 per cent) resulted in many equilibria and that subjects chose them. Schofield (1985), among others, provided the theoretical basis for when an equilibrium exists as a function of the dimensionality of the policy space, the voting rule and the distribution of voters' preferences. These theoretical findings spurred experimentalists to examine other changes to the standard committee experiment. For example Wilson and Herzberg (1987) theoretically predicted and experimentally demonstrated that when a single player holds veto power, that player's ideal point is the equilibrium. Haney et al. (1992) empirically show committee choices converging to equilibrium when a weighted voting rule is used. Such a rule requires that a single player always be included in a coalition. These results are representative of the kind of work that has dominated the experimental spatial committee agenda.

Experiments on spatial committees have added to a clearer understanding of institutional mechanisms. Experimental results demonstrate that changing who has the power to set the agenda, how the agenda is built, how many votes are needed and whether players enjoy veto powers, matters.

C

Electoral Mechanisms

A second area of interest for collective choice experimentalists is with electoral mechanisms. Three broad directions have been taken that treat different aspects of representative democracies. The first is concerned with candidate behaviour. At the heart of this research is the question of whether candidate positions will converge to equilibrium when it exists. The second direction is concerned with voter behaviour, particularly how voters behave when they have little information about candidate positions. The final direction deals with the way in which electoral rules determine the likelihood that 'types' of candidates are elected, where types usually refer to racial and ethnic minority candidates.

The initial experimental work on candidate behaviour focused on candidates who cared only about winning and varied the information conditions that the candidates have about the preferences of voters. Most experiments use a unidimensional policy space that guarantees an equilibrium. This equilibrium is defined by the policy preference of the median voter. In the experiments elections are sequential, with two candidates announcing positions in the policy space and voters choosing between the candidates. Voters are assigned ideal points in the policy space, the winning candidate is required to implement the announced policy and voters are paid an amount that decreases with the distance of the winning position from their ideal point. Candidates are paid only if they win. Once the election is over another election is held with candidates free to change their previously announced policy. Not surprisingly, all candidates quickly adopt the position of the median voter when they are fully informed about voter preferences. Under incomplete information about voters,

candidates also converge to the median voter's position, by responding to feedback about the vote share accruing to different policy positions, as in McKelvey and Ordeshook (1985). If candidates have policy preferences whereby their earnings depend not only on winning but also on implementing a policy close to their own preferred position, then the median voter result no longer holds (see the experimental results by Morton 1993).

When voters are uninformed about candidate positions, are they able to cast accurate ballots? With minimal information, such as biased endorsements or polls, subjects do very well at inferring candidate positions. Lupia and McCubbins (1998) and Morton and Williams (2001) consider various aspects of voter information and show that voters are able to quickly determine the positions of candidates and cast their vote accordingly.

Finally, several experiments have focused on differing electoral mechanisms and what they mean for the type of candidates that gain election. For example Gerber et al. (1998) compare two voting mechanisms in an experiment to test whether one or the other disadvantages a racial or ethnic minority candidate. A form of cumulative voting (in which voters can cast more than a single vote) leads to more minority candidates being elected. This should be no surprise to collective choice theorists who have long noted that different electoral mechanisms lead to predictable variation in outcomes. Cox (1997) offers an extended discussion of such mechanisms.

What We Know

Collective choice experiments provide several insights. First, when a Nash equilibrium of the underlying game exists it is a strong predictor of the outcome of the experiment. The second finding is that when there is no Nash equilibrium for the underlying game, subjects choose outcomes that cluster in predictable areas of the policy space, but the process by which that occurs is not settled. At the same time, experimentalists have implemented institutional mechanisms altering such games, thereby producing an equilibrium that subjects choose. Often those institutional changes benefit one actor (for example, by assigning agenda control to a particular player). A third finding is that incomplete information does not prevent convergence to equilibrium for either candidate platform choice or voter behaviour. The fourth finding returns to Arrow's original insight: voting mechanisms can be manipulated to achieve predictable, but very different, outcomes. It all depends on the mechanism that is implemented.

Collective Models of the Household

Olivier Donni

Abstract

Collective models of the household are based on two fundamental assumptions: (*a*) each agent is characterized by specific preferences and (*b*) the decision process results in Pareto-efficient outcomes. The main results of the theory of collective models then refer to the empirical issue of deriving testable restrictions on household behaviour and recovering from this some information on the structural model that can be used to carry out welfare comparisons at the individual level.

Keywords

Collective models of the household; Exclusive goods; Household behaviour; Indirect utility function; Pareto efficiency

JEL Classifications

D11

Until recently 'unitary' models, which assume that household members act as if they maximize a unique utility function under a budget constraint, were largely predominant in the literature on household behaviour. There is increasing agreement, however, that economists cannot ignore the fact that most households are composed of several individuals who take part in the decision process. Consequently, the 'collective' models, which postulate that (*a*) each household member has specific, generally different preferences and (*b*) the decision process results in Pareto-efficient outcomes, have attracted considerable attention from the profession during recent years.

To examine the properties of collective models, let us consider a household consisting of two persons, *A* and *B*, who make decisions about consumption. These persons are characterized by well-behaved utility functions of the form: $u_i(\mathbf{x}_A, \mathbf{x}_B, \mathbf{X})$, where $\mathbf{x}_i$ denotes a vector of private goods consumed by member i and $\mathbf{X}$ a vector of public goods ($i = A, B$). This specification of preferences is very general; it allows for altruism but also for externalities or any other preference interaction. We denote the vector of prices for private goods by $\mathbf{p}$, the vector of prices for public goods by $\mathbf{P}$ and the household total expenditure by y. Finally, we suppose that there exists a vector of distribution factors, that is, a set of exogenous variables which influence the intra-household

allocation of resources without affecting preferences or the budget constraint. Examples are given by the respective contribution of each member to the exogenous household income, the state of the marriage market or divorce legislation. These variables, which are often assigned a crucial role in the derivation of the results, are denoted by **s**.

To simplify notation, let $\pi' = (\mathbf{p}', \mathbf{P}')$ be the vector of prices. Then, efficiency essentially means that household behaviour can be described by the maximization of a utilitarian social welfare function, that is,

$$\max_{\mathbf{x}_A, \mathbf{x}_B, \mathbf{X}} \mu(\pi, y, \mathbf{s}) u_A(\mathbf{x}_A, \mathbf{x}_B, \mathbf{X}) + (1 - \mu(\pi, y, \mathbf{s})) u_B(\mathbf{x}_A, \mathbf{x}_B, \mathbf{X}) \quad (1)$$

subject to $\mathbf{p}'(\mathbf{x}_A + \mathbf{x}_B) + \mathbf{P}'\mathbf{X} = y$. In this programme, the function μ determines the location of the household equilibrium along the Pareto frontier. If $\mu = 1$, then the household behaves as though member A always gets her way whereas, if $\mu = 0$, it is as if member B is the effective dictator. We denote the solutions to Eq. (1) by $\mathbf{x}_A(\pi, y, \mathbf{s})$, $\mathbf{x}_B(\pi, y, \mathbf{s})$ and $\mathbf{X}(\pi, y, \mathbf{s})$.

Characterization

The first objective of the theory of collective models is to investigate the properties of the household demands derived from Eq. (1). These properties can either be tested statistically or be imposed a priori for simplifying the estimation task. From this perspective, one crucial point is that individual demands for private goods, $\mathbf{x}_A$ and $\mathbf{x}_B$, are generally unobservable by the outside econometrician; demands for these goods are observed only at the household level, $\mathbf{x} = \mathbf{x}_A + \mathbf{x}_B$ To be useful, the restrictions derived from the collective setting have thus to characterize household demands, **x** or **X**, instead of individual demands, $\mathbf{x}_A$ and $\mathbf{x}_B$.

Let $\boldsymbol{\xi} = (\mathbf{x}', \mathrm{X}')$ be the vector of household demands. We define the Pseudo–Slutsky matrix as follows:

$$\mathbf{S} = \frac{\partial \boldsymbol{\xi}}{\partial \pi'} + \frac{\partial \boldsymbol{\xi}}{\partial y} \boldsymbol{\xi}'$$

There exist at least three different sets of testable restrictions that characterize household behaviour.

SR1 Condition

Browning and Chiappori (1998) and Chiappori and Ekeland (2006) show that household demands compatible with Eq. (1) have to satisfy the following condition:

$$\mathbf{S} = \sum + \mathbf{R}_1,$$

where Σ is a symmetric, semi-definite matrix and $\mathbf{R}_1$ is a rank one matrix. The interpretation is the following. For any given pair of utility functions, (a) the budget constraint determines the Pareto frontier as a function of π and y, and (*b*) the value of μ determines the location of the household equilibrium on this frontier. Consequently, a change in π implies a shift of the Pareto frontier. The latter entails the modification of household demands described by Σ. However, the value of μ varies as well, hence the location of the equilibrium moves along the Pareto frontier. Since the frontier is of dimension one, this effect is very restricted and defined by $\mathbf{R}_1$.

Proportionality Condition

The particular structure of Eq. (1) leads to further restrictions on behaviour. To make things simple, let us suppose that the vector of distribution factors is twodimensional: $\mathbf{s} = (s_1, s_2)$. Then, Bourguignon et al. (1993) demonstrate the following result:

$$\frac{\partial \boldsymbol{\xi}}{\partial s_1} = \theta \frac{\partial \boldsymbol{\xi}}{\partial s_2},$$

where θ is a scalar. Thus, the response to different distribution factors is co-linear. The interpretation is that distribution factors can only change the location of the outcome on the frontier (through function μ), and the latter is of dimension one.

Specific Conditions

The econometrician is often inclined to put more structure on preferences. For example, let us suppose that agents have utility functions of the form: $u_i(\mathbf{x}_i, \mathbf{X})$. In that case, we say that agents are

'egoistic' in the sense that the utility does not depend on the partner's consumption. This assumption implies, in particular, that the decision process can be decentralized. In a first step, household members agree on the level of public goods as well as on a particular distribution of the residual expenditure between them. In a second step, they maximize their utility function, taking into account the level of public goods and their own budget constraint. It means, formally, that there exists a pair of functions ($\rho_A(\mathbf{p}, \mathbf{X}, y^*, \mathbf{s})$, $\rho_B(\mathbf{p}, \mathbf{X}, y^*, \mathbf{s})$), satisfying $\rho_A + \rho_B = y^*$ where $y^* = y - \mathbf{P}'\mathbf{X}$, such that the demand for private goods by member i is the solution to

$$\max_{\mathbf{x}_i} u_i(\mathbf{x}_i, \mathbf{X}) \text{ subject to } \mathbf{p}'\mathbf{x}_i = \rho_i.$$

Hence, household demands for private goods, conditionally on the demands for public goods, can be written as:

$$\mathbf{x} = \mathbf{x}_A(\mathbf{p}, \mathbf{X}, \rho(\mathbf{p}, \mathbf{X}, y^*, \mathbf{s})) + \mathbf{x}_B(\mathbf{p}, \mathbf{X}, y^* - \rho(\mathbf{p}, \mathbf{X}, y^*, \mathbf{s})),$$

where $\rho = \rho_A$ and $y^* - \rho = \rho_B$. This structure generates strong testable restrictions because the same function $\rho(\mathbf{p}, \mathbf{X}, y^*, \mathbf{s})$ enters each demand for private goods. Bourguignon, Browning and Chiappori (1995) explicitly derive these restrictions under the form of partial differential equations, whereas Donni (2004) shows that the demands for public goods have a particular but different structure, which implies testable restrictions as well.

Welfare Analyses – Identification

One of the main sources of interest in collective models is to provide the theoretical background for performing welfare comparisons at the individual level. The key concept in that case is what Chiappori (1992) calls the 'collective' indirect utility function. Let us suppose again that agents are egoistic. If so, the collective indirect utility function is defined as follows:

$$v_i(\pi, y, \mathbf{s}) = u_i(\mathbf{x}_i(\pi, y, \mathbf{s}), \mathbf{X}(\pi, y, \mathbf{s})). \quad (2)$$

This expression describes the level of welfare that member i attains in the household when he or she faces the price-income bundle(π, y) and a set of distribution factors $\mathbf{s}$. This representation of utility differs from the 'unitary' indirect utility function in that it implicitly includes the sharing function, and hence an outcome of the collective decision process. However, the knowledge of Eq. (2) is usually sufficient to evaluate the impact of economic policies on individual welfare.

In general, if agents are egoistic, the collective indirect utility functions can be retrieved. Nonetheless, the econometrician must observe the demand for some specific goods, referred to as 'exclusive', which benefit only one person in the household. More precisely, we say that good $X(x)$ is exclusively consumed by member i if $\partial u_j/\partial X = 0 (\partial u_j/\partial x_j = 0)$ for $j \neq i$. The intuition is that the household demand for 'exclusive' goods can be used as an indicator of the distribution of bargaining power within the household. Donni (2006) considers the case of purely private consumption ($\mathbf{X} = 0$) and shows that, if there is a single exclusive good, the collective indirect utility functions can be identified up to composition by an increasing transformation. Similarly, Chiappori and Ekeland (2003) consider the opposite case of purely public consumption ($\mathbf{x} = 0$) and show that, if there are two exclusive goods (one for each member), the identification is still possible. However, the general case with both private and public consumption has not been completely treated until now; see Blundell, Chiappori and Meghir (2005) for a first investigation.

Bibliographical Note

The main idea of collective models can be traced back to Leuthold (1968), who estimates a model of household labour supply based on non-cooperative game theory, where the individual is the basic decision-maker. However, this model differs from collective models in that the underlying decision process does not result in efficient outcomes. It actually belongs to the family of 'strategic' models (which are sometimes

referred to as 'collective' models in a broad sense). Nevertheless, a significant advance towards the development of collective models is made by Manser and Brown (1980) and McElroy and Horney (1981) at the beginning of the 1980s. These authors study the properties of models based on bargaining theory, which implies Pareto-efficiency. In that case, the location along the Pareto frontier is determined by the Nash (or Kalai–Smorodinsky) solution. However, the first formal investigation of a model based on the sole efficiency assumption is due to Chiappori (1988, 1992) in the context of labour supply decisions. This model is not explicitly examined in this article because it can be seen as a particular case of the model of consumption. Note, however, that Apps and Rees (1997), Chiappori (1997), Donni (2003), and Fong and Zhang (2001) present theoretical extensions of Chiappori's initial model, whereas Chiappori, Fortin and Lacroix (2002) exhibit empirical results. Finally, we must mention that several authors have generalized collective models to inter-temporal decisions and uncertain environment. One of the most representative examples of these studies is given by Mazzocco (2005).

Collective Rationality

Lu Hong

Abstract

This article reviews the concepts of individual rationality and collective rationality as they appear in the economics literature. In particular, the existing literature on social choice and aggregate demand points to a fundamental disconnect between these two notions of rationality. A possible reconciliation of this disconnect is suggested.

Since ancient times, men have argued that choice should be governed by 'desire and reasoning directed to some end' (Sen 1995). Much modern economic theory is based on this rational choice principle paradigm. In an individual choice problem, the individual is assumed to have a preference ordering on the set of alternatives. The individual choice is rational if, for any given decision situation, the choice made is always the best among all feasible alternatives according to the preference ordering. In a collective choice problem, be it that of a society or a committee, the definition of this rational choice principle becomes problematic. As there is presumably a huge disparity among the desires and ends of the individuals within the collective, by whose desire and whose end should the collective choice be governed? Is it reasonable to expect the collective choice to be guided by a preference ordering? If so, how should it reflect individual preferences, as the choice made by the collective influences everyone in it?

C

Collective Rationality and Social Choice

Of particular interest to the idea of collective rationality is the study of social choice.

In a seminal work, Arrow (1951) connects collective rationality to social choice through the idea of the existence of a social welfare function. Formally, consider a large set of conceivable alternatives, X, that a society faces. A preference ordering R (weakly preferred) on X is a binary relation on X that is both complete and transitive. Its asymmetric and symmetric parts are denoted by P (strictly preferred) and I(indifferent) respectively. There are n number of individuals in the society. Each individual i has a preference ordering R_i on the set X. A *social welfare function* (SWF), F, maps a profile of individual preference orderings $(R_1,\ldots,R_n)$ to a preference ordering on X. The preference ordering $F(R_1,\ldots,R_n)$ is then interpreted as the *society's preference* on X for the society consisting of individuals with preference orderings $(R_1,\ldots,R_n)$. If such an SWF exists, then the social choice to be made from any set of feasible alternatives can be determined by comparing any pair of feasible alternatives according to the society's preference. The social choice thus made is guided by a preference ordering to reach the best among feasible alternatives – *collective rationality* is achieved. In other words, such an SWF, if it exists, is a preference aggregation procedure aggregating individual preference orderings into a society's preference ordering according to which a rational choice can be made.

In isolation, collective rationality is trivial to reach because an SWF always exists. For example, take any preference ordering R on X; the constant function that maps every possible profile of

individual preference orderings to R is an SWF. Obviously, this SWF is not meaningful since no information about individual preferences is reflected by society's preferences. For an SWF to reasonably aggregate individual preferences, some minimal set of conditions should be imposed. Arrow (1951) considers four conditions: U - (universal domain: an SWF's domain contains all possible individual preference orderings), P (Pareto principle: if all individuals strictly prefer one alternative to another, then the society strictly prefers the first alternative to the second), I (independence of irrelevant alternatives: the way the society ranks a pair of alternatives should depend only on the way individuals rank the same pair, not on how they rank any other alternatives), and D - (non-dictatorship: no single individual always gets to determine the society's preference). He shows the famous *Arrow's Impossibility Theorem*: It is impossible to have a social welfare function satisfying U, P, I and D simultaneously. In other words, collective rationality is impossible to achieve universally if society is to take into account all individuals in a minimally reasonable way.

Arrow's Impossibility Theorem jump-started the modern day study of social choice. In the huge literature of social choice theory, two strands directly relate to collective rationality formulated in the context of Arrow's Impossibility Theorem. One strand focuses on identifying domain restrictions so that social welfare functions satisfying Arrow's three other conditions exist. For example, the SWF which derives society's preference from majority voting on each pair of alternatives (majority rule) with universal domain will lead to many cycles in society's preference, violating the transitivity requirement of a preference ordering. However, if individual preferences are restricted to those that are single-peaked when alternatives can be represented in one dimension, then majority rule will not generate cycles and satisfies all other requirements of Arrow's Theorem. In general, this strand of literature proves that collective rationality can be meaningfully restored for some restricted domains (Gaertner 2002). However, domain restrictions are severe, and outside of them the problem of society's preference cycles is global (McKelvey 1979).

The second strand of literature directly examines the formulation of collective rationality in the definition of Arrow's social welfare function. Arrow's SWF requires society's preferences to be orderings, that is, binary relations that are complete and transitive. Suppose that we weaken collective rationality to requiring only that society's preferences be, say, acyclic as opposed to fully transitive. Can impossibility then be avoided? More generally, is the strong collective rationality formulated by requiring society's preferences to be orderings to blame for the impossibility? This line of research concludes that, even with a weakened notion of collective rationality, the impossibility remains (Sen 1995). Therefore, social choice cannot be expected to be collectively rational, even weakly.

Collective Rationality and Strategic Behaviour

The aforementioned work implicitly assumes that truthful individual preferences are aggregated. If, instead, strategic behaviour is allowed, then even if we require a social choice function to be only non-dictatorial (a social choice function maps a profile of individual preferences into an alternative – a choice of the society), every such social choice function can be manipulated. This is the Gibbard–Satterthwaite impossibility theorem (Gibbard 1973; Satterthwaite 1975). That is, even if the collective makes up its mind about what is good for the society in a given circumstance, as long as individuals are free to report their preferences and the collective does not always choose the top alternative of a given agent's reported preference, then the collective's goal cannot be achieved.

Collective Rationality and Aggregate Demand

The disconnection between collective rationality and individual rationality exists in other areas of economics. In consumer demand theory, the Debreu–Mantel–Sonnenschein theorem (Debreu

1974; Mantel 1974; Sonnenschein 1973) states that generally aggregate demand functions do not exhibit any regularity (such as being downward sloping regarding price) even when all individual demand functions are derived from rational decisions in the sense of preference maximization under budget constraints. More specifically, for any given shape of the aggregate demand function (not necessarily downward sloping), there exists a preference profile, one preference for each consumer, such that the aggregate demand function is generated by the individual demand functions derived from that preference profile. On the other hand, empirical evidence suggests that aggregate demand functions often exhibit some regularity even when individual demand functions do not exhibit regular properties from preference maximization under budget constraints (Kirman 2004).

Possible Reconciliation of Individual Rationality and Collective Rationality

The findings in social choice theory and demand theory suggest a fundamental separation between collective and individual rationality. On the one hand, if individuals in a collective are rational, the collective choice is responsive to individuals, and the collective power does not lie in some proper subset of the collective (democratic), then the collective choice cannot be 'collectively rationalized'. On the other hand, in some situations, collective choices can be 'rationalized' even when individuals in the collective do not act as rational individuals. This separation between collective and individual rationality is not unlike Buchanan's critique of Arrow's formulation of collective rationality:

> We may adopt the philosophical bases of individualism in which the individual is the only entity possessing ends or values. In this case no question of social or collective rationality may be raised. A social value scale as such simply does not exist. Alternatively, we may adopt some variant of the organic philosophical assumptions in which the collectivity is an independent entity possessing its own value ordering. It is legitimate to test the rationality or irrationality of this entity only against this value ordering. (Buchanan 1954, p. 116)

The philosophical bases of individualism have many followers in economics. Binmore (1994, p. 142) wrote: 'Game theorists of the strict school believe that their prescriptions for rational play in games can be deduced, in principle, from one-person rationality considerations without the need to invent collective rationality criteria provided that sufficient information is assumed to be common knowledge.' Under the standard assumptions of game theory accounting for individual interests, these game theorists will prescribe that players defect in the Prisoner's Dilemma game. Such play leads to a Pareto-inferior outcome and thus is in conflict with the collective interest. This is not problematic if game theory is a normative theory which prescribes what people should do rationally. However, as a predictive theory it fails to match what people actually play in the Prisoner's Dilemma game. Experimental evidence shows rampant cooperation among players of the Prisoner's Dilemma game (Rapoport and Chammah 1965; Ledyard 1995).

If we make the organic philosophical assumption that a collective is an independent entity, then do we arbitrarily assume a criterion of collective rationality? A more reasonable way of thinking about a collective being as organic is, perhaps, to consider that, in a collective, individuals become social creatures, not mere individuals, and as such their choices have social consequences that they take into account. This can be modelled as individuals' preferences over a given set of alternatives changing depending on whether they are individuals or members of a collective. How preferences are specifically influenced may reflect culture, social convention or custom, so that they are context-dependent. But whatever the cause, this may create sufficient restrictions on the preference domain that collective rationality results as a consequence of some aggregation procedure that is democratic.

Keywords

Collet, Clara E.; Women's employment

After a period as a schoolteacher in Leicester, Clara Collet became one of Charles Booth's assistants on his Survey of London Life and Labour in 1886. In 1893 she entered the civil service as labour correspondent and later senior investigator for women's industries in the newly established Labour Department of the Board of Trade. The earnings and employment of women became and remained Clara Collet's main concern; her contemporaries recognized her as the principal authority on the subject in Britain. Articles on female labour and earnings were among her contributions to the first edition of Palgrave's *Dictionary of Political Economy* in 1894, and the thorough and lucid reports which she produced on women's industrial employment figured in Parliamentary Papers, contributing to the passing of the original Trade Boards Act of 1906. After her retirement in 1920 from what had by then become the Ministry of Labour, Collet herself served on a number of trade boards, and wrote the section on Domestic Service for the *New Survey of London Life and Labour* directed by her former chief, Sir H. Llewellyn Smith.

The first woman Fellow of University College, London, where she took her MA degree in 1885, Clara Collet was one of the founders in 1890, along with Henry Higgs and H.R. Beeton, of the Economic Club which met there monthly, and acted as its secretary from 1905 to 1922.

She was also a founder member of the British Economic Association, which later became the Royal Economic Society; she served on its Council from 1920 to 1941, and on that of the Royal Statistical Society from 1919 to 1935.

Collusion

Kevin Roberts

Although collusive practices are not restricted to the economic relationships of a well-defined sub-group in society, it is common to use the term collusion in the context of cooperative activity between different firms. With regard to the study of collusion, research has centred on the conditions most conducive to collusion and, in both theoretical and empirical work on the operation of collusive arrangements (see Scherer 1980, Chaps. 6 and 7).

If economic agents are self-interested maximizers then, given that cooperation between a group of firms will almost certainly make possible higher profits for each member of the group than is possible without cooperation, there is a presumption that collusive arrangements will be widespread. Thus it is important to understand why collusion should fail to be universal. In fact, a more general issue is also raised by this. Taking the argument one stage further, direct cooperation between a group of firms and its consumers is likely to make possible benefits to everybody as compared with a situation where firms and consumers are separated by an anonymous market. This cannot be the case for the economy as a whole if it is Pareto efficient (e.g. the standard perfectly competitive economy without externalities) but it will still be the case that cooperative action by a group of agents within the economy will allow that group to gain at the expense of the rest of the economy. The study of the problems faced by colluding firms should hope to throw light on these more general issues.

1. Consider a well defined group of firms producing identical or similar products, the implication being that demand for the products is interrelated. As a first step, assume that cost and demand functions faced by each firm are common knowledge (every other firm in the group knows these functions, every firm knows this, and so on). If the firms meet together to collude then some joint action will emerge. Cooperative game theory concerns itself with this solution but, for the present exercise, it is sufficient to note two of the main determinants of the eventual solution. First, there are the outcomes made possible by cooperative action. Assume profits can be redistributed within the group–side-payments can be made. Then if cooperative action fails to maximize joint profits all firms can be made better off. Given the common knowledge assumption so that there is no argument for inefficiency based upon the mis-perceptions of firms, joint profit maximization, with the group of firms acting like a multi-product monopolist, should emerge.

   Side-payments may not always be possible. For instance, collusive behaviour is outlawed in many countries and, though it may be difficult to detect whether actions by firms are part of some collusive arrangement, the transfer of money between firms is much more likely to be capable of detection. But without side-payments, actions which influence the size of joint profits also influence the distribution of those profits; the consequence of this being that distributional considerations will influence the actions chosen by firms. For instance, the

cooperative Nash bargaining solution (Nash 1950) leads to actions which maximize the *product* of individual gains above some status quo position – compared with joint-profit maximization, there is movement towards the equalization of gains above the status quo. This may be viewed as a compromise between ignoring distributional considerations and the other extreme where only distributional considerations count.

The second major determinant of the solution reached will be what each firm can expect to achieve if it refuses to accept a particular proposed collusive action for the group. The status quo of the Nash bargaining solution may be interpreted in this way. This is the most obvious component of 'bargaining power' for an agent. The requirement that firms must prefer the collusive action to what can be achieved by reneging, places restrictions on the collusive solution. Under the assumption that firms are interrelated only through the demand structure and that this interrelationship implies that the goods produced by the collusive firms are substitutes, then the worst that can happen to a firm if it refuses to accept a collusive arrangement is that all other firms maximize their production and the reneging firm chooses production to maximize profits in this hostile environment. Given this scenario, there will usually be a large range of collusive actions which offer more to firms than can be achieved by reneging. However, it is not enough for firms to say that they will 'punish' a reneging firm in this way, there must be grounds on the part of the reneging firm for believing that punishments will be carried out – it must be a credible threat in the sense that if the firm reneges, other firms have an incentive to punish the firm. The credibility restriction in this environment is captured by the so-called 'perfect folk theorem' of repeated games (see Rubinstein 1979, for a published version of the theorem) – firms called upon to punish will have the strongest incentive to punish if all other firms punish that firm for not punishing in the first place. This argument leads to the conclusion that any collusive outcome can be maintained as long as all firms are better-off than the best they could achieve under maximum retaliation from other firms. Here it should be noted that as, by definition, a firm will be happy to choose its Nash strategy if all other firms do the same, the Nash equilibrium is a feasible punishment solution. Thus there will always be an effective deterrent if all firms are better-off under collusion than in the Nash equilibrium (Friedman 1971).

2. Thus far, the story has assumed that there are no information problems for the (potentially collusive) group of firms. Exogenous uncertainty faced by all firms is not a particular problem but when there are informational asymmetries between firms, the study of collusion is much richer. In fact, almost all the theoretical literature on collusion takes some informational asymmetry as a starting point and it is useful to survey some of this literature from the viewpoint of the informational asymmetry which is being postulated.

   It is convenient to distinguish between two forms of asymmetry – adverse selection where, for instance, some firms do not know the cost and demand conditions of other firms, and moral hazard where it is the behaviour of other firms which cannot be observed. In the former case, it is preferences that cannot be observed, in the latter case it is actions. Both forms of asymmetry can have important effects upon the structure of collusive arrangements that could be expected to emerge.

3. Taking the adverse selection case first, it is fairly reasonable to assume that a firm will have a better knowledge of the demand and cost conditions that it faces than other firms. Although firms may be attracted by the simplicity of adopting a collusive arrangement based upon solely common information, this solution ignores the efficiency gains that may be achieved from making the collusive outcome sensitive to the privately held information of firms. Clearly, the main problem that arises is that each individual firm must have the incentive to reveal this private information. Consider a simple model with just two firms, 1 and 2. Assume that the revenues they receive

when they produce outputs q_1 and q_2 are given by $R_1(q_1, q_2)$ and $R_2(q_1, q_2)$. Each firm has a constant marginal cost of production β_1 and β_2 and assume that this is private information, firm 1 knowing the true value of β_1, firm 2 knowing the true value of β_2. Assume, for simplicity, that β can take on only two values, β and $\overline{\beta}$, $\underline{\beta} < \overline{\beta}$. Collusion will result in the adoption of output levels for each firm and the levels may be sensitive to the private information β_1 and β_2 – $q_1(\beta_1, \beta_2)$ and $q_2(\beta_1, \beta_2)$. However, this can only be implemented if a firm does not pretend to be a high cost firm $(\overline{\beta})$ when it is low cost $\left(\underline{\beta}\right)$ and vice versa; for firm 1, profit maximization implies

$$R_1\left[q_1\left(\underline{\beta}, \beta_2\right), q_2\left(\underline{\beta}, \beta_2\right)\right] - \underline{\beta} q_1\left(\underline{\beta}, \beta_2\right) \geqq R_1\left[q_1(\overline{\beta}, \beta_2), q_2(\overline{\beta}, \beta_2)\right] - \underline{\beta} q_1(\overline{\beta}, \beta_2)$$

and

$$R_1\left[q_1(\overline{\beta}, \beta_2), q_2(\overline{\beta}, \beta_2)\right] - \overline{\beta} q_1(\overline{\beta}, \beta_2) \geqq R_1\left[q_1\left(\underline{\beta}, \beta_2\right), q_2\left(\underline{\beta}, \beta_2\right)\right] - \overline{\beta} q_1\left(\underline{\beta}, \beta_2\right)$$

This places restrictions on the class of solutions that can be implemented. Combining the inequalities gives

$$\left(\overline{\beta} - \underline{\beta}\right)\left[q_1\left(\underline{\beta}, \beta_2\right) - q_1(\overline{\beta}, \beta_2) \geqq 0\right.$$

which implies that the lower the marginal cost, the more a firm is allowed to produce. Given that the collusive solution will usually entail a restriction in output as compared with what a firm would like to choose (the other firm's output remaining constant), the firm must be provided with a disincentive from pretending to be a low-cost firm when it is high-cost and this will come from variations in q_2 – to provide the right incentives to firm 1, the output of firm 2 should be negatively correlated with the marginal cost of firm 1.

The foregoing demonstrates that the implementability requirement gives some structure to the collusive solution. But the exact outcome chosen will be the result of bargaining between the firms concerned. This bargaining process may involve the transfer of information prior to collusive agreements being reached (Roberts 1985).

Recognition of the adverse selection problem gives theoretical insight into the form of collusive practices that are discussed in the more applied literature. In general discussions a distinction is drawn between implicit and explicit collusion. However, in models without information problems, each firm is aware of the agreement that would be decided upon if it met with other firms and is aware how reneging firms would be dealt with. In this case, there is no need for firms to collude explicitly and the distinction between implicit and explicit collusion is not useful. But when adverse selection exists, it is clear that a rule which makes other firms' behaviour depend upon the private information of some firm will require information transmission between firms. The idea of implicit collusion can be rationalized as a situation where either no information is transmitted or, to take a less extreme case, where information is transmitted through aggregate market-wide indices, e.g. the equilibrium price in the industry.

The existence of adverse selection can also provide a theoretical rationale for mark-up pricing as a collusive outcome (Roberts 1983). When firms are selling in the same market, cost conditions facing firms are more likely to be the source of private information than demand conditions. While it may be impossible for other firms to observe the cost *function* of a firm, it may be possible to observe the level of costs at the output being produced. As this observation can be used as a proxy for the private information of the individual firm, a collusive agreement will involve the output and price levels of firms being dependent upon cost levels – this provides a rationale for why the firms' behaviour may be sensitive to average, rather than the conventional marginal, costs.

4. Over the last 20 years, most of the theoretical literature on collusion has considered

situations where the actions of firms fail to be perfectly observed by other firms – a situation of moral hazard. If the preferences of firms are common knowledge then the problem is not one of deciding upon the collusive solution but, instead, of policing that solution.

The simplest example of imperfect monitoring arises when there is a delay before the action of a firm is observed by others. If time units are set equal to the delay time then a firm will gain from reneging on a collusive agreement if

$$(1-\beta)\Pi^R + \beta\Pi^P > \Pi^C$$

where $\prod^C$ is the profit per unit time under the collusive agreement, $\prod^R$ is the maximum profit that the firm can achieve by reneging given that other firms keep to the collusive agreement $\prod^P$ is the profit the firm can achieve when it is being punished by the other firms and β is the discount factor for the firm. Obviously, $\Pi^R \geqq \Pi^C$ so that the longer the delay before other firms perceive reneging (the smaller the β), the more incentive a firm has to renege. As the degree of punishment that can be inflicted is restricted by the requirement that other firms have to punish, and this incentive itself is diminished when there is a delay in observing behaviour, the smallest possible $\prod^P$ will rise as the delay time increases so reinforcing the incentive to renege. For a detailed analysis of this problem, see Abreu (1986).

The other main form of imperfect monitoring that has been considered deals with the case where individual firm behaviour is never observable but market-wide aggregates can be observed by all firms. This was the situation which was studied by Stigler (1964) in his seminal paper on collusion and by many authors since (a recent analysis is to be found in the work of Porter 1983, and Green and Porter 1984). In the case studied by Stigler, firms observe the demand conditions for their own output and this gives an indication of the prices that other firms are charging. Green and Porter take the simple case of a homogeneous product being produced by similar firms. There is some uncertainty in demand so that a 'low' market price may be a result of this uncertainty or of 'cheating' on the collusive agreement by some firms. Green and Porter consider 'trigger-price' punishment strategies which take the form of the group moving to the Cournot equilibrium for a fixed time T if the market price drops below some level $\tilde{p}$. A feature of this informational set-up is that all firms suffer from this punishment. The trigger-price strategies are set so that cheating does not occur though, because of the uncertainty, a proportion of time is spent in the punishment regime. There is a direct trade-off between the gains from a collusive agreement that severely restricts output and the costs of punishment that will be suffered in the maintenance of this agreement. Notice that as there is no adverse selection, there are no requirements for the firms to meet together to decide upon collusive behaviour – it may be far-fetched but there is nothing to rule out a system of implicit collusion with trigger-price strategies. For this reason, these moral hazard models are often described as non-cooperative models of collusion.

5. The theory and practice of collusion are much discussed in texts on industrial organization. The foregoing has tried to make clear that the structure of information asymmetry in the market is crucial for understanding the operation of collusive agreements. With a particular informational set-up, the structure of the set of collusive agreements which will not entail reneging is now quite well understood. Despite much work, there is rather less understanding of the exact agreement that will be settled upon.

Colonialism

M. Abdel-Fadil

> Everywhere do I perceive a certain conspiracy of rich men seeking their own advantage under the name and pretext of the commonwealth. (Sir Thomas More)
> Modern colonialism, as a historical phenomenon of territorial expansion, is intimately entwined with the rise and expansion of the modern capitalist world system. So colonialism is entwined with the history, economics, politics and ruling ideas of the modern capitalist society. On the other hand, and to avoid any terminological confusions, the term *imperialism* should be reserved to designate the new nexus of financial and technological dependency relations and arrangements marking the new distinct stage of mature capitalism. (Magdoff 1970)
> During the modern colonial period (1870–1945) colonialism has emerged as a general description of the state of subjection – political, economic and intellectual – of a non-European society as a result of the process of colonial organization. (Fieldhouse 1981)

The Age of Colonialism: Historical Background

The age of colonialism began about 1500, following the European discoveries of a sea route around Africa's southern coast (1488) and of America (1492). Colonialism thus expanded by conquest and settlement after a period of extensive exploration. The improvement in navigational instruments helped a great deal to make substantial progress in the discovery of new geographical territories.

Portugal emerged as the leading nation in such process of overseas expansion. 'The search for wealth in the form of gold, ivory, spices and slaves spurred the Portuguese and may have been the strongest motivating force behind the colonization drive of the Portuguese during the 16th century' (*Encyclopaedia Britannica* 1768, Vol. 4, p. 881).

The old colonial period, which lasted nearly three centuries, following the major Portuguese and Spanish conquests, may be viewed largely as a commercial venture. The Spaniards and the Portuguese resorted to their warships, gunnery and seamanship to keep the main trade routes open. The Spanish sovereigns created in 1504 the House of Trade (Casa de Contracion) to regulate commerce between Spain and the New World. Their purpose was to establish state monopoly over overseas trade, and thus pour the maximum amount of bullion into the royal treasury (*Britannica* 1768, Vol. 5, pp. 882–3).

The old colonial system was disrupted in the 18th century as new contradictions developed due to the rapid advance of the Industrial Revolution in England, and by the progressive control England was able to exercise over world shipping. Such new developments led to a policy of opening the American ports to international trade, a policy at variance with the type of colonial relations prevailing between Spain, Portugal and their colonies. These relations were organized exclusively around the exploitation of precious metals (Furtado 1970, p. 20).

The century between the 1820s and the outbreak of the World War I saw the establishment of the modern colonial order. For during that period European countries had achieved complete dominance over world trade, finance and shipping. On the other hand, the political and military authority of the European conquerors was backed by superiority in technology, applied science, organization and information systems (Bagchi 1982).

Between the late 1870s and World War I (1914–18), the colonial powers added to their possessions an average of about 240,000 square miles (620,000 sq.km.) a year, while during the first 75 years of the 19th century the rate of increase in new territories acquired by colonial powers averaged about 83,000 square miles (215,000 sq.km.) a year. By the year 1914, the colonies extended over approximately 85 per cent of the surface of the globe.

Against this historical background, John Hicks establishes a useful distinction between two types of colony: colonies of settlement and trading-post colonies (Hicks 1969, p. 51). A third type of colony was identified as 'the plantation colonies'. In such case, the colony which started as a colony of settlement was gradually transformed into a trading colony (ibid., p. 53).

The Colonization Debate

While there is a strong connection between mercantile expansion and colonization, it would be a mistake to emphasize the crude economic interpretation of colonialism by narrowing down colonialism to the process of control of supplies of raw materials, mineral resources and markets in underdeveloped and precapitalist regions. In fact, such a narrow economistic approach eliminates a vital aspect of colonialism relating to political activity and the drive for dominance over the daily lives of the people of the colonized regions (e.g. French colonialism).

Nonetheless, colonialism must be viewed, dialectically, as a complex phenomenon of capitalist expansion, operating in terms of time and space. To illustrate this point, S.H. Frankel described such a process as a *disintegrating* but also a *formative* process, a unique process in the history of mankind (Frankel 1953). Some other writers justified colonial rule on the ground that 'Colonialism was a necessary instrument of "modernization" which would help other peoples to do what they could not have done, or have done as well, by themselves' (Fieldhouse 1981, p. 43). At the other end of the spectrum, radical theorists, notable among them Walter Rodney, claim that under colonialism 'the only things that developed were dependency and underdevelopment' (Rodney 1972, p. 256).

One of the most articulate arguments put forward in defence of the colonial rule in underdeveloped areas is that of Lord Bauer, who contends that:

> The colonial governments established law and order, safeguarded private property and contractual relations, organized basic transport and health services, and introduced some modern financial and legal institutions. This environment also promoted the establishment or extension of external contracts, which in turn encouraged the inflow of external resources, notably administrative, commercial and technical skills as well as capital.
>
> These contacts also acquainted the population with new wants, crops, commodities and methods of cultivation and opened new sources of supply of a wide range of commodities. These changes engendered a new outlook on material advance and on the means of securing it: for good or evil these contacts promoted the erosion of the traditional values, objectives, attitudes and customs obstructing material advance. (Bauer 1976, p. 149)

This argument only confirms the deep-seated Western biased view, claiming that material progress and advance can only be achieved by eroding the traditional values, customs and production structures of pre-capitalist and primitive societies. Rosa Luxemburg (1913) would see in Lord Bauer's view an eloquent proof of her radical contentions about colonialism and territorial expansion, by the emerging capitalist nations.

But what is at issue is not the possibility or not of achieving material progress or advancement, but the terms on which these transformations in the material and socioeconomic structures were operated. From our viewpoint, what needs to be stressed is the loss of sovereignty which the process of European colonization entailed for

practically all colonized peoples. In Africa, for instance, European colonizers often crushed, suppressed or amalgamated states at will. In most instances, the direct colonial rule was designed to direct and reorder the day-to-day lives of the African peoples (Ajayi 1969).

Seen in a radically different light, thinkers such as Albert Memmi, Jean-Paul Sartre and Franz Fanon placed greater emphasis on the ideological implications and the sociopsychological consequences of the process of colonization. According to Fanon, colonialism tended not only to deprive a society of its freedom and its wealth, but of its very character, leaving its people intellectually and morally disoriented (Fanon, English edition, 1966).

Patterns of Colonial Trade

Historians tend to agree that the conquest of colonies was designed to the economic advantage of the European conquerors. Some historians (e.g. E.J. Hobsbawm) would go as far as to claim that the Industrial Revolution in England would not have been accomplished without the conquest and penetration of 'underdeveloped' markets overseas (Hobsbawm 1968, p. 54).

In fact, the primary aim of all European states was to use commercial regulations to maximize their share of colonial trade in both directions and the profits they made from it. The English Navigation Acts, dating from the 1650s, may be taken as typical in this respect. According to these Acts, all colonial trade must be carried in British-owned and registered ships. All goods imported to the colonies must either be the product of Britain or be transhipped and pay duty there. Any colonial exports so 'enumerated' must be carried direct to a British port in the first instance (Deane 1965, p. 204). The aim of such rules and regulations was to give British shipowners, merchants and manufacturers an assured benefit from colonial commerce and to enable the government to tax colonial trade. This clearly indicates the close association between the process of colonization and the rise of various foreign-trade monopolies held by the charted colonial companies.

Hence, against all claims of the 'Free-Trade' school, the British cotton industry did not rely on its competitive superiority, but relied heavily on the monopolistic practices embodied in colonial trade-regulations, and enforced by the British commercial and naval supremacy (Hobsbawm 1968, p. 58). On the other hand, the terms of trade between the colonized areas and the metropolitan countries had a tendency to deteriorate steadily over time, so that the primary producers in colonized areas tended to obtain proportionally less with their labour than they could have done had they concentrated on producing food or other subsistence crops for their own use or for the home market (Fieldhouse 1981, p. 78). This may be characterized, in modern terminology, as 'unequal exchange', which emphasizes once again the exploitative nature of colonial trade.

The Internal Control of the Colonial Economy

The key to understanding colonialism as a historical phenomenon lies in analysing the mechanism of the internal control of the colonial economy. In this connection, one has to answer two fundamental questions. Why did the Western countries spend so much energy, blood and money in seeking to procure colonial possessions? What are the direct and indirect economic benefits of colonialism?

In the colonial economy, top priority was given to infrastructure investment: railways, harbours, telegraphs, rivers and roads, since it was believed that these constitute the prerequisites of a modern economy, making it possible to link internal areas of production to the world commodity markets. In the agricultural sector, it is still an open question whether plantations, owned and run by foreigners, made any significant contribution to the development of the colonial economy. On the positive side, they served as the main vehicle of introducing new crops, attracting foreign capital, expanding the base of the cash economy and the wage-labour force, and increasing agricultural productivity. On the negative side, the crops of such plantations were subject to severe

fluctuations on the international commodity markets, thus subjecting the colonial economy to severe cyclical fluctuations.

In matters of industrialization, many observers tend to agree that the colonial powers did not positively encourage industrialization in their dependencies, and in many instances their basic policies led to some sort of de-industrialization (Bagchi 1982). In this respect, many writers invoke the record of colonization in India from the days of the East Indian Company. For the balance of historical evidence points to the fact that up to the 18th century the economic conditions of India were relatively advanced, and Indian methods of industrial production were comparable with those prevailing in any other advanced part of the world (Baran 1957, p. 144).

On the other hand, Bill Warren has offered a neo-Marxist view, opposed to the 'Dependency School', regarding the effects of colonialism on the development of productive forces in Third World countries. His main argument runs as follows: 'Direct Colonialism, far from having retarded or distorted indigenous capitalist development that might otherwise have occurred, acted as a powerful engine of progressive social change' (Warren 1980).

Nonetheless, Warren's positive account of the effects of colonialism on the process of capitalist development in Third World countries tends to be rather unitary in spirit. For the pattern of resource allocation in colonial territories had been shaped and administered largely by foreign investors, bankers and merchants. According to Paul Baran, the principal impact of foreign enterprise on the development of the underdeveloped and precapitalist regions 'lies in hardening and strengthening the sway of merchant capitalism, in slowing down and indeed preventing its transformation into industrial capitalism' (Baran 1957, p. 205).

This very nature of the process of capitalist development under colonialism led some authors, such as H. Alavi, to offer the highly controversial concept of the 'colonial mode of production'. This concept was offered as a theoretical construction designed to allow for a variety of relations other than those which characterize the 'capitalist mode of production', as experienced in the advanced capitalist economies of the 'centre' (Alavi 1975). In this respect, Alavi and company established the distinctive features of the 'colonial mode of production' on the basis of empirical investigation of the circuits of capital and forms of labour recruitment of what comes to be called by other authors (i.e. Samir Amin and Gunder Frank) 'colonial capitalism' or 'peripheral capitalism' (Booth 1985, p. 169). Yet the difficulties and confusions surrounding the concept of a 'colonial mode of production', as a distinct mode of production, remain formidable.

Decolonization and Neocolonialism: Two Sides of the Same Coin

The drive towards decolonization in the post-World War II period was a response to the economic crisis of an ageing colonial system. This colonial system was found to involve considerable, and sometimes unacceptable, financial costs to the metropolis. Moreover, colonialism had become increasingly discredited among the people of the colonizing nations themselves, just as the emotional strains of suppressing nationalistic movements in colonized regions had become largely intolerable for public opinion (Fieldhouse 1981, p. 24).

Nonetheless, the process of decolonization proved to be a nominal process in the sense that the formal end of colonial rule did not necessarily result in genuine economic independence for the former colonies. There is now a community of view among left-wing economists and writers that decolonization took place when and because foreign monopoly capital felt confident that the colonial society and economy had been so restructured that their interests could be preserved without direct political control. In other words, colonialism had been merely transmitted into perpetual neocolonialism (Baran 1957).

The term 'neocolonialism', which has gained wide acceptance since the mid-1950s, is meant to designate a state of affairs characterized by a structure of dependency relationships whereby the former colonial territories are kept in their

subordinate place within the imperialist system. This is maintained and sustained by means of chronic and structural balance of payments difficulties, arising from the trade, aid and investment relationships with their former or new metropolitan countries (Warren 1973, p. 35).

In sum colonialism may be seen in a historical perspective as one decisive and dramatic stage in the evolution of international economic relationships. The establishment of colonial rule constituted an arbitrary break in the normal course of history, splitting up regions and creating new artificial entities, transplanting new alien values and institutions into colonized societies. One may finally wonder whether it would not have been better for the people of the colonized regions to remain autonomous until certain indigenous forces could gain momentum and generate new conditions for socioeconomic development and material progress.

Colonies

Donald Winch

The economic advantages and disadvantages of colonies, the best means of establishing them and ensuring their development, and the principles that should govern trade and other relations with the mother country, have persistently served as fertile topics for policy and theoretical debate in the history of political economy. The treatment given here will be confined to the British debate on colonies from the late eighteenth to the first decades of the twentieth century.

The British empire was composed of colonies and ex-colonies which had differing histories of acquisition and varying political and economic relationships with the mother country. It follows that the problems which they posed were equally diverse, as illustrated by the differences between the economies of the British West Indies before and after slavery was abolished, the question of public land disposal and emigration to Canada, Australia and New Zealand, and the tasks of administering an Indian sub-continent with a largely peasant population living close to minimum subsistence levels. To this list can be added the problems of integrating Scotland and Ireland

into the English economy and polity after the respective Acts of Union in 1707 and 1808, where 'colonial' issues – in a technical rather than emotive sense – were often at stake, even if the term was not used to describe them. Indeed, Ireland and India as subsistence farming economies posed similar problems to British administrators, despite major differences in their cultural backgrounds and political status within the empire. For that matter, even the United States after independence could for some purposes be treated as having a 'colonial' relationship with Britain, largely because it remained a major outlet for British capital and labour.

The sheer magnitude of the problems of empire and their changing nature over more than two centuries would guarantee that they bulked large in the minds of British economists. A few strategic examples will show that there has always been a fairly intimate relationship between economics, economists, and empire. Adam Smith may well have advised the imposition of the Townshend duties on North America in 1763, and he was certainly involved in advising the British government on the consequences of American breakaway when these earlier attempts to exert fiscal control led to successful revolt. Malthus held the first Chair of political economy in Britain at an educational institution at Haileybury established to train the servants of the East Indian Company; and James and John Stuart Mill together devoted nearly 40 years to the service of the Company. The younger Mill was also a consistent supporter of schemes involving the 'systematic colonization' of Australia and New Zealand, as well as taking a major interest, along with most of his classical predecessors and successors, in the problems of the Irish economy. The controversy over imperial preference at the turn of the twentieth century underlined the gulf that existed between historical or institutionalist economists and their more orthodox opponents, led Alfred Marshall, who believed that the increasing challenge to Britain's industrial hegemony did not justify abandonment of deductive methods of economic reasoning or those cosmopolitan free trade principles which had spurred British prosperity earlier. Finally, of course, there is Keynes, whose first employment as a civil servant was within the India Office, and whose first major economic work was a treatise on *Indian Currency and Finance* (1913) – a work which attempted to do for its day what Sir James Steuart had done when he wrote *The Principles of Money Applied to the Present State of the Coin of Bengal* in 1772.

A treatment based on chronology and recurring themes seems the best way of dealing with the diversity of Colonies as a topic of economic interest, though it should be remembered that colonies and empire was never treated solely as *economic* problems, even after the inauguration, largely under Marshall's auspices, of a measure of professional distance in these matters.

The initial and longest period in the history of colonial policy began in England during Elizabethan times and effectively ended with the dismantling of what had become known as the 'old colonial system' in the 1820s. This system was loosely based on the amorphous doctrines which Adam Smith subjected to attack in the *Wealth of Nations* as a central part of his condemnation of the 'mercantile system' (later known as Mercantilism). During this mercantile period colonies generated a large body of literature which reflected the overwhelming concern with national power and economic self-sufficiency as the prime objectives of state intervention. Thus colonies not only served direct strategic purposes as naval or military bases, they were also treated as sources of precious metals, and of strategic and other raw materials necessary to Britain's early manufacturing industries – of particular value when carried in British ships and bought through monopolistic arrangements at prices lower than could be obtained on the world market. Colonies were variously regarded as protected export markets, outlets for surplus population, and sources of tribute, in addition to serving occasionally as prison settlements. Although the development of free trade doctrines, together with associated monetary ideas on specie-flow mechanisms, eventually succeeded in undermining many of the arguments in favour of colonial possessions and regulations, economic nationalism and neo-mercantilistic ideas and policies have always exerted a powerful attraction, especially in countries that were

industrial later-comers or anxious to overcome the problems of underdevelopment by means of import-substitution and/or export promotion.

During the eighteenth century, the established wisdom on the subject of colonies came under question largely because the supposed benefits of trade controls to the mother country were connected with the growing cost to Britain of defending and governing her North American colonies. Among the earliest critics of the colonial system from this point of view was Josiah Tucker, who argued that existing benefits in the form of export markets and imported goods would accrue to Britain under free trade, and without the attendant military and economic burdens of empire. Provoked by David Hume's essays on commerce and money, Tucker also engaged in an important dispute with Hume on the question of whether trade relations between rich and poor countries could be considered as equalizing or not, and if so, by what process – perhaps through rising labour costs and prices in the richer trading partner, or through some other mechanisms of stimulus and emulation in the poorer country. The dispute was of relevance to free-trade relations between England and Scotland after Union, and of potential relevance to Britain's relations with Ireland and other 'colonies', whether acknowledged as such or not. Indeed the Hume–Tucker debate was an early example of recognition of the essential similarities between international and interregional trade in a world in which currencies were linked through the gold standard. It also concerned relative rates of growth and the respective merits of agriculture and manufacturing as the basis for a nation's wealth and prospects for economic development. Would those who had the advantages of an early start acquire world dominion and monopoly; and hence would poorer and later starters in the race be forced to employ protective measures to establish and maintain their infant industries? If noticed, the debate would have foreshadowed later issues raised by Friedrich List and Henry Carey with Germany and the United States in mind, as well as other questions such as 'free trade imperialism', the 'permanence' of the dollar problem after World War II, and the debate on 'dependency' and the development of post-colonial underdevelopment in the 1960s and 1970s.

Smith's extensive treatment of colonies in the *Wealth of Nations* (especially Book IV, chapter 7) became the *locus classicus* of the anti-mercantile position, where much of his discussion was interwoven with an account of the founding of the European colonies which brought matters up to the present, namely to the issues underlying Britain's dispute with its American colonies. Whereas Edmund Burke had advocated the relaxation of trade controls and taxation as a means of preserving the political status quo, Smith maintained that Britain's pretensions to empire would remain those of a shortsighted shopkeeper unless some system could be found whereby the debts and current burdens of empire could be shared by the colonies themselves; and he emphasized the point by closing the *Wealth of Nations* with a warning about the potential long-term effects on British growth prospects of existing arrangements. Hence the elaborate scheme he advanced for an imperial (Anglo-American) free trade zone, with provision for complete fiscal harmonization and legislative union. However, since he regarded this proposal as utopian, its purpose was chiefly to underline the precise conditions under which the burdens of empire could be made acceptable. Much the same result could be achieved through free trade and a treaty of friendship, without provision for imperial government.

Smith's close dissection of the various gains and losses involved in maintaining the monopoly of colonial trade employed a quasi-mercantilist idea of 'vent for surplus', as well as other arguments about the effects on profits of colonial markets which could not be squared with later Ricardian orthodoxy on the doctrine of comparative costs, capital accumulation, Say's Law, and the permanent causes of declining profits. Ricardo also pointed out circumstances in which it was possible for the mother country to so regulate the trade of a colony as to make it less beneficial to the colony, and more advantageous to the mother country than free trade – an early version of the terms-of-trade argument for tariffs (not meant for use) which in the hands of Robert Torrens was to

blossom into a case for an imperial *Zollverein* a few years later.

With the support of most political economists, however, the system of colonial preferences was gradually and unilaterally dismantled, beginning with the efforts of Huskisson and Robinson in the 1820s. The views of special interest groups, especially those connected with shipping and the West Indies, which Smith had expected to prevail, were outflanked by an uncertain combination of intellectual argument, political opportunism, and a general realization that Britain's industrial dominance meant that mutual restrictions merely restricted the dominant partner without conferring equivalent benefit. A similar combination involving humanitarian arguments prevailed on the related matter of West Indian slavery and the slave trade. The keystone of Britain's rather isolated status as a free-trading nation was installed with the abolition of the Corn Laws in 1846, a policy that had considerable long-term significance for British agriculture and Britain's relationship to colonial suppliers of food and raw materials, including the United States as well as colonies of recent settlement.

During the 1830s and 1840s public debate on colonies and colonization was dominated by the activities of Edward Gibbon Wakefield and the colonial reformers, a group of radicals dedicated to the revival of 'the lost art of colonization'. Their programme entailed the creation of self-governing colonies as outlets for Britain's surplus capital and labour, avoiding the evils of simply 'shovelling out paupers', abolishing penal settlements, and creating 'civilized' communities enjoying the benefits of free trade and high rates of growth. Wakefield's diagnosis of the simultaneous existence in Britain of surplus capital and labour, and the consequent need for new fields of employment abroad, was developed in opposition to Ricardian orthodoxy on the wage fund and Say's Law. His ideas on the optimal economic development of colonies also conflicted with Smith's view that countries of European settlement enjoying an abundance of land were likely to make rapid economic progress. The key to high rates of growth lay in achieving the correct balance between capital, labour, and their 'field of employment' by restricting access to land. This could be achieved by setting a price on land sufficient to delay dispersal of the wage-labour force, and by using the proceeds of land sale for the purpose of bringing in new immigrants. This policy meant that public land disposal and immigration had to remain an imperial rather than purely local concern, thereby creating scope for conflict when colonies achieved self-government. The Wakefield policy came to be seen as a symbol of imperial oppression, an attempt to place colonial development within a straitjacket designed with European conditions in mind. It also entailed loss of freedom in disposing of one of the main sources of revenue available to self-governing colonies. The colonial reformers' hopes of establishing an empire in which free trade ruled were another casualty of self-government when it led to tariffs being raised by Canada and Australia against British and other goods.

What now seems remarkable is the rapidity and extent of influence exerted over British colonial policy by Wakefield's untried theories, though modern development economics may yield comparable examples. He was also highly successful in convincing a number of leading political economists, not least John Stuart Mill, that his ideas deserved to form the basis for future policy. Mill gave prominence to Wakefield's ideas in his *Principles of Political Economy* and other writings by consistently championing 'systematic colonization' as a solution to Britain's population difficulties; and by treating its application to new countries as a valid exception to the general principle of *laissez faire*, namely as a case where the self-interest principle acting under competitive conditions would lead to a sub-optimal result as far as the community was concerned. As part of his general modification of Ricardo's assumptions concerning capital scarcity and the distant prospect of the stationary state, Mill also endorsed the conclusions of Wakefield's heterodox diagnosis of Britain's economic condition, while denying that it was in conflict with Say's Law and other received Ricardian doctrines. By acknowledging the importance to Britain of the export of capital and labour to colonies, Mill not only removed an obstacle to support for colonization, and hence to

the extension of empire, he opened up a major exception to the comparative cost doctrine as an interpretation of Britain's trading pattern: the trade with colonies now became akin to interregional trade. It should also be noted that Mill, confirming the tradition that the only new economic arguments for protection have been advanced by those who favour free trade as a general rule, gave a cautious endorsement to the infant industry case for tariffs.

India was never a colony in the same sense that North America, Australia and New Zealand were British colonies. Attempts were often made to prevent or discourage European colonization before 1830, and until 1858 India was governed by the East India Company acting on a renewable Charter granted by Parliament. The Company had been subjected to closer government control in the late eighteenth century, deprived of its commercial monopoly in 1813, and finally ceased trading altogether in 1833 when it lost its exclusive privileges over the China trade. These developments represented another victory for the forces of free trade, and they blunted the force of Smith's criticisms both of monopolies and government by trading companies. As we have seen in the case of Tucker, free trade ideas could be associated with a case for complete 'emancipation' (Bentham's term) of all colonies. (It was an association of free trade with anti-imperialism which was an invitation for revisionist historians to counter with a neat, perhaps over-neat, inversion by drawing attention to 'free-trade imperialism'.) But there were fewer spokesman for such ideas in relation to India, where other notions of European superiority and responsibility held sway, along with more mundane considerations connected with the retention of investment, employment, and trading opportunities.

India had provided Smith with a prime example of a stationary or declining state, something that could either be attributed to the deficiencies of its system of government and taxation, or to those of a backward people whose culture constituted a barrier to economic progress, though usually to a combination of both. In addition, criticism from divergent quarters was made of the flow of tribute leaving India for Britain, much of it financed by exports of textiles that competed with domestic industry: Indian commerce came in conflict with British manufacturing interests, which were placated by the imposition of duties on Indian imports. But with the reorganization of the Company, especially after 1813, came new priorities and opportunities for those with ambitions to bring the light of post-Smithian, and more especially, Ricardian political economy to bear on the problems of Indian administration. Such a task proved highly congenial to James Mill, a critic of the Company's monopoly powers who was appointed by the Company in 1819 and rose to the rank of Chief Examiner in charge of political, judicial, and fiscal correspondence with India. It was largely through Mill's efforts, later endorsed by his son, John Stuart Mill, that the Ricardian rent doctrine came to play such a large part in the conduct of Indian affairs. It provided the basis for the *ryotwari* system of land tenure, whereby the state became the sole landlord and met its revenue needs by levying *ryots* or peasant-farmers according to Ricardian principles of pure rent. By confining the state's exactions to rent it was thought that the peasant farmer would enjoy normal profits and wages, and the state would eliminate an intermediary or landowning class of *zemindars* or rent-receivers. The system embodied action according to a clear analytical proposition, antagonism to rent as a form of private income, and a view of the prospects for Indian economic development that treated the peasant proprietor as a capitalistic entrepreneur, freed from the arbitrary exactions of landowners and responding to market incentives – which is not to say that the application of these Western economic ideas to Indian conditions was any more successful than the *zemindari* alternative.

In Ireland, where similar economic conditions of a growing population dependent on a backward agriculture obtained, it proved more difficult to bypass the Irish landowner in order to grant the kind of security of tenure to the peasant proprietor that either existed or was the aim of administrators in India. Indeed, the initial view of economists during the early classical period was unsympathetic to the preservation of peasant

proprietorship in Ireland. The favoured solution was consolidation of tenant-holdings as a preliminary to the creation of a capitalistic form of farming employing agricultural wage-labour along English lines, together with emigration or absorption of the displaced population into alternative employment. Before, but especially after the Great Famine of 1846, emigration, largely unplanned, was the only part of this programme that operated. Under the leadership of John Stuart Mill, J.E. Cairnes, W.T. Thornton and Henry Fawcett, the earlier diagnoses and remedies were entirely recast; a more positive evaluation of the possibilities of transforming cottier tenants into peasant proprietors enjoying security of tenure was registered and advocated as the basis for a solution to Irish problems. It was a position that ran directly counter to English property ideas and involved recognition of the role of custom as opposed to contract in designing policies and institutions for societies that did not conform to the English model.

Mill's deployment of a more relativist approach in policy matters was later to be seen as a welcome, though incomplete concession to a succeeding generation of more full-blooded historical and institutionalist critics of deductive economic theory, with its built-in bias in favour of rational economic man – a creature originally invoked by Mill to underline the contrast with societies where custom prevailed. Such critics were more numerous and vocal after 1870, and the resulting split within the economists' ranks coincided with a campaign for 'fair trade' in the 1880s which blossomed into Joseph Chamberlain's scheme of tariff reform along imperial preference lines – an unwitting return to Torrens's imperial *Zollverein*. The historical economists, led by William Cunningham and W.J. Ashley, had already followed Schmoller and other German exemplars in according a more positive valuation to Mercantilism, and this presaged their endorsement of tariff reform as an imperial remedy for Britain's declining competitiveness. At the price of forsaking free trade, Britain could offer preferential treatment to imperial food and raw materials in return for similar preferences in the markets of her ex-colonies. There had already been a revival of interest in imperial federation, which could be portrayed, as it was by John Shield Nicholson, as a return to Adam Smith's project of empire. While much of this belongs to the larger subject of imperialism, a term which has always carried more nationalistic and ideological oxygen, the episode is chiefly of interest here because it was the occasion for a major challenge to economic orthodoxy. Chamberlain's use of arguments supplied by such economists as W.A.S. Hewins brought Marshall into the professional and political fray with his *Memorandum on Fiscal Policy of International Trade* (1908), a work which is still perhaps the best brief restatement of the free trade position based on a combination of neoclassical trade theory and an empirical analysis of contemporary conditions in the colonies as well as in Britain.

Marshall's pupil, John Maynard Keynes, was not as impressed by his master's memorandum when he looked back on it from the vantage point of 1930. At this time Keynes had decided that a revenue tariff was an acceptable policy for Britain to follow, though not for reasons connected with imperial solidarity. Thus when Neville Chamberlain achieved his father's goal with the passage of the Import Duties Act in 1932, followed by the Ottawa Agreements which began the period of imperial preference, Keynes withdrew his support for tariffs. Nevertheless, any account of the revolution associated with Keynes's name is likely to be incomplete without some reference to the ending of free trade in Britain, coupled as it was with the inauguration of an era in which external monetary constraints on British domestic policy were weakened. Of more long-term significance to imperial policy in the interwar period, however, was the revival of interest in state-assisted settlement in the white dominions and the new emphasis on colonial development, with Africa as well as India now assuming a larger role in official, if not professional, economic thinking. At this point colonies and colonial policy become

something else, the beginnings of modern development economics.

Colquhoun, Patrick (1745–1820)

D. P. O'Brien

Keywords
Colquhoun, Patrick; Education; Unproductive labour

JEL Classifications
B31

Colquhoun was born in Dundee. A successful early career in business led to the position of Lord Provost of Glasgow in 1782 and 1783. In 1789 Colquhoun moved to London and became active as a magistrate. He worked on the provision of poor relief and put forward plans for the reform of London's police. He died in London in 1820.

Colquhoun's interest in poor relief led to his *New and Appropriate System of Education for the Labouring People* (1806), a pamphlet based on his own experience of running a school in Westminster. Like Thomas Chalmers later, he argued for the necessity of education to raise the standards and aspirations of the poor, though primarily in order to curb vice rather than population. This, he believed, was the most cost-effective way of tackling poverty. His *Wealth, Power and Resources of the British Empire* (1814), his last important work, is the one for which he is best known. This contained detailed figures on incomes and occupations and the relative importance of agriculture and manufacturing in Great Britain and Ireland. He also included a history of the public revenue, and descriptive material on the colonies.

The work was not very securely based; McCulloch, who had first-hand experience of trying to construct large-scale statistical data for his *Commercial Dictionary*, was severely critical of it in the *Edinburgh Review* and in *Brande s Dictionary.* But it was followed by later writers and Colquhoun's estimate that unproductive labour, one fifth of the total, received one third of output was widely quoted.

Colson, Léon Clément (1853–1939)

R. F. Hébert

French engineer, economist and statistician, Colson was born at Versailles on 13 November 1853, and died at Paris on 24 March 1939. Trained in mathematics as an engineer at the Ecole Polytechnique and the Ecole des Ponts et Chaussées, Colson extended his interests to statistics and economics, eventually teaching the latter at both his alma maters and at the Ecole des Hautes Etudes Commerciales and the Ecole des Sciences Politiques. Despite a lifelong career in the French Ministry of Public Works, he found time to produce several notable works, including his monumental *Cours d'économie politique*.

Colson received high marks for the technical competence of his theoretical exposition. According to Antonelli, his *Cours* rendered the doctrines of the French Liberal School 'scientific'. Divisia hailed it as the best work on pure theory since Walras. Colson particularly demonstrated his competence in the field of production by erecting a theory of full employment on the idea of capital–labour substitution and the equalization of factor returns at the margin. He followed the Austrian theory of value, but at the same time showed more sympathy to Walras than his contemporaries did. His work also had a certain affinity with Marshall's in that it integrated mathematics and geometry into the exposition of economic theory. As with Cheysson, Colson's economic views were affected by his statistical studies as much as the latter were affected by the former. Despite exceptional difficulties, he was one of the first to attempt an estimate of French national income in the early years after World War I.

Colson was elected to the Institut International de Statistique in 1906, to the Academie des Sciences Morales et Politiques in 1910 (replacing Cheysson), and to the Conseil Supérieure de Statistique in 1912. He belonged to the French Legion of Honour and the Société d'Economie Politique, of which he was president from 1929 to 1933. He became an honorary fellow of the Royal Statistical Society (London) and was elected an original fellow of the Econometric Society, founded in 1931. His most imposing legacy, however, was the generation of 20th-century French economists and engineers he trained at the *grandes écoles* during the interwar period.

Colwell, Stephen (1800–1871)

Henry W. Spiegel

Stephen Colwell, American protectionist, was born in Virginia (now West Virginia). After practising law, he eventually became a successful industrialist and entrepreneur in Philadelphia, where he was a leading citizen and philanthropist. He was a friend of Henry Carey's and shared many of Carey's views, especially his ardent protectionism. Colwell's appeal for high tariffs on iron manufactures and other goods resounded in many publications. Some of these were addressed to the Presbyterian clergy and he drew on religion to fortify his economic views. Colwell buttressed his appeal by making it part of a wider view of the world that may be characterized as elitist and supportive of high wages but also of inequalities of wealth and status. These were to be offset by a stewardship of wealth, that called for private charity rather than public relief for the poor, which Colwell opposed. High wages and private charity thus became complements of high tariffs.

Colwell's arguments ran counter to the teachings of the classical economists, whom he criticized on grounds that were similar to the criticisms made by the exponents of German historical economics and economic romanticism. Colwell was impressed by the protectionist views of Frederick List and found a translator for the original German of the latter's *National System of Political Economy*, to which he himself wrote an introduction.

Colwell is also remembered as the author of *The Ways and Means of Payment*: *A Full Analysis of the Credit System with its Various Modes of Adjustment* (1859), a massive volume that treats of the financial controversies of the time. In this work Colwell supported a private national bank, inconvertible paper money, the real-bills doctrine, the demonetization of gold, and a national clearing system, all amidst an economy of high prices. He denied the validity of the quantity theory of money and advised against a 100% reserve plan. He wrote the book from a point of view that considered money the handmaiden of commerce.

Combination

John Saville

'Combination' is a term used for a variety of forms of organization. An obsolescent usage relates to business firms which have come together in some kind of merger and today are usually referred to as monopoly, cartel, industrial combination or multinational. In Britain during the 18th century and for most of the 19thcentury combination was understood to mean associations of working men whose purposes were the raising of wages or the alteration of working conditions. The term 'trade union' did not come into common use until after 1830 and only in the second half of the century did it supplant 'combination'.

Combined labour action in the 18th century was widespread although by no means was it all directed by or channelled through formal organizations. The Webbs (1894, ch. 1) were in error in insisting that only those associations that were formally constituted and in continuous existence should properly be counted among the early trade unions. In the 18th century, especially, it was the collective presence of workers that was the crucial determinant of industrial response. Formal organization was not a necessary condition of industrial militancy, and 'collective bargaining by riot' is a well-documented phenomenon (Hobsbawm 1964, ch. 2). In 1718 and 1724 West of England clothiers complained to Parliament that weavers had 'threatened to pull down their houses and burn their work unless they would agree to their terms'. A study of Lancashire textile workers (Turner 1962) emphasized that the essence of 18th-century unionism was the persistence of collective pressures which in given circumstances encouraged collective action. Associations among the Lancashire textile workers developed informally out of the occupational life-style within the community. A settled group would encourage habits of association and common action, and skill was always a consolidating factor, but there was also much activity among the unskilled and migrant groups.

An incomplete listing of recorded industrial disputes gives a total of 383 for the whole of Britain between 1717 and 1800 (Dobson 1980, ch. 1). Most of these were in England, and of the English figure of 333 disputes just over a third (120) occurred in London, the main centre of the artisan trades in the 18th century. The occupational breakdown for the whole country shows 64 incidents from among the textile workers, mostly in the wool industry; only seamen and ships-carpenters (each with 37) and tailors (with 22) exceed a total of twenty. Those between ten and twenty include coalminers, workers in the shipbuilding industries, textile workers other than those in wool or silk, shoemakers, and most trades in building. The range of additional trades for which some disputes were listed is considerable, and hardly any occupation except the service industries was free from industrial conflict (Rule 1981, ch. 6).

The London journeymen tailors were the most effective combination in Britain during the 18th century. Their organization seems to have been established around 1700 as the result of the coming together of five 'box' clubs: box clubs being a version of the friendly society. In order to function effectively the clubs were associations in continuous existence, and their rules and regulations later provided the basis for the discipline of a trade union. The meeting places of the box clubs were public houses recognized by the trade and known as the 'house of call'. The box club and the house of call were the type of organization common to all the trades that succeeded in establishing more or less continuous associations. The tailors' combination first came into prominence as the result of a petition presented to the House of Commons in 1721, which asserted that 15,000 London journeymen had entered into a combination and engaged upon a strike. The report of a House of Commons committee was followed by an Act (7 Geo 1, c. 13) which fixed wages by the day for summer and winter, and which also prohibited combinations. While the Act was going through Parliament the journeymen briefed counsel, at a reported cost of £700.

Legislation against combinations in specified trades was common during the next hundred years; examples affect the wool trade, (12 Geo, I, c. 34), hatters (22 Geo II, c. 27), silk weavers (17 Geo III, c. 55), and the paper trade (36 Geo III, c. 111). At the end of the century, in 1799, there was passed a general Act (to be repealed and replaced the next year by 40 Geo III, c. 60) which made illegal all combinations whose purpose was obtaining an advance in wages or the lessening in the number of hours worked; and for the next quarter of a century the Combination Laws were in force, although in respect of certain trades they were not always rigorously applied (Webb and Webb 1894, ch. 2). In 1824 all previous statutes in respect of combinations were repealed but this Act was in turn repealed and replaced the following year by 6 Geo IV, c. 129, which permitted combinations

on strictly defined terms and listed punishments for the use or the threatened use of intimidation, molestation or violence in the pursuit of the declared objects of the industrial action.

The ending of the complete legal prohibition of combinations was largely due to a growing appreciation of the requirements of a labour market in the period of early industrialization. It was also in part the result of adroit political pressure by Francis Place and, inside Westminster, Joseph Hume. The most weighty supporter of those who accepted the demand that workingmen's combinations should be free of legal restraint was J.R. McCulloch, who spoke in the name of orthodox political economy. McCulloch argued that the Combination Laws were unjust in that employers and their workmen were not put on the same level; they were dangerous because they engendered contempt for the law and encouraged class hatred; and they were futile because no action could permanently drive up the level of wages above the natural rate. McCulloch believed in peaceful combination: 'There is no good reason why workmen should not, like the possessors of every other valuable and desirable article, be allowed to set whatever price they please upon the labour they have to dispose of' – but he was clear above all that no artificial levels of wages could possibly maintain themselves in a competitive market. He saw the usefulness of combinations in a strictly narrow context. He warned against strikes, as normally benefitting those employers outside the strike action, and underlined the danger of industry-wide strikes in reducing the competitiveness of home industry compared with foreign production (O'Brien 1970, pp. 366–70). He was notably adamant against any use of force or intimidation in the day-to-day activities of the combinations and was particularly opposed to attempts to compel workmen to join combinations or participate in strikes or other action; and he commended the clauses in the 1825 Act which imposed prison sentences for those convicted of such intimidation. McCulloch elaborated his ideas in the *Essay on Wages* of 1826, which he published in a revised version in the *Treatise on Wages* of the early 1850s, and he summarized his views in an article on 'Combination' in the 8th edition of the *Encyclopaedia Britannica* of 1854.

The character of trade unionism changed in certain respects during the second quarter of the 19th century as a result of the influence of Owenism and the ideas of the anti-capitalist theorists such as Hodgskin, Gray and Thompson (wrongly designated as the 'Ricardian socialists'). It is important not to exaggerate the nature of the change since unions remained what they had always been: defensive-offensive bodies concerned with the betterment of their members. But in the decade after the legalization of combinations for peaceful agitation there was a notable growth of cooperative organizations and some support for Owen's communitarian ideas. Radical political economy worked in the same direction. The distortion of exchange values, so it was argued, meant that labour exchanged below and commodities above their natural values, and under-consumption and the usual accompaniments of economic crisis were the result. Hence a concern with equitable exchange relations with an emphasis upon the Labour Exchanges of the early 1830s and a longer term preoccupation with money and the banking system (N.W. Thompson 1984). Owenism, with its ideas of cooperation was a central strand in the organization of the Grand National Consolidated Trades' Union in 1834–5 from which, it should be noted, a number of skilled societies held aloof; and Owenism, which was critical of policies such as mutual support funds for unemployment, sickness and death, and remained only a partial influence upon union attitudes. After the failure of the Grand National in the mid-1830s the combinations which survived – almost entirely made up of skilled workers and craftsmen – continued with their traditional sectional approaches to industrial problems. There remained a residue of Owenite ideas – in cooperative production for example which the Christian Socialists of 1848–1854 were able to draw upon (Raven 1920; Saville 1954) – but these were attitudes which became progressively weaker in the decades after the half century.

Combinations of working men for industrial purposes generated a continuous opposition, amounting to hatred, among the employing classes, whose distrust and dislike goes back to the early beginnings of modern industrial society. This hostility, as well as fear, has been a component part of the English liberal tradition and has influenced politicians, administrators and the judiciary. The last group is especially important in that while politicians have slowly modified their views and gradually legislated in more sympathetic ways in respect of trade union rights and status – at least until the last quarter of 20th century – the judiciary have been more wayward in their judgements and have followed quite closely the vagaries of middle class opinion. This opinion has moved between reluctant acquiescence and straight hostility, and the history of the law relating to combinations and trade unions has exhibited batches of legal decisions which have negated the intentions of Parliament. This was true of the late 1860s and during the 1890s, the latter period culminating in the Taff Vale decision. The hostility of educated opinion towards these industrial associations of working men was well illustrated in a letter written by Richard Cobden, the quintessential middle-class liberal of the 19th century, addressed to his brother in 1844: 'Depend upon it, nothing can be got by fraternising with the trade unions. They are founded upon principles of brutal tyranny and monopoly. I would rather live under a Dey of Algiers than a Trade Committee' (Morley 1881, p. 299). These have been enduring sentiments.

Combinatorics

A. P. Kirman

Combinatorics, or combinatorial mathematics, is a difficult field to define. It cuts across many branches of mathematics yet a mathematician will clearly sense which problems are of a combinatorial nature. Perhaps the simplest definition is that it is concerned with configurations or arrangements of elements, usually finite in number, into sets. Three basic types of problem are posed. Firstly the existence of certain configurations; secondly, once their existence is proved, the classification or enumeration of the configurations meeting the requirements imposed; and thirdly the construction of algorithms for finding the configurations in question.

Why has combinatorics been the poor relation of the mathematical tools used in economics? The first and most obvious explanation is that the evolution of theoretical or mathematical economics has led us in the opposite direction to that in which combinatorics is useful. Ever since the

'marginal revolution' there has been clear emphasis on the use of differential methods and an implicit acceptance of the perfect divisibility of goods. Indeed if we consider the most elaborate extension of the basic Arrow–Debreu model it is to one in which there is a continuum of agents and a continuum of goods. This is just the sort of context in which the combinatoric approach is of little use.

Yet the economist may well feel that discrete problems are of importance and that indeed the world is best represented as one where goods are not infinitely divisible and where the number of agents is finite. Now given the standard assumptions of convexity, at least in production, the perfectly competitive model may indeed be regarded as a satisfactory ideal or limiting case and the finiteness of a real economy is just an inconvenience. In this case it would seem that combinatorics has little role to play.

However although we may consider taking divisibility as a reasonable idealization in a large economy (even this may be questioned – *see* ▶ Indivisibilities) as soon as convexity is dropped as an assumption for production the problem of finiteness cannot be avoided. If there are increasing returns to scale there will be a minimum profitable plant size and there will be a fundamental indivisibility. At this point combinatoric analysis comes back into its own, and no argument can be made for using infinitely divisible goods as a reasonable approximation. Thus the existence of non-convexities will lead us back into a situation which may, for example, be game-like and in which we will be looking for a solution with a finite number of large plants.

This is to suggest that realism may lead us away from the smooth differential world to which economists are accustomed towards a discrete one in which combinatorics plays an important role.

Nevertheless, till now, finiteness and the combinatoric approach have not occupied a significant place in economics. However, some examples will show that certain branches, although not central, have made extensive use of such an approach.

The development of mathematical programming, in particular of linear programming, has relied particularly on combinatorics. The algorithms developed to solve such problems are essentially combinatoric. Many economic models have been built on the basis of the 'activity analysis' or fixed coefficient production approach.

Game theory has made extensive use of combinatorics and provides an interesting example of how the combinatoric approach can be confronted with one using continuous functions or compact sets.

Combinatoric arguments are used to show that the core of a balanced game is non-empty. A simple argument shows that a market game is balanced and further it can be shown that the only allocations remaining if we replicate a given economy are competitive. This leads us to the conclusion that a competitive or Walrasian allocation exists. Now the latter statement is known to be equivalent to the existence of a fixed point for a continuous mapping. Thus we arrive by combinatorical methods at the same result as that obtained by an apparently very different tool.

This argument is reinforced by the fact that the algorithms developed for finding approximate competitive equilibria are essentially combinatoric in nature. They consist in systematically examining points in the price space, of evaluating the total excess demand of an economy at these points and finding a path which leads to a reduction in the excess demand until it is close to zero. Again, the approximation of fixed points of countinuous functions is obtained by a combinatoric approach.

There are many other examples of ways in which combinatoric analysis has proved useful. Arrow's theorem on the impossibility of a social welfare function is typically proved in the case of a finite number of individuals faced with a finite number of social alternatives. The problem is to find a way of aggregating individual preference orders on these alternatives into a social order in a way which satisfies certain simple axioms. The usual line of proof consists of finding certain configurations of individual preferences which

lead via the axioms to a contradiction with the existence of a social order. The reasoning here too is combinatoric. The introduction of graph theory to describe communication patterns in economics has brought into economic theory a field which has long been regarded as fundamentally combinatoric. The use of 'matching' models to analyse job search and unemployment is yet another example.

Whilst these few rather arbitrary examples show that combinatorial analysis has not been absent from economic theory it is also clear that it has not been central.

However, it seems likely that economics is to evolve towards the sort of models now widely studied in computer science, away from global optimization towards more simple forms of 'rationality' as embodied in simple automata. Furthermore the computation of equilibrium even for underlying continuous models is becoming increasingly important. All this together with a recognition of certain fundamental indivisibilities in economics is likely to move combinatorics to a much more central position on the stage of economic theory.

Command Economy

Richard E. Ericson

Abstract

The concept of a 'command economy', a construct in the theory of comparative economic systems, is defined, and its origins, characteristics, and consequences for any society in which it is implemented are explored. The impossibility of the absolute centralization which it requires generates compromises with the market forces it aspires to replace, fostering a symbiotic marketized 'second economy' which systematically undermines its foundations. Hence, although initially appearing to be a true alternative to the market economy, a command economy, most nearly realized in the Soviet Union (1930–87), proved to be ultimately non-viable, collapsing under reforms attempting to make it competitive with market systems.

A command economy is one in which the coordination of economic activity, essential to the viability and functioning of a complex social economy, is undertaken through administrative means – commands, directives, targets and regulations – rather than by a market mechanism. A complex social economy is one involving multiple significant interdependencies among economic agents, including significant division of labour and exchange among production units, rendering the viability of any unit dependent on proper coordination with, and functioning of, many others.

Economic agents in a command economy, and in particular production organizations, operate primarily by virtue of specific directives from higher authority in an administrative/political hierarchy, that is, under the 'command principle'. Thus the life cycle and activity of enterprises and firms, their production of output and employment of resources, adjustment to disturbances, and the coordination between them are primarily governed by decisions taken by superior organs responsible for managing those units' roles in the economic system. One of the most distinctive features of such an economy is the setting of the firm's production targets by higher directive, often in fine detail. The administrative means used include planning, material balances, quotas, rationing, technical coefficients, budgetary controls and limits, price and wage controls, and other techniques aimed at limiting the discretion of subordinate operational units/firms. The command principle strives to fully and effectively replace the operation of market forces in the key industrial and developmental sectors of the economy, and render the remaining (peripheral) markets manipulable and subordinate to political direction. Thus the command principle is likely to clash with the operation of market forces, yet a command economy may nonetheless contain and rely on the market mechanism in some of its sectors and areas, for example, influencing labour allocation, or stimulating small-scale private production of some consumables.

The term 'command economy' comes from the German *Befehlswirtschaft*, and was originally applied to the Nazi economy, which shared many formal similarities with that of the Soviet Union. It has received its fullest development in the analysis of the economic system of the Soviet Union, particularly under Stalin, although it has been applied to wartime administration of the US economy (1942–6; see Higgs 1992), the Mormon economic system in mid-19th century Utah (Grossman 2000), and the Inca production system in the 16th century Andes (La Lone and La Lone 1987). Synonymous or near-synonymous terms include 'centrally planned economy', 'centrally administered economy', 'administrative command economy', 'Soviet-type economy', 'bureaucratic economy' and 'Stalinist economy'.

The command economy's conceptual origins go back to the Viennese economist Otto Neurath, who in the years before and after the First World War developed an extreme version (to the point of moneylessness) based chiefly on prior experience with wartime economies (Raupach 1966). The concept of the command economy has since become a central conceptual framework in the analysis of economic systems, as it captures a logically coherent alternative to 'the market' as a way of organizing socially complex economic activity and interaction. The Soviet Union provided the most complete, and for a while successful, example of a command economy as a working alternative to a market system. Indeed, apart from the relatively short-lived Nazi case, and even briefer ones under emergency conditions in some other countries, especially in wartime, actual instances of command economies are virtually limited to Communist-ruled countries, with the USSR as the prototype and prime exemplar. Thus, what follows is mainly inspired by the Soviet example (Ericson 1991) as it existed, essentially little altered since its appearance in the 1930s, until its collapse in the aftermath of President Gorbachev's *perestroika*, begun in 1987.

Nature of the Command Economy

The seminal analysis of the nature, characteristics, and problems of a command economy is Grossman (1963).

Any complex social economy must, for its very survival, maintain at least a 'tolerable' micro-balance, 'that minimal degree of coordination of the activities of the separate units (firms) which assures a tolerably good correspondence between the supply of individual producer and consumer goods and the effective demand for them' (Grossman 1963, p. 101). In such an economy, appropriate balance can be achieved through decentralized, market-based (monetized, price-mediated) interaction of autonomous units, or by virtue of explicit specific coordinating directives (commands, targets) from some higher authorities. While the former is characteristic of a market economic system, the latter is defining of a 'command economy'. In the latter operational-level units (for example, firms) must merely 'implement' commands; they become 'executants' of plans and directives from above, plans which must insure balance through the coherence and consistency of the instructions they give. Thus the command mechanism requires relative centralization and severe restriction on the autonomy of subordinate operational units. It derives from the overwhelming priority of social goals, and requires the severe limitation, if not total destruction, of autonomous social and economic powers and the enforcement of strict obedience to directives.

A command economy is hence a creature of state authority, whose marks it bears and by whose hand it evolves, exists and survives. Command economies are imposed, whether through external duress or imitation, or indigenously in order to achieve specific purposes such as (a) maximum resource mobilization towards urgent and overriding national objectives, such as rapid industrialization or the prosecution of war; (b) radical transformation of the socio-economic system in a collectivist direction based on ideological tenets and power-political imperatives; and (c), not least, curing the disorganization of a market economy brought about by price control, possibly occasioned by inflationary pressure arising from (a) and/or (b).

The command economy therefore requires a formal, centralized, administrative hierarchy staffed by a bureaucracy, and it also needs to be embedded in (at least) an authoritarian, highly centralized polity if it is not to dissolve or degenerate into something else. And that bureaucracy, if it is to effectively implement the command principle, must exercise full control and discretion, if not necessarily formal ownership, with respect to the creation, use and disposal of all productive property and assets. At the same time, each office or firm and every economic actor within the command structure holds interests which, if only in part, do not coincide with those of superiors or of the overall leadership. This generates important problems of vested interests, principal–agent interaction, incentive provision, and general enforcement of the leadership's will, and calls for a variety of monitoring organizations (party, police, banks, and so on). The term 'command' must not be taken to preclude self-serving behaviour, bureaucratic politics, bargaining between superiors and subordinates, corruption, peculation and (dis)simulation. On the contrary, such behaviour tends to be widespread in a command economy; yet the concept of a 'command economy' remains valid so long as, in the main, authority relations and not a market mechanism govern the allocation of resources.

When not externally imposed, command economies typically arise from a millennialist elite, with unique access to 'the truth', achieving the political power to impose its will, while facing a crisis of apparently overwhelming proportions. The perception of a life-threatening crisis, driving the need for massive mobilization of all social resources and rendering potentially disastrous any hesitation or dissent, any questioning of ways and means, naturally leads, pushed by the 'logic of events', to the usurpation of all power of discretion, all legitimate authority, by the 'knowing' elite, which then becomes responsible for all that is done or not done in the society and the economy. The crisis may be artificial or real ('hostile encirclement'), externally or internally imposed (the need to industrialize, to 'catch up'),

but it requires moving resources rapidly and massively, forcing new activities and interactions in the face of severe scarcities, of shortage of competent personnel, of massive uncertainties, and of strongly held, stark priorities. Indeed, a sense of overwhelming urgency and need for haste drove the elite of the Soviet Union in the 1930s to test and establish, through trial and error over several decades, the institutional structure of a 'command economy', albeit *less than absolute* from both necessity and choice (for example, due to the 'lessons' of 'War Communism') (Grossman 1962; Zaleski 1968).

Consequences of Command

Rational application of the command principle calls for planning, which is basically of two types. Longer-term, developmental planning expresses the leadership's politico-economic strategy (for example, five-year and 'perspective' plans); shorter-term, coordinative planning (annual, quarterly, monthly, ten-day) ideally translates the strategy into resource allocation while aiming to match resource requirements and availabilities for individual inputs, goods, and so on, in a sufficiently disaggregated way for given time periods and locations. The task of elemental coordination, of microbalance, so effortlessly accomplished by any functioning (however poorly) market system, is overwhelmingly large, and grows rapidly with industrialization and economic development, both of which lead to exponential growth of the complexity of the economy, and hence of the planning problem. With centralization and the abandonment of markets comes the need for massive, detailed coordinative planning, for 'making ends meet' in the expanding web of interconnections that must be maintained for economic life to continue. Coordinative planning serves, therefore, as the basis for specific operational directives to producers and users, thereby implementing the command principle to achieve the prime imperative of a social economy – 'balance'.

> It is *this* task that in fact consumes the largest part of the so-called planning in the command economy . . . Coordinative planning as it is conducted in the Soviet Union does little by way of consciously steering the economy's development or finding efficient patterns of resource allocation. Its overwhelming concern is simply to equate both sides of each 'material balance' by whatever procedure seems to be most expeditious (Grossman 1963, p. 108).

A major problem is that detailed planning and the corresponding directives are often late, are insufficiently detailed, may lack the requisite information, hence often cannot be effectively coordinated, and owing to their rigidity are peculiarly vulnerable to uncertainty (Ericson 1983). Information in the command sector, by the logic of the system, tends to flow vertically up and down the administrative hierarchy rather than horizontally between buyer and seller, adding to difficulties of demand–supply coordination by informationally isolating operational units from their suppliers and users. In addition, problems of motivation, accountability (down as well as up), inappropriate decision-making parameters, and divergent interests complicate the procedure. Even at best, this manner of resource allocation can hope to attain only internal consistency (in the sense of effectively matching partially disaggregated requirements and availabilities) but not a higher order of economic efficiency. Economic calculation in pursuit of efficiency enters, if at all, at the project-planning stage, and not short-term resource allocation and use.

These problems are aggravated by the logic of haste that drove imposition of the command economy – 'the pressing contrast between urgent political goals and available resources' (Grossman 1963, p. 108). The necessary attention to the growing problem of balance further militates against any effort to consider developmental objectives or efficiency in making allocative decisions, so that a further bias against allocative efficiency is built into the command economy. Coupled with limited ability to gather, filter, process, and communicate information, and to compute solutions to planning problems, this creates a fundamental and growing inability to acceptably solve the underlying coordination problem, and hence further undermines any consideration of efficiency.

The logic of 'command' has a number of other consequences reflected in the institutions of such

an economy. Planning in a command economy must be largely in *physical terms* due to the crucial importance of balance. The bottom line of the planning process must be available physical units of required inputs, in appropriate assortment, quantity and timing, necessitating physical targets for production and input utilization. Thus tens of thousands of materials and equipment balances must be drawn up and coordinated for each plan period, and then broken down and allocated in directives to specific implementers. And, to be directly usable, these must be in physical or crypto-physical (constant price) units that directly relate to the production processes being coordinated. Using economic-value units requires flexible and changing, marginal scarcity-based prices for valuation, as well as giving significant autonomy to subordinate units that inevitably then will make the trade-offs in assortment, quantity and timing within planned constraints on values (that is, 'budgets'). Hence, such valuations pose a fundamental challenge to the command economy.

Planning in physical terms, however, leads to 'enormous waste and inefficiency, to production for waste as much as for use' (Grossman 1963, p. 110). There are at least three fundamental sources of this elemental waste: *grossness*, *aggregation*, and *unit of measure.* The need for these arises from the overwhelming complexity of the task of planning for, and directing the operation of, a complex social economy and the necessarily limited information gathering, processing, and dissemination capabilities of any economic agent or agency. However, the emphasis on *gross output* leads to 'input intensiveness', waste, and ignoring cost considerations. *Aggregation* leads to persistent subcategory imbalance in assortment, quality, type, timing, and so on, while *units of measurement* determine suboptimization objectives, distorting implementation decisions, particularly when they are, for material balance reasons, input oriented. Thus each of these is essential for the feasibility of directive central planning, of the command mechanism, yet each loses, or destroys, essential information for the 'proper' (in the eyes of the system directors) implementation of plans, and opens space for creative interpretation of instructions/commands, and hence for 'suboptimization' by implementing units whose interests are not perfectly aligned with those of the centre (Nove 1977). While the command mechanism logically requires unauthorized initiative to be forbidden, and strictly punished when exercised, the size of the task it faces inevitably opens the opportunity, indeed often the need, for such unauthorized initiative. Thus the physical quantity planning required by the command economy to maintain minimal functional 'balance' contains its own antithesis, unleashing forces that undermine the consistency of the plan and the coherence and balancedness of its realization. This fundamental contradiction lies behind most of the critical problems of the command economy in the Soviet Union and the myriad efforts to resolve them within the framework of the command mechanism that comprise the endless waves of reform following victory in the Great Fatherland War of 1941–5.

The 'logic of command' thus imposes a need to restrict autonomy, to restrict the capability of economic units to pursue any other than 'planned' or commanded purposes: economic agents must not have the capability to autonomously acquire and deploy resources for any purposes outside the plan. Comprehensive material balance planning and centralized materials and equipment allocation provide a necessary component, but one that is insufficient unless resources, including human, are denied the capability of autonomous movement and application. Severe restrictions on labour mobility, albeit not as severe as under Stalin, are required, as are comprehensive restrictions on the use of any 'generalized command over goods and services' – that is, money – that might be used to alter their patterns of allocation and use in the economy. The system must be substantially demonetized in order to '... constrict the . . . range of choice in the face of the state's demands' (Grossman 1966, p. 232).

Thus money must be deprived of 'moneyness' and prices must be kept 'passive', as mere accounting and measurement units. According to the logic of the command economy, the availability of money and the prices at which commodities and products are provided should have no essential impact on the allocation of goods and services,

or on the nature and direction of economic/industrial development; all real activity is preordained in the plan and its subsequent implementing commands. The role of money is then to facilitate monitoring of commanded performance through the financial flows it generates. Thus monetary prices do not, and indeed should not, reflect to a substantial degree social goals and priorities; they merely reveal and measure the flow of commanded activity. Producer prices (and most retail prices), wages, prices of foreign currencies, and so on are generally centrally set and controlled, often remaining fixed for long periods of time. Micro-disequilibria naturally abound, while the widely perceived dubious meaningfulness of such prices and the administrative allocation of most producer goods in physical terms combine to sustain the system of detailed production plans and directives in terms of physical indicators – yet another bar to more efficient planning and management.

Finally, an absolutely essential, indeed defining, institution of the command economy is the *physical rationing* of resources and producers' goods. This is where the market is most fully and directly replaced, and where the central authorities have the ability to most directly influence and control the behaviour of subordinate operational units. It implements the centralized mobilization of resources to priorities, the most direct response to crises and challenges. And it most directly denies to subordinates the capability to produce, to develop, in ways outside those authorized in the plan. This makes the coexistence between the command principle and the market mechanism a source of continual conflict, as the market opens unauthorized opportunities to subordinates. In the Soviet Union the command principle, aided by the club of materials rationing, repeatedly pushed back and eliminated the market mechanism when (timidly) introduced in reforms, until the system collapsed in chaos, and the introduction of a full-fledged market economy was begun in 1992 (Schroeder 1979; Aslund 1995). Thus the nature of the command system makes it fundamentally incompatible with real markets, although some market institutions can, and indeed must, be allowed to function both within the non-state sectors and as the interface between them and state economic institutions/sectors.

Inherent Challenges to the Command Economy

As Grossman notes in his seminal article (1963, p. 107), 'The chief persistent systemic problem of a command economy is the finding of the optimal degree of centralization (or decentralization) under given conditions and with reference to given social goals'. The fundamental dilemma is that full centralization poses an insoluble problem, while decentralization abandons the ability to direct, to control development, and to ensure the pursuit of social goals and priorities. With regard to the pure planning problem, a large body of theoretical literature arose in the late 1960s, and continued into the 1980s, on the problem of decentralizing the planning process to make its informational and computational burden manageable (Eckstein 1971; Bornstein 1973). But the problem is far greater, and less studied, with respect to implementation; rational planning is swamped by the struggle to maintain elemental coordination.

Decentralization Versus Priority

Looked at through the prism of relative advantages, operational decentralization shortens 'lines of communication', increasing flexibility, adaptation and responsiveness to a changing environment through local initiative and innovation, and vastly simplifying the decision problem of economic agents. But it does so at the cost of weakening or losing the 'advantages of centralization', including enforcement of regime values, capability for large-scale resource mobilization, concentration of scarce talent in central decision-making organs, and the maintenance of macro-balance. In particular, decentralization compromises the ability of the centre to directly manage the development and structure of the economy and to force the achievement of critical priorities regardless of cost. Furthermore, decentralization requires the introduction

of the alternative coordination mechanism to insure tolerable micro-balance – the market – as decentralization undercuts the ability to directly coordinate, to balance from above. Thus, to prevent catastrophic imbalance, a more active money with economically flexible market prices must be allowed to function in a decentralized system.

The impossibility of planning and commanding the performance of all economic agents in full operational detail, however, forces some decentralization. This creates a chronic threat to balance which is thus a continuous argument for (re) centralization of planning and materials allocation. Furthermore, a partial decentralization of planning and management in a command economy may do more harm than good; it may impair balance without yielding sufficient benefit. Yet a complete decentralization, in the sense of a virtually full devolution of the major production decisions to the firm level, would be disastrous from the standpoint of balance, unless the price structure were properly altered to provide proper signals to firms *and* suitable behavioural rules were prescribed, that is, unless a market mechanism were introduced. Thus the logic of command predicts a 'treadmill of reforms' (Schroeder 1979), an array of countervailing strengthenings of the oversight and control organs (in particular, the Party), and enhancements of their role in the economy, accompanying moves towards decentralization in the state sector. It also explains the Soviet institutional arrangement of inter-firm contracts as a decentralized implementation device. These are required to specify details of interaction within planned categories, and establish observable, and hence legally enforceable, commitments to planned implementation, constraining the autonomy necessarily granted through the minimal decentralization. And it explains the logic of the continuing restraints on the use of money and the continuing efforts at effective price control to keep the autonomy of agents restricted to the minimum necessary for the continued functioning of the less-than-absolute command economy.

Even limited decentralization requires that money be used in the command sector (as well as in the household sector), but its role as a bearer of options and as the means of pecuniary calculation for decision-making is necessarily limited and deliberately subordinated to the planners' will and the administrators' power. Banks and the treasury accommodate the money needs of production, ensuring a soft budget constraint for the individual firm. At the same time, the 'moneyness' of money at the firm level is low, hemmed in as it is by administrative constraints and impediments, including the rationing of nearly all producer goods, and by the widespread 'seller's market' (shortages of goods and absolute lack of buyers' alternatives). This monetary ease, together with the sellers' market, plays an important role in ensuring individual workers' job security at the firm level and full employment in the large, while keeping the firm largely insensitive to money costs and/or benefits.

Within the command sector, money and prices have a necessary role in determining terms of alternate resource uses *only within* planned/commanded categories, and money has the role of limiting total claims to resources in areas, or at a level of detail, beyond the reach of plan directives. This requires 'businesslike management' within the firm – *khozraschet*, which is a 'set of behavioral rules that is supposed to govern the actions of Soviet managers beyond their primary responsibility, the fulfillment of output targets'. It pushes the firm toward 'technical efficiency' and limitation of 'claims on society's resources for productive use. . . . *khozraschet* is a system that is well devised to control the behavior of managers in a command economy where a certain amount of devolution of power to them is inevitable, and where, further, managers' goals and values do not necessarily coincide with the official ones' (Grossman 1963, p. 117). Thus money also has the role of facilitating the monitoring of performance in the command sector.

While administrative orders are the rule in a command economy, backed up by greater or lesser degree of state coercion (depending on country and period), any decentralization of implementation naturally relies on monetary ('material') incentives to elicit desired individual compliance and performance. Compounding the incentive problems arising from differences in information and interests between central authorities and implementing

agents is the fact that the physical and other indicators to which the material incentives are linked may often be poor measures of social benefit (as seen by the leadership). Furthermore, resort to such rewards widens the distribution of official earnings and raises questions of permissible limits of income inequality. Yet there may be little choice in that the state must in effect compete with the much higher incomes from the *second economy.* Indeed, the Soviet Union during War Communism, Cuba in the 1960s, and the People's Republic of China during some periods before Mao's death in 1976 tended to downgrade material incentives in favour of normative controls, but never did quite abolish them.

The behaviour of the Soviet-type firm has been much studied (Granick 1954; Berliner 1957; Nove 1977; Freris 1984). Because its directives and the corresponding managerial incentives stress physical output, produced or shipped, and thanks to its low sensitivity to cost and the ambient sellers' market, the firm often sacrifices product cost, quality, variety, innovation and ancillary services to its customers to sheer product quantity. By the logic of command and the requirements of plan manageability, firms operate in an environment with sole suppliers and assigned users, reducing complexity by eliminating 'wasteful' redundancy in production and distribution. Thus firms in a command economy are largely insulated from any product competition, both from the outside world and from other domestic firms, thanks to the climate of administrative controls and the prevalent excess demand for their output. Difficulties with supply, frequent revision of its plans, interference by Party and other authorities, and other systemic problems also stand in the way of its more efficient and effective operation. Indeed, to function at all, the firm's management is frequently forced to break rules and even resort to criminally punishable acts.

This compounds a further critical challenge posed by necessary decentralization – the conflict between the will, purposes, incentives and priorities of the higher authorities and those at lower levels, particularly of the firms and their managements. Even the best-motivated managers, following all official rules and incentives, will sometimes fail to replicate the decisions that their superiors would have made had they been in a position to make them. This problem is aggravated by the inevitable ambiguity, incompleteness and inconsistency of those rules, incentives and the information available on the spot. Only binding physical constraints and observable outcomes can be systematically enforced, making 'centralized materials allocation the most powerful weapon at the disposal of the central authorities' (Grossman 1963, p. 118). Thus, where material inputs are less determinate of a unit's activities, this information and incentive problem is greater, and the defiance of central will relatively more widespread and successful. This observation explains the non-viability of any reform that fails to fundamentally alter the materials allocation system.

Under-Planned, Ill-Commanded Sectors

A major challenge to the command economy also arises from the existence of sectors outside, or only partially affected by, the command principle. In the Soviet Union these included most of agriculture, much of housing, the household sector and some consumer goods and services. 'Markets' were allowed to function for the distribution of final consumer goods and services, including agricultural produce, for much of the activity of the 'collective' sector in agriculture and for household labour supply. For transactions with 'personal property' within the household and collective sectors, money was active and agents responded to market prices, while in the quasi-markets interfacing with the state sector – for example, labour and consumer goods – money was relatively active but prices remained largely controlled and non-market. These are sectors where information on needs/preferences and capabilities proved too difficult to acquire reliably in real time for acceptable allocation and balance to be commanded, and so at least one side of a market was allowed to function with an active money. Here, the command mechanism proves too crude and clumsy, and hence politically counterproductive, to be used outside of pressing emergencies. Indeed, this might be considered a lesson of War

Communism, the first experience with a command economy in Soviet Russia, 1918–21.

In view of the theoretical incompatibility of command and market, how could these 'market' sectors be successfully grafted on to the command mechanism? An explanation (Grossman 1963) rests on the trade-offs between the authorities' limited capabilities, the complexity of those sectors, and their centrality to regime priorities. A sector which provides significant inputs to physical planning and plan fulfilment, where the unpredictability in the flow of goods is unacceptable, cannot be left to the market without seriously undermining command. However, if a 'market' sector can be treated as a residual for purposes of materials planning and allocation, a buffer for planning, then its coexistence is acceptable. Further, if its operation is characterized by rapid change and complexities rather outside the core interests of the regime, if without disrupting the industrial core greater incentives and risk can be placed on those peripheral agents, and if non-market constraints can force the desired market response from it, then the centre will want to separate that sector from the command sphere, lowering its coordination burden by shifting it to the market.

These considerations were indeed active in the case of those sectors 'left to the market' in the Soviet Union: consumer goods retailing, the acquisition of labour services, the support of households in the countryside through a private agricultural sector, and a few peripheral and interstitial activities. Indeed, any attempt to truly 'marketize' any other sectors or activities in the command economy is doomed to fail unless the loss of fervour, of the sense of mission and urgency, leads to abandonment of the command mechanism. Yet even the existence of these limited market sectors, providing an outlet for incentive earnings and diverted resources, exerts a continuing corrosive pressure on the command economy and its control mechanisms.

The Cancer of 'Money'

A truly monumental challenge to the command economy lies in the role of money in any *less-than-absolute* command economy. As the complete centralization of decisions in the production sector (let alone in the household sector) is an impossibility, something must be left to local initiative and dispersed decision making. Thus *khozraschet* is a logical necessity, '... an unfriendly bridgehead that threatens to seize ground whenever the planner fails or defaults' (Grossman 1966, p. 228). With the inevitable devolution of some decision making to firms and households, money acquires a necessary and critical role in the command economy, going well beyond that consistent with the logic of command. That role arises from the need to economize in making decentralized decisions, and as a medium of exchange and store of value in the decentralized interactions that relate to all decisions. In acquiring this role, this 'moneyness', it allows accumulations of power outside the control of the regime. Money is a 'bearer of options' whose power and influence must be restrained if the command mechanism is to operate properly – to determine priorities and to insure maximal commitment to their achievement. As Grossman (1962, p. 214) noted, 'Money is a form of social power that may lead resources astray and is subject to only imperfect control by political authority.'

Thus the power of money has to be curbed in a command economy by limiting balances available to households and firms, by compartmentalizing money into cash and 'firm' circuits, and by erecting barriers and limits to the use of 'monies' in each category, although that undercuts the effectiveness of attempted decentralizations. Liquidity, 'moneyness', is constrained by the institutional structures and by all the characteristics and conditions of the 'sellers' market', rendering 'money' the only non-scarce commodity, in unusable excess to the extent the command mechanism is effective. Monetary policy in the properly functioning command economy reduces to limiting the volume of cash in the economy ('macro-monetary' control) through wage fund restrictions and cash control absorption plans of the retail sector, and the allocation of firm balances in restricted categories ('micro-financial' control) in just sufficient quantity to support the implementation of the plan, with confiscation of

excess funds to prevent unauthorized activity by the firm (Garvy 1977).

Similarly, the price system, expressed in terms of that money, must also be mobilized to the purpose of control. The inflexible, administratively segmented, average cost-based prices in command economies are a logical necessity of command- and haste-based shortage. For all the problems they cause, all the unintended consequences and distortions in the behaviour of subordinates, such prices help to keep money largely passive, at least in the core state sectors, and allow both money and prices to remain instruments, rather than disrupters, of command. More than being ideologically justified, such prices are a response to the pragmatic and pressing requirements of running a shortage economy with a rapidly developing system of centralized direction of enterprises and of materials allocation.

Money, however, is not so easily contained. Once in unobserved hands, it exercises its 'command over goods and services' without reference to plans, commands or regime priorities. Hence, given any discretion, in any sphere of activity not directly monitored agents will naturally use money in ways they find desirable, placing new demands on a physical system otherwise tautly planned and characterized by general scarcity. This is facilitated by the existence of agents and spheres of activity outside the command system, providing 'legitimate' sources and uses for monies, however acquired or disposed. And the possibility of acquiring money provides incentives for unauthorized activities, incentives to undertake unplanned interactions and reallocations. An active money vastly expands the sphere of discretion of 'subordinate' agents beyond any authorized by a decentralizing reform, and calls for severe administrative restrictions, a reduction to passivity, if it is not to disrupt the planned activities and discretion of the central authorities.

Yet attempts to administratively constrain the influence, the 'corruptive' power, of money become increasingly futile once the 'genie' has been 'let out of the bottle'. Even limited decentralizing reform, allowing money to influence some (subcategory) production and allocation decisions, inevitably lets loose more liquidity, more of a command over goods and services, than desired. This arises from a multitude of factors: errors in both physical and financial plans, inherent incompleteness of plans and commands due to limited information and time and to the necessity of aggregation, changing circumstances and shocks to the economy, mistakes in implementation and in responding to shocks, the irregularity and disruptions in the materials allocation system, the behavioural response of even the most enthusiastic and best-intentioned agents to these problems, and so on. All of these can lead to an unexpected lack of funds for doing what was commanded (if only implicitly), and hence disruption of commanded performance, unless additional liquidity is provided.

Thus monetary policy in a command economy, once money is allowed any room for activity, must be accommodating; a lack of funds can never be allowed to disrupt planned performance, just as an excess of funds cannot be allowed to facilitate unplanned or unauthorized activity. Thus the role, the influence, of money has a natural, inexorable tendency to grow: insufficient funds become an immediate problem generating new money through credits or additional allocations, while unused funds tend to stay hidden until ferreted out by inspection or accidental discovery. And as it grows, so does the challenge to the command principle. An increasing number of agents, in both the state and non-state sectors, has a growing ability to access resources, to divert them in the name, if not always the interest, of implementing decentralized plans, and thus to challenge the priorities of the political authorities. This growing challenge becomes a cancer in the system, a growth that undermines its health and feeds tendencies destructive of the priorities of the regime and its rulers.

The 'Second Economy'

As the command economy matures, as the messianic fervour with which it was imposed wanes and the use of extraordinary force diminishes in ensuring compliance with commands, these challenges to command metastasize into a competing yet

symbiotically attached and dependent economic system: the *second economy.* This name highlights the distinction of this sphere of economic activity from the officially sanctioned, 'first', command economy. It is thus defined as 'all production and exchange activity that meets at least one of two criteria: (a) being directly for private gain; (b) being in some significant respect in knowing contravention of existing law' (Grossman 1977, p. 25).

In the Soviet Union, attempts to strengthen 'material incentives' and activate 'the profit motive' in order to increase the effectiveness and technical efficiency of the implementation of central plans and directives and to stimulate technological progress and innovation, and the growing monetization of the agricultural sector, opened the door to massive expansion of money supply and eroded the barriers between the currency and the enterprise bank account monetary circuits. Collective farms and their subsidiary enterprises, owners of 'small means of transport', vodka manufacture and distribution, and the Caucasus republics (Georgia in particular) proved particularly rich sources of illicit (from the system's perspective) monetization and private 'entrepreneurial' activity. This both raised the spectre of inflation and opened the door to vastly increased opportunities for manipulation by self-interested subordinates in the command sector. Thus the use of 'economic levers' greatly increased the opportunity for and incidence of bribery, corruption, speculation, and even 'honest' private labour.

While the fundamental cause of the appearance and growth of the 'second economy' undoubtedly lies in the congenital institutional weaknesses of the command economy discussed above, there are a number of proximate sources that make it unsurprising. These include extensive price control, with consequent scarcity and misallocation, high taxes on non-state activities/incomes, prohibitions of private activity, unmet individual consumption needs, poorly protected impersonal (state) property, the personal power of bureaucrats and 'gatekeepers', and other historical factors, including the end of terror. These provide both motives and opportunities for officially illicit activity and for the authorities to overlook that activity. With the ageing of command and the decay in enthusiasm of its agents, the growth of such a second economy appears natural.

Thus growing 'monetization', the existence of ready and waiting market sectors, and the decline in the use of violent instruments of enforcement lead to a growing sphere and importance of activities outside the purview of 'planning' and 'command'. These market-mediated activities are at times supportive, helping to achieve tolerable micro-balance in the increasingly complex economy, but often are in violation of planned implementation and regime values. Private interests, necessarily allowed some leeway, grow in significance, increasingly seizing ground from command. In the Soviet Union, the private agricultural sector, initially permitted only to secure survival of the peasantry under the extractive pressure of rapid industrialization, and the consumers' personal services sectors provided the basis for a ubiquitous, if still systemically marginal, second economy.

But then even the core industrial sectors under the command mechanism find their managers and activities increasingly influenced by this illegitimate, shadow market, system, as managers are often forced to break rules and undertake illegal acts in order to do their job. Such acts, together with ubiquitous and protean illegal activity on private account, add up to a large underground economy characteristic of every command economy, which together with legal private activity (allowed in varying degree in different countries) both supports and supplements the 'first economy' and is inimical to it. While the second economy significantly adds to the supply of goods and services, especially for consumption, it also redistributes private income and wealth, contributes to the widespread official corruption, and generally criminalizes the population. Virtually every area of economic life is touched upon, and often entangled with, 'second economy' activities, while legal private activity naturally opens a loophole for illegal trading and entrepreneurship, generally below the purview of the authorities. And it goes hand in hand with the extension of corruption, ensuring that it remains outside of official notice.

Those 'violations' of legality within the command sector, a 'shadow economy', build informal

inter-enterprise relations which are generally beneficial to the operation of state enterprises. They work to substantially correct the allocative failures of the command mechanism, improving firm performance and hence benefiting its management, and also provide lucrative opportunities for managers to directly benefit through the activization of barter, personal connections, and bribery. However, they also spawn further distortions in economic behaviour, as managers seek to generate access to cash, the life blood of the 'second economy', to extract rents, and to hide their activity from supervisory and statistical organs.

Thus the second economy plays a dual and contradictory role in the command economic system. First, it addresses a number of the problems of coordination and balance endemic to the command mechanism, reallocating both producers' and consumers' goods, facilitating plan fulfilment and the use of financial incentives, and generating new incomes and 'politically safe' outlets for private initiative. Hence it becomes important for enhancing consumer welfare, for production stability, and even for social stability. The 'second economy', and in particular its 'shadow' side, plays an essential role in the first economy as a 'pressure valve', a release 'fixing command' by maintaining micro-balance and covering 'holes' in economic life left by the mistakes or oversight of the planners and central managers. And this role becomes increasingly important as the economy grows more complex and diversified, and hence becomes less susceptible to conscious oversight and direction.

As the central authorities struggle with their loss of control, searching for a solution through reform, decentralization and recentralization, monetization and administrative restriction, agents in the economy take advantage of gaps in control, of the autonomy and discretion offered by growing liquidity of the quasi-money in the system, to deal with problems of coordination and balance, inconsistency of plans and commands, and ubiquitous shortages and scarcities. Of course they operate in light of their own partial information, and in their own (private as well as official) interests, but in so doing save the system from collapsing under its own weight and rigidity (Powell 1977). Thus the second/shadow economy provides a spontaneous surrogate economic reform that imparts a necessary modicum of flexibility, adaptability and responsiveness to a formal set-up that is too often paralyzing in its rigidity, slowness, and inefficiency. In doing so, the second economy also provides a valuable stabilizing influence on society and the polity, making life livable and the system humanly manipulable and responsive to private inducement. It makes everyone complicit in the way things work, equally 'guilty' before state and society, while providing an almost legitimate, and not politically dangerous or directly destructive, outlet for individual initiative and entrepreneurship. Finally, it relieves inflationary pressures (a 'monetary overhang') resulting from the command economy's necessary combination of monetary looseness and pricing rigidity.

Despite this positive functional role, the second economy also has a less positive *systemic* impact. It mocks the pretense of social direction and control, subverts its egalitarian impulse by accentuating differences in access and income, and gives the lie to the pretense of a 'new' ideologically correct ('Soviet') man. Its very existence and usefulness thus subvert the ideology of the regime, and it works against and undercuts regime priorities by exposing the incompetence and incapacity of the authorities. Its provision of alternatives weakens the 'plan, production, and labour discipline' so essential to the proper operation of the command mechanism. Indeed, it attacks the core of the command mechanism as it '... elevates the power of money in society to rival that of the dictatorship itself, rendering the regimes implements of rule less effective and less certain' (Grossman 1977, p. 36). In particular, it corrupts officialdom and distorts prices, adding a (positive or negative) 'second economy margin', both 'in kind' and in money, breaking prices as an effective instrument of control. This weakens monetized incentives for state activities by providing competing, and often better, alternatives to them. Hence the second economy, and in particular the 'shadow economy' in the state sector, completes the cancerous development of agent autonomy, of the ability to work outside the plan and its

subsequent commands, by providing viable alternatives to the plan.

Other dysfunctional impacts, undermining the operation of the command system, arise from its diverting of resources and products to unplanned sectors and activities, including diversion from development/investment priorities to consumers. This naturally generates undesirable (from a system perspective) redistribution of incomes, although recipients, including many high-placed officials, find it very desirable. Indeed, it is further disruptive of command by creating a 'two-tiered' system of prices and incomes, of consumer goods and labour markets. One tier is comprised of the low-priced, scarcity-ridden quasi-markets of the 'less-than-absolute' command economy, where the unenterprising, the overly scrupulous, and the 'slow' can survive. The other tier consists of real, albeit highly distorted, markets in the generally high-priced, risky but well-endowed second economy where the enterprising, entrepreneurial, and criminal can thrive. In this high tier, substantial incomes are generated and allocated, although they largely accrue to corrupt officials and 'gatekeepers' of scarce materials or permissions who can extract rather phenomenal 'rents'. The inequities this generates further undermine the legitimacy of the regime and generate potentially explosive social pressures, only partially relieved by the second economy's 'pressure valve' aspects.

Finally, it is worth noting that the second/shadow economy, through its activity outside of the officially measured sphere, seriously distorts statistical data and the information available to planners and allocators in the official economy, and, due to its illegality, also hides necessary information from other agents in the shadow economy. This aggravates the economic problems that spawn 'second/shadow economy' activities, deepening the contradictions between the centre and decentralized agents, and further corroding the institutional structures of the command economy.

Performance and Fate

Command economies have been instrumental in radically transforming societies more or less according to their drafters' intents, in mobilizing resources for rapid industrialization and modernization, at times on a vast scale, and in rapidly amassing industrial power and military strength. Indeed, they have shown themselves highly effective in rapidly implementing large-scale projects and achieving overriding social goals, albeit at great cost. It is this effectiveness, when cost is no object, which explains why the command principle is resorted to in times of emergency and war. Hence in the Soviet Union command facilitated defence during, and rapid recovery and rebuilding of the Stalinist economy after, the massive trauma of the Great Fatherland War. Economic growth has been especially marked (though not unparalleled by market economies) where large amounts of unemployed and underemployed labour and rich natural resources could be mobilized and combined with existing (advanced, Western) technology, and where the public's material improvement could be restrained, or even seriously depressed, under strong political control. As these possibilities waned, and as the economies grew in size and complexity and thus became less amenable to centralized administrative management, rates of growth declined sharply. At the same time, the shortcomings of the command mechanism in adapting production to demand and its changes – providing consumer welfare, effecting innovation, serving export markets – became more apparent and less tolerable. This led to much discussion and repeated attempts at controlled institutional reform, at decentralizing and stimulating subordinate initiative without sacrificing ultimate control.

Some actual reforms in the externally imposed command economies of eastern Europe went so far as to introduce or extend the market mechanism to such a degree that one could no longer regard the system as a Soviet-type command economy, even if, before the 1990s, one could not speak of it as a full-fledged market economy either. Yugoslavia since the early 1950s, Hungary since 1968 and especially in the 1980s, and post-Mao China are the most important cases in point. Other actual reforms were of a minor or 'within-system' nature, aiming to decentralize certain types of decisions while eschewing the market

mechanism and retaining the hierarchical form of organization and the command principle. In the hope of stimulating efficiency to revive growth rates, the decentralizing measures were accompanied by a number of other 'reforms' relating to organizational structure: prices (still controlled), incentives, indicators, materials rationing, and so on. The Soviet reforms of 1965, and those in the 1970s and 1980s prior to *perestroika*, were of that kind; many similar ones took place in other Communist countries after the mid-1950s and prior to the overthrow of Communism in 1989. On the whole, such reforms had little success in addressing the problems of the command economy. Bureaucratic and political obstacles apart, the attempt to decentralize economic decisions without bringing in a market mechanism almost inevitably leads to economic difficulties. The beneficiaries of devolution of decision-making lack the necessary information to produce just what the economy requires or to invest to meet prospective needs, and the coordination of plan-subsequent command is lost. Moreover, they may apply the additional power at their disposal to advance particularist causes or to divert resources into illegal channels. Microeconomic disequilibria mount, and soon superior authorities step in to recentralize on a case-by-case basis and the reform withers away (Grossman 1963; Wiles 1962, ch. 7; Kontorovich 1988).

This failure of reform reflects the inherent contradictions of the command economy framed in the irreconcilable conflict between 'command' and 'money' discussed above (Ericson 2005). The Soviet command economy, driven by the urgent need for and haste in industrialization and military development, initially relegated the influence of money and the market to the margins of the system, where they handled areas and activities in which command had been revealed as counterproductive during War Communism. That system, the 'less than absolute command economy', substantially industrialized, triumphed in the Great Fatherland War, and recovered to an almost perfect replica of its pre-war self by 1950. But by then the strains of its inherent inflexibility and the bounded rationality of the system's planners and managers began telling on continuing growth and the development of the economy. With economic growth came increasing complexity and growing intractability of the central planning and economic management problem. Some decentralization became essential, and increasingly so as time passed, opening the door once again to the rise of money as a significant influence on the operation and development of the economy. And that influence was only enhanced by the ageing and mellowing of the system. With the passing of 'terror' as an effective incentive mechanism, the stabilization of personnel and the regularization of procedures, it became ever harder to control agent behaviour, to contain the distractions of money and the self-interests it mobilized, and to uncover the rents that well-placed agents were able to extract, thus aggravating the inherent agency problems of the command economy.

The remaining years of the Soviet system thus witnessed an epic struggle, barely perceptible at first, but increasingly evident as reforms, decentralizations, reorganizations and recentralizations cycled around each other in the search for a solution to the increasingly evident and destructive malperformance and waste, and aggravating behavioural distortions in response thereto, generated by the struggle between the 'command principle' and the weak, but inexorably emerging, 'market'. Initially reflected in the dysfunctions of the marginal and quasi-markets of the command economy, and in the struggle to harness a 'passive' money to the purposes of command, the role of money grew along the 'treadmill of reforms' into the rival, if still largely subordinate and complementary, 'second economy', and in particular its 'shadow' component, on which the 'command principle' increasingly came to depend for its effectiveness. As long as the Soviet system remained a 'command economy', commands had to have last word, and money remained largely relegated to the sidelines, exercising its influence within the quasi-monetized instruments ('economic levers') of the command mechanism and the distorted markets of the second economy.

This inherent conflict, played out over Soviet history, revolves around a number of fundamental

dualities, elemental oppositions which characterize these primary forces. The 'command principle' derives most basically from the urge, the will to control, to 'rationally' determine and direct the future, exercised by a 'gnostic' elite, immanent in the Party. It knows what needs to be done, by whom and how, and can tolerate no dissent or deviation. Juxtaposed to this 'Will of Society' stand the millions of independent 'wills', desires and objectives, anarchically coordinated through 'the market', whenever that set of institutions broke through the barriers and limits placed by 'command'. This provides the foundation for the eternal struggle between 'central priorities and control' and 'agent incentives and capabilities'.

This opposition is severely aggravated by urgency, by 'virtuous haste', in the pursuit of overriding social goals and central objectives. For the mobilization for, and focus of resources on, these priorities trample on the information, capabilities and goals of individual and organizational agents which must perforce implement that mobilization, implement those priorities. 'Effectiveness' in the pursuit of social objectives becomes opposed to 'efficiency' in the attainment of any objectives, denies trade-offs based on local information and incentives, and hence blocks flexibility in response to changing circumstances. Indeed, the single-minded pursuit of overriding objectives, of absolute priorities, naturally disrupts the fine coordination, the requirements of 'balance', necessary to consistently and efficiently pursue any objectives.

Throughout the history of the Soviet Union, the needs of centralization, given Soviet social goals, stood in fateful opposition to the necessity to decentralize in order to keep the system tolerably functioning. The latter necessity spawned repeated (partial) remonetizations and a 'second economy' that both shored up the operational foundations of the 'first economy' and undermined its long-term viability, corroding its ideological and systemic foundations. Money so unleashed intensified the dysfunctions and contradictions of the 'command economy', spurring further repeated 'reforms' and 'experiments' that merely further aggravated the inconsistencies, the 'oppositions' in the system, until the central leadership, largely unintentionally and out of ignorance, destroyed the 'command economy' in the radical systemic and economic 'restructurings' beginning with *perestroika* in 1987.

Commodity Fetishism

Andrew Levine

Abstract

An analysis of Marx's notion of 'commodity fetishism' – as a theory of the necessary (systemically induced) misperception of underlying production relations by participants in market exchanges. The appeal of the notion to the two main opposing tendencies of mid- and late 20th-century Marxism – Marxist humanism and structuralist Marxism – is discussed. Reasons are proposed to account for a recent decline of interest in the phenomenon among both economists and philosophers. It is suggested, however, that the concept remains viable.

Since Plato, philosophy and then science have assumed first, that there is often a difference between appearance and reality; and, then, that it is sometimes possible to grasp what really is the case by investigating how things appear. Marx's account of commodity fetishism, a crucial step in his account of the capitalist mode of production, implements these assumptions explicitly. It describes how exchange relations appear to economic agents, where the appearance belies the reality at the same time that it provides cognitive access to it.

Market exchanges occur in all modes of production capable of sustaining an economic surplus. In capitalism, the process is generalized – not just in the sense that markets structure economic life but also, more importantly, because everything is commodified that can be. Universal commodification is the result of a protracted process that is definitively launched once labour – or, more precisely, labour power (labour time, adjusted for differences in intensity) – is commodified. The commodification of labour power is pivotal because this commodity is the sole source of value and therefore, ultimately, of wages, profits and rents. The generation and distribution of surplus value, of what is produced in excess of what is needed to reproduce the labour power expended in production processes, is the invisible underlying reality upon which perceptions of exchange relations depend. To persons engaged in buying and selling labour power, what appears is just that, as in any other exchange, individuals aim to do as well for themselves as they can, given

their resources, their preferences, and the production technologies available to them. But what is really going on is a struggle over the distribution of the economic surplus at the point of production. That reality is opaque. Economic agents are therefore governed by the appearance of rational economic agents maximizing payoffs to themselves. In his account of commodity fetishism, Marx shows how this inevitable misperception helps to reproduce and sustain the underlying reality.

When Marx expressly addresses this phenomenon at the conclusion of the opening chapter of the first volume of *Capital* (1867), the economic agents he describes are property-holding individuals. Thus it is not exactly capitalism that he aims to model, but 'simple commodity production', an ahistorical idealization. However, the cogency of his account is unaffected as his analysis becomes more historical and concrete – to the point that the direct producers are, as in full-fledged capitalism, a property less proletariat with nothing to exchange except, of course, their own labour power. Commodity fetishism is therefore a general and pervasive fact wherever capitalist social relations hold sway. Thus the term denotes a systemic opacity at the level of appearance that helps to hold economic agents in thrall by masking the exploitation of labour. Because this misperception sustains the exploitation that engenders it, revolutionaries intent on overthrowing capitalism must tear away the veil of illusion by revealing the exploitation of workers that exchange relations conceal.

Marx does not directly address *how* commodity fetishism comes into being or how it is sustained. But he does provide fragments of an explanation when he focuses on the atomizing effects of market relations. All resource allocation mechanisms are social in the sense that they bring together a host of disparate and heterogeneous economic activities. However, where the commodity form prevails, the social character of market transactions is apparent only after goods and services are produced. The workers know that the corn they consume is produced by farmers, and the farmers know that the tools they use in growing corn are made by workers. Everyone also knows that, without food, workers would not be able to make the tools farmers use; and that, without tools, farmers would not be able to grow food for the workers. It is therefore evident in retrospect that workers and farmers are engaged in a collective endeavour. But it is not similarly evident prospectively. From that vantage point, it seems only that farmers and workers – and also the capitalists who provide them with means of production – are making individual choices aimed at bringing about the best outcomes for themselves, given the constraints they face. Even if they believe that these essentially egoistic activities are somehow socially beneficial, they can justify this belief by appealing to the workings of an 'invisible hand'. Because there is no visible hand that directs the process, the terms of interaction appear *as if* they are forces of nature to which individuals must accommodate. Thus market relations appear as infrangible constraints that human beings are obliged to operate within, not as social constructions that human beings can change. In terms that Kant introduced and that Marx, following Hegel, effectively assumed, freedom (autonomy) is then forfeit. Wills are heteronomously determined, governed by laws of an (apparently) impersonal *other* (the market system itself). To be free, we must therefore take control of the aggregation mechanism we have concocted. We do so by putting reason in command – not just at the individual level of the rational economic agent, but at the societal level as well.

What Marx says about commodity fetishism is concise and intriguing. For these reasons, and because it summarizes the very abstract analysis of the commodity form with which *Capital* begins, his account of the phenomenon has always been well known. 'Commodity fetishism' is one of those terms that everyone associates with Marx. But, even in what remains of Marxist circles, the basic tenets of Marx's account have faded from ongoing discussions. A number of factors have contributed to this turn of events: among them, the legacy of the so-called 'value controversy' of the 1970s; the efforts of mathematical economists in the 1970s and 1980s to put the categories of Marxist economic analysis on a sound, analytical footing; and attempts by analytical philosophers, working on Marxist themes, to reconstruct and, when possible, defend core Marxist positions. The

conclusion that has emerged is that, *pace* Marx, there is nothing special about the commodification of labour power and therefore that the theory of surplus value cannot be sustained in the way that Marx believed. Nowadays, it is only the most doctrinaire Marxists who uphold the labour theory of value, the basis for Marx's account of commodity fetishism. This fact along with the decline of political movements that identify with the Marxist tradition and, its inevitable consequence, waning interest in Marx's work itself, has, for the time being, made commodity fetishism a matter of concern mainly to historians of economic thought.

Not long ago, the situation was quite the opposite. From roughly the 1950s through the 1970s, commodity fetishism played a central role in the two most important and innovative tendencies in Marxist theory: Marxist humanism and structuralist Marxism. These were opposing tendencies, politically and substantively. But they converged on according commodity fetishism centre stage.

Marxist humanists sought to de-Stalinize Marxism by recovering its Left Hegelian roots. This meant reading Marx's work through the prism of his early writings, before he broke with his 'erstwhile philosophical conscience', as he proclaimed in 1845 in *The German Ideology.* For the Left Hegelians, Ludwig Feuerbach's philosophical anthropology, elaborated in *The Essence of Christianity* (1841), was fundamental. There Feuerbach 'inverted' the theological dogma that 'God makes Man' by showing how the God idea is an 'objectification' of essential human traits. Lacking materiality, God is purely an objectification, an 'alienated' expression of the human essence. In taking consciousness of this fact, one recovers essential humanity and becomes emancipated from the thrall of its systemic misrepresentation. In the *Paris Manuscripts* (1844), Marx applied the Feuerbachian programme to objects of labour; 'objectifications' too of essential humanity, but also material things and therefore not objectifications only. Feuerbach arrived at his conclusions by 'interpreting' the theology of Right Hegelian theologians. His working hypothesis was that they had gotten the concept of God right, but that they radically misconstrued what the concept *means*. In the *Paris Manuscripts* Marx treated (Smithian) political economy the same way. He assumed that it correctly describes 'economic facts'. The task, then, was to interpret those facts – in order to reveal the alienation they express and, in so doing, to advance the emancipatory project of Left Hegelianism. How successful Marx was in implementing this programme is subject to debate. What is clear is that, as the focus of his theoretical work turned away from Hegelian philosophy towards political economy, history and politics, he became disabused of the idea that Adam Smith or any other classical economist had gotten political economy descriptively right. His life's project, thereafter, was to rework the conceptual apparatus of classical economics – more usually in its Ricardian, not Smithian, form – with a view to revealing the real 'laws of motion' of the capitalist mode of production. In this endeavour, Feuerbachian philosophical anthropology seemed to play no role. But, following the lead of Georg Lukacs (1923) several decades earlier, the Marxist humanists pointed out that there was, in *Capital*, an explicit point of connection – in the text on commodity fetishism. It was there that Marx brought his analysis of the commodity form to completion. But it was also there that, in modelling the commodity form, Marx identified the objectification of essential human traits in the process of capital accumulation. In consequence, capital, becomes a 'fetish', a *god* in Feuerbach's sense – one who controls economic behaviour by force of (illusory) power.

Structuralist Marxists, like Louis Althusser, were intent on reading Left Hegelianism out of the Marxist canon. They therefore treated Marx's references to fetishes and gods as ironic figures of speech, even as they attempted to enlist the text on commodity fetishism in the service of opposition to Marxist humanism. Borrowing a concept from the French philosopher Gaston Bachelard (1884–1962), Althusser (1965) disparaged Marx's early work by asserting the existence of an 'epistemological break' within the Marxist corpus. What he had in mind was roughly a 'paradigm shift' – not, however, within an ongoing scientific practice but between pre-scientific modes of thought and the inception of a new science. In Althusser's account, two

previously monumental epistemological breaks had occurred – one that established mathematics in ancient Greece, and one that established the sciences of nature in 17th-century Europe. Marx's achievement was supposedly on a par with these; he opened up a science of history. He did so by anticipating the structuralist turn the 'human sciences' (in France mainly) would later take – first in linguistics and psychology, later in anthropology and psychoanalysis. Specifically, in *Capital* and other writings of his maturity, Marx explained a range of diverse 'surface' phenomena by construing them as effects of the workings of a relatively small number of underlying, generally invariant 'deep' structures. The text on commodity fetishism lent itself to this construal of Marx's explanatory practice in as much as it depicted the perceptions of economic agents as effects of the unseen but causally efficacious process of surplus value extraction. Thus Marx's account can be seen as a theory of necessary (systemically induced) *misperception* – consonant with notions of explanation that contemporaneous structuralists endorsed. Perhaps the most innovative use Althusser made of commodity fetishism was in his theory of ideology, according to which modes of production constitute experiential subjectivity by 'interpellating' the human subjects who support or 'bear' them.

We now inhabit a different intellectual universe. In the past several decades, it has come to be widely believed, by erstwhile Marxists as much as by 'bourgeois economists', that Marx's focus on production rather than exchange inhibited the development of analytical economic tools. In so far as this belief is sound, the emphasis Marxists placed on commodity fetishism is partly to blame. The explanatory strategies of Marxist humanists and of structuralists have fallen into disrepute, too – largely because, in both cases, though for different reasons, the alleged connections between appearance and reality were never satisfactorily explained. No sustainable account was given either of how interpretation should proceed in the Marxist humanist case or, in the structuralist case, of how deep structures can be discerned in surface phenomena. Thus, commodity fetishism has fallen on hard times. However, we should not conclude that there is nothing viable in the concept or in the theoretical traditions that, until recently, magnified its importance. Hegelianism certainly, and structuralism possibly, still have much to teach us. The last word may not yet have been said on the theory of surplus value, either. If and when interest in Marx resumes, it will certainly be useful to revisit these issues. The notion of commodity fetishism played a key role in mid- and late 20th-century Marxism. The core idea it articulates – that necessary misperceptions sustain the capitalist order – can again provide useful insights. The concept may not be forever doomed to be of historical interest only.

Commodity Money

François R. Velde and Warren E. Weber

Abstract

Commodity money is a medium of exchange that may be transformed into a commodity, useful in production or consumption. Although commodity money is a thing of the past, it was the predominant medium of exchange for more than two millennia. Operating under a commodity money standard limits the scope for monetary policy, actions that alter the value of money. However, it does not eliminate monetary policy entirely. The value of money can be altered by changing the commodity content or legal tender quality of monetary objects, or by restricting the conversion of commodities into money or vice versa.

A commodity is an object that is intrinsically useful as an input to production or consumption. A medium of exchange is an object that is generally accepted as final payment during or after an exchange transaction, even though the agent accepting it (the seller) does not necessarily consume the object or any service flow from it. Money is the collection of objects that are used as media of exchange. Commodity money is a medium of exchange that may become (or be transformed into) a commodity, useful in production or consumption. This is in contrast to fiat money, which is intrinsically useless.

Commodity money can also be thought of as a medium of exchange that contains an option to consume a predetermined service flow at little or no cost. The option can be exercised in various ways, depending on the object. Coins can be melted down (at little cost) and the metal applied to non-monetary uses. In the case of paper or token money under a commodity money standard, the medium of exchange itself is intrinsically useless, but it is costlessly convertible into a specified quantity of the commodity on demand. Fiat money can also be converted into goods or services, but in quantities that will depend on market prices.

Commodity money is a thing of the past; countries worldwide now use fiat money standards. However, this is a relatively recent development. Commodity money, primarily in the form of coined metals, was the predominant medium of exchange for over two millennia. Although operating under a commodity money standard limits the scope for monetary policy, it does not eliminate it entirely. The history of commodity money is replete with numerous ways in which governments have altered the monetary system to achieve various goals.

From Commodity Money to Fiat Money

In early or primitive societies, it is often difficult to characterize the general patterns of trades and transactions, let alone determine how generally accepted a particular commodity might be. Nevertheless, a wide range of commodities have been reportedly used as money (cowry shells, wampum, salt, furs, cocoa beans, cigarettes and so on), perhaps the most exotic being the stone money of the island of Yap in Micronesia.

General acceptability of monetary objects is most clearly ascertained when the objects are standardized and exchanged repeatedly. With metallic commodities, the standardized objects are called coins. Coinage of metal began in the eastern Mediterranean region or the Middle East, India and China between the 6th and 4th centuries

BC. Coinage has developed in parallel and broadly similar ways in these areas.

The metals most commonly used have been gold, silver and copper (in decreasing order of scarcity), in varying degrees of fineness (silver mixed with substantial amounts of copper, called billon). Lead, tin and various copper alloys (bronze, brass, potin) have also been used, although less frequently than the more common metals. The metal is either mined or acquired through trade. The most common method of coinage is striking with a die, although cast coins are also found. In many legal traditions the right of coinage is a prerogative of the public or central authority, although it may be delegated or leased to regional authorities or private parties. This prerogative may also extend to mining. In other words, the rules governing the supply of commodity money vary from government monopoly to minimal regulation.

In Europe and the Mediterranean, coinage – an invention mythically linked to Croesus, King of Lydia – began near the Aegean Sea in the 6th century BC. The use of money developed considerably in Greek and Roman times, leading to a three-tiered system of gold, silver, and copper denominations. In the Roman empire, the provision of coinage was a government monopoly. The collapse of the empire in the West led, after a long transition, to a purely silver-based monetary system, with a largely decentralized provision of minting. Uniformity of coinage was restored under Charlemagne but quickly disappeared along with political fragmentation. Gold returned in common use from the mid-13th century. By the 14th century, most mints in western Europe operated along similar lines, with more or less unrestricted coinage on demand provided by profit-making mints. A great multiplicity of monetary systems persisted, giving rise to both foreign exchange markets (the earliest financial markets) and money changers (the first financial intermediaries).

The first instances of token coinage (coins that are intrinsically useless but are claims to fixed amounts of the commodity) appeared in the 15th century in Catalonia. Notes convertible on demand appeared in the 17th century, in Sweden and later in England. For a more complete discussion of medieval European coinage, see Spufford (1988).

Coins appear to have been used in India in the early 4th century BC and were probably used before then. The earliest coins were so-called punch-marked coins and were adaptations of Greek prototypes. Coins were first used in China and the Far East about the same time as in India. The distinctive bronze coinage with the square hole in the middle first appeared in the 3rd century BC. Early coins in eastern Islamic lands were copies of Byzantine gold and bronze coins; those in the East were copies of Sassanian silver coins. For more on coinage in India and the Far East, see Williams (1997).

Until the 19th century, coins typically bore no indication of face value, and their market value could fluctuate even relative to one another. From the late Middle Ages, governments increasingly sought to regulate the value of coins in some manner, in particular assigning face value or legal tender value by decree. It became desirable to turn the collection of objects used as a medium of exchange into a stable system with fixed exchange rates between the objects. This was achieved to a large degree with bimetallism, a system in which gold and silver coins remained concurrently in circulation at a constant relative price. Its heyday was the mid-19th century, but beginning in 1873 the system was quickly abandoned, and by the First World War countries were using either gold only or (in Africa and eastern Asia) silver only. (Bimetallism is discussed in more detail in Redish 2000, and Velde and Weber 2000.) The development of banking in the 19th century also led to increased use of (convertible) notes and other monetary instruments.

The First World War brought about the suspension of convertibility of the notes in many countries. Most countries returned to convertibility between 1926 and 1931, but the onset of the Great Depression reversed the movement. After the Second World War the only major country whose currency was in any way directly tied to a commodity was the United States under the Bretton Woods system: dollars were convertible

by non-residents of the United States into gold on demand, while other currencies of the system were convertible into dollars. The link between gold and the dollar was severed in 1971. Fiat money standards are now universal.

The Nature of Commodity Money

The definitions of commodity and fiat monies given above make it seem as if there is a clear distinction between the two. It is more helpful, however, to think of media of exchange along a continuum. An object serving a purpose as a medium of exchange has value above its intrinsic content, reflecting the value of the service as a medium of exchange.

Because the value of a commodity qua commodity and the value as a medium of exchange can differ, the value of all commodity monies has a fiat component. A pure fiat money is one for which this fiat component makes up its entire value. A nice theoretical discussion of commodity and fiat monies is given by Sargent and Wallace (1983).

Price-Level Determination

It is natural that the medium of exchange in an economy is what becomes the unit of account, the unit in which debt contracts and the prices of goods and services are expressed. It is natural because the money appears on one side of virtually every transaction.

Because commodity money has an intrinsic value apart from that which it obtains by being a medium of exchange, its relative price will not be zero. Thus, in a commodity money economy, the value of money (the inverse of the price level) is bounded away from zero. Moreover, in a canonical commodity money system (see below) with unlimited minting at a set price, the value of money and its quantity tend to remain within a band. If the value of money falls far enough, it becomes preferable to exercise the option and convert some of it into other, non-monetary uses, thus reducing the quantity and preventing the value from falling further. Conversely, if the value of money rises high enough, it becomes worthwhile for agents to turn metal into coins at the mint at the set price, thus increasing the quantity of money. Such a self-regulating commodity money system provides an anchor to the price level. This has been touted as one of the advantages of a commodity money system, particularly in the case of the gold standard.

The question of price-level determination becomes more complicated when multiple commodity monies are made out of different commodities. An example is the circulation of full-bodied gold and silver coins. Should the unit of account be the gold coin or the silver coin? This matters because under a commodity money system a monetary authority does not have the ability to set the exchange rate between monies of different commodities forever. Thus, to the extent that the unit of account is used in contracts to determine the amount of future payments, the choice of the unit of account can affect the allocation of goods and services. This was one of the issues surrounding the possible adoption of a bimetallic standard mentioned above.

The inability of the monetary authority to set the exchange rate between different monies goes away under a pure fiat money system. Because fiat money is (virtually) costless to produce, the monetary authority can costlessly exchange one money for another to maintain whatever exchange rate is desired between different monies that it issues.

Monetary Policy

The fact that a commodity is used as money alters its value. This is because part of the total quantity of the commodity – namely, the metal locked up in the form of coins, or the reserves held by the monetary authority – is not available for non-monetary uses. The allocation between monetary and non-monetary uses is determined in equilibrium. Restrictions on the ability to change this allocation, such as restrictions on melting or exporting coins, or limitations on the minting of metal, will have an effect on the equilibrium value of the money even if it has no immediate effect on

the allocation itself. (Since money is an asset, its valuation is forward looking.) Thus, there is scope for monetary policy under a commodity money standard, although what constitutes monetary policy is different from and more limited in scope than what holds under a pure fiat money standard.

Monetary policy consists in actions that tend to alter the value of money. In a commodity money system, the value of money is the value of the option we have described. (The strike price of the option is zero, since the commodity is the money.) Most aspects of monetary policy with commodity money consist in modifying this option, typically by modifying the institutions governing the exercise of the option rather than by modifying the quantity of money, which the authority usually cannot control directly. When the monetary authority is directly involved in the provision of the money, it may directly profit from its actions. Potential profit is often an important consideration of monetary policy.

The canonical form of a commodity money standard comprises the following. One or more commodities are chosen to be the standard to which the monetary system will be anchored. The monetary authority defines the specifications of the monetary objects (weight, fineness) and defines the unit of account in terms of these monetary objects. The conversion of commodity into commodity money and vice versa is as costless as possible. In particular, the monetary authority provides for unlimited (and even costless) conversion of the commodity into monetary objects (coins or notes). Conversely, it places no hindrances on the conversion of monetary objects into commodities (coins can be melted, notes are convertible on demand), nor does it place limitations on the consumption of the commodity or its service flow (free possession, unrestricted import and export of the commodity). The monetary objects are unlimited legal tender.

One type of monetary policy modifies the specifications of monetary objects and units of account. An example is debasement, which is reducing the commodity content of a monetary object (and, frequently, of the corresponding unit of account). The result of debasement is inflation, since nominal prices will be adjusted to maintain the relative prices of goods and money. And, just as occurs with fiat money, inflation has the effect of transferring wealth from nominal creditors to nominal debtors. Since governments generally tended to be debtors, debasements were used to reduce the amount of their debts. Historically, debasements also had the secondary effect of increasing seigniorage revenue, since the quantity of coins minted tended to increase significantly after debasements that involved the introduction of new coins (see Rolnick et al. 1996; Sargent and Smith 1997). Debasements were also used by governments to remedy malfunctions of a multiple-denomination commodity money system (see Sargent and Velde 2002).

A second type of monetary policy adds or modifies restrictions on the conversion of commodity into money or money into commodity. For example, minting might be restricted by quantity, in which case the authority decides how much to mint. Minting might be unlimited but subject to a fee, called seigniorage. Governments typically charged such a fee, both to cover the actual costs of minting (called brassage) and as a tax (England was the first, in 1666, to provide minting at no cost). The rate of this tax or, equivalently, the price paid by the mint for bullion might be changed. These restrictions tended to alter the allocation of the commodity between monetary and nonmonetary uses, and hence the value of the commodity and the money.

A third type of monetary policy sets limits to the legal tender quality of certain coins, or changes their legal tender value. Since coins did not have face values until the 19th century, it was up to monetary authorities to set, and from time to time alter, the legal tender values of coins. Frequently, foreign coins were authorized as legal tender at rates set for domestic coins. Countries attempting to maintain bimetallism in the face of fluctuations in the relative price of gold and silver often had to adjust the face value of either their gold or silver coins. Changes in the legal tender values could also be motivated by fiscal considerations or by attempts to target a particular price level or exchange rate.

The physical nature of the medium of exchange led to a particular set of concerns.

Coins, like anything else, depreciate with use, through wear and tear. Since coins of different values have different usage rates, the depreciation rate varied by denomination. Also, being roughly constant over time, depreciation depended on the age of the coin. Finally, imperfect minting technology as well as actions by the public (clipping, sweating) aggravated the disparities between coins. This factor introduced heterogeneity among coins and hindered the achievement of a stable and uniform monetary system. Improvements in coin production partially remedied the problem, as did periodic recoinages.

When the monetary objects consist not only of coins but also of paper currency or tokens that are demand promises to the commodity, a fourth type of monetary policy is available: suspension of convertibility. The monetary authority can refuse to honour the promise of convertibility for some period of time. An example is the suspension of convertibility by the Bank of England between 1797 and 1819 during the wars with France. During the 19th century suspensions were not uncommon during financial or fiscal emergencies, with the understanding that the suspension would end after the emergency and convertibility would be restored at the preexisting parity. This understanding has been described as a state-contingent gold standard (see Bordo and Kydland 1996).

When there is a central bank, an additional monetary tool is to change the discount rate, the interest rate at which the central bank lends reserves to the banking system. During the gold standard period, this was the primary means by which central banks affected the exchange rate of their money against the monies of other countries.

Conclusion

Commodity money is a thing of the past; countries worldwide now use fiat money standards. This practice has led to an efficiency gain in the sense that resources that were once tied up in coins are now available for consumption and production (perhaps prompting John Maynard Keynes to refer to gold as the 'barbarous relic').

It has also led to a greater scope for monetary policy because the supply of money can be changed almost costlessly. However, along with this greater scope has come the greater potential for governments to use inflation to collect seigniorage revenue or to reduce the real value of their debts. How to use the freedom that commodity money restricted is still a matter of debate.

Commodity Reserve Currency

Albert Gailord Hart

Commodity Reserve Currency (CRC for short) is a proposal for re-establishing an international monetary 'standard' – basing it upon a 'basket' of widely used commodities. Recent experience shows the inconvenience of lacking a standard. While restoration of a gold standard has many supporters, gold has become so remote from the goods-and-services economy that for decades now governments have had scope to play tricks with its price; and since the early 1970s, the value of gold has been highly unstable. Can there be a commodity standard other than gold, less abstract and linked to articles of everyday use? A good way to study this question is to examine the feasibility and desirability of CRC.

Pioneers of the CRC proposal were Jan Goudriaan and Benjamin Graham. Variant proposals have come from a number of economists, including Lord Keynes and Friedrich Hayek. The nearest approach to a standard version is probably still the submission of 1964 to the United Nations Conference of Trade and Development by Albert Hart, Nicholas Kaldor and Jan Tinbergen. No governments or major multilateral bodies have sponsored CRC, though there has been official and private use of 'baskets' of currency units (ECU, etc.), and of 'baskets' of securities (traded on various private commodity exchanges).

Advocates of CRC propose that it be administered by a multinational agency, which we may call IMA – presumably to be a branch of the International Monetary Fund. A currency unit (which following Lord Kaldor we may call the Bancor) is to be defined as the value of a basket of primary commodities, with fixed physical composition.

Like the administrator of a traditional gold standard, IMA must buy or sell at a stated price (plus or minus a margin to avoid a hair-trigger effect) as much of the monetary commodity (i.e. the commodity baskets) as may be offered or demanded. As to the margin, some CRC proponents suggest 5 per cent on each side of par; but a wider range would have great advantages. Prices of the individual component commodities could fluctuate more than the basket. Any one commodity price could rise; but if its rise would bring the basket above the posted selling price, sales of baskets by IMA would bring a compensating fall of other prices.

The price of a basket with fixed physical composition is an index number of commodity prices, weighted by the quanta of the various items included. Hence CRC may be viewed as a scheme to stabilize an index of primary-commodity prices. CRC thus would have a counter-cyclical effect – holding within bounds the fluctuation of income for the world's exporters and producers of primary commodities, and by the same token the fluctuation of major elements in the world's cost of living.

An effective CRC would require that national currencies be tied to the Bancor by fixed exchange rates, or at least by not-too-movable pegs. The general stabilization effect of the proposal would vanish if major currencies were allowed to float against the Bancor.

Many primary commodities have been proposed for a CRC basket. Major criteria for inclusion are:

(1) *Standardization*, of the sort necessary to run futures markets on a commodity exchange – with rules for dealing with quality differences.
(2) *Storability* for at least a year or two without excessive cost or loss of quality. Security against fire, looting, requisition by local governments, etc., is implied.
(3) *Improbability of major price manipulations* by governments or by combinations of producing enterprises. Long before OPEC rose to power in 1973, this criterion led advocates of CRC to omit petroleum from the proposed basket.
(4) *Reliability of commodity contracts*, enabling the IMA to replace physical holdings with contracts for future or spot delivery if this will reduce costs. Use of futures could be of

humanitarian importance in case of shortages of foodstuffs such as rice.

These criteria would admit most of the world's important grains, fibres, fats and oils, beverage crops, primary metals – and probably a number of basic chemicals and forest products. Amounts of the various commodities in the basket would reflect their weight in world production and/or trade.

The CRC basket must be large (worth several million US dollars), because for efficient trading each element must be a multiple of a wholesale lot. This large basket-size would be appropriate, since CRC is designed as a vehicle for holding national monetary reserves rather than for retail or even wholesale trade.

IMA holdings of the various commodities must be parcelled out to points of delivery and storage along the normal trade routes of the commodities. Correspondingly, IMA purchases and sales must be handled by agents at the various trading points. To tell whether at any moment baskets must be bought or sold, IMA must sum up bids or offers reported by these agents. IMA must take the initiative – instructing all agents to sell or buy – whenever the sum of bid prices for the elements of the basket adds up to the posted selling price for the basket, or the sum of asked prices to the buying price.

Objections to CRC have hinged primarily on costs and/or on the difficulties of getting a CRC system under way. There has been continuing debate about the size of the reserve needed to validate IMA selling offers, about the cost of holding stocks of various suggested commodities, etc. Such costs must be compared with benefits from reducing cyclical fluctuations in primary producers' incomes, etc. – and of doing so without engaging in commodity-by-commodity operations. Benjamin Graham used to stress that the success of such operations hinges on restriction of commodity production, whereas success of CRC would stimulate production. For this and other reasons, the cost/benefit problem is complex.

During episodes of worldwide commodity stringency, accumulation of a commodity reserve has seemed impossible. When there has been a great piling up of stocks (as at this writing in early 1986), it has seemed as if mobilization of stocks held by the European Economic Community, the United States, various other governments such as Brazil, cartels such as that for tin, and private concerns such as copper companies, might permit a very rapid start.

Starting a CRC during a period of widespread shortages could be highly inflationary; starting it during a general economic downswing could mitigate a recession. There is debate as to whether accumulation of a reserve must stick to previously agreed proportions of the different commodities, or whether (as proposed by Keynes and more recently by Kaldor) the IMA should buy individual commodities at such dates and prices as seem wise. On this route, the composition of the CRC basket and the selling-price offer would grow out of the process of accumulation. This variant, plainly, would increase the similarity of IMA's operations to those of commodity 'stabilization' groups and remove the impersonality held to be the central virtue of the Goudriaan/Graham scheme.

Common Factors

Heather M. Anderson

Abstract

This article outlines and illustrates several types of common factor models that are found in the applied economics literature. These factor models include those based on principal components, classical factor analysis, dynamic factor analysis and common features, and the discussion addresses the identification and estimation of factors, as well as the use of common factor models.

Economic analysis frequently involves the study of variables that exhibit similar behaviour, and it is often of interest to model this comovement. Well-known examples of comovement in multivariate data sets include business cycles in macroeconomic indicators and shifts in the entire term structure of interest rates, and researchers sometimes attribute this comovement to a small set of underlying forces or latent 'factors' that influence each variable in the system. It is then convenient to think of the variation in each variable in the system as the sum of two types of (unobserved) components, one of which captures variation that is due to 'common factors', while the other captures all other variation. Models that attribute comovement to common factors are called common factor models, and common factor analysis involves the identification and study of the common factors.

Common factor models are particularly popular in empirical settings because they offer parsimony, and simplify estimation by reducing the number of parameters that need to be estimated. Economists will typically be interested in interpreting common factors so that they can explain why comovement occurs. Economic theory sometimes predicts common factors. Perhaps the best-known example of this is the capital asset pricing model, in which the (excess) return for the market portfolio is the common factor in the (excess) return for each individual stock. Another well-known example arises when the term structure of interest rates is modelled, because the no arbitrage condition implies that the entire term structure is determined by a single factor, which is the instantaneous interest rate.

A simple model that captures the concept of common factors in a set of N time-series in the (demeaned) vector $Y_t = (Y_{1t}, Y_{2t}, \ldots, Y_{Nt})'$ is given by

$$Y_t = AF_t + \varepsilon_t, \tag{1}$$

where F_t is an $r \times 1$ vector that contains r common factors, A is an $N \times r$ factor loading matrix (with $rank(A) = r < N$), and ε_t contains N idiosyncratic components. With the use of Σ_Y, Σ_F and Σ_ε to denote the variance covariance matrices of Y_t, F_t and ε_t, it is usual to assume that Σ_ε is diagonal, and it is also common to normalize the set of r factors in F_t by assuming that $\Sigma_F = I_r$.

Model (1) is similar to conventional factor models that are often used in cross-sectional settings, although the variables are specified here as time series, to facilitate discussion on dynamic factor models. If there is no serial correlation in Y_t or F_t, or if estimation is undertaken as if this is the case, then (1) is called a static factor model. It is usual to assume that F_t and ε_t are jointly stationary, that $E(\varepsilon_t) = 0, E(F_t\varepsilon_t') = 0$, and that ε_t contains no serial dependence, but these latter assumptions can be relaxed, depending on the type of factor model under consideration.

There are many ways to identify the factors in (1), and standard techniques include the use of principal component analysis, factor analysis and canonical correlations to estimate the parameters of various associated reduced rank regressions. More recently, researchers have focused on the time series properties of multivariate data-sets, and modern factor models include dynamic factor (or index) models, and models that incorporate common features. These latter models incorporate various ways of allowing the factors to follow specific dynamic processes, or to contain specific time-series properties.

Principal Component Models

Principal component analysis involves the intuition that most of the variance in Y_t will be attributable to variance in the r components in F_t. The factors F_t are modelled as linear combinations of Y_t, and their identification is based on finding the r (orthogonal) linear combinations of Y_t that have the most variance. In practice this involves finding the eigen values $\lambda_1 > \lambda_2 > \ldots > \lambda_N$ and associated eigenvectors $f_1, \ldots, f_N$ of the form $f_i = \beta_i' Y_t$ that are associated with the roots of the equation $|\widehat{\Sigma}_Y - \lambda I| = 0$, where $\widehat{\Sigma}_Y$ is an estimate of Σ_Y. The β_i are picked so that $\left(\widehat{\Sigma}_Y - \lambda_i I\right)\beta_i = 0$ and $\beta_i'\beta_i = 1$, and the factors F_t are then defined by $F_t = (f_1, \ldots, f_r)$. This decomposition ensures that $E\left(F_t'\varepsilon_t'\right) = 0$, but it implies that the ε_t (which are each linear combinations of $(f_{r+1}, \ldots, f_N)$) will be correlated with each other so that Σ_ε will not be diagonal. Principal components estimators of common factors and factor loadings are also the least squares estimators of the reduced rank regression given by

$$Y_t = \underset{(N\times r)}{A}\ \underset{(r\times N)}{B}\ Y_t + \varepsilon_t, \tag{2}$$

where BY_t contains the r factors $F_t = (f_1, \ldots, f_r)$. Anderson (1984, ch. 11) provides a standard reference.

In practice, one needs to determine r before estimating common factor models, and this is often based on the ratio given by $\frac{\lambda_{r+1}^2+\ldots+\lambda_N^2}{\lambda_1^2+\ldots+\lambda_N^2}$. This ratio measures the loss of information in the reduced rank system relative to an unrestricted system, and typically investigators will choose r so that this ratio is kept small. Bai and Ng (2002) have developed model selection criteria that are consistent as $\{N, T\} \to \infty$.

Principal components are usually used for dimension reduction, and economic interpretation of the resulting factors is rarely straightforward. However, Stone (1947) has summarized a set of series from the US national accounts, associating the first three principal components with income, income growth and time and Chamberlain and Rothschild (1983) have promoted the use of principal components for estimating approximate factor models of asset prices. Stock and Watson (2002) have suggested the use of diffusion indexes (principal component factors associated with large macroeconomic data sets) for forecasting key macroeconomic variables, and the interest here centres on using information in the factors rather than interpreting the factors themselves.

Classical Factor Models

Classical factor models are closely related to principal components models, but the underlying intuition and assumptions are different. In this case the key assumption is that Σ_ε is diagonal so that the ε_t describe idiosyncratic effects that are unique to each variable in Y_t, while the factors describe joint effects in Y_t. The assumptions that $E(\varepsilon_t) = 0$ and $E\left(F_t\varepsilon_t'\right) = 0$ still hold, and the ε_t are assumed to contain no serial dependence. Under these

assumptions $\Sigma_Y = A\Sigma_F A' + \Sigma_\varepsilon$, and estimates for A, Σ_F and Σ_ε can be found by maximizing the function

$$L_T(A, \Sigma_\varepsilon) = -\frac{T}{2}\ln|\Sigma_Y| - \frac{1}{2}\sum_{t=1}^{t=T} Y_t'\Sigma_Y^{-1}Y_t$$

subject to the condition that $rank(A) = r$ and a set of normalization restrictions that will uniquely identify the $(r+1)(N+\frac{1}{2}r)$ parameters. Researchers often use the joint restrictions that $\Sigma_F = I_r$ and that $A'\Sigma_\varepsilon^{-1}A$ is diagonal for normalization, but other normalizations are common (see Anderson 1984, ch. 14, for details). If Y_t and ε_t are normally distributed then L_T (A, Σ_ε) is the log likelihood for Y_t (if we ignore the constant term), but, even when Y_t and ε_t are not normally distributed, the maximization of $L_T(A, \Sigma_\varepsilon)$ delivers quasi-maximum likelihood estimates. There are several ways of using the estimates of A and Σ_ε to obtain estimates of the factors in F_t, and perhaps the best-known of these is Bartlett's (1937, 1938) method based on generalized least squares given by

$$\widehat{F}_t = \left(\widehat{A}'\widehat{\Sigma}_\varepsilon^{-1}\widehat{A}\right)^{-1}\widehat{A}'\widehat{\Sigma}_\varepsilon^{-1}Y_t.$$

As above, it is necessary to determine r prior to estimating the factors, and, on the assumption of normality, the likelihood ratio test statistic for testing H_0: $r = s$ versus H_A: $r > s$ is given by

$$-T\left[\ln|\widehat{\Sigma}_Y\right| - \ln|\widehat{A}\widehat{A}' + \widehat{\Sigma}_\varepsilon|] = -T \quad \Sigma_{i=s+1}^{i=N}\ln\left(1-\widehat{\lambda}_i^2\right),$$

where the $\widehat{\lambda}_i$ are the characteristic roots of $\widehat{A}'\widehat{\Sigma}_\varepsilon^{-1}\widehat{A}$ (in decreasing order) and $\hat{A}$ is estimated under the null. The test statistic is asymptotically distributed as a χ_q^2 with $q = [(N-s)^2 - N - s]/2^\circ$ of freedom under the null.

There are numerous applications of classical factor analysis to economic problems, and an early example includes Stone's (1945) factor analysis of the demand for N commodities. Another example includes a factor model of returns by Deistler and Hamann (2005).

Dynamic Factor Models

Classical factor models are not well suited to multivariate analysis of time series because they assume no serial correlation in ε_t, and, if there are any dynamics in F_t, then they are implicit and not explicitly modelled. Dynamic factor models address these concerns by treating the ε_t and F_t as autoregressive moving average (ARMA) processes. The innovations that underlie the N processes for ε_t are assumed to be mutually uncorrelated, and uncorrelated with the innovations that underlie the F_t at all leads and lags, but the factors themselves can be mutually correlated. Different variables in Y_t can then move together because they are functions of the same factor (s), or because they are functions of different factors that are themselves correlated.

The identification and estimation of small-scale dynamic factor models is sometimes based on spectral techniques (see Geweke 1977; or Sargent and Sims 1977), and use of the Kalman filter in the time domain (as in Engle and Watson 1981, or Harvey and Koopman 1997) provides an alternative approach. Dynamic factor models have been particularly popular for estimating factor models of business cycles (as in Geweke and Singleton 1981), but they have also been used for studying the term structure (Singleton 1980) and fluctuations in employment across different industrial sectors (Quah and Sargent 1993).

Recent work has shifted towards the identification and estimation of common factors in large-scale models, relying on the use of large N to obtain consistent estimates of the factors. One strand of this literature adopts a static framework and standard principal components to estimate the factors, and then builds dynamic models of the factors. The resulting models are sometimes called approximate dynamic factor models. Applications of this approach include Stock and Watson's diffusion index (2002), and Bernanke and Boivin's (2003) estimation of a monetary policy reaction function. Another strand of this literature allows different variables to depend on different lags of common factors. These 'generalized dynamic factor models' are estimated using 'dynamic principal components', which are the principal components of

spectral density matrices at different frequencies. Applications of this latter approach include a study of business cycle dynamics in the United States (Forni and Reichlin 1998) and the development of a coincident index for Europe (Forni et al. 2000).

Canonical correlation-based models

Principal component and factor models assume that the factors are linear combinations of the N variables in Y_t, but sometimes it is useful to assume that the factors are linear combinations of M variables contained in another multivariate time series denoted by X_t. The variables in X_t will often include lags of the variables in Y_t, but X_t can also include variables that would be classified as explanatory variables in a regression context. The factors in (1) can now be written in the form $F_t = B'X_t$ (where $rank(B) = r < \min\{N, M\}$). In what follows, we assume that the ε_t in (1) are white noise and uncorrelated with X_t.

The main idea behind a canonical correlations approach is to find linear combinations of X_t that are strongly correlated with linear combinations of Y_t, and, as for principal component models, the estimators of common factors and factor loadings are the least squares estimates of a reduced rank regression. In this case the regression is

$$Y_t = \underset{(N\times r)}{A}\ \underset{(r\times M)}{B}\ X_t + \varepsilon_t, \tag{3}$$

and the factors and factor loadings are related to the r largest roots of $R = \Sigma_Y^{-\frac{1}{2}}\Sigma_{YX}\Sigma_X^{-1}\Sigma_{XY}\Sigma_Y^{-\frac{1}{2}}$, which is the multivariate generalization of the (squared) correlation coefficient between two variables. If we order these roots (also called squared canonical correlations) so that $\lambda_1^2 > \lambda_2^2 > \ldots > \lambda_r^2$, and let $V_1, V_2, \ldots V_r$ be the r associated eigenvectors, then the factor loadings and factors are given by $A_i = \Sigma_Y^{-\frac{1}{2}}V_i$ and $B_iX_t = \Sigma_Y^{-\frac{1}{2}}\Sigma_{YX}\Sigma_X^{-1}V_iX_t$. Anderson (1984, ch. 12) provides a detailed discussion of canonical correlations, while Izenman (1980) discusses the associated reduced rank regressions. When the variables in X_t are simply lags of the variables in Y_t, then the first factor is the best predictor of Y_t based on past history, the second factor is the next best predictor, and so on, and the factors provide a set of leading indicators for Y_t. When X_t consists of explanatory variables for Y_t, then the factors are often called coincident indices. One can base a test of $H_0 : r = s$ versus $H_A : r > s$ on the test statistic $-T\Sigma_{i=s+1}^{i=N}\ln\left(1-\widehat{\lambda}_i^2\right)$, which has a χ^2 distribution with $(m - s)(n - s)$ degrees of freedom under the null.

Common Feature Models

Common feature models are a special class of factor models in which the common factors have a statistical characteristic of interest, while the idiosyncratic components fail to have this characteristic. Common features were first introduced by Engle and Kozicki (1993) when they discussed serial correlation features – a situation in which each of N variables is serially correlated, but there are linear combinations that are white noise. Here, the presence of $N - r$ white noise linear combinations implies a factor model in which there are r serially correlated factors (which are sometimes called common cycles). An earlier example of a common feature model is Stock and Watson's (1988) common trend model which is valid when variables are cointegrated (as in Engle and Granger 1987). In this case the common factors are integrated of order one but the remaining components (often called error correction terms) are stationary. Other examples of common features include Vahid and Engle's (1993) common trend–common cycle representation, and common nonlinearity (Anderson and Vahid 1998).

The identification of common features involves finding linear combinations of the data that do not have the feature, and this can be done using a canonical correlations approach in which the variables in X_t model the characteristic of interest. To illustrate, lags of Y_t are put into X_t when testing for serial correlation features in Y_t, and lagged levels are included in X_t when testing for common trends. Factors associated with the lowest eigen values define linear combinations

that do not contain the feature, while factors associated with the highest eigen values are used to model the common features. Johansen's (1988) procedure provides a well-known example of this, although inference in this case is based on non-standard (rather than χ^2) distributions because the factors are non-stationary.

A well-known example of a common feature model is the real business cycle model of King et al. (1988), in which a common factor (productivity) generates the trend in output consumption and investment, and another factor (the deviation of capital stock from steady state) generates the common cycle.

Common Land

T. Williamson

The legal status of common land is a source of considerable popular confusion. With the notable exception of some village greens, commons do not represent areas which are owned by nobody, nor areas which are owned by everybody, nor even by everybody within a given locality. Since the early medieval period, commons have been owned by specific individuals, usually the lord of the manor within which they lie. The term 'common' refers not to ownership, but to rights held in common by certain people to use the product of the soil of the area in question. In turn, this means that the owner cannot enclose the land; hence the unfenced open space which is still the most characteristic feature of a common (Campbell and Clayden 1980).

These rights are not now, nor have they been in the historic past, generally shared by everyone living within a given locality. Instead they are usually attached to specific dwellings, or to their sites. Except, therefore, where the owner has so decreed, the use of commons as recreational open spaces by a wide public is not in the strict sense defensible in law.

Commons, of course, were not in origin primarily places for recreation. They formed a vital element in the pre-industrial rural economy. Commons represent the attenuated remnants of the medieval wastes: areas which were not used to produce arable crops, but to provide a range of other resources. The principle rights exercised by commoners were, and are: *common of pasture*, or the right to pasture animals; *pannage*, or the right to allow pigs to eat acorns or beech mast; *common in the soil*, or the right to take minerals, gravel, stone, sand etc. for use on the commoner's holding; *estovers*, or the right to take small branches, bracken etc. for fuel, fencing or animal litter; *turbary*, or the right to dig peat or turf for use as fuel; and *piscary*, the right to take fish from streams or ponds on the common. Of these rights, that of common of pasture has normally been by far the most important.

The early history of common land is obscure. It appears that in the early Saxon period, areas of open waste were much more extensive than they were to become in the medieval period, and the rights to their use were more loosely defined and often exercised by much wider groups. The name of Sherwood Forest, for example – the Shire Wood – indicates that it was once the common woodland of the entire shire of Nottingham. Limitation and closer definition of rights to common waste occurred during the population increase of the early medieval period (Hoskins and Stamp 1967). As arable expanded, common grazing dwindled, and areas of waste which had formerly been shared by communities were now divided between them, often after violent disputes. But there were also disputes within communities, as manorial lords, in association with their more prosperous tenants, attempted to take areas of the common waste into private ownership. The medieval struggle for the commons culminated in the Statute of Merton (The Commons Act of 1235), which decreed that freeholders had to be left with sufficient pasture to maintain the mixed farming of their holdings. However, the rights of the customary tenants were not protected by statute law, and the passing of the law for the first time clearly enshrined in national law the concept that the manorial lord rather than the community itself was the *owner* of the common waste of a manor.

The continual expansion of arable at the expense of the common wastes during the period before 1300 had other effects. There was an increasing tendency for commons to be *stinted*, that is, for the number of beasts put out by each commoner to be more carefully regulated. There were a number of ways in which this could be organised, the most usual being by the rules of levancy and couchancy, that is, where the right to turn out was measured by the capacity of the commonable tenement in such a way that only as many animals could be turned out as the tenement

was able to support (with the aid of hay etc.) through the winter.

The extent to which the commons survived during the medieval period varied considerably from region to region, as the result of the interplay of a number of factors. Essentially, commons survived best where population densities were low and where much land was unsuitable for arable agriculture. Thus large areas survived in the uplands of the north and west. But there may have been more complex social and economic factors which were also important in the preservation of common grazing, especially in lowland areas, for the distribution of commons in medieval England does not appear to be a direct and simple reflection of demographic pressure or environmental factors. In certain parts of the south and east of England – areas of dispersed settlement and irregular field systems, poorly developed communal controls and individualistic agriculture – some communities seem to have lacked the management structures necessary to act corporately to plough up areas of common grazing, even in areas of high population and moderately fertile soils, such as Norfolk. In addition, poor controls on the alienation of land and the practice of partible inheritance led to an early proliferation of smallholders for whom the resources provided by the commons were of vital importance. In such areas the conversion of waste to arable agriculture ground to a halt rather earlier than in the classic open-field areas of the Midlands.

In the latter areas, communities were more cohesive and communal controls on agriculture and land-use better developed. There were often stronger manorial controls on the alienation of land, holdings did not fragment to the same extent and there was less economic polarisation within the farming community. It may be this that explains why in many of these areas so much of the wastes were ploughed up in the 12th and 13th centuries, as arable prices, and the need for food for consumption, increased. Whatever the explanation, it appears that in many parts of the central Midlands, areas of common grazing were almost entirely destroyed by the end of the 13th century. The arable strips of many villages ran right up to the parish boundary, meeting with those of neighbouring villages.

This was not true of all areas in the Midlands, however. Conversion of grazing to arable was more retarded in the Forest areas. Such areas were not necessarily densely wooded; the term *forest* was a legal rather than a descriptive or environmental term, referring to areas to which forest law applied. This was a body of rules and restrictions originally intended to preserve deer for the royal chase and which *inter alia* attempted to limit the destruction of suitable habitats through the expansion of arable cultivation. In reality, forest law functioned more as a source of revenue, for encroachments on the wastes were tolerated if a fine was paid. Nevertheless, in areas like Rockingham Forest in Northamptonshire, these institutional factors combined with the relatively marginal nature of local soils to preserve extensive areas of open waste.

As arable expanded at the expense of grazing, in the areas of irregular field systems and dispersed settlement surviving commons often became foci for settlement. The poorly developed nature of communal controls in such areas was probably the stimulus for this development; farmers and smallholders moved to the edge of areas of common grazing not only for the convenience provided by such a location, but also, as it were, to stake a visible claim to their use. The freedom to alienate land and the irregular nature of field systems in these areas made such settlement migration possible, for they allowed the acquisition of blocks of land adjacent to the common upon which farmsteads could be established. This development seldom occurred in areas of regular open-field systems, nucleated settlement, and strong community controls.

Thus it was mainly in the south–east and the north–west of England that the medieval period saw the development of straggling settlements around the perimeter of commons. This process went furthest in parts of East Anglia, where complex manorial organisation and the presence of substantial numbers of free tenants practising partible inheritance led to a proliferation of smallholdings and wholesale migration away from earlier village sites. Farmsteads clustered around

areas of common which thus became large village greens, leaving the parish church – marking the original Saxon site of settlement – isolated in the fields some distance away (Wade Martins 1975).

Lowland commons have a distinctive form. They have straggling, concave outlines, formed by a series of rough arcs; roads funnel into the common where these arcs join. This characteristic shape probably derives from the fact that commons are the remnants of more extensive areas of waste which had been continuously encroached upon for centuries before their outline became fossilised, usually in the early medieval period. The perimeters of commons are often defined by particularly massive and ancient banks and ditches.

Today, many commons are wooded, but this is normally a relatively recent feature, resulting from a relatively recent decline in the intensity of grazing. By the end of their medieval period, commons had usually lost whatever woodland they had formerly carried; it had been destroyed by felling and over-grazing, and only names like 'Wood Green' sporadically reflect their former nature. Medieval woodland, in contrast, was not usually common land, but land which had been enclosed from the waste and over which the use and access of others had been limited (Rackham 1976).

By the end of the Middle Ages, there were considerable regional variations in the extent of common land. Commons survived better in the upland areas of the north and east than in the more fertile lowland zone. Within the lowland areas, they tended to survive better in the south and east of England, and in the west country, than in the classic open-field areas of the Midlands, with the exception of the forest areas, where they usually also survived well.

These variations were a factor in the local and regional development of rural society in the post-medieval period. In particular, areas in which extensive commons survived tended also to be the areas in which the decline of the small freehold farmer, which continued at varying rates throughout the post-medieval period, was retarded. In areas like the Fens, small farmers used their rights to extensive commons to adopt forms of livestock farming as specialized agricultural regions emerged in the 15th century. Survival of commons also allowed small cottagers to maintain a measure of economic independence, and the more extensive commons attracted large numbers of squatters, often part-time craftsmen. As a result, areas in which large commons survived tended to have a reputation for lawlessness. The opportunities which such areas offered to the poor also ensured that they often experienced particularly rapid population growth in the early modern period. In Northamptonshire, for example, forest villages in the 17th century were on average around half as populous again as non-forest villages (Hoskins and Stamp 1967, p. 52).

Much enclosure of common land occurred during the 16th and 17th centuries. Nevertheless, in 1688 Gregory King estimated that there were still 10 million acres of heaths, moors, mountains and barren land in England and Wales, and a further 3 million acres of forests, parks, and commons, the majority of which was common land. Today, the total area of common land in England and Wales is around 1.5 million acres. Even allowing for a high degree of inaccuracy in King's estimates, there has clearly been a dramatic reduction in the area of common land as a result of Parliamentary enclosures, mainly in the late 18th and early decades of the 19th centuries. Enclosure was principally inspired by a desire on the part of the larger landowners to profit from the conversion of the remaining commons to arable, or their improvement as pasture, both of which were difficult or impossible where the land was subject to the use and access of a large number of local inhabitants. The high prices of arable during the Napoleonic Wars were a particular stimulus to enclosure of open heaths and wastes, especially on the light soils of eastern England (Turner 1980, pp. 63–93).

The enclosure of commons was, like the enclosure of open fields, closely connected with the decline of the small owner-occupier which had continued almost uninterrupted throughout the early modern period. As land fell into the hands of relatively few people, so it became easier to obtain the agreement necessary to enclose, especially as with the advent of Parliamentary

Enclosure a majority in favour of enclosure was judged on the basis of the area of land which the agreeing landowners held, rather than on their number.

Yet as well as being in part a consequence of the decline of the small proprietor, enclosure of commons also served to accelerate this process. The allotments received by those small farmers or cottagers who were able to prove the legality of their claim to common rights were seldom sufficient compensation for the advantages lost through enclosure, especially when legal and fencing costs were taken into account. For many small farmers, enclosure was the final misfortune which led to their departure from farming; for the small cottager, enclosure often led to increased, if seasonal, reliance on poor relief (Snell 1985).

Today, the distribution of surviving common land in England and Wales continues to be very uneven, with more in the highland zone than in the lowlands. Within the lowlands, there are still fewer commons in the Midland counties than in the south and east, or in the west country. In lowland areas, most commons are now principally valued for their amenity value, or for their role as nature reserves or Sites of Special Scientific Interest. Common land now survives as such only where it has been registered under the terms of the Commons Registration Act of 1965. All existing common land is listed in the final register, which was closed on 1 August 1972.

Common Law

P. S. Atiyah

Common law is a system of law and legal processes which originated in England shortly after the Norman Conquest and after several centuries of continuous development was exported to the English colonies, and so came to be the basis of the law of the greater part of the United States, as well as of Australia, New Zealand, most of Canada and (to a lesser degree) also of India, Pakistan, Bangla Desh and many parts of Africa. The chief characteristic of the common law has always been that its development has lain largely in the hands of the judges, and that it has therefore grown and changed incrementally, case by case, in the course of actual litigation.

In modern times the term ‘common law’ is used in a variety of senses. In the broadest sense, it continues to be used to refer to the entire system of law originating in England which now forms the basis of the law in the greater part of the former British Empire, often nowadays called the ‘common law world’. In this sense the common law is often contrasted with the ‘civil law’ which derives from the law of ancient Rome, and today operates in most of Western Europe, as well as in a number of other countries (such as Japan and Egypt) which have borrowed their law from European countries. One of the chief characteristics of the modern civil law is that it derives its authority from one or more basic Codes of law; and it remains a principal distinction between common law and civil law countries that the former have not generally codified their law. And even in

common law jurisdictions (such as California, for example) where there does today exist a kind of common law Code, it differs fundamentally in nature from the civil law Codes; in particular the system of precedent, and the authority of the judges to interpret and develop such common law Codes are quite different from those recognised in civil law countries.

The term 'common law' is also often used in various narrower senses. In the most important of these narrower senses, the common law is often contrasted with legislation, so that the lawyer in a common-law country still thinks of legislation as a type of law different from the 'common law', which is basically judge-made law. The term 'common law' is sometimes used in yet a third relevant sense in which it is distinguished from a body of law, known technically as 'Equity' which was originally supplementary to the common law, and was developed in the separate Court of Chancery. Today common law (in this narrow sense) and 'Equity' are almost everywhere merged and administered by a single set of courts.

The common law (in the first two senses identified above) has traditionally been associated with the economics of the free market in at least two different ways. First, there is a strain of thought, represented in particular by Hayek (1973), which seems to suggest that a system of law, like the common law, which is largely judge-made, is inherently more likely to favour and protect individual freedoms, and among them (or especially) economic freedoms. But this is an implausible and indeed eccentric claim, which seems to involve confusion of the first two senses of the term of 'common law' referred to above. Because most redistribution is accomplished in modern democracies by legislative measures, it is easy to assume that a legal system which owes little to legislation will be more likely to recognize and protect the freedom of the market, but the amount of redistribution which occurs in a legal system does not necessarily depend upon whether that society is part of the common law world. There is no a priori reason to suppose that judges left to themselves by a legislature will necessarily favour the economics of the market. In the last analysis, the policies favoured by judges will depend upon their own preferences, their culture and traditions.

But there is a second way in which the common law has traditionally been associated with the freedom of the market, and this association rests upon the historical facts of the last three centuries. The concept of the Rule of Law which came to be recognized and defended in England after the revolution of 1688 has been seen by many as having favoured the development of a free market economy in England prior to and during the early years of the industrial revolution. Because of the historical fact it was for a long time almost an article of faith among English writers that the common law and the freedom of the market were closely associated. This view is today less strongly held in England, as a result no doubt of the fact that, while Englishmen still like to believe in the Rule of Law (despite grave doubts in some quarters as to whether this concept has much meaning), they are by no means so wedded to the free market as they were. In America, where the Constitution of 1788 substantially embodied the English traditions as to the Rule of Law, as well as the then accepted ideology of the free market, the association between the two has survived rather more strongly.

The reasons for the traditional belief in the close association between the common law and the freedom of the market must therefore be sought in history, and in particular in English history during the period from approximately 1770 to 1870, when the free market economy was largely in process of being established. And of all parts of the common law, none was more important for this purpose than the law of contract, because this was the part of the law most intimately related to the economic system. Indeed, the story of English law between 1770 and 1870 was to a large degree the story of how the law of contract was converted into the law of the free market, and of how the ideology of freedom of contract became one of the great intellectual movements of history (Atiyah 1979).

The first three-quarters of the 18th century was a period of transition in England, during which many older ideas about contract and the market were being displaced by the newer ideas which

gradually became dominant towards the end of the century. Among the older ideas at least three can be identified as particularly hostile to the laws needed to serve the emerging free market economy. First, there was a regulatory element in the law and the economy dating back to Tudor times, represented for instance by statutory controls of wages and prices of many commodities, and by the apprenticeship laws which controlled entry to many trades with outdated and largely unnecessary restrictions. Secondly, there was a paternalistic element in much contract law at this time, with the courts still being willing to relieve various classes of persons from the consequences of bad bargains which they had made. This paternalism was particularly pronounced under various doctrines of Equity, such as rules for the relief of mortgagors, rules against the enforcement of contractual penalties and forfeitures, rules for the protection of seamen and 'expectant heirs', and so forth. Thus, in the third sense of the term the 'common law' identified above, it can be said that the common law was always more market-oriented than Equity. Thirdly, there was a traditional moralistic element in the contract law of the 18th century, and this also took different forms, such as the general hostility to usury (as to which see Simpson 1975, pp. 510–18), and the attempts to regulate the way in which essential foods and drinks were sold by use of the traditional marketing offences. The 'moral' roots of older law were also related to ideas about 'just prices' which, though rarely openly recognized in the common law, seem to have been influential at least in some of the cases in Equity, where there are signs that the Chancellors did have some vague sense of unease if they were asked to enforce contracts at prices which seemed to them very unfair, or on terms which were (in the language of the law) 'unconscionable'.

In addition to these specific instances of interference with the binding force of private contracts, there were important respects in which the whole concept of a general contract law remained relatively undeveloped at this time. Thus, while the law recognized and enforced specific types of contracts, such as contracts for the sale of land, contracts of insurance and so forth, there was, as yet, little sign of a general law of contract, governing all types of transaction. Then also, it remains unclear how far the contract law of this period actually recognized and enforced wholly executory contracts, in the sense of awarding damages for breach of a contract prior to any acts of performance or detrimental reliance by any of the parties. And finally, it is clear that, from the standpoint of today, the law of contract in the 18th century had not yet freed itself from dependence on the law of property. Of course, in one sense contract law can never be free from a dependence on property entitlements, because contract law is the mechanism by which entitlements are exchanged; but there are clear signs in the 18th century that contract law was still closely tied to property law in another sense, in the sense (for instance) that the proprietary aspects of many transactions were still regarded as more important than the promissory or contractual aspects. So, for instance, the right of a mortgagor to redeem the mortgaged property was protected by the courts, even when by the terms of the mortgage documents he had forfeited that right by delay in repaying the loan. It was assumed that if the mortgagee received back his money, with interest and costs, he was adequately protected by the law, even though the contract itself would have given him more extensive rights.

During the century beginning around 1770 these older ideas and traditions gradually gave way before the ideology of freedom of contract; but it would be wrong to think that this ideology did not have long roots and antecedents in still earlier periods. There are, even in the 16th and 17th centuries, many signs of incipient economic liberalism among the lawyers such as Coke, who bequeathed to the common law a hatred of monopolies as well as a passion for individual liberties (Wagner 1935). And Thomas Hobbes, in a well-known passage in *Leviathan*, had swept away all the medieval learning about 'just prices' and declared that '[t]he value of all things contracted for, is measured by the Appetite of the Contractors; and therefore the just value, is that which they be contended to give' (Hobbes [1651] 1968, p. 208). So the ideology of freedom of contract certainly had origins going back well

beyond the 18th century. Nevertheless, it does seem (though the matter remains controversial) that major changes in the law began during the course of that century which gathered pace as the century progressed.

Certainly, a great deal occurred to change the character of contract law from the last quarter of the 18th century until well into the 19th century, and there is much evidence that many of these changes in the law were profoundly influenced by classical economic theory, and perhaps still more by popular versions of classical economic theory. First, the relics of the Tudor regulatory economy gradually disappeared. Wage regulation had become increasingly obsolete in practice during the 18th century, and a major challenge to the older laws in the name of freedom of contract had taken place in the celebrated case of the Gloucestershire Weavers (1756–7), (Atiyah 1979, pp. 73–4). By the early 19th century most of the legislation authorizing the fixing of wages had been repealed. So too was the Statute of Apprentices, after many years during which its operation had been gradually whittled down by the judges. Secondly, the signs of paternalism which are still found in 18th-century Equity seem to have disappeared gradually as the judges hardened their hearts and toughened their minds. For example, signs of an attempt to introduce implied warranties on the sale of goods for the protection of buyers, which can be detected in the 18th century, were largely scotched, and the principle of *caveat emptor* reasserted with full vigour. The equitable doctrines allowing the courts to relieve various unfortunates from the effects of hard bargains were gradually whittled down, although they never disappeared altogether. Third, the moralistic elements in the law were also gradually whittled down. The law of contract came increasingly to be seen to be neutrally enforcing agreements which must be presumed to be beneficial to both parties. The only moral component left in the law of contract during the 19th century seemed to derive from the binding nature of promises.

The subjective theory of value also seems to have been largely accepted by the judges even before it had been wholly accepted by economists. Although the common law had always insisted that a promise be supported by some 'consideration', some reason, before it would be enforced (and to that extent at least contained a paternalist element), the growing acceptance of the subjective theory of value meant that the doctrine of consideration became much less important during the 19th century. So far instance, in *Haigh* v. *Brooks* (1840, 113 English Reports 124) the judges enforced a promise to pay £9000 in return for the giving up of a guarantee previously given by the promisor, even though it now appeared that the guarantee might be unenforceable and legally worthless. The promisor had valued it at £9000, said the judges; it was not for them to say that the document was worthless. For similar reasons, the prejudice against usury had gradually been overcome, and the usury laws were totally repealed in England in 1854.

In these ways, then, the principle that contracts are binding and must be strictly enforced had been greatly strengthened, and exceptional cases had been whittled down by the middle of the 19th century. In addition, other changes had occurred in the general nature of contract law, which were closely related to the growing trend to see contract law as the law of the free market. First, it was during this period that a general law of contract came into existence for the first time in the common law world. And the process of generalization was important to the ideology of the law in a number of respects. In particular, the generalizing of contractual ideas meant that the law had to become more abstract, more broadly principled. Principles had to be developed which could be applied equally to (say) commercial contracts for the sale of wheat, to contracts of employment, and (for instance) to personal contracts such as the contract to marry. This abstraction may have helped the law become more neutral, less inclined to pursue any redistributive tendencies, such as may exist where (say) there is a separate body of legal doctrine dealing with contracts of employment, or with residential leases, or with loan transactions.

Next, it seems clear that another major development during this period was the gradual shift in emphasis in contract law away from treating

contracts as present, or partly performed exchanges, and towards treating them as private planning devices, made in advance to allocate risks. The wholly executory contract became clearly recognised by the law, so that it now became possible for a person to sue for damages for breach of a pure promise, even where no performance or detrimental reliance had taken place. The justification for requiring damages to be paid in such circumstances was never clearly enunciated, and indeed, specific justification was rarely seen to be necessary. It was widely assumed that the broad principle of freedom of contract required, not only that parties be left free to make their own exchanges, but that the law should be available in aid of a party to enforce his claim to damages where the other failed to perform. John Stuart Mill was the first economist to point out that a policy of laissez-faire could not be used to justify the enforcement of executory contracts (Mill 1848, vol. 2, p. 386), but even modern economists do not generally pursue this line of thought, though some libertarians have done so.

And finally, 19th-century contract law increasingly freed itself from its dependence on property law. Although obviously entitlements still remain the subject matter of all contracts, contract law has become much less concerned with specific items of property, and is more concerned with wealth as a kind of fungible property. The reason for this was basically that 19th-century contract law was dominated by the needs of merchants and traders, to whom all property is in principle replaceable with money. A merchant can be assumed to be indifferent between a piece of property, and the value of that property. Similarly, as contracts came to be increasingly seen as fundamentally risk-allocation devices, the particular entitlements or property to which the risks attached became less important.

By the last quarter of the 19th century, the process of developing a mature body of general contract law had largely been completed in England, and although a similar process took place in America (Horwitz 1977), there is ground for believing that that was not completed for another fifty years or so. Freedom of contract had, apparently, reached its highest point. But although this was true of the ideology of freedom of contract among lawyers and judges, it was not really true of the views of economists or of the politicians, or of the public. By the late 19th century, neoclassical economists were already beginning to write sceptically about the sweeping effects of freedom of contract which had been attributed to the classical economists, and were pointing out the many possible causes of market failure such as information difficulties, externalities and monopoly. And although most of the older regulatory legislation had been repealed in the first half of the 19th century, Parliament had at the same time been gradually building up a completely new body of regulatory enactments dealing with new industrial problems – factories, coal mines, safety at sea for seamen and emigrant passengers, public health, the adulteration of food and drink, regulation of the weights and measures used for sales, and so on. Much of this new legislation had been a pragmatic response to perceived evils, and though some of it could have been justified economically by arguments concerning misinformation or externalities, much of it would have been difficult to justify except on the assumption of paternalistic or redistributive motives. Some of it may have been inspired by sheer impatience, an unwillingness to give the market time to work, or a belief that the short-term costs of market failures were so severe that legislative correction was necessary without regard to the long term distortions this might produce.

What is quite clear is that by the time the English common law and common lawyers had accepted the teachings (as they were thought to be) of the classical economists on freedom of contract, these teachings were already somewhat out of date. The result was that the mature common law of contract was seriously deficient in a number of respects. It was first of all deficient in its almost total neglect of the problem of externalities. Contracting parties were entitled to pursue their own interests, regardless of the effect of their

contract on third parties, or the public. Only in the most extreme cases of actual illegality would the courts generally refuse to uphold a contract. Secondly (although this certainly could not be laid at the door of the classical economists), there had been, during the 19th century, a serious neglect by common lawyers of the problem of monopoly. This may well have been largely due to the fact that for the greater part of this period the British economy was itself highly competitive, and in little danger from monopolies. But the complacent assumption that cartels were unstable and were always vulnerable to internal or external competition was in England (though not in America) carried over by lawyers and courts into new conditions towards the end of the nineteenth century, and well into the present century, when it was utterly out of date. A second result of this failure of the common law to keep pace with economic theory and political reality, was the growing gulf between the common law and legislation. Once again, extensive legislative intervention with freedom of contract began to become commonplace, and much of it was increasingly redistributive in character.

During the course of the present century this process continued at an increasing pace until 1980 or thereabouts, since when there are signs that history has virtually reversed itself. Disillusion with the free market, particularly in England, increased during the great depression in the 1930s until, by the end of World War II, a Labour Government was elected to power with a massive majority and with a mandate to lay the foundations for a socialist state and a socialist economic system. Since then England has increasingly learned to live with a 'mixed economy', to a large part of which the traditional law of contract seems irrelevant because the public sector is often controlled by public laws rather than by contract law. But even in areas where private law continues to operate, the common law of contract has become increasingly affected by legislative intervention. Virtually all types of consumer transactions are today controlled or affected to some degree by legislation, including consumer credit contracts, contracts of employment, residential leases, and insurance contracts. Unconscionable, or unfair contracts are increasingly subjected to judicial control. Many areas of law which were formerly controlled largely by contract, such as family law, are now subject to extensive judicial discretionary control. Even business and commercial contracts are subject to vast bodies of legislative and regulatory laws, some, such as the modern monopoly anti-trust laws, being designed to preserve the operation of a competitive market, but much of it still being designed to restrict competition or the operation of the free market.

America has not gone so far down this road as Britain and other common-law countries, and indeed, for a long time, in the late 19th and early 20th centuries, constitutional decisions of the United States Supreme Court in the name of freedom of contract, actually prevented similar developments. Much legislative intervention with freedom of contract was, during this period, declared unconstitutional, frequently over the dissent of Justice Holmes. By the late 1930s, however, the majority of the court had largely accepted Holmes's view, and since then, legislative intervention with freedom of contract has not been regarded as per se unconstitutional. This shift in the court opened the door to the same kind of regulation and intervention which had already been taking place in Britain, and although America has not, like Britain, brought large-scale industries within the public sector and therefore partially outside the control of contract law, most of the other legislative developments of the British type certainly have their parallel in America. No doubt some contracts are more regulated in Britain, but conversely there are plenty of examples of legislative interference with freedom of contract in America which are not to be found in Britain.

These vast changes in the operation of the common law have accompanied or brought with them a change in ideology once again. Paternalism and redistribution were, at least until around 1980, increasingly favoured by many writers and

teachers of contract law, as well as large sectors of the electorate. Even the judges became much more sympathetic to arguments based on concepts like unconscionability and inequality of bargaining power. In America, unconscionability was given express legitimacy as a device for overturning unfair contracts by the Uniform Commercial Code, and was increasingly used by the judges as a matter of common law as well. Many relationships of a contractual character (for instance, that of physician and patient) and others of a virtually contractual character (for instance, that between manufactures of products and ultimate purchasers and consumers) are, both in American and Britain, increasingly regulated by tort law rather than contract law, at least where things go badly wrong and legal actions for damages are brought based on negligent conduct, or on defects in the goods. In such malpractice or products liability actions the appropriate standards of care or quality are set by judges and juries and not by the contracting parties, and contractual exculpatory clauses are often denied legal validity.

Since about 1980 there have been increasing signs that the tide has turned yet again, both in Britain and America. Obviously, and visibly, British and American governments have since then been trying to reassert the virtues of the free market and roll back the frontiers of regulation, and in this they are being vigorously supported by some lawyers and law teachers in America, though not to any real extent in Britain. It is not yet clear what the impact of this is going to be on the future of the common law of contract. One possible scenario is that, as in the late 19th century, the courts will be behind the times, but that on this occasion they will be hostile to the reasserted belief in the free market and will continue to defend paternalist and redistributive intervention in free contracts, particularly where one of the parties to the contract is a consumer or 'small man' thought to be weak in bargaining power. But another possible scenario is that the new enthusiasm for the free market will prove but a short-lived hiccup in the long-term trend towards paternalist and redistributive policies. In either event it seems unlikely that for many years to come British or American courts will be enforcing contracts according to the full rigour of the common law.

The concept of common property has become famous in economics since Garett Hardin (1968) wrote his celebrated article on 'The Tragedy of the

Commons'. In this article, common property is taken to mean the absence of property rights in a resource, or what is equivalently known as a regime of 'open access'. Under such a regime, where a right of inclusion is granted to anyone who wants to use the resource, Hardin argued, inefficiency inevitably arises in the form of over-exploitation of the resource accompanied by an over-application of the variable inputs. Open access leads to efficiency losses because 'the *average product* of the variable input, not its *marginal product*, is equated to the input's rental rate when access is free and the number of exploiters is large' (Cornes and Sandler 1983, p. 787). The root of the problem lies in the fact that the average product rule does not enable the users to internalize the external cost which their decisions impose on the users already operating in the resource domain. Of course, the efficiency losses are conceivable only in a world of resource scarcity, implying that the variable input is subject to decreasing returns. Such losses are considerable since they amount to the dissipation of the whole resource rent. Here is the crucial intuition behind the open access regime: when no property right is attached to a resource, the value of this resource is zero in spite of its scarcity.

Efficiency losses are to be measured not only in static but also in dynamic terms. Indeed, in an open access regime resource users are induced to compare average *instantaneous* returns with the input's rental price even though they may well be aware that they thereby contribute to reducing the future stock of the resource. The problem is simply that they are forced to follow a myopic rule because there is no way in which they can reap the future benefits of restraint in the present. Thus, for example, by refraining today from catching juvenile fish or from cutting down saplings in the forest, a villager can receive no assurance that he or she will be able in the next period to catch mature fish or to fell fully grown trees.

The main criticism levelled by numerous social scientists against the concept of open access is that the corresponding regime is rarely encountered on the ground. The typical regime, according to these critiques, is one under which a community possesses a collective ownership right over local natural resources. Under common property, therefore, a right of exclusion is assigned to a well-defined user group, and Hardin has created a lot of confusion by using the word 'commons' to refer to the alternative situation where no such right is granted to any agency. What is not always clear, however, is whether the ownership right involves only the ability to specify the rightful claimants to the resource, or whether it also involves the ability to define and enforce rules of use regarding that resource (for example, regulations about the harvesting season and production tools, allowed quotas of harvestable products of the resource, or taxes). Baland and Platteau (1996) have coined the term 'unregulated common property' to refer to the former situation, while the term 'regulated common property' is used for the latter.

Two polar situations can be considered on the basis of this analytically important distinction between two types of common property regimes. At one extreme, if common property is perfectly regulated, in the sense that the rules of use designed and enforced by the owner community allow a perfect internalization of the externalities, common property becomes equivalent to private property with a sole owner from an efficiency standpoint. This illustrates the general result that, absent transaction costs, institutions do not matter. At the other extreme, a strictly unregulated common property in the above sense implies that, as the number of users becomes quite large, over-exploitation of the resource becomes as important as under the open access regime: the rent attached to the resource is totally dissipated (see Platteau 2000, ch. 3).

Between these two extremes we find the situations most typically observed on the ground and described in the numerous field studies devoted to this topic (see Ostrom 1990; Baland and Platteau 1996, for a review of such studies). In such instances, rules of use exist alongside membership rules, yet they tend to be imperfectly designed and imperfectly enforced by the village community. One key reason for these imperfections is the governance costs that unavoidably plague any collective decision-making process. Governance

costs include all those costs incurred to reach a collective agreement and to organize a community of users. They are likely to be higher when the group is larger and when its membership is more heterogeneous (whether measured in terms of diversity of objectives or of wealth inequality). Moreover, governance costs are enhanced by the opportunistic tendencies of rights-holders not only to violate or circumvent collective rules but also to eschew efforts to create collective mechanisms of decision-making and enforcement. Costs arising from these proclivities are also dependent on the size of the user group: they are lower if the number of resource users is smaller and, at the limit, they are nil when there is a single user.

As a consequence of the aforementioned limitations, resources are less efficiently managed under a common property regime than they could be under a private ownership system. This is especially true if, owing to their scarcity, the resources carry high values which should be reflected in high rents. Population growth and market integration are thus two forces that tend to increase the monetary value of the efficiency losses arising from common property, that is, the forgone rents. This, at least, is the conclusion drawn by the so-called property rights school of Chicago economists (see, for example, Demsetz 1967; Barzel 1989). The advantages of private property appear all the more decisive as such a regime enables users to internalize externalities without incurring any governance costs. This is because it establishes a one-to-one relationship between individual actions and all their effects: 'A primary function of property rights is that of guiding incentives to achieve a greater internalization of externalities ...' (Demsetz 1967, p. 348).

Nevertheless, this ignores the costs of privatizing natural resources, which involve both directs costs and opportunity costs. Direct costs comprise transaction costs, such as the costs of negotiating, defining and enforcing private property rights. The usual argument is that such costs increase with the physical base of the resource. Thus, the wider the resource base (or the less concentrated the resource) the higher are the costs of delimiting and defending the resource 'territory' (Dasgupta 1993, pp. 288–9). For many natural resources, the costs of dividing the resource domain appear prohibitive under the present state of technology. For example, the open sea – or, more exactly, the fish stock contained in it – presents insuperable difficulties for private appropriation. The enforcement of exclusive property rights to individual patches of the ocean would, indeed, be infinitely costly. This is especially evident when fish species are mobile and move within wide water spaces, since exclusive rights are too costly to establish and enforce whether over the resource or over the territory in which the resource moves.

The opportunity costs of privatization, for their part, correspond to the benefits that are lost when the common property regime is abandoned. Here, we can think of scale economies that may be present not only in the resource itself but also in complementary factors. The obvious advantage of coordinating the herding of animals so as to economize on shepherd labour in extensive grazing activities is probably the best illustration of the way scale economies in a complementary factor may prevent the division of a resource domain. Another important category of opportunity costs is the insurance benefits associated with common property. When returns to a resource are highly variable across time and space, the need to insure against such variability is yet another consideration that may militate against resource division. When a resource has a low predictability (that is, when the variance in its value per unit of time per unit area is high), users are generally reluctant to divide it into smaller portions because they would thereby lose the insurance benefits provided by keeping the resource whole.

For instance, herders (fishermen) may need to have access to a wide portfolio of pasture lands (fishing spots) in so far as, at any given time, wide spatial variations in yields result from climatic or other environmental factors. On the assumption that the probability distributions are not correlated too much across spatial groupings of land or water

and that they are not overly correlated over time, a system offering access to a large area within which right-holding users can freely move appears highly desirable from a risk-reducing perspective.

The conclusion of the above discussion is, therefore, that the balance of the advantages and disadvantages of various property regimes is a priori undetermined. Economic theory, however, does provide useful guidance about which circumstances are more favourable to the persistence of common property or, conversely, to its demise and replacement by private property. Furthermore, instead of being fixed once for all, the balance sheet is susceptible to evolution depending on the transformation of the parameters on which the benefits and costs of privatization depend. Thus, the direct costs of resource division may fall with technological progress. For example, the introduction of modern borehole drilling facilitates the privatization of common grazing areas (Peters 1994). It is therefore not only the factors which enhance resource value but also those which reduce the direct costs of partitioning that may favour the private appropriation of natural resources.

C

Common Property Rights

Steven N. S. Cheung

In a society where individuals compete for the use of scarce resources, some rules or criteria of competition must exist to resolve the conflict. These rules, known as property rights, may be established in law, in regulation, in custom or in hierarchy ranking. The structures of rights may take a variety of forms, ranging from private property rights at one extreme to common property rights at the other. Most fall somewhere in between: either set of rights would be rare in its purest form.

In a private property, the delimitation of the right to its use is expressed in dimensions or characteristics inherent in the property itself. These rights are exclusive to some private party, are freely transferable, and the income derived from them is not attenuated, restrained or infringed by laws or regulations. Hence price control, taxation, and social restriction of transferability may be regarded as violations of private property rights. In a common property, there is no delimitation or delineation of its use rights to any private party. No one has the right to exclude others from using it, and all are free to compete for its use. Hence there are no exclusive use rights, no rights to be transferred, and in the limiting case, no

net income can be derived from using the common property.

This last condition rests on an economic proposition known as the dissipation of rent. It argues that because of the lack of exclusive use rights, individuals competing for the use of a common property will reduce its rental value or net worth to zero. The reason is that if no one has an exclusive claim to the value (i.e. rent) of that property, its use will invite competition to the point that each and every competing user can earn no more than the alternative earning of his own resources required in the exploitation of that common property. In other words, under competition and with no one having a special advantage, a 'prize' that has no exclusive claimant will be dissipated or absorbed by the costs of other resources which must be dedicated to its winning. Hence the net value of the prize won is zero.

The usual examples of common property rights cite a public beach and marine fisheries, and the dissipation of rent typically implies excessive use or over-exploitation. However, the dissipation may take the form of under-exploitation. For example, a piece of fertile land under common ownership may be used for herd grazing, or left idle, instead of being planted as an orchard.

In the real world, the complete dissipation of rent is rare indeed. This is because the supply curve of labour or of other inputs may be rising (some intramarginal rent may be captured), the competing users may have different opportunity costs (the non-marginal users may be enjoying rent), or entry may be restricted by regulations, by customs or by information costs. Still, with common property rights some dissipation of rent is inevitable, and no society can afford to surrender a large portion of its valuable resources to this structure of property rights.

A property may be held in common because its capturable rent is lower than the cost of enforcing exclusivity. In this case, the dissipation of rent is no waste. However, to the extent that rent dissipation is viewed as a waste, its occurrence must be attributable to the omission of some constraints in the analysis. Attempts to reduce rent dissipation go far to explain why common property in its 'pure' form is seldom observed. In marine fisheries, for example, numerous regulations govern the fishing season, the size of fish caught, the boat size and the mesh size, and various licensing arrangements restrict the number of boats and fishermen. The market value of a fishing licence, sometimes enormous, is one measure of the ocean rent captured. Even for public beaches, regulations of some type will often be found to govern the use of those most in demand.

Whereas regulations and restrictions on entry in the use of a common property often serve to reduce dissipation, the rent that can be captured is usually less than if the property were privately owned. To reconcile this observation with constrained maximization, we must infer that, enforcement costs aside, other transaction costs associated with the changing of institutional arrangements must restrain the formation of private property rights.

No economy can survive if the majority of its scarce resources are commonly owned. Regulations may, indeed, reduce rent dissipation; but in the process they not only distort the use of the resources but also invite corruption and the emergence of special interests. An unrestrained common property, strictly speaking, is propertyless in ownership; if its structure is extended to all resources, starvation for all must result. If one rules out private property rights, then to avoid the imposition of an infinite array of regulations the remaining alternative is the communal system or the communist state.

In a communist state there is no private owner of productive resources: each constituent is propertyless, in the literal sense of the word. Since the dissipation of rents associated with common properties will guarantee starvation, in a communist state the rights to use resources, and to derive income therefrom, are defined in terms of rank. That is, stripped of all ownership rights over valuable and productive resources, the citizens of a communist state hold differing rights to use resources and to obtain income according to

their status. In the people's communes in China under the Great Leap Forward, for example, no one owns the productive resources (i.e. everyone is propertyless), but comrades of different ranks enjoy different rights and privileges. 'Rank' as such has value and is subject to competition, therefore a system of 'property' rights is implicit. However, the valuable rights are now defined in terms other than the inherent properties of the productive resources.

This is, in fact, the key distinction between a private property system and a communist state: the former delineates rights in terms of certain dimensions of the productive resources themselves; the latter delineates rights in terms of a characteristic (rank) of people deprived of productive human capital. In the communist state, the competition for and protection of rank will draw on the use of valuable and productive resources (another form of rent dissipation). Moreover, the lack of market prices increases the cost of information, and the lack of contractual choices increases the cost of enforcing performance. What is saved in return are the costs of delineating and enforcing rights in properties.

It is among these varied costs – broadly defined as transaction costs – that we find the key divergence in economic performance between the communist and the private property systems. If one ignores transaction costs, the delineation of rights in terms of rank will produce the same use of resources as would the delineation of rights in properties. However, it can be convincingly argued that the broadly defined transaction costs are generally higher with communal than with private rights. Communism fails, not because it does not work in theory, but precisely because in practice its costs of transaction are higher than those in a system of private property rights. Still, the delineation of rights in ranks is a way to reduce rent dissipation in a propertyless state.

Strictly speaking, the dissipation of rent associated with common property is no 'theory' at all, because dissipating rent merely to produce an equilibrium does not explain behaviour. Worse, to stand aside and simply permit rent to dissipate is inconsistent with the postulate of constrained maximization.

What is useful and important from the standpoint of economic explanation is to view whatever rent dissipation does occur as necessarily a constrained minimum because, under the maximization postulate, each and every individual has an incentive to reduce that dissipation. Behaviour associated with the dissipation of rent must therefore be regarded as attempts to reduce that loss, and this altered view explains many observations. That some dissipation remains must then be attributable to the constraints of transaction costs. The challenge to the economist is to specify and identify what these costs are and how they will vary under differing circumstances.

Common Rights in Land

Leigh Shaw-Taylor

Abstract

'Common rights' and 'common land' refer to rights to use land in common in some way. Of several forms of common rights in pre-industrial Europe and elsewhere, only one – free access to land – involved what economists commonly think of as common rights. Common rights in Europe were largely swept away during the 18th and 19th centuries by a process termed 'enclosure'. Some economic historians have reconsidered the inefficiency of open fields in an English context, but at present the data are too poor to allow a plausible rebuttal of the views of 18th-century critics of the open fields.

Common rights are rights to use land in common. The most important of these rights was the right to graze livestock on common grassland. But rights to gather fuel (wood, peat, gorse and turves), fertilizers, timber for building and other natural resources were also important. Common land is land used by a number of distinct individuals or households whose rights over the land are known as common rights.

Today we are accustomed to think of land as private property with a clear owner and possibly a tenant. Although in some countries there may be legal rights of public access to certain types of wild or agricultural land, it is generally the case that the owner or tenant of the land has exclusive rights to use the land and, within the limits of planning or zoning laws, may use it as he or she wishes. But in Europe, for at least a thousand years and ending only in the 19th century, a high proportion of land was 'common land' which many individuals were entitled to use for a variety of purposes.

It cannot be overemphasized that common land was generally not open-access land – land which anyone could use. There were regulations governing who could use the land, what they could use it for and how much they could use it. When economists think of common land and common rights they may have Garett Hardin's 'tragedy of the commons in mind' (Hardin 1968). The principal subject of Hardin's article was in fact population growth, not historical common land or common rights.

However, Hardin used a theoretical common land system as a model for the exploitation of open-access resources. In this system each herder could put as many animals as he wished on to the common pastures. Hardin argued that individual herders would choose to graze more and more animals on the common, thus inevitably leading to over-grazing and degradation of the resource. This model offers important insights into the destruction of, or damage to, unregulated open-access resources such as the atmosphere or fish stocks in the oceans. If common land and common rights had operated in this manner, it is unlikely that they would have remained a key part of European agriculture for so many centuries.

In the rest of this article the following questions are addressed: what were common rights? What was common land? Who had common rights? How was common land regulated? Was it efficient? How and why did it come to an end and with what consequences? The answers to these questions varied from one village to another across Europe and what follows is necessarily highly simplified (see de Moor et al. 2002, for a more detailed overview).

Common Land

The types of common land and the terminology used to describe such land varied across Europe.

Nevertheless, four major types of common land may be distinguished. First, the archetypical form of common land and the one with the widest geographical distribution is variously referred to as common waste, common pasture, waste, or common. This land was permanently common and most often grassland used for grazing animals. Usually such land was not suitable for arable cultivation typically because its natural fertility was low but sometimes for other reasons such a propensity to seasonal flooding. On some common wastes other resources were available, such as peat, turf, gorse or wood.

Second, in many parts of Europe much of the arable land (the land on which crops were grown) was also subject to common rights. Such land, known as open- fields, common fields, or common arable, was privately owned and cultivated but subject to common grazing. In its classic form each farmer held a number of long thin strips of land scattered over an extensive area and intermixed with the strips of other farmers. Each farmer cultivated his own crops on the arable. But when the harvest was over, or in years when the land was being fallowed, all those with common rights could turn their livestock into the fields to graze. Thus the open fields alternated between private and common land over the course of the agricultural cycle.

Third, common woodland for the production of fuel and timber was widespread on the European continent but unusual in England. This was similar to common waste in that it was permanently in common use.

Fourth, common meadows, which were permanent grasslands for the production of hay, were divided into separate blocks in private use but after the hay had been harvested were open to common grazing. Thus, like the open fields, common meadows alternated between private land and common land over the agricultural cycle.

Common Rights

As private property, the right to cultivate the common arable or to harvest the hay in common meadows lay with the owner of the land or the owner's tenant. Access to the common rights was considerably more complex and took different forms in different places; but it is possible to distinguish four main forms of access. First, in England and some parts of the Continent, the ownership or tenancy of particular buildings or landholdings was a prerequisite. Second, in many parts of the Continent citizenship of (as distinct from residence in) a commune or a municipality which itself owned the common resource was necessary, sometimes in combination with a property qualification. Third, in other parts of the Continent membership of a cooperative association which owned the common resources was necessary. Membership of these institutions was sometimes inherited, but sometimes it was attached to buildings or land (as in the first case). Fourth, there were cases were all residents in an area had common rights. But outside largely uninhabited areas, such as northern Sweden, this situation was unusual.

In consequence by no means all individuals or households enjoyed common rights. The proportion of the population that enjoyed common rights varied considerably from one region to another and changed over time. Where individuals or households did have common rights, the kinds and levels of the rights they enjoyed were determined by local regulations.

Regulation

Common land was almost invariably regulated by local institutions, often at the level of the individual village or manor. The institutions varied but were usually manor or village courts or village assemblies or committees of some kind, with the decisions made by a group of jurors. These institutions normally issued sets of rules, ordinances or by-laws which governed the usage of the commons and set fines for the infringement of rules. Officials or monitors were appointed to police the by-laws. The degree to which these institutions and their by-laws were subject to the influence of feudal overlords and the state varied considerably across Europe.

The by-laws provided the basic regulatory framework for managing the commons (for

examples of by-laws see Ault 1972). Their most critical function was to restrict the usage of common land and thus prevent a 'tragedy of the commons' developing. This was done in two ways. First, the by-laws would normally serve to restrict common rights to well-defined groups of users. For example, in much of England only those holding land in the open fields or with certain recognized dwellings, known as common-right houses, were allowed to pasture animals in the open fields or on the common pasture, while on much of the Continent pasture rights were restricted to citizens of communes or the holders of ancient farmsteads. Second, by-laws defined the amount of resources to which each commoner was entitled.

Thus, by-laws might specify the amount of peat or wood each commoner was entitled to dig or cut each year or the number and type of animals which could be kept, and for which months of the year they might be kept on the common pastures, open fields and common meadows.

The number of animals each commoner could put on the common land was generally controlled by one of two types of rules. One, known as 'stinting', simply specified the number and type of animals (the stint) which each commoner might keep on the common. Often the stint was proportional to the area or the value of land held. The other form of access, known as 'levancy' and 'couchancy', stated merely that each commoner could keep as many animals on the common as he could overwinter (that is, feed when the common was closed) on his own holding. How this was policed in practice is a moot point, but it certainly served to limit numbers and may have differed little from stinting in practice.

One consequence of these types of rule is that some individuals had no common rights at all. Another is that different individuals who did have common rights could have very different levels of access. The situation varied too much to allow generalization, beyond the suggestion that the level of inequality in England was probably greater and had proceeded further at an early date than anywhere else.

Enclosure

The process by which common land and common rights were abolished and replaced by recognizably modern forms of private property was part and parcel of a broader reform of landholding known as 'enclosure' which could also entail the consolidation of scattered holdings and the wholesale reallocation of land to create ring-fenced farms. Enclosure in some form is probably as old as common land itself. In England significant enclosure took place in the medieval period and from the 17th to the early 19th centuries. In most of Europe the widespread attack on common land began in the late 18th century in the wake of Physiocratic critiques. The later Napoleonic reforms and a subsequent series of state-sponsored drives to modernize agriculture in the 19th century led to more sustained enclosure. Some common land survives to this day, generally in mountainous areas.

Efficiency

By the 18th century common rights and common land were being widely criticized by agricultural improvers and others for restricting agricultural productivity. Most agricultural writers have accepted this view of common land as inefficient, and associated enclosure with major increases in productivity (Emle 1936; Chambers and Mingay 1966; Overton 1996). Common rights and common land imposed two kinds of limitation on agricultural improvement. First, the communal regulation of common land made it more difficult to introduce new agricultural techniques and technologies or to respond to changes in market opportunities. Second, the sharing of the outputs from common land made individual investment less attractive. The spread of nitrogen fixing crops and new drainage technologies, which often allowed the cultivation of formerly uncultivable common land, together with better transport links made enclosure a steadily more pressing issue in the 18th and 19th centuries.

A number of economic historians have reconsidered the inefficiency of open fields in an

English context. McCloskey (1976) has argued that the scattering of land in open fields in the medieval period was an efficient insurance against risk in a non-market economy. Allen (1992) has argued that enclosure did facilitate major technological changes obstructed by common land but that these innovations made only very marginal contributions to increased efficiency. Clark (1998) has argued that the inefficiencies imposed by common land were relatively modest and that, given the costs involved, enclosure was not economic until after 1750. However, the issue remains controversial essentially because it is inherently difficult to measure the agricultural productivity of farming in the 18th and 19th centuries with any degree of reliability. In other words, at present the data are too poor to allow an entirely plausible rebuttal of the views of 18th-century critics of the open fields. Moreover, much enclosure took place in the medieval period and in the 17th century (Wordie 1983) and any fully satisfactory theory of the efficiency or otherwise of open fields would need to be able to account for the longer-term chronology of enclosure. The persistence of open-field farming in France has been investigated by Grantham (1980) and Hoffman (1989).

Another controversial issue is the importance of common land to the poor. Many historians have argued that the poor derived considerable benefits from common land and that enclosure was socially damaging; but this remains controversial (see Neeson 1993; Shaw-Taylor 2001. The extent to which the poor benefited from common land and common rights is hard to reconstruct, poorly understood, and varied considerably across Europe.

Common-Pool Resources

This article has been concerned exclusively with common land and common rights as they existed in Europe before the 20th century. However, it should be noted that while open fields and common meadow may be peculiarly European forms, common waste and institutions for its management can be found all over the world. Analytically, these systems are part of a larger family of 'common-pool-resource' systems (Ostrom 1990) which have been adopted in many parts of the world to manage not just land but water resources and fish stocks as well.

Commons was born on 13 October 1862 in Hollandsburg, Ohio, and died on 11 May 1945 in Raleigh, North Carolina. He studied at Oberlin College (BA, 1888) and Johns Hopkins University (1888–90). He taught at Wesleyan, Oberlin, Indiana, Syracuse, and Wisconsin (1904–32).

The founder of the distinctive Wisconsin tradition of institutional economics, Commons derived his theoretical insights (generalized in his *Legal Foundations of Capitalism,* 1924, and *Institutional Economics,* 1934) from his practical, historical and empirical studies, particularly in the field of labour relations and in various areas of social reform. He drew insight not only from economics but also from the fields of political science, law, sociology and history. A principal adviser and architect of the Wisconsin progressive movement under Robert M. La Follette, Commons was active as an advisor to both state and federal governments. He was instrumental in drafting landmark legislation in the fields of industrial relations, civil service, public utility regulation, workmen's compensation and unemployment insurance. He served on federal and state industrial commissions, was a founder of the American Association for Labor Legislation, was active in the National Civic Federation, National Consumers' League (president, 1923–35), National Bureau of Economic Research (associate director, 1920–28), and the American Economic Association (president, 1917). He participated in antitrust litigation (especially the Pittsburgh Plus case) and in movements for reform of the monetary and banking system (often associated with Irving Fisher, who considered Commons one of the leading monetary economists of the period).

The critical thread uniting Commons's diverse writings was the development of institutions, especially within capitalism. He developed theories of the evolution of capitalism and of institutional change as a modifying force alleviating the major defects of capitalism. Commons came to recognize and stress that individual economic behaviour took place within institutions, which he defined as collective action in control, liberation, and expansion of individual action. The traditional methodologically individualist focus on individual buying and selling was not capable, in his view, of penetrating the forces, working rules and institutions governing the structural features of the economic system within which individuals operated. Crucial to the evolution and operation of the economic system was government, which was a principal means through which collective action and change were undertaken.

Commons rejected both classical harmonism and radical revolutionism in favour of a conflict and negotiational view of economic process. He accepted the reality of conflicting interests and sought realistic, evolutionary modes of their attenuation and resolution. These modes focused on a negotiational psychology in the context of a pluralist structure of power. He sought to enlist the open-minded and progressive leaders of business, labour and government in arrangements through which they could identify problems and design solutions acceptable to all parties.

In other contexts, he sought to use government as an agency for working out new arrangements to solve problems, such as worker insecurity and hardship, rather than promote systemic restructuring, although to many conservatives his ventures were radical enough. To these ends Commons and small armies of associates engaged in fact finding – his look-and-see methodology – in a spirit of bringing all scientific knowledge to bear

on problem solving. From these experiences, indeed already manifest in the underlying strategy, Commons developed a theory of government as alternately a mediator of conflicting interests and an arena in which conflicting interests bargained over their differences; a theory of the complex organization – in terms of freedom, power and coercion – and evolution of the legal foundations of capitalism, which centred in part on the composing of major structural conflicts through the mutual accommodation of interests; and a theory of institutions with an affirmative view of their roles in organizing individual activity and resolving conflict.

The institutions Commons studied most closely were trade unions and government, particularly the judiciary. He developed his theory of the economic role of government in part on the basis of his study of the efforts of workers to improve their market position and in part on the use of government by both enemies and friends of labour. Commons's was an interpretation of trade unions as a non-revolutionary development, as collective action seeking to do for workers what the organizations of business attempted to do for their owners and managers. His study of the reception given unions and reform legislation led him to recognize the critical role of the United States Supreme Court (and the courts generally), and its conception of what was reasonable in the development and application of the working rules which governed the acquisition and use of power in the market. Accordingly, Commons developed a theory of property which stressed its evolution and role in governing the structure of participation and relative withholding capacity in the market.

Commons also developed a theory of institutions which focused on their respective different mixtures of bargaining, rationing and managerial transactions, all taking place within a legal framework which was itself subject to change.

Although Commons's institutionalism had different emphases from that of Thorstein Veblen, for example, in that Commons stressed reform of the capitalist framework, they shared a view of economics as political economy and of the economy as comprising more than the market. Unlike Veblen, Commons was not antagonistic toward businessmen, and indeed accepted capitalism, though not necessarily on the terms given or preferred by the established power structure.

Commons was one of the few American economists to found a 'school', a tradition that was carried forward by a corps of students, especially Selig Perlman, Edwin E. Witte, Martin Glaeser and Kenneth Parsons. Much mid-20th-century American social reform, the New Deal for example, drew on or reflected the work of Commons and his fellow workers and students.

Communications

Roger G. Noll

The economics of communications is a loose, somewhat vaguely defined amalgam of topics in applied microeconomics. Although having close

ties to the microeconomic theory of the economics of information, it is probably best characterized as a subfield of industrial organization, regulation and public enterprise that deals with the communications sector: telecommunications, broadcasting, the print media, the performing arts and the postal system. Of course, the activities that constitute this list are somewhat arbitrary, but they reflect what is both taught and studied by people in the subfield as well as some important economic realities that make specialized studies of the communications sector a valid category among distinct intellectual pursuits. First among these realities is that the industries in the communications sector are closely linked. Broadcasting competes with the performing arts for both audience and inputs, and telecommunications competes with the postal service. Moreover, telecommunications networks are capable of delivering broadcast services, and vice versa. Among the products over which the postal system, telecommunications and cable television compete is the delivery of the output of the print media.

Another unifying theme across communications industries is the connection of the study of the sector to the economics of public goods and externalities. Communications is the production and dissemination of information. Some aspects of the production of information are public goods, and the dissemination and use of information can have important external effects. Moreover, most of these external effects are non-economic phenomena such as political participation, the cultural values held by members of a society or the level of violence. Because of the unique character of these externalities, the motives for public policy in communications are closely linked with a society's fundamental political and social values. Thus, freedom of speech and the extent of the right to privacy, as well as the use of control of communications to manipulate the political process, are at the heart of debates over communications policy.

Rationales for Government Intervention

Not surprisingly, the role of the public sector is very large in the communications sector in nearly every nation. Subsidization, nationalization and extremely detailed regulation of prices and attributes of the product are common. In market-oriented societies, telecommunications and mail are nationalized or subject to economic regulation for much the same reasons that underpin the same policies in other infrastructural industries: that these industries are natural monopolies and that their performance and pattern of development profoundly affect the development of much of the rest of the economy. But even here, unique externality arguments are brought forth as additional factors to be taken into account by policymakers. First, subscription to the telecommunications network or access to mail delivery creates the capability to receive communication from others. A person who decides to mail a letter or place a telephone call presumably considers only his or her net benefits from the communication; the willingness to pay of the recipient (positive or negative) is not taken into account. Thus, for example, the extent of phone service and the pattern of calling can be expected to be inefficient if each person bears the full cost of, first, subscribing to the network, and then placing telephone calls. In particular, if some potential customers have too low a willingness to pay to become subscribers, but are also desired objects of communications by others, the number of subscribers will be too low if subscribers must bear the full cost of connecting them to the network. This argument constitutes the foundation for the 'universal service' objective; that is, a policy of maximizing the number of subscribers to the telephone network, and the policy practised nearly everywhere of adopting a price structure for telephone services that subsidizes installation charges, pay-telephone prices and/or monthly access charges to the local network, especially for customers in high-cost areas such as rural communities.

A second externality of the telecommunications system is said to be its contribution to national security. A joint product of a private telecommunications network is a ready resource that can be commandeered and used by government in times of national emergency, such as foreign attack, natural disasters or accidents. The use of communications to coordinate a response to

such an event, then, should play a role in affecting the capacity and design of the telecommunications system, and often is the basis of an argument for building into the system more redundancy and interconnectability than might otherwise be optimal and than independent private concerns would undertake on their own. These contingent needs by government have been said to constitute a separate natural-monopoly argument, an example of 'economies of scope' between private and public uses that can only be captured if the private system is a single, integrated whole. In the United States, for example, the Department of Defense was a consistent critic of proposals to relax regulation and increase competition in the telecommunications industry during the 1960s and 1970s.

The externalities associated with the mass media have to do with the social, political and psychological consequences of the content of information, and for the most part are dealt with by scholars from disciplines other than economics. (The main exception is research on the effects of advertising, where an inconclusive debate has raged for decades as to whether the informational value of advertising exceeds the sum of its direct costs and possible resource misallocation owing to manipulation and misperceptions of consumers.) The analytical foundation for the belief in the importance of informational externalities is the proposition that people's behaviour as citizens, parents, consumers, workers, friends, and so on, can be significantly affected, at least in the short run, by the informational content of the mass media. Once one accepts this proposition, the next logical step is to entertain the idea that censorship by the state, at least in principle, can prevent some of the external diseconomies of destructive content, while proactive state interventions to channel the content of the media towards greater educational and otherwise uplifting content can provide additional social benefits.

The most obvious manifestations of these ideas are in broadcasting. The British Broadcasting Corporation was founded on openly paternalistic principles about the potential of radio broadcasts for educational and other uplifting purposes. Until the recent move towards decentralization through cable television and towards private, commercial television, a core principle of French broadcasting policy was to preserve French culture and values by limiting and censoring programmes from other nations. In Germany, decentralized, regional quasi-public broadcast monopolies were created after World War II to protect simultaneously against capture by the national government or by the national print media barons, either of which, it was feared, might use broadcasting to arouse nationally destructive political passions. And in the United States, broadcast licensing has, until recently, enforced a long set of standards for evaluating competitors for a given license, including personal characteristics and other business holdings of the licensee and both performance and promise about the extent of 'public service' programming offered by commercial as well as non-commercial (educational) outlets.

Of course, other mass media are not free of similar policy constraints, although the print media and the arts are usually accorded greater freedom in the content of their messages than are broadcasters. The areas of policy controversy are the definition of the liability for slanderous attacks and the concomitant definition of privacy rights, the boundaries between pornography and legitimate expression, and the principles separating sedition from reasonable political discourse.

The core economic issue in this debate is whether the 'marketplace for ideas' works well without intervention, or at least better than is the case with active political intervention by the very government authorities whose security and power can be affected by the content of communications. The argument for non-intervention is twofold. Positively, it is that in the end people's tastes in ideas should be accorded the same status as their tastes in other goods as long as the consumption of communications produces no external diseconomies. If communications cause bad behaviours, then if people are informed about this fact – and about the punishments exacted if those behaviours are manifest – they will efficiently anticipate this in making decisions about which communications to receive and how to treat those that are received. And, as with goods, ideas about how the world works that prove correct will be perceived, at least eventually, as superior to less correct ideas.

Negatively, the argument for an unregulated marketplace for ideas is a pessimistic forecast of how political intervention is likely to work: a combination of orientation towards propaganda to serve the interests of preserving the status quo and an extreme sensitivity to either vocal, organized single-issue groups seeking to impose their values on others or a tyranny of the majority that persecutes those who stray too far from current norms.

The other side of the dispute, usually advocated more by non-economists, is rooted in observed relationships between communications and behaviour, perhaps best documented in the study of the effects of television on violence (especially by children) and on the manipulation of the news for short-term political objectives. This position regards the efficiency of the marketplace for ideas as demonstrably poor, at least in the short run; implicitly, it accords less credence to the proposition that individuals are as rational – indeed, are even proactive – in selecting among competing communications as economic theory assumes. Proponents of intervention especially emphasize the unformed and manipulable attitudes of children.

The final pervasive feature in the communications sector that deserves further elaboration is the partially non-rivalrous nature of the consumption of information. All information is a public good in the sense that once a new information product has been created for a first user, it does not have to be created again for subsequent users: in principle, at least, the first use of information does not preclude its use by others. In practice, this characteristic may be unimportant. Information must be disseminated in some way to subsequent users, and the cost of dissemination may exceed the cost of secondary creation – as for example can be the case for a simple computer program. Or, information may be very cheaply privatized so that the public goods characteristic introduces no significant inefficiency to a private market system of distribution. Nevertheless, the publicness of information is a serious issue in an assessment of the performance of allocational institutions in the communications sector, and in the design of private market processes for allocating resources the problems of publicness must be addressed. Whether the product is a written news report, a novel, a theatrical production, a television broadcast, or 'Dial-A-Joke' on the telephone, the problem is fundamentally the same: producers will not supply a product unless they can recover the opportunity cost for creating it, yet the marginal cost of providing the product to one more consumer does not include any of the production costs of the information. Hence, efficient provision of information requires one of the following: subsidies of the production of information, or price discrimination with protection against arbitrage so that consumers with relatively low willingness to pay for information will not be inefficiently excluded. In practice, both are common. Governments subsidize broadcasting and performing arts by direct payments, and certain users of the postal and telecommunications system either directly or by engaging in price discrimination (e.g. the differences in basic monthly service rates of telephones between residences and businesses, and the lower postal rates for circulating the print media). Of course, neither direct subsidies nor discriminatory prices are explicitly designed in a quantitative sense to offset the inefficiencies of private provision of public goods, so that the issue of optimal pricing of communications services is an active and still-developing field of research. The focus here is on the two fields in which most of the work has been done: telecommunications and broadcasting. Moreover, the discussion includes research on market structure issues because of their close connection to the implications of alternative pricing policies.

Pricing and Market Structure in Telecommunications

The telecommunications industry in the United States offers an array of services that until very recently were provided as joint products by a legally protected monopoly. When the monopoly was secure and unquestioned, the pricing problem was to devise a price structure that recovered joint and fixed costs with minimal loss of efficiency. As the natural monopoly presumption came to be

called into question, the pricing problem began to incorporate another dimension, to provide appropriate signals to potential competitors so that the market structure would evolve efficiently.

To understand the rudiments of the telephone pricing problem requires some basic knowledge about the technical characteristics of the telecommunications network. The traditional telephone system is best conceptualized as having four components: customer terminal equipment (a telephone, a computer terminal, a switchboard); a pair of copper wires connecting each terminal device to a central switch; the central switch that serves the local community; and a hierarchy of transmission conduits and additional switches that serve to connect the local switches. Typically the telephone price structure has three elements: an installation charge for activating a customer's copper wire pairs; a basic monthly service charge for renting terminal equipment and the copper wire pairs; and a message toll for placing telephone calls. The common practice is for the installation charge to cover only a fraction of installation costs as a means of encouraging universal service, and for the basic monthly charge to entitle the subscriber to unlimited local calling – sometimes not confined to other telephones connected to the same local switch, but also including calls through adjacent local switches. Usually the basic monthly charge is much higher (by a factor of 2 or 3) for business than for residences, but within each of these categories it tends to be approximately the same over wide geographic areas regardless of differences in cost of service.

Until about 1960, the revenues from installation charges and the basic monthly rate approximately covered the cost of local service (including local switches). But as long-distance toll calls became more important, telephone companies increasingly used toll revenues to cover part of the cost of the local system. This required no increase in toll prices; indeed, long-distance prices generally were falling because technological change was extraordinarily rapid in this segment of the system. By simply letting prices fall a little more slowly than costs, a large and growing fraction of local network costs could be paid for by toll. These revenues could be used to construct systems in high-cost rural areas without causing increased prices for basic service elsewhere, again to encourage universal service.

Since toll calls pass through local switches they impose a cost on the local network, because local switches must be designed to be large enough and complex enough to accommodate them. Consequently, toll prices would bear some local system costs in an efficient pricing structure. In addition, however, toll calls also contributed to 'non-traffic sensitive' (NTS) costs – the terminals and copper wire – even though, by definition, the magnitude of investment required for this equipment was unrelated to the amount of calling.

Obviously, this pricing structure not only encouraged universal service but encouraged local calling (with a zero price at the margin) while discouraging long-distance calling compared to an efficiency standard. Encouraging subscriptions to the system may be warranted on efficiency grounds, although the magnitude of the subscription externality has not been quantified, and so it is not possible to tell whether the amount of the subsidy is justified. Likewise, a subsidy of local calls may be desirable, but the method of subsidization is of doubtful validity. The external benefit (or cost) of a call falls on the person being called, not on society generally.

Hence, the optimal pricing structure involves a sharing of the costs of calling between the parties to a conversation, where the costs involve the operating costs of the system and the effect of calls on the required capacity of the switching system. Only if metering costs were large in comparison with the costs of calling would it make sense not to charge for calls, but with modern electronic switching metering costs are not significant, so that one cannot justify a subsidy for local calls. Moreover, even if one could, there is no justification for taxing long-distance calls to pay the subsidy unless one believes that the externality of a local call is substantially more important than the externality of a long-distance call.

The general structure of an optimal price structure for the telephone network, given important externalities and natural monopoly, can be derived as follows. Begin with a basic monthly charge that

would pay the marginal cost of terminals and copper wire connections to the local switch, and toll charges on all calls that pay the marginal cost of the switching and transmission facilities that are traffic sensitive. These prices need further adjustment, for they may collect too much or too little total revenue. But prior to this adjustment they must also be uniformly adjusted downwards to account for the externality of subscribing and calling (assuming that people like to receive phone calls). The adjustment for the toll rate can simply be passed on to the recipient of the call; however, the basic monthly rate must come down for everyone. At this point the likely case is that the basic monthly rate does not cover the NTS costs, so that further adjustments must be made. One possibility is a subsidy paid from an economy-wide tax, but more likely the additional revenues will come from the rate structure of the telephone company. The first-best solution is to raise infra-marginal prices, such as the cost of the first few calls made per month, producing what amounts to quantity discounts for all types of calls. Alternatively, one could adopt Ramsey pricing, raising the price the most for services with relatively inelastic demand.

The resulting price structure would have a number of very interesting features. Call recipients would pay a share of the price of a call. To implement this so as only to charge for calls with a positive benefit, the shared cost would start a decent interval after the call is answered, and subscribers who desired it could be permitted to designate in advance that they would bear the full cost of their calls. All prices would be built on marginal costs, which means peak-load pricing of calling and prices for both basic access and calling that were higher in high-cost areas. To the extent that Ramsey prices were invoked, they would most certainly rely primarily on basic monthly charges, for this has by far the lowest demand elasticity: estimates range between -0.02 and -0.10. Thus, even if there is a significant externality associated with subscribing to the network, the Ramsey pricing method for paying for it involves raising the price of basic access. Or, putting the matter another way, ignoring this externality in setting prices will have very little effect on subscriptions to the system, and hence very little effect on efficiency. Finally, differences between residential and business basic monthly charges would exist only if their externality value differed, they imposed different costs on the system or they had different price elasticities.

Obviously, the pricing structure of telephone service has never reflected these principles. Until the 1970s, government officials perceived the extent of inefficiency of the pricing structure as something of an academic issue and largely ignored it. But technological change and the false signals to entrants from the price structure have led to strong pressures for competitive entry into the formerly secure telephone monopoly. Computer technology has vastly diversified the demand for telecommunications, as well as vastly increased its magnitude, and computers and other advances in microelectronics have altered the technology of supply. Examples of the broad range of new computer-based services include on-line connections to mainframes and data bases for technical and business use, automatic teller machines, remote sensing for protection against fires and burglars, and reservation services. Each of these uses has somewhat different technical requirements, so that the optimal market structure for the industry may well be to have a product-differentiated oligopoly, even if each has unexploited economies of scale. Moreover, the greater demand created by these technical advances allows considerable exploitation of scale economies even in a segmented system.

On the supply side, advances in electronics have changed the basic character of the local network. No longer are high-density networks built of dedicated copper wire pairs for each terminal. Instead, micro-electronic technology allows multiple signals on the same wires, and small-scale switches distributed throughout the local network that serve to concentrate lines from many terminals into a smaller number of active circuits, taking advantage of the fact that not all terminals are in use simultaneously. This reduces the unit cost of capacity and hence the significance of scale economies in the local network. Moreover, it undermines a cornerstone of the optimal-pricing structure that was developed

above by eliminating most of the NTS costs. If, as is becoming the case, customers own their terminal equipment, and if line concentration begins when a small number of terminals are aggregated into a single pathway to the first switch, then nearly all of the system that is owned by the local telephone company consists of traffic-sensitive investment. Hence, the trend should be away from reliance on the basic monthly charge and towards greater reliance on message tolls for calling.

The failure to adjust the pricing system to the realities of costs and technology adds to the pressure for competitive entry in the parts of the system where prices are higher than the costs of service. Specifically, the attempt to tax long-distance service in order to subsidize local calling makes relatively intense users of long-distance service ripe candidates for a competitive long-distance supplier. Large companies with many telephone lines who can provide their own concentrated connections between their facilities have a strong incentive to bypass subscriptions to the local network. And other electronic pathways for communications, such as cable television and point-to-point uses of the radio spectrum, can be exploited to bypass the telecommunications network.

Thus far, government officials responsible for telecommunications policy whether as operators of public enterprises or regulators of private utilities, have focused more on the structural aspects of the problem than on pricing issues. Even in the United States, which has perhaps the greatest commitment to competition, government policy regarding entrants has been the binding constraint on the growth of competition, and the price structure is still replete with inefficiencies. The likely explanation for this phenomenon is the belief by political actors that the cost of local service to residences is the price that is most visible politically and that rationalized pricing will cause residential service to become more expensive, either from raising basic monthly charges or from message toll for local calls. To avoid raising residential price, political actors therefore believe that they have to keep some other prices above the cost of service, and to maintain these prices in the face of diminished or perhaps even non-existent natural monopoly they must erect barriers to competitive entry aimed at the overcharged customers.

Prices and Market Structure in Broadcasting

The most common way to pay for broadcasting is to provide signals to the audience at no charge, and to rely on either advertising or government subsidies as to the source of revenues. In one sense such an arrangement seems to fit the fact that broadcasts are a classic public good; the marginal cost to the broadcaster of one more person receiving a broadcast is zero, and consumption among members of the audience is completely non-rivalrous. Hence, any attempt to charge a viewer for a programme can introduce inefficiency to the extent that anyone is thereby excluded from participation who also has a positive willingness to pay to join the audience.

The difficulty with free broadcasting, however, is that it does not necessarily result in programmes that maximize the net willingness to pay of the audience. Ignoring for a moment the frictions in the political process and the incentives of political actors to manipulate programme content to their private benefit, both subsidized and advertiser-supported television lead broadcasters to measure their success primarily on the basis of the size of audience. In a subsidized system, the objective would be to make certain that political support is as high as possible, and in an advertising system, in which the broadcaster is selling the attention of viewers, revenues are more or less proportional to audience size. The issue in both cases is not whether audience satisfaction is maximized but whether it is kept high enough for a large enough number of people to maximize revenues from a payment system that is not based on the intensity of preferences but on the number of satisfied customers. In particular, small groups with intense willingness to pay for an unusual type of programming material will generally not have their preferences satisfied even if their aggregate

willingness to pay exceeds that of a large audience for the traditional mass-audience programme.

Three means are available for coping with this state of affairs. One is to expand the number of broadcast options until all groups are satisfied. Suppose that there is a large mass audience and a series of small, specialized ones. As the number of stations expands, the audience for mass programmes each can expect will be the total mass audience divided by the number of stations. Eventually, there will be enough stations so that the largest specialized taste will constitute a larger audience than the share of the mass audience the next station could expect to capture, so that a strategy to maximize audience will lead to specialization. In the United States, this is more or less the policy with respect to radio broadcasting. In the early years of radio, the Federal Communications Commission tried to assure diversity in commercial broadcasting by specifying the format (e.g. type of programmes) that a station could broadcast. Recently, station formats have been deregulated, yet the multiplicity of categories remain, in much the same fashion that there is a broad spectrum of magazines and books by type of material.

In television, the strategy of increasing the number of stations is more difficult to follow. Television stations consume far more radio frequency space than radio stations, and no nation has thus far been willing to allocate enough high-quality radio spectrum to television to provide much of a test as to whether specialization might take place in a more extensive industry. An unplanned test, however, is under way in Italy, where in the 1970s the courts declared that the government had no constitutional right to limit the number of television stations, and largely unregulated entry has taken place on a massive scale. It is too soon to tell what the ultimate outcome of this system will be.

The second mechanism to produce more diversity in television is to allow the audience to express a willingness to pay, commonly by installing cable television with much higher capacity than off-air television and charging customers on the basis of the number and type of channels that they elect to receive. The inefficiency inherent in this system is the cost of privatizing broadcasts so that on either a per programme or per channel basis they can be sold. Prior to the extensive development of cable television in the United States, the common speculation was that privatization of broadcasts would cause a diversion from traditional mass audience programming, with more activity in cultural programmes, educational broadcasting and public affairs. The expectation was based upon the belief that higher-income groups were more interested in diversity and would have more influence in determining the content of for-pay systems. In practice, this expectation has not been realized. The new cable-oriented networks for the most part offer programming that is like that provided by off-air broadcasters, such as movies, sports events and regular series. The principal exception is in public affairs, where national cable news and public events networks have succeeded. Educational and cultural programming, however, has been largely unsuccessful. The inference to be drawn is that scarcity in television stations caused an excess demand for television, but primarily for programmes that were much like those featured by off-air stations, largely oriented towards the mass audience.

The third means for increasing diversity is to create a single, multi-outlet monopoly broadcasting entity. If such an entity seeks to maximize total audience, it will not have as much incentive to duplicate mass programming, because audience substitution from one channel to the next will have no value. A second or third mass-audience station will increase the size of the total audience, but the evidence indicates that the effect is small compared to audience diversion. For example, in the United States the first television station captures a little less than half of the potential audience available in prime evening viewing time. No matter how many additional stations are added, the maximum viewing share appears to be about 80%, and this is almost totally achieved after three or four stations are operating. This suggests that a multichannel monopolist would either diversify programming on the second or third channel, or simply elect not to broadcast on more than one or two channels, depending on the relationship

between the value of a net increment to the audience and the costs of adding another channel.

American public television provides an example of a novel method of support, for it is one of the few attempts to implement a decentralized decision process for acquiring a public good (here programmes). The first component of the system is the method of public financing, which involves multiple year, advance funding to erect some barrier to political manipulation of programmes. The public funds are then divided into three components: a budget for experimental programming that is spent by an independent, quasi-public entity (the Corporation for Public Broadcasting); a budget for the technical operation of the national network (Public Broadcasting Service); and a direct subsidy of local stations. This subsidy is based in part on the success of the station in obtaining private contributions from its audience. Thus the station subsidy amounts to an attempt to overcome the free-rider problem faced by viewers by providing matching funds for their contributions.

The second component of the system is the mechanism by which stations decide which programmes will appear on the network. This is accomplished by a combination voting and price system. The price of a programme for each station is determined by the size of the community it serves, and stations then vote on each programme proposal. If some stations vote against the proposal, the prices faced by the supporters are increased by an amount necessary to allow the programme to cover its costs, and voting proceeds again. The process continues until programmes are either purchased or discarded; usually fewer than a dozen iterations are required to reach a decision. Stations voting against a programme are excluded from broadcasting it; however, stations may later join the group paying for it by paying a premium price.

The programme acquisition process decentralizes network programming to the stations, thereby serving two ends. First, because the station budgets depend on contributions, or the voluntary willingness to pay of the audience, there exists a feedback mechanism from the audience to the network that is similar to a pay-TV system. Second, the network schedule becomes less vulnerable to political attack, for centralized government officials who might seek to control it face a collective of over 150 station licensees, who, in turn, are actively using contributions patterns to make decisions about which programmes to acquire.

The American system of financing public television does not, of course, have pristine efficiency properties; neither the voluntary audience contributions nor the mechanism whereby stations select programmes is an incentive-compatible mechanism. Nevertheless, in the inherently imperfect world of public goods acquisition, they appear to perform remarkably well, and experimental investigations in a laboratory setting suggest that the method of acquiring programmes can be productively employed in a variety of settings for collective decisions.

Remaining Issues

Two aspects of the communications sector make it a ripe area for continuing study. First is the rapidly evolving technology of supply and demand, and the second is the pervasive and changing influence of political processes on the structure and performance of the sector.

With changing technology has come a significant change in the pattern of demand for services. This suggests that historical patterns of use and estimates of service-specific demand are unreliable predictors of the future. Yet relatively little research has investigated how changing technology – lower costs, greater possibilities of use, more technical capabilities – have affected key aspects of demand: the rate of growth by service and customer category and the own-and cross-elasticities of demand.

Changing technical possibilities and demand should also feed back into the political forces that guide the development of the sector. Most advanced industrialized nations are in the midst of transition in at least some policies regarding communications, such as the privatization and introduction of competition in telecommunications in Japan and Great Britain, and the

elimination of the state broadcasting monopolies in France and Italy. These changes deserve study on two counts: how these dramatic policy changes affect performance, and what political forces they may be creating that will shape policy and industry structure in the future.

A period of rapid change is one in which important new knowledge is likely to be forthcoming. One can anticipate that a summary of the economics of communications a decade or two hence will contain significant and surprising new insights.

Communism

Ernest Mandel

The term 'communism' was first used in modern times to designate a specific economic doctrine (or regime), and a political creed intending to introduce such a regime, by the French lawyer Etiénne Cabet in the late 1830s; his works, especially the utopia *L'Icarie*, were influential among the Paris working class before the revolution of 1848. In 1840, the first 'communist banquet' was held in Paris – banquets and banquet speeches were a common form of political protest under the July monarchy. The term spread rapidly, so that Karl Marx could entitle one of his first political articles of 16 October 1842 'Der Kommunismus und die Augsburger *Allgemeine*

Zeitung'. He noted that 'communism' was already an international movement, manifesting itself in Britain and Germany besides France, and traced its origin to Plato. He could have mentioned ancient Jewish sects and early Christian monasteries too.

In fact, some of the so-called 'Utopian socialists', in the first place the German Weitling, called themselves communists and spread the influence of the new doctrine among German itinerant handicraftsmen all over Europe, as well as among the more settled industrial workers of the Rhineland. Under the influence of Marx and Engels, the League of the Just (Bund dez Gerechten) they had created, changed its name to Communist League in 1846. The League requested the two young German authors to draft a declaration of principle for their organization. This declaration would appear in February 1848 under the title *Communist Manifesto*, which would make the words 'communism' and 'communists' famous the world over.

Communism, from then on, would designate both a classless society without property, without ownership – either private or nationalized – of the means of production, without commodity production, money or a state apparatus separate and apart from the members of the community, and the social-political movement to arrive at that society. After the victory of the Russian October revolution in 1917, that movement would tend to be identified by and large with Communist parties and a Communist International (or at least an 'international communist movement'), though there exists a tiny minority of communists, inspired by the Dutch astronomer Pannekoek, who are hostile to a party organization of any kind (the so-called 'council communists', *Rätekommunisten*).

The first attempts to arrive at a communist society (leaving aside early, medieval and more modern christian communities) were made in the United States in the 19th century, through the establishment of small agrarian settlements based upon collective property, communally organized labour and the total absence of money inside their boundaries. From that point of view, they differed radically from the production cooperatives promoted for example by the English industrialist and philanthropist Robert Owen. Weitling himself created such a community, significantly called Communia. Although they were generally established by a selected group of followers who shared common convictions and interests, these agrarian communities did not survive long in a hostile environment. The nearest contemporary extension of these early communist settlements are the *kibbutzim* in Israel.

Rather rapidly, and certainly after the appearance of the *Communist Manifesto*, communism came to be associated less with small communities set up by morally or intellectually selected elites, but with the general movement of emancipation of the modern working class, if not in its totality at least in its majority, encompassing furthermore the main countries (wealth-wise and population-wise) of the world. In the major theoretical treatise of their younger years, *The German Ideology*, Marx and Engels stated emphatically:

> Empirically, communism is only possible as the act of dominant peoples 'all at once' and similtaneously, which presupposes the universal development of productive forces and the world intercourse bound up with them. . . .The proletariat can thus only exist worldhistorically, just as communism, its activity, can only have a 'world-historical' existence.

And, earlier in the same passage,

> . . . This development of productive forces (which at the same time implies the actual empirical existence of men in their world-historical, instead of local, being) is an absolutely necessary practical premise, because without it privation, is merely made general, and with want the struggle for necessities would begin again, and all the old filthy business would necessarily be restored . . . ([1845–6] 1976, p.49).

That line of argument is to-day repeated by most orthodox marxists (communists), who find in it an explanation of what 'went wrong' in Soviet Russia, once it was isolated in a capitalist environment as a result of the defeat of revolution in other European countries in the 1918–1923 period. But many 'official' Communist Parties still stick to Stalin's particular version of communism, according to which it is possible to

successfully complete the building of socialism and communism in a single country, or in a small number of countries.

The radical and international definition of a communist society given by Marx and Engels inevitably leads to the perspective of a *transition* (transition period) between capitalism and communism. Marx and Engels first, notably in their writings about the Paris Commune – *The Civil War in France* – and in their *Critique of the Gotha Programme* [of the German social-democratic party], Lenin later – especially in his book *State and Revolution* – tried to give at least a general sketch of what that transition would be like. It centres around the following ideas:

The proletariat, as the only social class radically opposed to private ownership of the means of production, and likewise as the only class which has potentially the power to paralyse and overthrow bourgeois society, as well as the inclination to collective cooperation and solidarity which are the motive forces of the building of communism, conquers political (state) power. It uses that power ('the dictatorship of the proletariat') to make more and more 'despotic inroads' into the realm of private property and private production, substituting for them collectively and consciously (planned) organized output, increasingly turned towards direct satisfaction of needs. This implies a gradual withering away of market economy.

The dictatorship of the proletariat, however, being the instrument of the majority to hold down a minority, does not need a heavy apparatus of full-time functionaries, and certainly no heavy apparatus of repression. It is a state *sui generis*, a state which starts to wither away from its inception, i.e. it starts to devolve more and more of the traditional state functions to self-administrating bodies of citizens, to society in its totality. This withering away of the state goes hand in hand with the indicated withering away of commodity production and of money, accompanying a general withering away of social classes and social stratification, i.e. of the division of society between administrators and administrated, between 'bosses' and 'bossed over' people.

That vision of transition towards communism as an essentially evolutionary process obviously has preconditions: that the countries engaged on that road already enjoy a relatively high level of development (industrialization, modernization, material wealth, stock of infrastructure, level of skill and culture of the people, etc.), created by capitalism itself; that the building of the new society is supported by the majority of the population (i.e. that the wage-earners already represent the great majority of the producers and that they have passed the threshhold of a necessary level of socialist political class consciousness); that the process encompasses the major countries of the world.

Marx, Engels, Lenin and their main disciples and co-thinkers like Rosa Luxemburg, Trotsky, Gramsci, Otto Bauer, Rudolf Hilferding, Bukharin et al. – incidentally also Stalin until 1928 – distinguished successive stages of the communist society: the lower stage, generally called 'socialism', in which there would be neither commodity production nor classes, but in which the individual's access to the consumption fund would still be strictly measured by his quantitative labour input, evaluated in hours of labour; and a higher stage, generally called 'communism', in which the principle of *satisfaction of needs* for everyone would apply, independently of any exact measurement of work performed. Marx established that basic difference between the two stages of communism in his *Critique of the Gotha Programme*, together with so much else. It was elaborated at length in Lenin's *State and Revolution*.

In the light of these principles, it is clear that no socialist or communist society exists anywhere in the world today. It is only possible to speak about 'really existing socialism' at present, if one introduces a new, 'reductionist' definition of a socialist society, as being only identical with predominantly nationalized property of the means of production and central economic planning. This is obviously different from the definition of socialism in the classical marxist scriptures. Whether such a new definition is legitimate or not in the light of historical experience is a matter of political and philosophical judgement. It is in any case another matter altogether than ascertaining

whether the radical emancipatory goals projected by the founders of contemporary communism have been realized in these really existing societies or not. This is obviously not the case.

The idea of a community indifference curve, as the term is commonly used, is due to Scitovsky (1942). The genesis of the idea is the fact that comparative statics and welfare analysis in economic models is simplified considerably if there is a social preference ordering over aggregate commodity bundles which reflects the collective individual preferences of agents. Scitovksy's notion of a 'community indifference curve' essentially allows the analytical convenience of social indifference curves, in certain circumstances, without having to assume a specific Bergson–Samuelson social welfare function or having to assume the restrictive assumptions on agents' preferences needed to guarantee that agents act collectively as a single individual.

The definition of a community indifference curve is basically simple. Suppose there are m commodities and n agents. Let x denote a commodity vector (as m-vector with non-negative coordinates) and u_i a utility function representing agent i's preferences. We will assume that ui is monotone increasing and quasi-concave. Given a vector $u' = (u_1', \ldots, u_n')$ of utility numbers, the community indifference curve at u', $CIC(u')$, is defined to be the set of all commodity vectors x such that there is a distribution $(x_1, \ldots, x_n)$ of commodity vectors satisfying $\sum_i x_i = x$ and $u_i(x_i) = u_i', i = 1, \ldots, n$, and there is no $x' \leq x$, $x' \neq x$ which also has this property. Thus one can obtain any vector $x \in CIC(u')$ by fixing the quantities of all but one good and minimize the amount of the remaining good subject to achieving u'. As pointed out by Samuelson (1956), the community indifference curve can be interpreted as a 'dual' to the utility possibility frontier. The utility possibility frontier, for a given x, is the set of all vectors u' of utility numbers achievable by a Pareto efficient distribution of x to the agents. Let $U(x)$ denote the utility possibility frontier for the commodity vector x. Then it is easy to see that $CIC(u') = \{x : u' \in U(x)\}$ and that $U(x) = \{u' : x \in CIC(u')\}$.

We will now describe the most important properties of community indifference curves. First, each $CIC(u')$ looks like the indifference curve of a monotone quasi- concave utility function. That is, the set of vectors x such that $x \geq x^1$ for some $x^1 \in CIC(u')$ is a convex set. For example, when $m = 2$, CIC(u') is a curve with a diminishing marginal rate of substitution. Second, unlike the utility possibility frontier, the community indifference curve is essentially an ordinal concept, that is it does not depend on the choice of utility functions representing agents' preferences, in the

following sense. Suppose, for each i, u_i and v_i are two utility functions representing agent i's preferences, and let $(x_1, \ldots, x_n)$ be a Pareto efficient allocation to the agents. Define $u' = [u_1(x_1),\ldots, u_n(x_n)]$ and $v' = [v_1(x_1), \ldots v_n(x_n)]$. Then $CIC(u') \equiv CIV(v')$. Clearly, community indifference curves can be parameterized by a given Pareto efficient allocation of goods rather than a given vector of utilities. Third, assuming smooth utility functions, the marginal rate of substitution for any two commodities on a community indifference curve is equal to the common marginal rate of substitution of each agent. Specifically, pick any $x \in CIC(u')$, and let $(x_1,\ldots,x_n)$ be the Pareto efficient allocation of x such that $u_i(x_i) = u_i^{'}$, $i = 1,\ldots,n$. Then for any two commodities h and h', the marginal rate of substitution of h and h' evaluated at $x \in CIC(u')$ is equal to the marginal rate of substitution of h for h' at x_i on agent i's indifference curve through x_i. Fourth, and very important, community indifference curves are not, in general, 'indifference' curves in the sense of being level curves of some function. Pick any x, and $u^{'}, u^{''} \in U(x)$, such that $u' \neq u^{''}$. Then by definition, $x \in CIC(u') \cap CIC(u^{''})$. Thus $CIC(u')$ must either coincide with $CIC(u^{''})$ or intersect properly. The condition for two community indifference curves never to intersect properly is then that $CIC(u') = CIC(u^{''})$ for all $u', u^{''} \in U(x)$, for all x. It turns out that this is true if and only if the agents have identical homothetic preferences, in which case the family of all community indifference curves will coincide with the family of indifference curves for the common preferences of the agents.

From the above definition and properties, the following observation constitutes the basic use of community indifference curves: if the economy is currently at a vector of utility numbers u', then x' is a commodity vector which lies above $CIC(u')$ if and only if there is some distribution of x' to the agents which will achieve a vector of utilities u'' such that $u^{''} > u'$. In this sense, x' is 'better' than any $x \in CIC(u')$. However, since from above community indifference curves can intersect properly, it may also be that there is a $u^{'''}$ such that $x' \in CIC(u^{'''})$ and an $x' \in CIC(u')$ such that x lies above $CIC(u^{'''})$, in which case x is also 'better' than x'. Thus it is important to realize that community indifference curves cannot be used to define a social ordering of aggregate output vectors. Nevertheless, community indifference curves can still be a useful analytical device. For example, consider a market economy with two produced goods. Consider an equilibrium in which all consumers face the same prices, in terms of the aggregate output vector x' and the vector of utilities u' obtained by the agents. Graphically this equilibrium can be represented by drawing the production possibility frontier and $CIC(u')$, noting they meet at x'. The slope of the production possibility frontier at x' represents the price ratio faced by firms, and the slope of the $CIC(u')$ at x' the common price ratio faced by consumers. If firms and consumers face the same price ratio, then the $CIC(u')$ must be tangent to the production possibility frontier at x. Thus no feasible x can be produced which can make all agents better off, so the situation is Pareto optimal. If, however, firms face different prices than the agents because of, for example, taxes or tariffs, then the slope of the $CIC(u')$ will be different from the slope of the production possibility frontier, and thus the two curves will intersect properly. In this case there must exist an x' on the production possibility frontier which lies above $CIC(u')$, so the original situation is Pareto inefficient.

Comparative Advantage

Ronald Findlay

Abstract

This article traces the evolution of the theory of comparative advantage and the gains from trade from the pioneering work of David Ricardo to the factor proportions approach of Eli Heckscher and Bertil Ohlin. Extensions of the basic models to many goods, factors and countries, and to the long run are noted, as well as the attempts at empirical testing of the predictions derived from them.

The modern economy, and the very world as we know it today, obviously depends fundamentally on specialization and the division of labour, between individuals, firms and nations. The principle of comparative advantage, first clearly stated and proved by David Ricardo in 1817, is the fundamental analytical explanation of the source of these enormous 'gains from trade'. Though an awareness of the benefits of specialization must go back to the dim mists of antiquity in all civilizations, it was not until Ricardo that this deepest and most beautiful result in all of economics was obtained. Though the logic applies equally to inter*personal,* inter*firm* and inter*regional* trade, it was in the context of inter*national* trade that the principle of comparative advantage was discovered and has been investigated ever since.

The Basic Ricardian Model

What constituted a 'nation' for Ricardo were two things – a 'factor endowment', of a specified number of units of labour in the simplest model, and a 'technology', the productivity of this labour in terms of different goods, such as cloth and wine in his example. Thus labour can move freely between the production of cloth and wine in England and in Portugal, but each labour force is trapped within its own borders. Suppose that a unit of labour in Portugal can produce one unit of cloth or one unit of wine, while in England a unit of labour can produce four units of cloth or two units of wine. Thus the opportunity cost of a unit of wine is one unit of cloth in Portugal while it is two units of cloth in England. On the assumption of competitive markets and free trade, it follows that *both* goods will never be produced in *both* countries since wine in England and cloth in Portugal could always be undermined by a simple arbitrage operation involving export of cloth from England and import of wine from Portugal. Thus wine in England or cloth in Portugal must contract until at least one of these industries produces zero output. If both goods are consumed in positive amounts, the 'terms of trade' in equilibrium must lie in the closed interval between one and two units of cloth per unit of wine. Which of the two countries specializes completely will depend upon the relative size of each country (as measured by the labour force *and* its productivity in each industry) and upon the extent to which each of the two goods is favoured by the pattern of world demand. Thus Portugal is more

likely to specialize the smaller she is compared with England in the sense defined above and the more world demand is skewed towards the consumption of wine relative to the consumption of cloth.

The Gains from Trade

Viewed as a 'positive' theory, the principle of comparative advantage yields *predictions* about (*a*) the *direction* of trade: that each country exports the good in which it has the lower comparative opportunity cost ratio as defined by the technology in that country, and about (*b*) the *terms* of trade: that it is bounded above and below by these comparative cost ratios. From a 'normative' standpoint the principle implies that the citizens of each country become 'better off' as a result of trade, with the extent of the gains from trade depending upon the degree to which the terms of trade exceed the domestic comparative cost ratio. It is the 'normative' part of the doctrine that has always been the more controversial, and it is therefore necessary to evaluate it with the greatest care.

In Ricardo's example the total labour force in each country is presumably supplied by an aggregate of different households, each having the same *relative* productivity in the two sectors. Thus *all* households in *each* country must become better off as a result of trade if the terms of trade lie strictly in between the domestic comparative cost ratios. The import-competing sector in each country simply switches over instantaneously and costlessly to producing the export good (moving to the opposite corner of its linear production-possibilities frontier, in terms of the familiar geometry), obtaining the desired level of the other good by imports, raising utility in the process. When one country is incompletely specialized, then all households in that country remain at unchanged utility levels, all of the gain from trade going to the individuals in the 'small' country. Thus we have a situation in which *everybody gains,* in at least one country, while *nobody loses* in either country, as a result of trade.

This very strong result depends upon Ricardo's assumption of perfect occupational mobility in each country. Suppose we take the opposite extreme of completely *specific* labour in each sector, so that each country produces a fixed combination of cloth and wine, with no possibility of transformation. In this case, labour in the import-competing sector in each country must necessarily *lose,* as a result of trade, while labour in each country's export sector must gain. It can be shown, however, that trade will improve *potential* welfare in each country in the Samuelson (1950) sense that the utility-possibility frontier with trade will dominate the corresponding frontier without trade, so that no one need be worse off, and at least some one better off, if lump-sum taxes and transfers are possible (Samuelson 1962).

International Factor Mobility and World Welfare

Another very important normative issue is the question of the relationship between the free-trade equilibrium and *world* efficiency and welfare. In the Ricardian model world welfare in general will *not* be maximized by free trade alone. In the numerical example considered here Ricardo stresses the fact that England can still gain from trade even though she has an *absolute* advantage in the production of *both* goods, her productivity being greater in both cloth and wine, though comparatively greater in cloth. Suppose that labour in Portugal could produce at English levels, *if it moved to England*; that is, the English superiority is based on climatic or other 'environmental' factors and not on differences in aptitude or skill. Then, if labour was free to move, and in the absence of 'national' sentiment, all production would be located in England, and Portugal would cease to exist. The former Portuguese labour would be better off than under free trade, since their real wage in terms of wine will now be two units instead of one. The English labour would be worse off, if the terms of trade were originally better than 0.5 wine per unit of cloth, but it is easy to show that they could be sufficiently compensated since the utility-possibility frontier for the world economy as a whole is moved out by the integration of the labour forces.

The case when each country has an absolute advantage in one good is more interesting. As is easy to see, from Findlay (1982), this case will involve a movement of labour to the country with the higher real wage under free trade, increasing the production of this country's exportable and reducing that of the lower-wage country under free trade. The terms of trade turn against the higher-wage country until eventually the real wage is equalized. The terms of trade that achieve this equality of real wages will be equal to the ratio of labour productivities in each country's export sector; that is, the 'double factoral' terms of trade will be unity. This solution of free trade *combined* with perfect labour mobility will achieve not only efficiency for the world economy as a whole but equity as well. 'Unequal exchange' in the sense of Emmanuel (1972) would not exist, while liberal, utilitarian and Rawlsian criteria of distributive justice would be satisfied as well, as pointed out in Findlay (1982). Despite all this, it still seems utopian to expect a policy of 'open borders', in *either* direction, for the contemporary world of nation-states.

Extensions of the Basic Ricardian Model

The two-country, two-good Ricardian model was extended to many goods and countries by a number of subsequent writers, whose efforts are described in detail by Haberler (1933) and Viner (1937). In the case of two countries and n goods the concept of a 'chain of comparative advantage' has been put forward, with the goods listed in descending order in terms of the *relative* efficiency of the two countries in producing them. It is readily shown that with a uniform wage in each country all goods from 1 to some number j must be exported, while all goods from $(j + 1)$ to n must be imported. The number j itself will depend upon the relative sizes of the two countries and the composition of world demand. Dornbusch et al. (1977) generalize this result to a continuum of goods in an extremely elegant and powerful model that has been widely used in subsequent literature. An analogous chain concept applies to the case of two goods and n countries, this time ranking the countries in terms of the ratio of their productivities in the two goods, with country 1 having the greatest *relative* efficiency in cloth and country n in wine. World demand and the sizes of the labour forces will determine the 'marginal' country j, with countries 1 to j exporting cloth and $(j + 1)$ to n exporting wine.

The simultaneous consideration of comparative advantage with many goods and many countries presents severe analytical difficulties. Graham (1948) considered several elaborate numerical examples, his work inspiring the Rochester theorists McKenzie (1954) and Jones (1961) to apply the powerful tools of activity analysis to this particular case of a linear general equilibrium model. It is interesting to note in connection with mathematical programming and activity analysis that Kantorovich (1965) in his celebrated book on planning for the Soviet economy worked out an example of optimal specialization patterns for factories that corresponds *exactly* to the Ricardian model of trade between countries.

The Three-Factor Ricardian Model

While most of the literature on the Ricardian trade model has concentrated on the model of Chapter 7 of the *Principles* in which it appears that labour is the sole scarce factor, his more extended model in the *Essay on Profits* has been curiously neglected, though the connections between trade, income distribution and growth which that analysis explores are quite fascinating. The formal structure of the model was laid out very thoroughly in Pasinetti (1960). The economy produces two goods, corn and manufactures, each of which has a one-period lag between the input of labour and the emergence of output. Labour thus has to be supported by a 'wage fund', an initially given stock that is accumulated over time by saving out of profits. Corn also requires land as an input, which is in fixed supply and yields diminishing returns to successive increments of labour. The wage-rate is given exogenously in terms of corn, and manufactures are a luxury good consumed only by the land-owning class, who obtain rents determined by the marginal product of land.

Profits are the difference between the marginal product of labour and the given real wage, which is equal to the marginal product 'discounted' by the rate of interest, in this model equal to the rate of profit, defined as the ratio of profits to the real wage that has to be advanced a period before. Momentary equilibrium determines the relative price of corn and manufactures, the rent per acre and the rate of profit, as well as the output levels and allocation of the labour force between sectors. The growth of the system is at a rate equal to the product of the rate of profit and the propensity to save of the capitalist class. It is shown that the system approaches a stationary state, with a monotonically falling rate of profit and rising rents per acre.

The opportunity to import corn more cheaply from abroad will have significant distributional and growth consequences. Just as Ricardo argued in his case for the repeal of the Corn Laws, cheaper foreign corn will reduce domestic rents and raise the domestic rate of profit, and thus the rate of growth. The approach to the stationary state is postponed, though of course it cannot be ultimately averted, while the growth consequences for the corn exporter are definitely adverse. The main doctrinal significance of this wider Ricardian model, however, is to reveal the extent to which the subsequent 'general equilibrium' or 'neoclassical' approach to international trade is already present within the Ricardian framework. For one thing, the pattern of comparative advantage itself depends upon the complex interaction of technology, factor proportions and tastes. In his Chapter 7 case the pattern of comparative advantage is *exogenous,* simply given by the four fixed technical coefficients indicating the productivity of labour in cloth and wine in England and Portugal. The production-possibility frontiers for each country are linear, and comparative advantage is simply determined by the relative magnitudes of the slopes. As demonstrated in Findlay (1974), however, the *Essay on Profits* model implies a concave production-possibilities frontier at any moment, since there are diminishing returns to labour in corn even though the marginal productivity of labour in manufactures is constant. With two countries the pattern of comparative advantage will depend upon the slopes of these curves at their autarky equilibria, which are *endogenous* variables depending upon the sizes of the 'wage fund' in relation to the supply of land and the consumption pattern of landowners, as well as the technology for the two goods.

As Burgstaller (1986) points out, however, the steady-state solution of the model restores the linear structure of the pattern of comparative advantage. The zero profit rate in the steady state requires the marginal product of labour to be equal to the given real wage, and this implies a fixed land–labour ratio and hence output per unit of labour in corn. We thus once again have two fixed technical coefficients, so that the slope of the linear production-possibilities frontier is once again an exogenous indicator of comparative advantage.

The 'neo-Ricardian' approach of Steedman (1979a, b) considers more general time-phased structures of production. Technology alone determines negatively sloped wage–profit or factor-price frontiers, any point on which generates a set of relative product prices and hence a pattern of comparative advantage relative to another such economy.

Factor Proportions and the Heckscher–Ohlin Model

While J.S. Mill, Marshall and Edgeworth all made major contributions to trade theory, the concept of comparative advantage did not undergo any evolution in their work beyond the stage at which Ricardo had left it. They essentially concentrated on the determination of the terms of trade and on various comparative static exercises. The interwar years, however, brought fundamental advances, stemming in particular from the work of the Swedes Heckscher (1919) and Ohlin (1933). The development of a diagrammatic apparatus to handle general equilibrium interactions of tastes, technology and factor endowments by Haberler (1933), Leontief (1933), Lerner (1932) and others culminated in the rigorous establishment of trade theory and comparative advantage as a branch of neoclassical general equilibrium theory.

The essentials of this approach can be expounded in terms of the familiar two-country, two-good and two-factor model, on which see Jones (1965) for a detailed and lucid algebraic exposition. The given factor supplies and constant returns to scale technology define concave production-possibility frontiers, on the assumption that the goods differ in factor intensity. This determines the 'supply side' of the model, which is closed by the specification of consumer preferences. Economies that have identical technology, factor endowments and tastes will have the same autarky equilibrium price-ratio and so will have no incentive to engage in trade. Countries must therefore differ with respect to at least one of these characteristics for differences in comparative advantage to emerge. With identical technology and factor endowments, a country will have a comparative advantage in the good its citizens prefer *less* in comparison to the foreign country, since then this good will be cheaper at home. Similarly, if factor endowments and tastes are identical, differences in comparative advantage will be governed by relative technological efficiency; that is, a country will have a comparative advantage in the good in which its relative technological efficiency is greater, just as in the Ricardian model. These differences in technological efficiency could be represented, for example, by the magnitude of multiplicative constants in the production functions; that is, 'Hicks-neutral' differences.

In keeping with the ideas of Heckscher and Ohlin, however, it is differences in factor proportions that have dominated the explanation of comparative advantage in the neoclassical literature. The Heckscher–Ohlin theorem, that each country will export the commodity that uses its relatively abundant factor most intensively, has been rigorously established and the necessary qualifications carefully specified, as in Jones (1956). Among the more important of these is the requirement that factor-intensity 'reversals' do not take place; that is, that one good is always more capital-intensive than the other at all wage-rental ratios or at least within the relevant range defined by the factor proportions of the trading countries.

The Stolper–Samuelson Theorem

Associated with the Heckscher–Ohlin theorem is the Stolper–Samuelson theorem (1941), that trade benefits the abundant and harms the scarce factor while protection does the opposite, and the celebrated factor price equalization theorem of Lerner (1952, though written in 1932) and Samuelson (1948, 1949, 1953), which states that under certain conditions free trade will lead to complete equalization of factor rewards even though factors are not mobile internationally. The normative significance of this theorem is that free trade alone can achieve world efficiency in production and resource allocation, unlike the case of the Ricardian model as pointed out earlier. The requirements for the theorem to hold, however, are very stringent, such as that the number of tradable goods produced be equal to the number of factors. It also requires factor proportions to be sufficiently close to each other in the trading partners so that the production patterns are fairly similar. Thus it would be far-fetched to expect the price of unskilled labour to be equalized between Bangladesh and the United States, for example.

The Specific-Factors Model

An important and popular variant of the factor proportions approach is what Jones (1971) calls the 'specific factors' and Samuelson (1971) the Viner–Ricardo model. In this model each production sector has its own unique fixed factor, while labour is used in all sectors and is perfectly mobile internally between them. Trade patterns still reflect factor endowments but factor price equalization does not hold in this model since the number of factors is always one greater than the number of goods. Gruen and Corden (1970) present an ingenious three-by-three extension of this approach, in which one sector uses land and labour, while the two others use capital and labour, thus neatly integrating the 'specific factors' model with the regular two-by-two Heckscher–Ohlin model. Findlay (1995, chs. 4 and 6) uses adaptations and extensions of the Gruen–Corden specification to introduce human

capital formation and the concept of a natural resource 'frontier' into the Heckscher–Ohlin framework.

Long-Run Extensions of the Factor Proportions Model

One limitation of the Heckscher–Ohlin model was that the stock of 'capital', however conceived, should be an endogenous variable determined by the propensity to save or time preference of each trading community, rather than being taken as exogenously fixed. Oniki and Uzawa (1965) extended the model to a situation where the labour force is growing in each country at an exogenous rate and capital is accumulated in response to given propensities to save in each country. One of the goods is taken to be the 'capital' good, conceived of as a malleable 'putty–putty' instrument. They demonstrated that the system converges in the long run to a particular capital–labour ratio for each country, which will be higher for the country with the larger saving propensity. In Findlay (1970, 1984), it is shown that as the capital–labour ratio evolves the pattern of comparative advantage for a given 'small' country in an open trading world will also shift over time towards more capital-intensive goods, thus formalizing the concept of a 'ladder of comparative advantage' that countries ascend in the process of economic development. Thus comparative advantage should not be conceived as given and immutable, but evolving with capital accumulation and technological change. Much of the loose talk about 'dynamic' comparative advantage in the development literature, however, is misconceived since it attempts to change the pattern of production by protection *before* the necessary changes in the capacity to produce efficiently have taken place. Other models which endogenize the capital stocks of the trading countries are Stiglitz (1970) and Findlay (1978) which utilizes a variable rate of time preference and an 'Austrian' point-input/point-output technology, which implies a continuum of capital goods as represented by the 'trees' of different ages, and Findlay (1995, ch. 2), which addresses the question posed by Samuelson (1965) of whether trade equalizes not only the marginal product or rental of capital but the rate of interest itself.

Empirical Testing

Empirical testing of the positive side of the theory of comparative advantage begins in a systematic way only with the work of MacDougall (1951) on the Ricardian theory and the celebrated article of Leontief (1954) that uncovered the apparent paradox that US exports were more labour-intensive than her imports. Leontief's dramatic finding spurred considerable further empirical research motivated by the desire to find a satisfactory explanation. The increasing scarcity of natural resources in the USA, by causing capital to be substituted for it in import-competing production, was stressed as an explanation for the paradox by Vanek (1963). The role of 'human capital' as an explanation was pointed to by Kenen (1965) and a number of empirical investigators, who found that US exports were considerably more skill-intensive than her imports, even though physical capital-intensity was only weakly correlated with exports and imports. This pointed to the need to reinterpret the simple Heckscher–Ohlin model in terms of skilled and unskilled labour as the two factors, rather than labour of uniform quality and physical capital. Since the formation of skill through education is an endogenous variable, a function of a wage differential that is itself a function of trade, we need a general equilibrium model that can simultaneously handle both these aspects, as in Findlay and Kierzkowski (1983) and Findlay (1995, ch. 4).

Many other extensions of the Heckscher–Ohlin theory are surveyed in Jones and Neary (1984) and Ethier (1984), while Deardorf (1984) and Feenstra (2004) give very incisive accounts of the attempts at empirical testing of the theory of comparative advantage in its different manifestations. Further important progress in empirical testing of the Heckscher–Ohlin model has been achieved by the work of Leamer (1984), Trefler (1995), Harrigan (1997) and Davis and Weinstein (2001).

Increasing Returns

Finally, the crucial role of increasing returns to scale in specialization and international trade has only recently been rigorously investigated, since it implies departures from perfect competition. Krugman (1979) and Lancaster (1980) introduced international trade into models of monopolistic competition with differentiated products, showing the possibility of gains from trade due to the provision of greater variety of similar goods rather than differences in comparative advantage, what is referred to as 'intra-industry' trade. Helpman and Krugman (1985) thoroughly examine and extend our knowledge in this area, while Grossman and Helpman (1991) expertly extend the monopolistic competition approach to deal with a number of issues involving endogenous technological progress and growth in the world economy.

Comparative Statics

John Nachbar

Abstract

Comparative statics in competitive general equilibrium (GE) environments provide insight into the operation of GE models and a means to confront GE models with data. This article focuses on a canonical comparative statics prediction: in an exchange economy, aggregate endowment changes are negatively related to equilibrium price changes. In particular, an increase in the aggregate endowment of a commodity lowers its equilibrium price.

Comparative statics in competitive general equilibrium (GE) environments provide insight into the operation of GE models and a means, at least in principle, to confront GE models with data.

For concreteness, I focus most of this article on what is arguably the canonical GE comparative statics conjecture: in finite exchange economies (that is, no production), equilibrium price changes are negatively related to endowment changes. In particular, if the endowment of good 1 increases and the endowments of other goods remain the same, then the price of good 1 falls. At the end of this article, I briefly survey other GE comparative statics results.

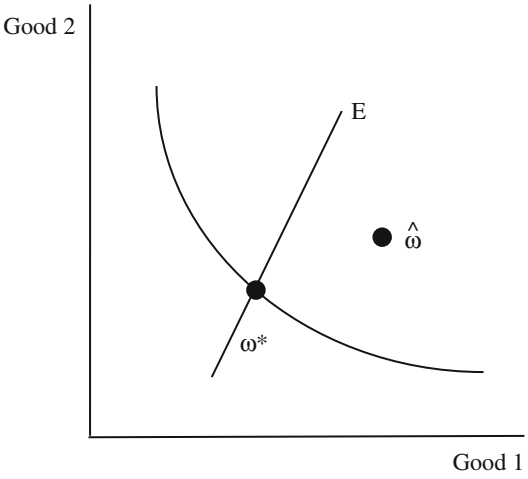
I break the analysis into three cases of increasing complexity.

Case I

There is a single consumer and two commodities. In an equilibrium of this trivial economy, the consumer eats her own endowment. Equilibrium relative prices (which are well defined even though there is no trade) are given by the slope of the consumer's indifference curve through her consumption/endowment point, ω^*. Let E denote her wealth expansion path through her initial endowment; E is the set of points where the slope of her indifference curve is the same as at ω^*.

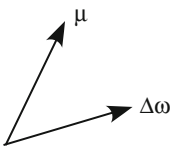
If the new endowment, $\hat{\omega}$ lies below E, as in Fig. 1, then the equilibrium price ratio p_1/p_2 falls. If $\hat{\omega}$ lies above E, then p_1/p_2 rises. If $\hat{\omega}$ lies along E, then p_1/p_2 remains unchanged.

The differential version of Fig. 1 is given by Fig. 2. The vector μ, the tangent to E, is the derivative with respect to nominal wealth of each good's demand (μ is mnemonic for marginal propensity to consume vector). To first order, the rule is that p_1/p_2 falls if and only if $\Delta\omega$, the vector of endowment changes, lies within 180° clockwise from μ. The vector μ incorporates second order information from the utility function and is, in particular, typically not collinear with the utility gradient.



Comparative Statics, Fig. 1 Comparative statics with one consumer and two commodities

Comparative Statics, Fig. 2 First order comparative statics with one consumer and two commodities



If the endowment of good 1 increases while the endowment of good 2 remains unchanged, then $\Delta\omega$ lies along the positive good 1 axis. Figure 2 implies that, in this case, p_1/p_2 falls if and only if good 2 is normal ($\mu_2 > 0$); whether good 1 is normal or inferior (or even a Giffen good) is irrelevant.

Case II

There is again one consumer but L commodities. If $\Delta\omega$ lies along the positive good 1 axis, then a natural conjecture, to generalize the above observation for $L = 2$, is that p_1/p_ℓ falls for each good $\ell > 1$, provided each of these goods is normal. Hicks (1939) showed that this conjecture is false in general but that it is true if the gross substitute property holds (GS; the matrix of partial derivatives of excess demand with respect to price has positive off-diagonal entries). GS holds automatically in the one-consumer, $L = 2$, case because, at equilibrium, when $L = 2$, GS is equivalent to the weak axiom of revealed preference (WA).

Matters are more complicated if two or more endowments are shifting at the same time. For multivariate endowment shocks, there appears to be little one can say in general about changes in the price ratio of any specific pair of commodities. Instead, the conjecture is that $\Delta\omega$ is negatively related to Δp, the vector of equilibrium price changes. Formally,

$$\Delta p \cdot \Delta\omega \leq 0.$$

Call this the comparative statics inequality, CS for short. Geometrically, CS says that the vectors Δp and $\Delta\omega$ lie at least 90° apart.

To interpret Δp as a change in relative prices, prices must be normalized. Consider linear price normalizations, in which all prices, in both the original economy and the perturbed economy, satisfy $p \cdot \lambda = 1$, where λ is an L vector. If all the coordinates of λ are positive, then a fall in the normalized price of good 1 means that the ratio

$$\frac{p_1}{p_{-1} \cdot \lambda_{-1}}$$

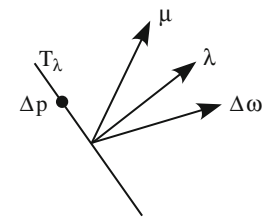
falls, where p_{-1} and λ_{-1} are subvectors corresponding to all goods other than the first: the price of good 1 falls relative to the value of a commodity bundle consisting of λ_ℓ units of each good $\ell > 1$. Standard choices of λ include $\lambda = (0, \ldots, 0, 1)$ (use the last commodity as numeraire) and $\lambda = \omega^*$ (normalize prices so that GNP remains constant; this is the Laspeyres normalization). Regardless of how, or whether, actual prices are normalized, one can re-normalize prices using whatever λ one chooses.

I can provide intuition for CS most easily by continuing to use figures for a two-good economy. Fix a normalizing vector λ Since $p \cdot \lambda = 1$ for all p, $\Delta p \cdot \lambda = 0$. Therefore, Δp lies along the line that is at right angles to λ, labelled T_λ in Fig. 3.

As drawn, $\Delta\omega$ lies within 180° clockwise from μ and hence p_1/p_2 falls. Therefore, Δp, normalized by λ, lies on the upper left-hand branch of T_λ. As illustrated, $\Delta\omega$ and Δp are more than 90° apart; hence CS holds.

On the other hand, suppose that $\Delta\omega$ lies in the cone spanned by λ and μ. Since $\Delta\omega$ again lies within 180° clockwise from μ, p_1/p_2 again falls and Δp again lies on the upper left-hand branch of T_λ. Now, however, $\Delta\omega$ and Δp are less than 90° apart. CS fails.

Comparative Statics, Fig. 3 Condition CS with two goods



In general, in a one-consumer economy, for any number of commodities and for any preferences, CS fails whenever there is a gap between λ and μ and $\Delta\omega$ falls into this gap. Conversely, if $\lambda = \mu$ (or, more generally, if λ is a scalar multiple of μ) then CS holds for any endowment change: $\Delta p \cdot \Delta\omega \leq 0$ with $\Delta p \cdot \Delta\omega = 0$ if and only if $\Delta\omega$ is collinear with μ (which is the differential analog of $\Delta\omega$ landing on the wealth expansion path E in Fig. 1). In one consumer economies, $\lambda = \mu$ is thus the unique (up to scalar multiplication) linear price normalization for which CS holds for all endowment changes.

If preferences are quasi-linear in good L, and consumption is interior, then $\lambda = \mu$ implies $\lambda = (0, \ldots, 0, 1)$; the last good is used as numeraire. If the preferences are homothetic then μ is a scalar multiple of the reference endowment, ω^*, and so one can set $\lambda = \omega^*$. Typically, however, $\lambda = \mu$ is different from price normalizations commonly used in economics.

The $\lambda = \mu$ normalization, although nonstandard, does have a sensible interpretation, provided μ is positive (all goods are weakly normal). If μ is positive, then a decrease in p_1 means that $p_1/(p_{-1} \cdot \mu_{-1})$ falls: the price of good 1 falls relative to the value of the consumer's *marginal* consumption of all other goods.

If $\Delta\omega$ lies along the positive good 1 axis and goods 2, . . ., L are normal, then a minor variation on CS implies that $p_1/(p_{-1} \cdot \mu_{-1})$ falls, even if good 1 is inferior. This is a Weaker conclusion then that of Hicks (1939) but it has a weaker hypothesis, since it does not assume the gross substitute property.

Case III

There are I consumers and L commodities. The generalization of CS is

$$\Delta p \cdot \Delta \overline{\omega} \leq 0,$$

where $\Delta \overline{\omega}$ denotes the change in the aggregate endowment. CS holds provided one uses an appropriate aggregate version of μ. Consider two alternatives. Each is a weighted sum of the individual marginal propensity to consume vectors, μ^i. In the first, $\overline{\mu}_{\Delta x}$, the weight on μ^i is consumer i's share in the change in the value of consumption, evaluated at the prices of the reference equilibrium. In the second, $\overline{\mu}_{\Delta \omega}$, the weight on μ^i is i's share in the change in the value of the endowment, again evaluated at reference equilibrium prices.

If one normalizes prices using $\lambda = \overline{\mu}_{\Delta x}$, then inequality CS holds provided *individual* excess demand satisfies the weak axiom (WA) at equilibrium. If $\lambda = \overline{\mu}_{\Delta \omega}$, then CS holds provided *aggregate* excess demand satisfies WA at equilibrium. See Nachbar (2002).

The hypothesis that aggregate excess demand satisfies WA is not implied by standard GE assumptions. One justification for nevertheless assuming WA is that it seems to be connected to the dynamic stability of the price adjustment process. WA holding at equilibrium is sufficient and almost necessary for local asymptotic stability under the Walrasian tâtonnement, for example. Comparative statics, by assuming that economies are at equilibrium, may therefore implicitly assume that aggregate excess demand satisfies WA. A second justification for assuming that aggregate excess demand satisfies WA is that this assumption, while strong, is not implausible in exchange economies. For some sufficient conditions for WA, see Becker (1962), Hildenbrand (1983), Grandmont (1992) and Quah (1997).

In the one-consumer case, the $\lambda = \mu$ price normalization was necessary as well as sufficient. There are analogous, but weaker, necessity results for $\overline{\mu}_{\Delta x}$ and $\overline{\mu}_{\Delta \omega}$. The important implication is that, because both $\overline{\mu}_{\Delta x}$ and $\overline{\mu}_{\Delta \omega}$ can vary with how the endowment changes are distributed across consumers, there may be *no* price normalization for which CS holds for all endowment changes. As the endowment distribution changes, the price normalization may have to change.

This illustrates an issue that has become a central theme in the recent literature on GE comparative statics. Given an arbitrary price normalization, standard GE assumptions impose no restrictions on the relationship between changes in equilibrium prices and changes in the aggregate endowment (see Chiappori et al. 2004). This negative result, a cousin of the Debreu–Mantel–Sonnenschein theorem (DMS), has a loophole: standard GE assumptions do provide comparative statics restrictions if one works with micro-level information (for example, on the endowment distribution) rather than exclusively with aggregates. In the CS results, micro-level data is used in the price normalization. Note that CS requires micro data even if one assumes that aggregate excess demand satisfies WA.

Relative to the objectives laid out in the first paragraph of this article, the results on CS comparative statics fare reasonably well in providing insight into the operation of GE models. The $\overline{\mu}_{\Delta \omega}$ result is much the easier to interpret, since it is computed with the use of endowment changes, which are exogenous. The $\overline{\mu}_{\Delta x}$ result, on the other hand, extends easily to production economies. In contrast, I do not know whether the $\overline{\mu}_{\Delta \omega}$ result has a useful analog for production economies.

The CS inequality fares less well as a tool for empirical work, because it requires a large amount of data just to estimate the normalization vector. The necessity results imply that this difficulty is intrinsic to CS.

Other Comparative Statics Results

Brown and Matzkin (1996), a path-breaking paper that has heavily influenced subsequent work in this area, exploits the DMS loophole noted above to give testable restrictions linking equilibrium prices with individual endowments. For related work, see Snyder (1999), Williams (2002), Kübler (2003) and Chiappori et al. (2004). Relative to CS, the Brown–Matzkin restrictions are easier to implement empirically

because they do not require estimating normalization vectors, but they are harder to interpret.

As already noted, CS-type reasoning can be extended to production economies (see Quah 2003; Nachbar 2004). CS-type reasoning can also be extended to asset pricing environments (see Quah 2003).

For shocks to preferences rather than endowments or technologies, the analog of CS is

$$\Delta p \cdot \Delta \overline{x} \leq 0,$$

where $\Delta \overline{x}$ is the change in equilibrium consumption. Profit maximization implies that this inequality holds for any price normalization. In this respect, the analysis of demand shocks is trivial compared with the analysis of supply shocks.

Interest in comparative statics has helped motivate research on the uniqueness, regularity, and stability of equilibria (see Kehoe 1987). Note that some of the comparative statics results cited above (for example, the Brown–Matzkin results and the $\overline{\mu}_{\Delta x}$ CS result) do not assume uniqueness or stability.

Finally, perhaps the most famous comparative statics results are the Stolper-Samuelson theorem and its dual, the Rybcyznski theorem (for a recent treatment, see Echenique and Manelli 2005). Stolper–Samuelson links changes in factor prices with factor intensities and changes in output prices. Rybcyznski links changes in final goods production with factor intensities and changes in factor supplies. Although it is possible to embed these results within a highly restricted GE model, they are partial equilibrium in spirit; wealth effects play no role.

Compensated Demand

Tatsuo Hatta

Hicks Compensation: Definition

When a consumer faces a price change under a given nominal income, his utility (or real income) level as well as his demand vector changes. Suppose, however, that his income level is

simultaneously changed as the price is changed so as to keep his utility at the initial level. This operation may be regarded as a compensation for the price change, and we call the resulting demand vector the *compensated demand* for the new price.

Thus the compensated demand is a function of the price vector and the utility level, and we may write it as

$$x = h(p, \mu), \tag{1}$$

where x and p are the consumption and price vectors, while μ is the utility level. We call h the *compensated* (*or Hicks*) *demand function*. Formally, it may be defined as the solution function of the following minimization problem:

$$\min_x p'x \text{ subject to } u(x) = \mu, \tag{2}$$

where u is the utility function.

Basic Properties

Hicksian Demand Rules

The Jacobian matrix of h with respect to p, denoted as h_p, is nothing but the Hicks substitution matrix. It has well-known properties:

$$p'h_p(p, \mu) = 0 \tag{3}$$

$$yh_p(p, \mu)y \leq 0 \text{ for all } y. \tag{4}$$

$$h_p(p, \mu) = h'_p(p, \mu). \tag{5}$$

Condition (3) is called the homogeneity condition, since it shows that the function h is homogeneous of degree zero with respect to p. Conditions (4) and (5) are called the negative semi-definiteness and the symmetry conditions, respectively. We will call these three conditions the *Hicksian Demand Rules*.

Shephard–Samuelson Lemma

The minimized expenditure value of problem (2) is a function of p and μ. This is called the *expenditure function*. Formally, we define it by

$$e(p, \mu) \equiv \min_x \{p'x | u(x) = \mu\}.$$

By definition, we obviously have

$$e_p(p, \mu) \equiv p'h(p, \mu). \tag{6}$$

There is a less obvious, but extremely useful, relationship between the compensated demand and the expenditure functions:

$$e_p(p, \mu) \equiv h(p, \mu). \tag{7}$$

This identity usually referred to as the *Shephard–Samuelson Lemma* was obtained by Hicks (1946, p. 331), Samuelson (1947, p. 68, 1953–54, pp. 15–16), and Shephard (1953).

To prove the Shephard–Samuelson Lemma, let x^* be an expenditure-minimizing vector that yields μ at the price p^*, i.e.,

$$x^* \equiv h(p^*, \mu). \tag{8}$$

Define the *gain function* g by

$$g(p) \equiv e(p, \mu) - p'x^*. \tag{9}$$

This and the definition of e imply that $g(p) \leq 0$. Also from (6) and (8), we have $g(p^*) = 0$. Hence the function g takes its minimum value of 0 when $p = p^*$. Therefore, the first and the second order minimization conditions yield

$$g_p(p^*) = 0 \tag{10}$$

and

$$y'g_{pp}(p^*)y \geq 0 \text{ for all } y \neq 0. \tag{11}$$

Equation 10 immediately proves (7).

To demonstrate the usefulness of the Shephard–Samuelson Lemma, let us prove the Hicksian Demand Rules from this Lemma. From (7) we have

$$e_{pp}(p, \mu) \equiv h_p(p, \mu).$$

This immediately yields (5). In view of (9) and (11), this also proves (4). On the other hand, (6), (9) and (10) yield

$$h(p^*, \mu) + p^{*'} h_p(p^*, \mu) - x^* = 0.$$

From (8), therefore, we obtain (3).

Uncompensated Demand

Reflection

The concept of the compensated demand is essential in analysing properties of the ordinary demand function. To see this, consider a maximization problem:

$$\max u(x) \quad \text{subject to} \quad y = p'x, \tag{12}$$

where y is the income level. Its solution function $m(p,y)$ is called the *ordinary* (or *Marshallian*) *demand function*. Define the *indirect utility function* by

$$v(p, y) \equiv u[m(p, y)]. \tag{13}$$

Problem (2) may be regarded as the expenditure minimization problem associated with (12). Newman (1982) calls it the *reflection* or the *mirror image* of maximization problem (12). If we let $\mu = v(p,y)$ in problem (2), the resulting minimum expenditure must equal y and the compensated demand must be equal to $m(p,y)$ in Problem (12). Thus we have

$$y \equiv e[p, v(p, y)] \tag{14}$$

and

$$m(p, y) \equiv h[p, v(p, y)]. \tag{15}$$

Roy's Identity

These identities yield *Roy's identity*,

$$v_p(p, y) \equiv - v_y(p, y) m(p, y). \tag{16}$$

To see this, differentiate (14) with respect to p and y to get

$$e_\mu[p, v(p, y)] v_p(p, y) \equiv - e_p[p, v(p, y)] \tag{17}$$

and

$$1 \equiv e_\mu[p, v(p, y)] v_y(p, y), \tag{18}$$

respectively. Multiplying by $v_y(p,y)$ on both sides of (17), and then applying (18), (7) and (15), we obtain (16).

Slutsky–Hicks Decomposition

Identities (14) and (15) also yield the *Slutsky–Hicks decomposition*,

$$m_p(p, y) \equiv h_p[p, v(p, y)] - m_y(p, y) m(p, y). \tag{19}$$

Thus the slope of the ordinary demand function equals the slope of the compensated demand function adjusted to the income effect.

To prove (19), differentiate (15) with respect to p and y to get

$$m_p(p, y) \equiv h_p[p, v(p, y)] + h_\mu[p, v(p, y)] v_p(p, y) \tag{20}$$

and

$$m_y(p, y) \equiv h_\mu[p, v(p, y)] v_y(p, y), \tag{21}$$

respectively. The only difference between (19) and (20) is their income terms. Applying (16) and (21) to the last term of (20), we get (19).

Slutsky Compensation

After a price change takes place, the Hicks compensation keeps the consumer on the same utility level as before the price change. As Mosak (1942) pointed out, however, Slutsky had a different concept of compensating the loss of real income. Slutsky considered a compensation that 'makes possible the purchase of the same quantities of all the goods that had formerly been bought', When a price change takes place, the Hicks-compensated and the Slutsky-compensated demand effects are generally different. When the price change is infinitesimal, however, they become equal, and this equality is called Mosak's Equality.

Mosak's equality has played an important role in index number theory. The Laspeyres index, which is widely adopted in practice, is based on the Slutsky compensation, since it indicates the change in income that would be needed in the current year in order to buy the commodity bundle bought in the base year. Under the Slutsky substitution effect, the individual can be no worse off and is likely to be better off since he is able to purchase at least the bundle he had before the price change. Thus he is 'overcompensated' for the price change (see Samuelson 1953, pp. 4–5). The price index that truly reflects the utility change should be based on the Hicks compensation. Such an index is difficult to compute because utility levels are not observable. Mosak's equality reveals, however, that for small price changes the Laspeyres index is a good approximation to the 'ideal' index.

Let us now formally state Mosak's equality. Define the function s by

$$s(p,x) \equiv m(p,p'x). \tag{22}$$

The function s is the demand function with the fixed endowment bundle x. We call $s_p\,[p, m\,(p, y)]$ the *Slutsky substitution matrix*. It represents the variation in demand when the price change is accompanied by an income compensation that keeps the original consumption bundle $m(p,y)$ on the budget plane. Mosak's Equality may now be expressed as

$$s_p[p, m(p,y)] \equiv h_p[p, v(p,y)]. \tag{23}$$

To prove this, first define the function w by

$$w(p,x) \equiv v(p,p'x). \tag{24}$$

The value of $w(p,x)$ represents the maximized utility level when the endowment bundle x is given. Differentiating this and applying Roy's identity, we get

$$w_p[p, m(p,y)] = 0. \tag{25}$$

Thus, if the utility maximizing bundle under a certain price vector happens to be equal to the endowment bundle, the utility level is hardly changed by a slight change of the price vector away from the initial one. Equations (15), (22) and (24), yield

$$s(p,x) = h[p, w(p,x)].$$

Differentiating this with respect to p and noting (24), we immediately have (23).

Historical Notes

Slutsky (1915) first established the homogeneity and symmetry conditions on the substitution matrix. Since he did not have the concept of utility-maintaining compensation or the compensated demand function, he derived these properties for the Slutsky compensated substitution matrix $s_p\,[p, m(p, y)]$ rather than for the Hicksian matrix $h_p\,[p, v(p, y)]$. During the 1930s, Hicks and Allen (1934) and Hicks (1939, 1946) gave verbal interpretations to the substitution matrix in terms of the Hicksian compensation. But in their formal derivation of its properties, they defined the substitution matrix to be the Slutsky substitution matrix, as is clear from the following passage from the Mathematical Appendix of Hicks (1946, p. 309):

> . . .it follows from the equation that the substitution term represents the effect on the demand for xs of a change in the price of xr combined with such a change in income as would enable the consumer, if he chose, to buy the same quantities of all goods as before, in spite of the change in Pr.

Thus they too did not explicitly state the function h, much less gave a name to it.

To the writer's knowledge, Samuelson (1947) is the first author who explicitly stated (1) and derived Hicksian rules directly from it, though he did not give a name to it (see Samuelson 1947, (43) on p. 103 and (99) on p. 114). Subsequently, Samuelson (1953, p. 8, n1) gave a heuristic proof of the symmetry and the negative-semidefiniteness condition of the Slutskycompensated substitution matrix as envelope properties, i.e. in a spirit very much similar to the one given above. In this path-breaking proof, however, he relied upon the indirect utility

function rather than the expenditure function, thus without using the mirror image minimization problem or the compensated demand function.

McKenzie (1956) and Karlin (1959) explicitly defined the function *h*, and derived its properties by taking full advantage of the Shephard– Samuelson Lemma. However, they had to use a *global* property of the expenditure function in deriving the negative semidefiniteness condition, which is a *local* property. The proof of this condition employed above is solely based on a *local* minimization condition, and serves as the mirror image counterpart of Samuelson's (1953) proof for the Slutsky substitution matrix. Diamond and McFadden (1973) attribute this proof method to Gorman (see Gorman 1976). The above proof of Mosak's equality is due to Hatta and Willke (1982).

Silberberg (1974) considered the general maximization problem with possibly many constraint functions where both target and constraint functions may be non-linear. Extending Samuelson's (1965) proof method, he showed that the compensated solution function of that problem satisfies generalized forms of the symmetry and non-negative definite conditions, as long as the constraint functions do not contain shift parameters. Silberberg's proof boils down to Gorman's in the standard expenditure minimization problem. Hatta (1980) extended the concept of the compensated demand function to the case where the same shift parameters may appear simultaneously in both target and constraint functions in the general problem. He showed that the properly compensated solution function in that problem satisfies generalized forms of symmetry and non-negative definite conditions. He also established an envelope theorem that contains both the Shephard–Samuelson Lemma and Roy's Identity as special cases. His proof integrates Samuelson's (1953) and Gorman's into one. The global characterization of the compensated demand function by McKenzie and Karlin was extended into *duality theory*, as surveyed by Diewert (1982).

In many branches of economics outside the demand theory, the concept of the compensated demand function was implicitly used without being explicitly stated. Examples are Hotelling's (1938) and Harberger's (1974) analysis of the *excess burden of taxation*, Hicks's (1956) *compensating* and *equivalent variation* that illuminate the concept of consumers' surplus, and Alonso's (1964) *rent bid function*, which keeps a consumer's utility constant regardless of the location he chooses. A number of economists of the Chicago School, including Friedman (1949), Bailey (1954), and Becker (1971), used the concept of the Hicks compensation in various welfare analyses. Each of these authors gave a different name to the concept. Friedman called its graph the *Marshallian demand curve* contrary to the current usage of this term; Bailey, the *constant-real-income demand curve*, and Becker, the *pure demand curve*.

The explicit use of the compensated demand function gave rise to dramatically clearer restatements and proofs of many existing theorems. Its usefulness has reached far beyond that, however. Since the early 1970s, this function has been used for the analyses of the welfare impacts of parametic shifts in various general equilibrium models, as stated by Ohyama (1974), Takayama (1974), Diamond and MacFadden (1974), Dixit (1975) and Hatta (1977, 1980), and comprehensively studied by Dixit and Norman (1980) and Woodland (1982).

The history of the compensated demand function is curious. The properties of its derivatives were known and the concept of Hicks compensation used in many fields of economics before the function itself was stated or named. Perhaps this is because economists has an unconscious reluctance in putting the elusive concept of the utility level as a variable of a function. Once explicitly stated and well understood, however, the compensated demand function has found a powerful use in welfare economics, precisely because it has the utility level, rather than income, as an explicit variable.

Compensating Differentials

Matthew E. Kahn

Abstract

Compensating differentials represent a wage premium for unpleasant aspects of a job. Jobs differ along several dimensions. Some jobs offer generous health insurance benefits. Others entail long hours or may expose workers to physical risks. Some are available only in polluted cities. In equilibrium, labour markets accommodate diversity by establishing wages that tend to make different jobs relatively close substitutes at the margin. Using hedonic wage regression techniques, researchers have estimated the equilibrium implicit market price that workers pay, through lower wages, for working in a more pleasant setting. This technique is widely used by labour and environmental economists.

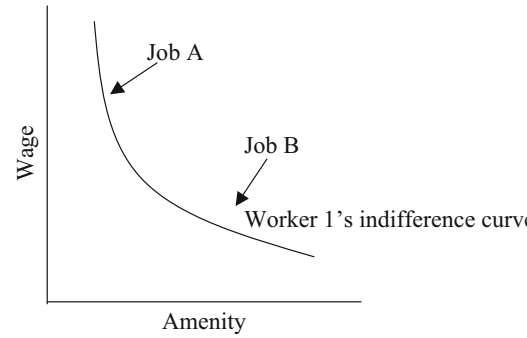
Compensating differentials represent a wage premium for unpleasant aspects of a job. Jobs differ along a number of dimensions. Some jobs offer generous health insurance benefits. Other jobs entail long hours or may expose workers to physical risks. Some jobs are only available in polluted cities. The theory of compensating differentials is based on the simple premise that there is 'no free lunch'. In market equilibrium, more unpleasant jobs will offer a wage premium relative to other jobs. Similarly, homes in nicer communities or high-quality-of-life cities will sell for a premium. To quote Sherwin Rosen (2002, p. 2), 'Markets accommodate diversity by establishing prices that tend to make different things relatively close substitutes at the margin. Adam Smith's insight that market prices tend to equalize their net advantages is fundamental to these problems. If one good has more desirable characteristics than another, the less preferred variety must compensate for its disadvantages by selling at a lower price.'

Defining Compensating Differentials

Jobs represent tied bundles of attributes. Suppose that a worker gains utility from earning a wage and from a job attribute. This attribute could represent job safety, or total days of vacation, or health insurance benefits. As shown in Fig. 1, there are two jobs, A and B. Each job represents a different bundle of a wage and a non-market job-specific amenity level. The two jobs differ: job B is the more pleasant of the two. If all workers have the same utility function, then in equilibrium this representative worker must be indifferent between the two jobs. Thus, job A must pay a higher wage than job B to compensate this worker.

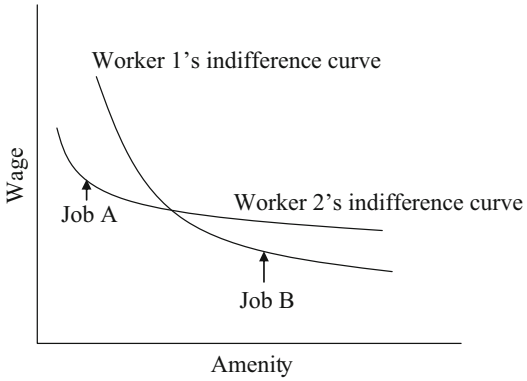


Compensating Differentials, Fig. 1

The econometrician can collect data on each job type's wage and amenities. In a more realistic economy where there are many types of jobs that differ with respect to the wage and their amenity level, the representative worker's indifference curve would be sketched out. The slope of the representative worker's indifference curve represents the compensating differential of how much lower a wage this worker would accept in return for a small increase in the job amenity.

To see how worker heterogeneity affects the interpretation about observed compensating differentials, consider the simple extension where we introduce two types of workers. These workers are equally productive but differ with respect to their demand for working in the more pleasant job. In Fig. 2, worker 1 values the job amenity more than worker 2. In equilibrium, job A will pay a compensating differential to attract workers to be willing to work in this job. Worker 2 will choose to work in job A while worker 1 will choose to work in job B. Firm A will prefer to hire worker 2 rather than worker 1 because worker 1 requires a larger compensating differential for working in the more unpleasant job. The profit maximizing firm seeks to minimize its costs of production.

The econometrician will observe the equilibrium wage paid to workers in job A and B. As shown in Fig. 2, this equilibrium wage–amenity relationship called the *hedonic wage function*



Compensating Differentials, Fig. 2

does not represent either worker 1's or worker 2's indifference curves. Instead, this hedonic wage function represents the envelope of the minimum wage that heterogeneous workers are willing to accept to do a job. This simple example highlights how introducing worker heterogeneity affects inference from observed data (see Rosen 2002). Figure 2 focuses on just one dimension of worker heterogeneity. The recent compensating differentials literature has explored the consequences of other dimensions of worker heterogeneity such as unobserved skill (IQ, for example) and a worker's ability to self-protect against injury on the job (Hwang, Reed and Hubbard 1992; Shogren and Stamland 2002).

Labour Econometric Applications of Compensating Differentials Theory

An enormous applied econometrics literature has estimated various versions of hedonic wage functions to recover estimates of the marginal valuation of non-market job attributes. One major focus of this research has been to estimate the value of life by measuring how much of a wage premium the marginal worker requires for working in a job with a higher probability of death (Viscusi and Aldy 2003). Other studies have used hedonic methods to measure the compensating differential for mandated government health insurance benefits (Gruber 1994).

The standard approach utilizes a large micro-data set. The dependent variable in such a study is a full-time worker's wage in a specific occupation, industry or city. For example, in Eq. 1 the dependent variable is the log of worker i's wage in industry j in year t. In an urban application, j would refer to a city rather than an industry. The researcher will include a large number of demographic controls, such as age, ethnicity, or education, to 'standardize' the worker. If one controls for these factors, the key variables of interest are the Z's in Eq. 1. In a labour economics application, the Z vector may represent a set of job specific attributes (length of day, job risk). In an urban economics application, the Z vector may represent attributes of the city where the job is located (climate, pollution, crime).

$$\mathrm{Log}\left(\mathrm{Wage}_{ijt}\right) = \gamma_0 + \gamma_1^* X_{it} + \gamma_2^* Z_{jt} + U_{ijt} \quad (1)$$

Ordinary least squares regression estimates of γ_2 are used to construct measures of the compensating differentials for job tasks and characteristics of employment locations. Estimates of such coefficients have been used to rank city quality of life (see Gyourko and Tracy 1991) and represent the first stage of the hedonic two-step for recovering demand functions for non-market goods such as air quality or climate (Rosen 1974; Ekeland et al. 2004).

If the population differs with respect to its tastes for job attributes, then γ_2 can be used to construct a worker's budget constraint. For example, in a job-safety regression if γ_2 equals minus \$100 then this means that a one-unit increase in job safety will cost the worker an extra \$100 in wages. The rational worker facing this budget constraint will take this trade-off into account when choosing the job that maximizes her utility.

Hedonic estimates of compensating differentials can also be used to bound worker preferences. To return to Fig. 2, a lower bound on worker 1's willingness to accept work in risky job A is the equilibrium wage paid to worker 2. Since we know that worker 1 chose the safe job and refused to work in job A at the wage that worker 2 accepted, worker 2's wage offer provides a lower bound (see Rosen 2002).

The typical hedonic wage regression study estimates Eq. 1 using ordinary least squares. This econometric approach will yield consistent estimates of y_2 if the unobserved determinants of wages (that is, the error term) are uncorrelated with the explanatory variables. What is the error term in this hedonic pricing equation? While a researcher might hope that it represents measurement error in the dependent variable, it is more likely that the error term represents unobserved attributes of the worker and unobserved attributes of the geographical area where the worker lives and works.

Unfortunately for researchers, people self-select where to live and work. A researcher would like to know what wage the same worker would earn in every industry and in every city. In a cosmopolitan city such as New York, superstars of all fields, ranging from Don Trump in real estate to Derek Jeter in baseball, have all chosen to work there. A naive cross-city hedonic researcher would observe these stars living in New York City earning high wages *relative* to observationally identical people in Tulsa, and would conclude, based on the wage regression, that New York City's quality of life must be worse than Tulsa's. Clearly, the problem with this inference is the 'apples to oranges' comparison. New York City's amenities are a normal good. The high-skilled earn higher salaries and are attracted to living and working in this city.

Conclusion

A job's wage is not a sufficient statistic for its quality. Coal miners are paid a relatively high wage but the work is dangerous and unpleasant. A major research agenda in labour economics investigates how much people implicitly pay for non-market job attributes. Credible estimates of wage compensating differentials for living in less polluted cities or working in risky industries would greatly aid policy analysis that seeks to measure the benefits of environmental and safety regulation.

Compensation Principle

John S. Chipman

Abstract

The compensation principle holds that one of two possible states constitutes an improvement over the other if the gainers could compensate the losers for their losses and still be at least as well off as in the original state. The conflict between potentiality and actuality – one situation is judged better than another if everybody *could* be made better off in the new situation even though some in fact become worse off – ensures that the compensation principle does not allow for value-free policy decisions.

The term 'compensation principle' refers to the principle that, in comparing two alternative states in which a given community of persons might find itself, one of the states constitutes an improvement over the other (in the weak sense including equivalence) if it is possible for the gainers to compensate the losers for their losses and still be at least as well off as in the original state.

If the hypothetical compensation is actually carried out, the principle reduces to the Pareto criterion: all are at least as well off, in one state compared to the other. There is no need to invoke the compensation principle in such a case. On the other hand, if the principle is used to compare two unique alternative states in which a community might find itself, neither of which is Pareto-superior to the other, the principle seems quite arbitrary unless interpreted in a broader context. There is a sense in which one person might be said to be basically healthier than another even though, at the particular moment, such a person might have a cold and the other one not. The compensation principle is usually used to make comparisons in this sense; one state of the economy is sounder, healthier, more robust, or has greater productive potential, than another. What this implies is that states under comparison are usually not unique, singleton states but composite ones, or sets of states. Formally, the objects being compared are usually sets of commodity bundles that could be made available to the aggregate of consumers, described in the literature as 'situations' in contrast to single 'points' in such sets (cf. Baldwin 1954).

Examples of comparisons in which the compensation principle is typically used are those between (*a*) a perfectly competitive system of industrial organization and an imperfectly competitive one; (*b*) free trade and no trade (or restricted trade); (*c*) the state of an economy before and after a war, or depression, or change in productive techniques. Most but not all of these types of comparisons are relevant to policy decisions; and the policy decisions are usually not of an ad hoc type (for which the compensation principle would hardly be appropriate) but of a fundamental nature concerning the underlying system of industrial organization and trade.

Inasmuch as the principle can be applied without the need to make interpersonal comparisons, some of its more ardent proponents have maintained that it is 'value-free'. However, there can be no doubt that it does require acceptance of some value judgements, since the Pareto criterion itself constitutes one – albeit a widely accepted one. Another value judgement implicit in the principle as it has usually been applied is that each individual is the best judge of his or her own well-being; while also quite widely accepted, this one is obviously controversial, and in fact government policy measures are often called for precisely in those instances where it is clearly an untenable assumption. But the most important and controversial way in which value judgements enter into the compensation principle is in the conflict between potentiality and actuality: one situation is judged better than another if everybody *could* be made better off in the new situation even though some in fact become worse off. This

lacuna in the principle has led Little (1950) and Mishan (1969) to formulations in which compensation tests are combined with explicit distributional value judgements, and Samuelson (1947, 1956) into a full-fledged ethical system in which compensation is carried out to the extent that the ethical norms dictate.

In many applications the compensation principle is difficult to formulate in a precise manner unless one assumes absence of externalities in consumption, so it is usually formulated (but with some notable exceptions – for example, Coase 1960) under the assumption that each person's welfare depends only on his or her own consumption of goods and services. In most applications, the data available for making comparisons are, almost inevitably, limited to aggregative information on the actual state of the economy in each situation; much of the work in applying the principle therefore consists in using economic theory to make inferences from the actual observations concerning underlying conditions in the economy. By its nature, the compensation principle is limited in its application to comparing alternative states (or sets of states) of a given community of individuals; thus, it cannot be applied (at least not literally) to historical comparisons of a country's condition over time (since the population has changed) or to comparisons of the living conditions of different countries (since the populations are different). However, extensions of the principle to cover such comparisons are possible provided suitable additional empirical assumptions and value judgements are accepted; for example, if all individuals are assumed to have identical preferences, one could ask whether there exists a redistribution of income in each period (or country) such that each individual in the one situation would be better off than each individual in the other. This would obviously entail additional value judgements along with the additional empirical assumptions.

Historical Development: From Dupuit to Hotelling

The compensation principle may be traced back to Dupuit (1844, pp. 359–60; Arrow and Scitovsky 1969, p. 272) and Marshall (1890, p. 447; 1920, p. 467) who used the concept of consumers' surplus to compare the losses of consumers (say from a bridge toll or an excise tax) with the gains to the government. The demonstration that the former exceed the latter, so that consumers cannot be compensated for their losses out of the government revenues, provided a convincing case for the superiority of income tax to an excise tax (or for the superiority of government subsidization of bridge construction to its financing of it by tolls), and at the same time provided scientific prestige and great intuitive appeal to a method that was able to reach such a definitive conclusion and furnish a measure of the 'deadweight loss'.

While Dupuit and Marshall used partial-equilibrium analysis, Pareto (1894, p. 58) was the first to introduce the concept into general-equilibrium theory, in the course of an article devoted to proving the optimality of competitive equilibrium. In the first part of this article (summarized by Sanger 1895), Pareto used as his criterion of optimality the sum of individual utilities; in the second part, however – acknowledging the criticisms and suggestions of Pantaleoni and Barone (both admirers of Marshall, which Pareto was not) – he reformulated the problem so as to sum not the utilities of different consumers but the quantities they consume. His criterion of optimality (1894, p. 60) was that it should be impossible for one person to gain without another losing – 'Pareto optimality' – a criterion that had also been introduced by Marshall (1890, pp. 449–50; 1920, pp. 470–1). A more refined version of Pareto's argument later appeared in the *Cours* (Pareto 1896–7, vol. 1, pp. 256–62; vol. 2, pp. 88–94).

The proposition formulated by Pareto (1894) anticipated what has now come to be known as the 'fundamental theorem of welfare economics', namely, that every competitive equilibrium is Pareto optimal and, conversely, every Pareto optimum can be sustained by a competitive equilibrium. Pareto considered the problem faced by a socialist state striving to attain an outcome in which it was impossible for one person to gain without another losing. The Ministry of Justice would concern itself with problems of income

distribution, and the Ministry of Production with resource allocation and choice of production coefficients. A weakness of Pareto's argument was that he assumed a price system already to be established – perhaps our socialist state needs the prices of its capitalist neighbours to guide it. Pareto further assumed that each individual's budget constraint was adjusted by the addition of a parameter (a lump-sum subsidy or tax) controlled by the government. The government's objective was to maximize the sum of these parameters, which he showed was equal to aggregate profit – the value of commodities consumed less the value of factor services supplied, equal to the value of firms' output less the outlay on their factor inputs. If it were possible to increase all the parameters, the existing situation would not be Pareto optimal; if their sum were a maximum, it would not be possible to increase one of them without decreasing another, and the outcome would be Pareto optimal. Pareto showed that maximization of aggregate profit at the given prices, subject to the resource-allocation and production-function constraints, would lead to cost-minimization and zero profits. (For mathematical details of Pareto's arguments see Chipman 1976, pp. 88–92). Pareto summarized this result by stating (1896–7, vol. 2, p. 94):

> Free competition of entrepreneurs yields the same values for the production coefficients as would be obtained by determining them by the condition that commodity outputs should be chosen in such a way that, for some appropriate distribution, maximum ophelimity would be achieved for each individual in society.

The last clause was Pareto's unfortunately awkward way of stating the criterion of Pareto optimality.

Barone (1908), who had originally spurred Pareto on to this line of argument, developed it further himself. He noted that a competitive equilibrium has the property that aggregate profit is at a maximum at the equilibrium prices, hence, for any feasible departure from this equilibrium, valuing consumption and factor services at the equilibrium prices, some individuals may gain and others will lose, the losses outweighing the gains so that, even if the gainers part with all their gains, the rest will still be worse off than originally. (Barone used what is now known as the criterion of revealed preference to make inferences concerning preferences from data on prices and incomes). Such a state was described by Pareto and Barone as 'destruction of wealth', and its measure by aggregate income loss at the competitive-equilibrium prices provided an alternative to the deadweight loss considered by Dupuit and Marshall. Barone (1908) also related his arguments to those of Marshallian consumers'-surplus analysis.

Lerner (1934) invoked the compensation principle in his proposed method for measuring monopoly power, describing it as 'a loss to the consumer which is not balanced by any gain reaped by the monopolist'. In this paper Lerner also formulated, apparently independently, the concept of Pareto optimality.

Hotelling (1938) made a noteworthy contribution by providing an alternative demonstration of the inferiority of excise taxes to income taxes, using the compensation principle directly. He considered a single individual consuming n commodities in amounts q_j and facing market prices p_j. Prior to the imposition of the excise taxes (or tolls), the individual consumes a bundle q^0 at prices p^0 and income (or fixed component of income) m^0, which maximizes a utility function $U(q)$ subject to the budget constraint $p^0 \cdot q = m^0$. Subsequent to the introduction of taxes, market (tax-inclusive) prices and after-tax income are p^1 and m^1 respectively, and a bundle q^1 is chosen which maximizes $U(q)$ subject to $p^1 \cdot q = m^1$. The government collects $r = (p^1 - p^0) \cdot \mathrm{q}^1 - (m^1 - m^0)$ in revenues. Since the government is assumed to collect $\left(p_j^1 - p_j^0\right) \cdot q_j^1$ in taxes on commodity j,p_j^0 must be identified with the production cost after the tax (as well as with the market price = production cost before the tax); this is a fairly restrictive assumption, since it implies that the tax does not affect production costs. (In this respect Hotelling's treatment is less general than Dupuit's and Marshall's, involving infinite elasticities of supply). We may denote the ad valorem excise-tax rate on commodity j by $t_j = p_j^1/p_j^0 - 1$, and a proportional income-tax rate by $t_0 = 1 - m^1/\mathrm{m}^0$ (negative

taxes are interpreted as subsidies). The government's revenues are

$$r = \sum_{j=1}^{n} t_j p_j^0 q_j^1 + t_0 m^0 = 0,$$

assumed zero since the government distributes the total proceeds of these excise taxes back to the consumer (or taxes the consumer if these are negative). The consumer's budget constraint after the imposition of the taxes is

$$\sum_{j=1}^{n} (1 + t_j) p_j^0 q_j^1 = (1 - t_0) m^0.$$

These two equations together imply that q^1 satisfies the budget constraint $p^0 \cdot q^1 = m^0$, hence q^1 was in the consumer's original budget set. Therefore, setting aside the 'infinitely improbable ... contingency' that q^0 and q^1 lie on the same indifference surface, Hotelling concluded (1938, p. 252) that 'if a person must pay a certain sum of money in taxes, his satisfaction will be greater if the levy is made directly on him as a fixed amount than if it is made through a system of excise taxes which he can to some extent avoid by rearranging his production and consumption'.

Unfortunately Hotelling overlooked the fact that if $t_j = t$ for all j then the government's budget constraint implies $p^0 \cdot q^1 = -m^0 t_0/t$, whence $t_0 = -t$ and $q^1 = q^0$. That is, a system of uniform ad valorem excise taxes is equivalent to a proportional income tax. This was pointed out by Frisch (1939) and accepted by Hotelling (1939). As Frisch made clear, what Hotelling really proved was the non-optimality of a system of non-proportional excise taxes or subsidies when selling prices are given. If these selling prices are equal to marginal costs, Hotelling's theorem shows that market prices should be proportional to marginal costs. Since incomes are fixed in Hotelling's formulation, income taxes may be regarded as lump-sum taxes. If institutional consideration make excise taxes impossible for one commodity (say leisure), then they must be zero for all commodities and optimality requires that prices be equal to marginal costs. (For a less charitable interpretation of Hotelling's contribution see Silberberg 1980).

Hotelling went on to assert that his proposition could be extended to many consumers (though no details or proof were provided), and he proceeded to examine the consumers'-surplus measure of loss $\frac{1}{2}(p^1 - p^0) \cdot (q^1 - q^0) = \frac{1}{2} T p^0 \cdot (q^1 - q^0)$ (where T is a diagonal matrix of excise-tax rates t_j). He also made some general observations (1938, p. 267) that, to this day, constitute what is probably the best statement to be found of the philosophy underlying the compensation principle.

The Years of the New Welfare Economics

In the cases to which the compensation principle was applied by Dupuit, Marshall, Lerner and Hotelling, compensation was made between the class of consumers on the one hand and a government or a monopolist on the other. While Pareto and Barone had discussed compensation between different classes of consumers (as had Hotelling in his general remarks) their work was unknown to English-speaking economists until the publication in 1935 of the English translation of Barone's 1908 work. Even this seems not to have struck home, however, since Kaldor (1939) cited passages from Harrod (1938) and Robbins (1938) to the effect that, since movement towards free trade would affect different classes differently, no scientific statement could be made concerning the beneficial effect of free trade without making interpersonal comparisons of utility.

Kaldor (1939) proceeded to sketch an argument to the effect that removal of an import duty (using the classical example of repeal of the Corn Laws) would result in a situation in which the losses incurred by the landlords could be compensated by the gains (through lower import prices) obtained by the other consumers. Such an argument cannot be correct, however, since, as Kaldor (1940) pointed out only a year later, it follows from Bickerdike's theory of optimal tariffs that a country can gain from the imposition of a sufficiently small duty, and, as Graaff (1949) and others later demonstrated, the compensation principle can be used to show that, with suitable

compensation, all persons can gain. Unless the rate of corn duty was above the optimal tariff rate, the opposite conclusion would follow to that indicated by Kaldor (1939).

A previous attempt by Pareto (1895) to show by means of the compensation principle that a tariff would lead to 'destruction of wealth' was defective, since he assumed trade to be balanced in domestic prices and thus he failed to take account of the improvement in the terms of trade and the beneficial effect of the tariff revenues.

Other attempts prior to 1939 to make the case for free trade suffered from vagueness both in specifying the criterion of gain and in specifying the alternative with which free trade was being compared. Ricardo (1815, p. 25) stated: 'There are two ways in which a country may be benefited by trade – one by increase of the general rate of profits . . . the other by the abundance of commodities, and by a fall in their exchangeable value, in which the whole community participate'. According to Cairnes (1874, p. 418), 'the true criterion of the gain on foreign trade [is] the degree in which it cheapens commodities, and renders them more abundant'. A hint of a compensation principle is found in Viner (1937, pp. 533–4):

> free trade . . . necessarily makes *available* to the community *as a whole* a greater physical real income in the form of more of *all* commodities, and . . . the state . . . can, by appropriate supplementary legislation, make certain that removal of duties shall result in more of *every* commodity for *every* class of the community.

Like Kaldor's statement, this is formally incorrect; but it was sufficiently suggestive to stimulate Samuelson (1939) into providing a formal proof of a gains-from-trade theorem, albeit under very restrictive assumptions.

Samuelson (1939) assumed that an open economy had a locus $\varphi(y, l) = 0$ of efficient combinations of outputs y and (variable) factor services l, and asserted that vectors of prices p and factor rentals w in competitive equilibrium would be such that aggregate profit $p \cdot y - w \cdot l$ is a maximum. This is the same as the proposition of Pareto (1894), and Barone (1908) referred to above. Letting x denote the bundle of commodities consumed, under both (balanced) free trade and autarky the budget equation $p \cdot x = p \cdot y$ holds. Letting superscripts 0 and 1 denote equilibrium values under autarky and free trade respectively, it follows that

$$p^1 \cdot x^1 - w^1 \cdot l^1 \geq p^1 \cdot x^0 - w^1 \cdot l^0.$$

Assuming all N individuals to be identical in their preferences and ownership of factors, and dividing this inequality through by the number of individuals, it states that each person chooses $(x^1/N, l^1/N)$ under free trade when $(x^0/N, l^0/N)$ is available, hence (if $p^1 \neq p^0$) each person prefers $(x^1/N, l^1/N)$ to $(x^0/N, l^0/N)$. Therefore free trade is Pareto-superior to autarky.

Samuelson went on to assert (1939, p. 204) that, if the assumption of identical individuals is dropped, then, although it could no longer be said that each individual was better off under free trade, 'it would always be possible for those who desired trade to buy off those opposed to trade, with the result that all could be made better off'. This argument went unchallenged until Olsen (1958) pointed out that, if compensation were paid from gainers to losers, a new equilibrium price constellation p^1 would result, and the argument no longer follows. For this reason Samuelson's 1939 results has come to be known as the gains-from-trade theorem for the 'small-country case', though this interpretation was not suggested by Samuelson at the time. But this description of Samuelson's result is inaccurate. Generalizing his argument we can say that if (x_i^t, l_i^t) are the allocations of (x^t, l^t) to individual i, where $\sum_{i=1}^{N} x_i^t = x^t$ and $\sum_{i=1}^{N} l_i^t = l^t$, the given the allocations (x_i^1, l_i^1) of (x^1, l^1) under free trade one can find Pareto-optimal allocations (x_i^0, l_i^0) of (y^0, l^0) under autarky such that

$$p^1 \cdot x_i^1 - w^1 \cdot l_i^1 \geq p^1 \cdot x_i^0 - w^1 \cdot l_i^0 \text{ for } i = 1, 2, \ldots, N.$$

This proves that for *any* free-trade equilibrium it is possible to find a weakly Pareto-inferior Pareto-optimal autarky equilibrium. It does not prove the obverse proposition that for any autarky

equilibrium it is possible to find a weakly Pareto-superior free-trade equilibrium. A general gains-from-trade theorem was therefore yet to be established, but Samuelson had provided an important first step.

Hicks (1939) ushered in the 'new welfare economics' with a synthesis building on Hotelling (1938) and Kaldor (1939) and based on the compensation principle, making it possible, according to him, to make policy proposals in favour of economic efficiency which were free of value judgements. Hicks's most original contribution (Hicks 1940) was his attempt to apply the compensation principle to data on a country's real national income. This was a natural thing to try to do, since Pigou's (1920) main work was devoted to evaluating a country's welfare by national-income comparison, and it was largely Pigou's resort to interpersonal comparisons in order to justify this that was the object of Robbins's (1938) criticism.

Hicks's (1940) basic tool was the 'revealed-preference' comparison which had been employed by Barone (1908) and Hotelling (1938). If observations are available at times 0 and 1 of a country's national income in period-1 prices, and it is recorded that $p^1 \cdot y^1 \geq p^1 \cdot y^0$ (where p^t, y^t are vectors of prices and outputs at time t), what can be inferred? In the first place, to make any headway one must assume that the observed situations are competitive equilibria. Let us define an allocation of a commodity bundle x as an $N \times n$ matrix X whose ith row, x_i, is the bundle of n commodities allocated to individual i, and whose row sum $\sigma(X) = \sum_{i=1}^{N} x_i$ is equal to x. As between two bundles x_i^0, x_i^1 consumed by individual i, let us define $x_i^1 R_i x_i^0$ to mean that x_i^1 is preferred or indifferent to x_i^0 by individual i, where R_i is a continuous, convex, monotonic total order, with P_i denoting strict preference and I_i indifference. (This relation assumes the absence of externalities in consumption). Finally, let $X^1 R X^0$ (resp. $X^1 P X^0$) mean that X^1 is weakly (resp. strictly) Pareto-superior to X^0 (i.e. $x_i^1 R_i x_i^0$ for all i, resp. $x_i^1 R_i x_i^0$ for all i and $x_i^1 R_i x_i^0$ for some i). Then, from the real-income comparison $p^1 \cdot y^1 \geq p^1 \cdot y^0$, Hicks noted that there does not exist an allocation X of y^0 that is weakly Pareto-superior to the actual allocation X^1 of y^1. This follows from the same argument that establishes the Pareto optimality of the assumed competitive equilibrium in period 1. The non-existence of an allocation X of y^0 such that XRX^t, where $\sigma(X^1) = y^1$, constituted for Hicks the definition of an 'increase in real social income'.

Kuznets (1948) pointed out by an example that, in the case considered by Hicks, it could also be true that there is no allocation X of y^1 which is weakly Pareto superior to the actual allocation X^0 of y^0. Accordingly he suggested that Hicks's criterion be supplemented by the condition that there should exist an allocation $\overline{X}$ of y^1 that is weakly Pareto superior to the actual allocation X^0 of y^0. But while the latter criterion implies $p^0 \cdot y^1 \geq p^0 \cdot y^0$, it is not implied by it, so a national-income comparison using current and base prices would still not yield Kuznets's criterion.

Kuznets's criticism of Hicks was similar to the objection raised by Scitovsky (1941) to the criterion proposed by Kaldor (1939). According to Scitovsky's interpretation of Kaldor, an allocation X^1 of y^1 is better than an allocation X^0 of y^0, if there exists a reallocation $\overline{X}^1$ of y^1, which is Pareto superior to X^0. Scitovsky objected that this gave preference to the *status quo ante*, and besides, he pointed out that the criterion was internally inconsistent in the sense that it allowed two such pairs (X^t, y^t) to be superior to each other. He therefore proposed that Kaldor's test be supplemented by the criterion that there exist a reallocation $\overline{X}^0$ of y^0 that is Pareto inferior to X^1.

The literature on 'compensation tests' suffered from ambiguity as to the domain of definition of the relations and internal inconsistency of the relations. It was pointed out by Gorman (1955) that the relations were intransitive. It was shown in Chipman and Moore (1978) that the Hicks–Kuznets and Scitovsky double criteria, as well as the national-income comparisons in terms of base- and current-year prices, could lead to cycles of three competitive equilibria each superior to its successor.

The definitive contribution to the subject of national-income comparisons was that of Samuelson (1950) who introduced what Chipman and

Moore (1971) described as the 'Kaldor–Hicks–Samuelson (KHS) ordering'. The objects under comparison in this approach are sets Y of commodity bundles y, e.g. production-possibility sets. Letting $A(Y)$ denote the set of allocation matrices X such that $\sigma(X) \in Y$, this ordering is defined by

$$Y^1 >_R Y^R 0 \Leftrightarrow \left[\forall X^0 \in A\left(Y^0\right)\right]\left[\exists X^1 \in A\left(Y^1\right)\right] X^1 R X^0.$$

In words, Y^1, is potentially superior to Y^0 if, for all allocations of commodity bundles in Y^0, there exists a (weakly) Pareto superior allocation of a commodity bundle in Y^1. This is a reflexive and transitive relation; it also satisfies the condition that $Y^0 \subseteq Y^1$ implies $Y^1 >_R Y^0$. Samuelson also introduced the important concept of a utility- possibility frontier, which is the relative boundary of a utility-possibility set $U(Y, R; f)$; this in turn is a set of N-tuples of individual utilities, $u = f(X)$, for some $X \in A(Y)$, where f is an N-tuple of positive-valued utility functions representing R. If the sets Y are 'disposable' (that is, containing for every $y \in Y$ the bundles y' with $0 \leq y' \leq y$), and the R_i continuous and monotonic, then the utility-possibility sets are also disposable. If Y is non-empty, compact disposable, and convex, and the R_i are continuous, monotonic, and convex, then, provided the f_i are continuous and concave, $U(Y, R, f)$ is non-empty, compact, and convex (cf. Chipman and Moore 1971, p. 24). If the f_i are only quasi-concave and not concave, $U(Y, R, f)$ need not be convex (cf. Kannai and Mantel 1978). The KHS ordering among consumption-possibility sets translates into set-inclusion of the corresponding utility-possibility sets. Samuelson (1959, p. 10) gave an example of a case of crossing utility-possibility frontiers in which $X^2 \in A(Y^2)$ was Pareto superior to $X^1 \in A(Y^1)$ yet Y^1 would be ranked higher than Y^2 in terms of some value judgement. This established that the 'compensation tests' were not 'relatively *wertfrei*'.

Another approach was followed by Chipman and Moore (1973, 1976a), who asked the following question: if competitive equilibria (X^t, y^t, p^t) are observed satisfying $p^1 \cdot y^1 \geq p^1 \cdot y^0$ and $p^0 \cdot y^1 \geq p^0 \cdot y^0$, where $y^t \in Y_t$ for $t = 0, 1$, under what conditions on preferences must this imply that $Y^1 >_R Y^0$? For the case $Y^t = \{y^t\}$ they showed that the preference relations R_i must be identical and homothetic. This is a global result; with positive consumptions of all commodities the condition could no doubt be weakened to the aggregation criterion of Antonelli (1886), Gorman (1953), and Nataf (1953), namely, that consumer i's demand for commodity j have the form

$$x_{ij} = a_{ij}(p) + b_j(p) m_i$$

where m_i is consumer i's income.

Samuelson (1956) applied the compensation principle in a striking way in his proposed alternative to the new welfare economics. He discovered that, if a social- welfare function has the separable form W[$f(x)$], then a social utility function $f_w(x) = \max\{W[f(x)] : X \in A(x)\}$ has the property that it can be achieved in a decentralized manner by means of an income-distribution policy assigning individual shares of aggregate income as functions of prices and aggregate income. The first complete proof of this result was presented in Chipman and Moore (1972) (see also Chipman and Moore 1979; Chipman 1982). The main tool of analysis used was the concept of a Scitovsky indifference surface (Scitovsky 1942) which is defined as the boundary of the set $\sum_{i=1}^{N} R_i x_i$ where $R_i x_i$ is the set of all commodity bundles preferred or indifferent to x_i by individual i. This set is necessarily a subset of the set $R_w x$ of aggregate bundles preferred or indifferent to x by the Samuelson social ordering. In a competitive equilibrium the aggregate consumption bundle minimizes aggregate expenditure at the equilibrium prices over both sets, hence the bundle x_i minimizes each individual's expenditure over $R_i x_i$ (cf. Koopmans 1957, pp. 12–13).

Gains From Trade and Optimal Tariffs

The new tools developed by Scitovsky (1942) and Samuelson (1950, 1956) made possible a rigorous

proof of a gains-from-trade theorem, as well as of the proposition that a country could gain by a tariff.

Kemp (1962) noted that Samuelson's 1939 theorem implied that for any point on the free-trade utility-possibility frontier, the autarky utility-possibility frontier must pass below it; he reasoned that, as a result, for any point on the autarky utility-possibility frontier, the free-trade utility-possibility frontier must pass above it. If this argument can be accepted, it follows that for every allocation $X^0 \in A(Y^0)$ where Y^0 is the autarkic production-possibility set, there exists a (weakly) Pareto-superior allocation $X^1 \in A(Y^1)$ where Y^1 is the free-trade consumption-possibility set. Then free trade is superior to autarky by Samuelson's 1950 criterion.

The trouble with this argument, however, is that it requires that one can define a free-trade utility-possibility frontier (or consumption-possibility frontier) with the strong topological property of homeomorphism to the $(N-1)$-dimensional unit simplex (intuitively, absence of 'holes'). That this need not always be possible, was shown by Otani (1972, p. 149), and indeed admitted by Kemp and Wan (1972, p. 513). It is always possible if world prices are fixed, beyond our country's control. In that case the free-trade consumption-possibility set Y^1 is the budget set enclosing the production-possibility set Y^0 (cf. Samuelson 1962, p. 821), and the gains-from-trade theorem follows immediately from the property $Y^1 \supseteq Y^0 \Rightarrow Y^1 >_R Y^0$. In similar fashion the famous 'Baldwin envelope' (Baldwin 1948) defines a well-behaved consumption-possibility set containing the production-possibility set, from which one can prove the superiority of restricted trade (with an optimal tariff) to autarky (cf. Samuelson 1962).

For the general case in which a country can influence world prices, a method was shown by Kenen (1957). If all but 1 of the N individuals are constrained to have the same level of satisfaction under trade as achieved under autarky, a net production-possibility set can be constructed which indicates the amount available for the Nth person. It remains only to show that the Nth person will gain from a movement from autarky to free trade. A similar approach was indicated by Vanek (1964).

Grandmont and McFadden (1972) and Chipman and Moore (1972) both used the concept of an income-distribution policy to establish the gains-from-trade theorem. In Chipman and Moore this policy was chosen to be one that maximizes a separable Bergson-Samuelson social-welfare function. A standard argument is used to show that social utility is at least as high under free trade as under autarky. It remains to show that a function $W(u)$ can be chosen so that the corresponding distribution policy ensures that an increase in social utility implies an increase in each individual's utility. This is achieved by choice of $W(u) = min_i \left(u_i - u_i^0\right)/c_i$ where $c_i > 0$ and u_i^0 is the level of utility achieved by individual i under autarky.

General-Equilibrium Theory

The compensation principle is used in the proof of the theorem that every competitive equilibrium is Pareto-optimal (Arrow 1952, pp. 516, 519; Koopmans 1957, p. 49; Debreu 1959, pp. 94–5), in the sense that arbitrary allocations of feasible output bundles among consumers are assumed possible, regardless of resource-ownership constraints. A pair (X^0, p^0) is a competitive equilibrium for the production-possibility set Y if $X^0 R X$ for all $X \in A(Y)$ satisfying $Xp^0 \leq X^0 p^0$ and $y^0 p^0 \leq y p^0$ for all $y \in Y$, where $y^0 = \sigma(X^0) \in Y$. Pareto-optimality means that one cannot find an $X \in A(Y)$ such that XPX^0. The proof is by contradiction: XPX^0 implies $Xp^0 \geq X^0 p^0$ (the vector inequality being weak in all components and strict in at least one) hence taking column sums, $yp^0 > y^0 p^0$.

The converse theorem, that every Pareto optimum can be sustained by a competitive equilibrium, requires stronger assumptions which are awkward to state (cf. Arrow 1952, p. 518; Koopmans 1957, p. 50; Debreu 1959, p. 95). The basic idea of the proof (Koopmans 1957, pp. 50–52; Debreu 1959, p. 96) can be sketched in terms of the concept of a Scitovsky (1942) indifference surface. If X^0 is a Pareto-optimal

allocation for a closed, convex production-possibility set Y, then the interior of the Scitovsky set of X^0 can be written $p_k x_k^0 + \sum_{i \neq k} R_i x_i^0$ for some k.

Defining the allocation X^1 by $x_k^1 p_k x_k^0$ and $x_i^1 R_i x_i^0$ for $i \neq k$ we have $X^1 \; PX^0$ hence $X^1 \notin A(Y)$. Therefore the interior of the Scitovsky set does not intersect Y, and these convex sets can be separated by a hyperplane defining the equilibrium prices. It is then verified that at these prices the properties of a competitive equilibrium are satisfied.

Debreu (1954, p. 590) introduced an alternative equilibrium concept according to which the condition that consumer preferences be maximized subject to their budget constraints was replaced by the condition that consumer expenditures be minimized subject to the constraints that the bundles considered be at least as desirable as the equilibrium bundles. (The second of the above theorems follows more easily under this alternative definition). For a given set of positive-valued utility functions representing consumer preferences, Arrow and Hahn (1971, p. 108) called this a 'compensated equilibrium'. As a means of proving existence of the latter they studied the utility-possibility frontier or 'Pareto frontier' (1971, p. 96), and obtained a new proof of the result of Chipman and Moore (1971) that the set of Pareto-optimal allocations X of Y (the 'contract curve') and the utility-possibility frontier are topologically homeomorphic to the unit simplex of dimension one less than the number of individuals. These results were further developed by Moore (1975).

Cost–Benefit Analysis

Hicks (1941, p. 112) made an interesting distinction between two tasks of welfare economics: (1) the study of (Pareto)-optimal organizations of the economy and (2) the study of deviations from such optima. More precisely, the first was concerned with when there was a deviation and the second with the size of the deviation. He also identified these two tasks with general- and partial-equilibrium analysis respectively, although there appears to be no justification for this other than the historical accident that consumers' surplus developed as a partial-equilibrium tool. He remarked that consumers' surplus is not needed for the first task, since lack of fulfilment of the proportionality between marginal utilities and marginal costs provides the needed information immediately. For the second task, he was not content with a ranking of the non-optimal states, but with measuring the size of their deviations from optimality, which of course would provide such a ranking. Thus, the staunch ordinalist in consumer theory became an equally ardent cardinalist in consumer theory.

Hicks's concepts of compensating and equivalent variation (Hicks 1942) may most conveniently be defined in terms of the minimum-income or income-compensation functions of McKenzie (1957) and Hurwicz and Uzawa (1971). Denoting the ith consumer's demand function by $x_i = h_i(p, m_i)$ (where x_i and p are n-vectors), and defining the indirect preference relation R_i^* by $(p^0, m_i^0)\, R_i^* (p^1, m_i^1)$ if and only if $h_i(p^0, m_i^0) R_i h_i(p^1, m_i^1)$, the income-compensation function is defined by

$$\mu_i(p; p^0, m_i^0) = \inf\{m_i : (p, m_i) R_i^* (p^0, m_i^0)\}.$$

Following Chipman and Moore (1980b), the generalized compensating variation in going from (p^0, m_i^0) to (p, m_i) is defined as

$$C_i(p, m_i; p^0, m_i^0) = m_i - \mu_i(p; p^0, m_i^0)$$

and the generalized equivalent variation by

$$E_i(p, m_i; p^0, m_i^0) = \mu_i(p^0; p, m_i) - m_i^0.$$

These reduce to Hicks's concepts when $m_i = m_i^0$.

The compensating variation expresses for each consumer the amount of money income he or she would be willing to give up (or the negative of the amount by which he or she would have to be compensated), at the new prices, to make up for the change in prices and income. One of the reasons for the great appeal of the concept is that these are amounts that can be added up over the set of consumers. In Hicks's words (1942, p. 127):

C

> the general test for a particular reform being an *improvement* is that the gainers should gain sufficiently for them to be able to compensate the losers and still remain gainers on balance. This test would be carried out by striking the balance of the Compensating Variations.

Denoting by m' the vector of N incomes in state t, and by M^t their sum, we can define a dual potential-improvement ordering between pairs of price-income pairs (p^t, M^t) as follows. Let $A^*(p, M)$ be the set of $(n + N)$-tuples (p, m) such that $\sum_{i=1}^{N} m_i = M$, and let R^* be the relation such that (p^0, m^0) $R^*(p^1, m^1)$ if and only if $(p^0, m_i^0) R_i^* (p^1, m_i^1)$ for $i = 1, 2, \ldots, N$. Then we define the dual KHS relation $>_R{}^*$ by

$$(p^0, M^0) >_{R^*} (p^1, M^1) \Leftrightarrow \left[\forall (p', m') \in A^*(p^1, M^1)\left(\exists (p, m) \in A^*(p^0, M^0)\right)\right] : (p, m) R^* (p', m').$$

Choosing price-income pairs (p^0, m^0) and (p^1, m^1) satisfying this definition, since $\mu_i(p^t; p, m_i)$ is an indirect utility function representing R_i^* for $t = 0$ or 1, we have $\mu_i(p^t; p^0, m_i^0) \geq \mu_i(p^t; p^1, m_i^1)$ for all individuals i, hence

$$M^0 = \sum_{i=1}^{N} m_i^0 = \sum_{i=1}^{N} \mu_i(p^0; p^0, m_i^0) \geqq \sum_{i=1}^{N} \mu_i(p^0; p^1, m_i^1)$$

so one obtains a multi-consumer analogue to the compensating variation from the formula

$$M^0 = \sum_{i=1}^{N} \mu_i(p^0; p^1, m_i^1) \geqq$$

$$M^1 - \sum_{i=1}^{N} \mu_i(p^1; p^1, m_i^1) = 0.$$

Likewise for the equivalent variation,

$$0 = \sum_{i=1}^{N} \mu_i(p^0; p^0, m_i^0) - M^0 \geqq \sum_{i=1}^{N} \mu_i(p^0; p^1, m_i^1) - M^0.$$

In the latter case the same indirect utility functions are summed on both sides of the inequality sign; it is a case where Benthamites and compensationists can find common ground.

Boadway (1974) considered the relationship between the condition of positive summed compensating variations and the fulfilment of compensation tests and came to the negative conclusion that the former was neither necessary nor sufficient for satisfaction of the latter in general, but was sufficient in the case of identical and homothetic preferences. Foster (1976) showed that, if there are no price distortions (but not otherwise), satisfaction of the compensation tests implies satisfaction of the 'cost–benefit criterion' (positive summed compensating variations). This conclusion is in accord with the above inequalities.

What about the Hicksian tenet that the size of the compensating variation is important so that one can compare two suboptimal states? This would require one to be able to conclude that, if the compensating variation from state 0 to state 2 is positive and greater than the compensating variation from state 0 to state 1, then state 2 should be superior to state 1 in terms of the dual KHS ordering. But this is not true even in the case of the single consumer. It was shown in Chipman and Moore (1980) that the function $C_i(p, m_i; p^0, m_i^0)$ cannot be an indirect utility function for unrestricted domain $(p, m_i) > 0$, and can be if m_i is held constant if and only if preferences are homothetic, and if p_1 is held constant if and only if preferences are 'parallel' with respect to commodity 1. If preferences are identical and homothetic, since $\mu_i = \mu$ is homogeneous of degree 1 in m_i, $\sum_{i=1}^{N} \mu_i(p^0; p, m_i) = \mu(p^0, p, M)$, so exact aggregative analogues are obtained to both the

compensating and equivalent variations. If the equivalent variation, which is an indirect utility function, is used, restrictions on consumer preferences are not needed, and the problem of finding an adequate indicator of the size of the deviation from a given Pareto optimum is satisfactorily resolved.

Game Theory

One of the striking aspects of von Neumann and Morgenstern's theory of games (1947) was not only its postulate of measurability of utility but also that of its transferability between players. Since this was introduced as a positive rather than a normative assumption, it has met with even greater resistance of the part of economists than the hedonist calculus. Indeed, it was not until Debreu and Scarf (1963) showed how game theory could be liberated from this restriction with their development of the concept of the core of an economy that game theory began to be taken really seriously by economists. The replacement of transferability of utilities by transferability of commodities bears a striking resemblance to the replacement in welfare economics of the calculus of utilities by the principle of compensation.

In some branches of game theory the assumption of transferable utility is still retained, but it has been made somewhat more plausible, or at least interpretable, by means of the postulate that the utility functions of all individuals are linear in one distinguished commodity used for making side payments (cf. Owen 1982, p. 122). These utility functions have the form

$$U_i(x_{i1}, x_{i2}, \ldots, x_{in}) = c_i x_{i1} + V_i(x_{i2}, \ldots, x_{in}).$$

This form of the utility function goes back to Edgeworth (1891, p. 237n) and even earlier (though in garbled form) to Auspitz and Lieben (1889, p. 471). In Edgeworth it was used to illustrate the phenomenon of exchange when the marginal utility of one commodity serving as money was held constant, in accordance with one possible interpretation of Marshall's theory of consumers' surplus. (In the case $n = 2$ he showed that the exchange in commodity 2 would be constant, but in commodity 1 'indeterminate'; see the reply by Berry 1891, on behalf of Marshall, and Marshall 1891, p. 756; 1920, p. 845). The above form for the utility function has been rediscovered many time, by Wilson (1939), Samuelson (1942), and others; cf. Chipman and Moore (1976b, p. 115). Barone (1894, p. 213n) gave the name 'ideal money (numéraire)' to a good with a constant marginal utility (commodity 1 in the above). For the case $c_i = c$ for all i, these 'parallel' preferences (cf. Boulding 1945) yield a special case of the family of aggregable Antonelli–Gorman–Nataf demand functions referred to above.

Concluding Observations

As Scitovsky (1941) pointed out, the compensation principle has been used in two quite different ways. Prior to Hicks (1940), it was used only to compare efficient with inefficient states of a given economy with a given technology or trading system. Starting with Hicks (1940), its use was extended to comparison of efficient states of an economy under different technologies. It has turned out that, in order for national-income comparisons to provide a correct indicator of potential-welfare improvement, very strong conditions are required concerning similarity of individual preferences: locally, the Antonelli– Gorman–Nataf conditions, and, globally, identical homothetic preferences. It is not even enough to assume that aggregate demand can be generated by an aggregate preference relation – for example, that preferences are homothetic and relative income-distribution constant (cf. Chipman and Moore 1980a). Even in such cases, strong value judgements (such as acceptance of a particular Bergson–Samuelson social-welfare function) are required in order to draw welfare conclusions from national-income comparisons.

When attention is restricted to the efficient operation of an economy with a given technology, it turns out that, in most cases of interest, the ranking of consumption-possibility criterion sets according to the Kaldor–Hicks–Samuelson criterion follows from their ranking by set-inclusion.

This does not mean, however, that the set-inclusion is always obvious or easy to prove.

The KHS ordering of consumption-possibility sets could be given simply a factual interpretation as indicating the 'productive potential' of an economy. But if it is given a normative interpretation then it obviously involves a value judgement, since a more efficient outcome, if it is not Pareto-superior, can obviously be judged worse in terms of some social-welfare function.

Samuelson's (1956) model of the 'good society', elegant though it is, is too sweeping for most economists to accept, and it begs the question of how the social-welfare function will be chosen. Little's (1950) and Mishan's (1969) attempts to link plausible distributional value judgements with compensation criteria have encountered unresolvable logical difficulties (cf. Chipman and Moore 1978). The hope that the compensation principle would allow policy decisions to be made free of value judgements has not been fulfilled. Nevertheless, much has been learned about the interrelationships among values, facts, and policies, and it can certainly be said that the development of the compensation principle has led to clearer thinking about economic policy issues.

Competing Risks Model

Gerard J. van den Berg

Abstract

A competing risks model is a model for multiple durations that start at the same point in time for a given subject, where the subject is observed until the first duration is completed and one also observes which of the durations is completed first. This article gives an overview of the main issues in the empirical econometric analysis of competing risks models. The central problem is the non-identification of dependent competing risks models. Models with regressors can overcome this problem, but it is advisable to include additional data. Alternatively, effects of interest can be bounded.

A competing risks model is a model for multiple durations that start at the same point in time for a given subject, where the subject is observed until the first duration is completed and one also observes which of the multiple durations is completed first.

The term 'competing risks' originates in the interpretation that a subject faces different risks

i of leaving the state it is in, each risk giving rise to its own exit destination, which can also be denoted by i. One may then define random variables T_i describing the duration until risk i is materialized. Only the smallest of all these durations $Y := \min_i T_i$ and the corresponding actual exit destination, which can be expressed as $Z := \text{argmin}_i T_i$, are observed. The other durations are censored in the sense that all is known is that their realizations exceed Y. Often those other durations are latent or counterfactual, for example if T_i denotes the time until death due to cause i.

In economics, the most common application concerns individual unemployment durations. One may envisage two durations for each individual: one until a transition into employment occurs, and one until a transition into non-participation occurs. We observe only one transition, namely, the one that occurs first. Other applications include the duration of treatments, where the exit destinations are relapse and recovery, and the duration of marriage, where one risk is divorce and the other is death of one of the spouses. More generally, the duration until an event of interest may be right-censored due to the occurrence of another event, or due to the data sampling design. The duration until the censoring is then one of the variables T_i.

Sometimes one is interested only in the distribution of Y. For example, an unemployment insurance (UI) agency may be concerned only about the expenses on UI and not in the exit destinations of recipients. In such cases one may employ standard statistical duration analysis for empirical inference with register data on the duration of UI receipt. However, in studies on individual behaviour one is typically interested in one or more of the marginal distributions of the T_i. If these variables are known to be independent, then again one may employ standard duration analysis for each of the T_i separately, treating the other variables T_j ($j \neq i$) as independent right-censoring variables. But often it is not clear whether the T_i are independent. Indeed, economic theory often predicts that they are dependent, in particular if they can be affected by the individual's behaviour and individuals are heterogeneous. It may even be sensible from the individual's point of view to use their privately observed exogenous exit rates into destinations j as inputs for the optimal strategy affecting the exit rate into destination i ($i \neq j$) (see, for example, van den Berg 1990). Erroneously assuming independence leads to incorrect inference, and in fact the issue of whether the durations T_i are related is often an important question in its own right.

Unfortunately, the joint distribution of all T_i is not identified from the joint distribution of Y, Z, a result that goes back to Cox (1959). In particular, given any specific joint distribution, there is a joint distribution with independent durations T_i that generates the same distribution of the observable variables Y, Z. In other words, without additional structure, each dependent competing risks model is observationally equivalent to an independent competing risks model. The marginal distributions in the latter can be very different from the true distributions.

Of course, some properties of the joint distribution are identified. To describe these it is useful to introduce the concept of the hazard rate of a continuous duration variable, say W. Formally, the hazard rate at time t is $\theta(t) := lim_{dt \downarrow 0} \Pr(W \in [t, \ t + dt))/dt$. Informally, this is the rate at which the duration W is completed at t given that it has not been completed before t. The hazard rate is the basic building block of duration analysis in social sciences because it can be directly related to individual behaviour at t. The data on Y, Z allow for identification of the hazard rates of T_i at t given that $T \geq t$. These are called the 'crude' hazard rates. If the T_i are independent, then these equal the 'net' hazard rates of the marginal distributions of the T_i.

We now turn to a number of approaches that overcome the general non-identification result for competing risks models. In econometrics, one is typically interested in covariate or regressor effects. The main approach has therefore been to specify semi-parametric models that include observed regressors X and unobserved heterogeneity terms V. With a single risk, the most popular

duration model is the mixed proportional hazard (MPH) model, which specifies that $\theta(t|\ X = x, V) = \psi(t)\ \exp\ (x'\beta)V$ for some function $\psi(.)$. V is unobserved, and the composition of the survivors changes selectively as time proceeds, so identification from the observable distributions of $T|X$ is non-trivial. However, it holds under the assumptions that $X \perp\!\!\!\perp V$ and $\text{var}(X) > 0$ and some regularity assumptions (see van den Berg 2001, for an overview of results). With competing risks, the analogue of the MPH model is the multivariate MPH (MMPH) model. With two risks,

$$\theta_1(t|\,x,\ V) = \psi_1(t)\ \exp(x'\beta_1)V_1 \text{ and}$$
$$\theta_2(t|\,x,\ V) = \psi_2(t)\ \exp(x'\beta l)V_2.$$

where $T_1, T_2|X, V$ are assumed independent, so that a dependence of the durations given X is modelled by way of their unobserved determinants V_1 and V_2 being dependent. Many empirical studies have estimated parametric versions of this model, using maximum likelihood estimation.

The semi-parametric model has been shown to be identified, under only slightly stronger conditions than those for the MPH model (Abbring and van den Berg 2003). Specifically, $\text{Var}(X) > 0$ is strengthened to the condition that the vector X includes two continuous variables with the properties that (a) their joint support contains a non-empty open set in $\mathbb{R}^2$, and (b) the vectors $\tilde{\beta}_1$, $\tilde{\beta}_2$ of the corresponding elements of β_1 and β_2 form a matrix $(\tilde{\beta}_1,\ \tilde{\beta}_2)$ of full rank. Somewhat loosely, X has two continuous variables that are not perfectly collinear and that act differently on θ_1 and θ_2. Note that, with such regressors, one can manipulate $\exp(x'\beta_1)$ while keeping $\exp(x'\beta_2)$ constant. The two terms $\exp(x'\beta_i)$ are identified from the observable crude hazards at $t = 0$ because at $t = 0$ no dynamic selection due to the unobserved heterogeneity has taken place yet. Now suppose one manipulates x in the way described above. If $T_1,\ T_2|X$ are independent, then the observable crude hazard rate of T_2 at $t > 0$, given that $T1 \geq t$, does not vary along. But, if $T1;\ T2|X$ are dependent, then this crude hazard rate does vary along, for the following reason. First, changes in $\exp(x'\beta_1)$ affect the distribution of unobserved heterogeneity V_1 among the survivors at t, due to the well-known fact that V_1 and X are dependent conditional on survival (i.e. conditional on $T_1 \geq t > 0$) even though they are independent unconditionally. Second, if V_1 and V_2 are dependent, this affects the distribution of V_2 among the survivors at t, which in turn affects the observable crude hazard of T_2 at t given that $T_1 \geq t$. In sum, the variation in this crude hazard with $\exp(x'\beta_1)$ for given $\exp(x'\beta_2)$ is informative on the dependence of the durations. An analogous argument holds for the crude hazard rate corresponding to cause $i = 1$.

Note that identification is not based on exclusion restrictions of the sort encountered in instrumental variable analysis, which require a regressor that affects one endogenous variable but not the other. Here, all explanatory variables are allowed to affect both duration variables – they are just not allowed to affect the duration distributions in the same way. Identification with regressors was first established by Heckman and Honoré (1989), who considered a somewhat larger class of models than the MMPH model and accordingly imposed stronger conditions on the support of X.

Although the MPH model is identified from single-risk duration data where we observe a single spell per subject, there is substantial evidence that estimates are sensitive to misspecification of functional forms of model elements (see van den Berg 2001, for an overview). This implies that estimates of MMPH models using competing-risks data should also be viewed with caution. It is advisable to include additional data. For example, longitudinal survey data on unemployment durations subject to right-censoring can be augmented with register data or retrospective data not subject to censoring (see for example van den Berg et al. 1994). More in general, one may resort to 'multiple-spell competing risks' data, meaning data with multiple observations of Y, Z for each subject. For a given subject, such observations can be viewed as multiple independent draws from the subject-specific distribution of Y, Z, on the assumption that the unobserved heterogeneity terms V_1, V_2 are identical across the spells of the subject. Here, a subject can denote a single physical unit, like an individual, for which we observe

two spells in exactly the same state, or it can denote a set of physical units for which we observe one spell each. Multiple-spell data allow for identification under less stringent conditions than single-spell data. Abbring and van den Berg (2003) showed that such data identify models that allow for full interactions between the elapsed durations t and x in $\theta_i(t|\, x, V)$, and, indeed, allow the corresponding effects to differ between the first and the second spell. The assumptions on the support of X are similar to above. Fermanian (2003) developed a nonparametric kernel estimator of the Heckman and Honoré (1989) model.

Another approach to deal with non-identification of dependent competing risks models is to determine bounds on the sets of marginal and joint distributions that are compatible with the observable data. Peterson (1976) derived sharp bounds in terms of observable quantities. They are often wide. In case of the marginal distributions of two sub-populations distinguished by a variable X, the bounds associated with the different X may overlap, whether or not X (monotonically) affects (one of) the marginal distributions. With overlap, the causal effects of X cannot even be signed.

Bond and Shaw (2006) combined bounds with regressors. In the case of a single binary regressor, the only substantive assumption made is that there exist increasing functions g and h such that $T_1, T_2|X = 0$ equals $g(T_1), h(T_2)|X = 1$ in distribution. In words, the dependence structure is invariant to the values of the regressors, so the latter affect only the marginal distributions. Specifically, the copula (and therefore Kendall's τ) of the joint distribution is invariant to the value of X. The assumption is satisfied by the aforementioned competing risks models with regressors. Clearly, by itself the assumption is insufficient for point identification. The bounds concern the regressor effects on the marginal distributions. If it is assumed that X affects the marginal distributions of T_i in terms of first-order stochastic dominance, the bounds are sufficient to sign the effect of X on at least one of the marginal distributions (so, in case of MMPH models, also on at least one of the individual marginal distributions conditional on V).

We end this article by noting some connections between competing risks models and other models. First, they are related to switching regression models, or Roy models. For example, if $T_i|X, V$ in the MMPH model have Weibull distributions, then we can write $\log T_i = x_i\alpha_i + \varepsilon_i (i = 1, 2)$ (for example, van den Berg et al. 1994), where we observe T_i iff $T_i < T_j (j \neq i)$. Second, competing risks models are building blocks of multivariate duration models, notably models where one of the durations is always observed (for example, T_1 captures the moment of a treatment and T_2 is the observed duration outcome of interest).

We have considered only continuous-time duration variables T_i that have different realizations with probability 1. Recently, semi-parametric and nonparametric results have been derived for discrete-time or interval-censored competing risks models and models where different risks can be realized simultaneously (see for example Bedford and Meilijson 1997; van den Berg, van Lomwel and van Ours 2003; Honoré and Lleras-Muney 2006). The biostatistical literature contains many studies in which specific assumptions are made on the dependence structure of the two durations T_i, enabling inference on the marginal distributions from data on Y, Z (see for example Moeschberger and Klein 1995, for a survey).

Competition

George J. Stigler

Abstract

Competition arises whenever two or more parties strive for something that all cannot obtain. The classical economists felt no need for a very precise definition of competition because they viewed monopoly as highly exceptional. In the late 19th century competition became the subject of intense analysis; the concept of perfect competition emerged as the standard model of economic theory and as first approximation in the concrete studies of applied microeconomics. The limitations of the concept in dealing with conditions of persistent and imperfectly predicted change will be removed only when economics possesses a developed theory of change.

Competition is a rivalry between individuals (or groups or nations), and it arises whenever two or more parties strive for something that all cannot obtain. Competition is therefore at least as old as man's history, and Darwin (who borrowed the concept from economist Malthus) applied it to species as economists had applied it to human behaviour.

A concept that is applicable to two cobblers or a thousand shipowners or to tribes and nations is necessarily loosely drawn. When Adam Smith launched economics as a comprehensive science in 1776, he followed this usage. He explained why a reduced supply of a good led to a higher price: the 'competition [which] will immediately begin' among buyers would bid up the price. Similarly if the supply become larger, the price would sink

more, the greater 'the competition of the sellers' (Smith [1776] 1976, pp. 73–4). Here competition was very much like a race: a race to obtain part of reduced supplies or to dispose of a part of increased supplies. Almost nothing except a number of buyers and sellers was necessary for competition to operate. And the greater the number of each, the greater the vigour of competition:

> If this capital [sufficient to trade in a town] is divided between two different grocers, their competition will tend to make both of them sell cheaper, than if it were in the hands of one only; and if it were divided among twenty, their competition would be just so much the greater, and the chance of their combining together, in order to raise the price, just so much the less. (ibid., pp. 361–2)

With such a loose concept, there was little occasion to speak of one market as being more or less competitive than another, although this very passage presented the commonsense idea that larger numbers of rivals increased the intensity of competition.

The competition of grocers in a town pertained to competition *within* a market or an industry. Smith made much of the competition of different markets or industries for resources, and he developed what has always remained the main theorem on the allocation of resources in an economy composed of private, competing individuals or enterprises. The argument may be stated: Each owner of a productive resource will seek to employ it where it will yield the largest return. As a result, under competition each resource will be so distributed that it yields the same rate of return in every use. For if a resource were earning more in one use than another, it would be possible for its return in the lower-yielding use to be increased by reallocating it to the higher-yielding use. And this theorem led to what John Stuart Mill called the most frequently encountered proposition in economics: 'There cannot be two prices in the same market' (Mill 1848, Book II, ch. IV, s. 3).

The competition of different markets or industries for the use of the same resources called attention to some problems which are less important within a single market such as the grocery trade in a town. One must possess knowledge of the investment opportunities in these different employments, and that knowledge is less commonly possessed than knowledge within one market. It often requires a good deal of time to disengage resources from one field and install them elsewhere. Both of these conditions were recognized by Smith, who spoke of the difficulty of keeping secret the existence of extraordinary profits, and of the long run sometimes required for the attainment of equality of rates of return.

For the next three-quarters of a century the prevailing treatment of competition followed the practice of Smith. One can find occasional hints of a more precise definition of competition, well illustrated by Nassau W. Senior:

> But though, under free competition, cost of production is the regulator of price, its influence is subject to much occasional interruption. Its operation can be supposed to be perfect only if we suppose that there are no disturbing causes, that capital and labour can be at once transferred, and without loss, from one employment to another, and that every producer has full information of the profit to be derived from every mode of production. But it is obvious that these suppositions have no resemblance to the truth. A large portion of the capital essential to production consists of buildings, machinery, and other implements, the results of much time and labour, and of little service for any except their existing purposes . . . few capitalists can estimate, except upon an average of some years, the amount of their own profits, and still fewer can estimate those of their neighbours. (1836, p. 102)

Senior is hinting at a concept of perfect competition, but the hint is not pursued.

The classical economists felt no need for a precise definition because they viewed monopoly as highly exceptional: Harold Demsetz has counted only one page in 90 devoted to monopoly in *The Wealth of Nations* and only one in 500 in Mill's *Principles of Political Economy*. Indeed the word 'monopoly' was usually restricted to grants by the sovereign of exclusive rights to manufacture, import or sell a commodity; witness the entry in the *Penny Cyclopedia* (1839):

> It seems then that the word monopoly was never used in English Law, except when there was a royal grant authorizing some one or more persons only to deal in or sell a certain commodity or article.
>
> If a number of individuals were to unite for the purpose of producing any particular article or commodity, and if they should succeed in selling such

> article very extensively, and almost solely, such individuals in popular language would be said to have a monopoly. Now, as these individuals have no advantages given them by the law over other persons, it is clear they can only sell more of their commodity than other persons by producing the commodity cheaper and better. (XV, p. 341)

The ability of rivals to seek out and compete away supernormal profits, unless prevented by legal obstacles, was believed to be the basic reason for the pervasiveness of competition.

In the last third of the 19th century the concept of competition became the subject of intense study. The most popular reason given for this attention is that the growth of large-scale enterprises, including railroads, public utilities, and finally great manufacturing enterprises, made obvious the fact that a simple concept of competition no longer fit the economy of an industrial nation such as England.

A second source of misgiving with the broad definition of competition is that it might not lead to the uniformity of returns to a resource predicted by the theory. The Irish economist Cliffe Leslie repeatedly made this charge:

> Economists have been accustomed to assume that wages on the one hand and profits on the other are, allowing for differences in skill and so forth, equalized by competition, and that neither wages nor profits can anywhere rise above 'the average rate', without a consequent influx of labour or of capital bringing things to a level. Had economists, however, in place of reasoning from an assumption, examined the facts connected with the rate of wages, they would have found, from authentic statistics, the actual differences so great, even in the same occupation, that they are double in one place what they are in another. Statistics of profits are not, indeed, obtainable like statistics of wages; and the fact that they are not so, that the actual profits are kept a profound secret in some of the most prominent trades, is itself enough to deprive the theory of equal profits of its base. (1888, pp. 158–9)

The easiest way to combat such criticisms was not to confront them with data – that path was not chosen for many years – but to define competition in such a way as to ensure the desired results such as uniformity of price.

The complications possible with competition were raised also on the theoretical side. William T. Thornton, in his book *On Labour* (1869), denied the fact that prices were determined by the 'law of supply and demand', particularly within labour markets. He employed bizarre examples, such as supply and demand curves which coincided over a vertical range, to show that price could be indeterminate or unresponsive to changes in supply or demand. These objections naturally called forth responses, from both J.S. Mill (*Collected Works*, V) and Fleeming Jenkin, a famous engineer.

The most persuasive reason for the increasing attention to the concepts of economics was the gradual move of economic studies to the universities, which proceeded rapidly in the last decades of the century. The expanding use of mathematics was one major symptom of the development of the formal and abstract theory of economics by Walras, Pareto, Irving Fisher and others. That formalization would scarcely be possible without a more precise specification of the nature of competition, and the precise specification of the nature of competition, and the replies to Thornton's criticisms were a precursor to this literature.

The groundwork for the development of the concept of perfect competition was laid by Augustin Cournot in 1838 in his *Mathematical Principles of the Theory of Wealth*. He made the first systematic use of the differential calculus to study the implications of profit-maximizing behaviour. Starting with the definition, Profits = Revenue − Costs, Cournot sought to maximize profits under various market conditions. He faced the question: How does revenue (say, pq) vary with output (q)? The natural answer is to *define* competition as that situation in which p does not vary with q – in which the demand curve facing the firm is horizontal. This is precisely what Cournot did:

> The effects of competition have reached their limit, when each of the partial productions Dk [the output of producer k] is *inappreciable*, not only with reference to the total production $D = F(p)$, but also with reference to the derivative $F'(p)$, so that the partial production Dk could be subtracted from D without any appreciable variation resulting in the price of the commodity. (Cournot [1838] 1927, p. 90)

This definition of competition was especially appropriate in Cournot's system because,

according to his theory of oligopoly, the excess of price over marginal cost approached zero as the number of like producers became large. The argument is as follows:

Let the revenue of the firm be q_ip, and let n identical firms have the same marginal costs, MC. Then the equation for maximum profits for one firm would be

$$p + q_i(\mathrm{d}p/\mathrm{d}q) = MC.$$

The sum of n such equations would be

$$np + q(\mathrm{d}p/\mathrm{d}q) = nMC,$$

for $nq_i = q$. This last equation may be written,

$$p = \mathrm{MC} - p/nE,$$

where E is the elasticity of market demand (Cournot 1838, p. 84).

Cournot believed that this condition of competition was fulfilled 'for a multitude of products, and, among them, for the most important products'.

Cournot's definition was enormously more precise and elegant than Smith's so far as the treatment of numbers was concerned. A market departed from unlimited competition to the extent that prices exceeded the marginal cost of the firm, and the difference approached zero as the number of rivals approached infinity. This definition, however, illuminated only the effect of number of rivals on the power of individual firms to influence the market price, on Cournot's special assumption that each rival believed that his output decisions did not affect the output decisions of his rivals. It therefore bore only on what we term market competition.

Cournot did not face the question of the role of information possessed by traders, and this question was taken up by William Stanley Jevons in 1871 in his *Theory of Political Economy*. He characterized a perfect *market* by two conditions:

> (1.) A market, then, is theoretically perfect only when all traders have perfect knowledge of the conditions of supply and demand, and the consequent ratio of exchange; . . . (2.) . . . there must be perfectly free competition, so that any one will exchange with any one else upon the slightest advantage appearing. There must be no conspiracies for absorbing and holding supplies to produce unnatural ratios of exchange. (Jevons 1871, pp. 86, 87)

By perfect knowledge Jevons meant only that each trader in a market knew the price bids of every other trader. The second condition ruled out any joint actions by two or more traders, without his noticing that with knowledge so perfect as to know the behaviour of rivals, there might appear the very conspiracies he ruled out. The two conditions dictated that 'there cannot be two prices for the same kind of article' in a perfect market, which he called the 'law of indifference'.

The merging of the concepts of competition and the market was unfortunate, for each deserved a full and separate treatment. A market is an institution for the consummation of transactions. It performs this function efficiently when every buyer who will pay more than the minimum realized price for any class of commodities succeeds in buying the commodity, and every seller who will sell for less than the maximum realized price succeeds in selling the commodity. A market performs these tasks more efficiently if the commodities are well specified and if buyers and sellers are fully informed of their properties and prices. Also a complete, perfect market allows buyers and seller to act on differing expectations of future prices. A market may be perfect and monopolistic or imperfect and competitive. Jevons's mixture of the two has been widely imitated by successors, of course, so that even today a market is commonly treated as a concept subsidiary to competition.

Edgeworth was the first economist to attempt a systematic and rigorous definition of perfect competition. His exposition deserves the closest scrutiny in spite of the fact that few economists of his time or ours have attempted to disentangle and uncover the theorems and conjectures of the *Mathematical Psychics* (1881), probably the most elusively written book of importance in the history of economics. His exposition was the most influential in the entire literature.

The conditions of perfect competition are stated as follows:

> The *field of competition* with reference to a contract, or contracts, under consideration consists of all individuals who are willing and able to recontract about the articles under consideration . . .
>
> There is free communication throughout a *normal* competitive field. You might suppose the constituent individuals collected at a point, or connected by telephones – an ideal supposition [1881], but sufficiently approximate to existence or tendency for the purposes of abstract science.
>
> A *perfect* field of competition professes in addition certain properties peculiarly favourable to mathematical calculation; . . . The conditions of a *perfect* field are four; the first pair referable to the heading *multiplicity* or continuity, the second to *dividedness* or fluidity.
>
> I. An individual is free to *recontract* with any out of an indefinite number, . . .
> II. Any individual is free to *contract* (at the same time) with an indefinite number;
>
> . . . This condition combined with the first appears to involve the indefinite divisibility of each *article* of contract (if any *X* deal with an indefinite number of *Y*s he must give each an indefinitely small portion of *x*); which might be erected into a separate condition.
>
> III. Any individual is free to *recontract* with another independently of, *without the consent* being required of, any third party, . . .
> IV. Any individual is free to *contract* with another independently of a third party; . . .

The failure of the first [condition] involves the failure of the second, but not vice versa; and the third and fourth are similarly related (Edgeworth 1881, pp. 17–19).

The essential elements of this formidable list of conditions are two:

1. There are an indefinitely large number of independent traders on each side of a market (the Cournot condition).
2. Each trader can costlessly make tentative contracts with everyone (hence the divisibility of commodities) and alter these contracts (recontract) so long as a more favourable contract can be made. The result is perfect knowledge (the Jevonian condition).

Edgeworth gave an intuitive argument for the need for an indefinitely large number of traders on both sides of a market. It proceeds as follows. Let there be one seller and two buyers, and let the seller gain all the benefits of the sale: each buyer is charged the maximum price he would pay rather than withdraw from the market. If now a second seller appears, he will find it advantageous to offer better terms to the two buyers: 'It will in general be possible for *one* of the [sellers] (without the consent of the other), to *recontract* with the two [buyers], so that for all those three parties the recontract is more advantageous than the previously existing contract' (ibid., p. 35). As the numbers of traders on each side increase, the price approaches the competitive equilibrium level where no individual trader can influence it.

A defect in this argument is that it ignores the fact that if the traders on one or both sides of the market, be they 2, or 2000 or 2,000,000, join together they can do better *individually* than by competing. If traders on each side join, however, there will be bilateral monopoly, not competition. Edgeworth gives no reason why the combination of traders fails to take place. Only in modern times has the reason for independent behaviour by rivals been established: the costs of reaching and enforcing agreements on joint action increase with both the number of rivals and the complexity of the transactions. At a certain level – quite possibly with only two traders under some conditions – the costs of joint action exceed the gain to at least some of the traders, and independent behaviour emerges.

Edgeworth's 'conjecture', as it is now often called, that a unique, competitive price would emerge when the number of traders became large, has given rise to a modern literature vast in scope and often highly advanced in its mathematical techniques (for references, see Hildenbrand 1974). One result in this literature is that in the case of a large (infinite) number of traders, no coalition of a portion of the traders can exclude traders outside the coalition from trading at the price-taking equilibrium.

Edgeworth's introduction of the requirement that the commodity or service that is traded be highly divisible is a response to the following problem:

> Suppose a market, consisting of an equal number of masters and servants, offering respectively wages and service; subject to the condition that no man can

> serve two masters, no master employ more than one man; or suppose equilibrium already established between such parties to be disturbed by any sudden influx of wealth into the hands of the masters. Then there is no *determinate*, and very generally *unique*, arrangement towards which the system tends under the operation of, may we say, a law of Nature, and which would be predictable if we knew beforehand the real requirements of each, or of the average, dealer; . . . (Edgeworth 1881, p. 46).

Consider the simple example: a thousand masters will each employ a man at any wage below 100; a thousand labourers will each work for any wage above 50. There will be a single wage rate: knowledge and numbers are sufficient to lead a worker to seek a master paying more than the going rate or a master to seek out a worker receiving less than the market rate. But any rate between 50 and 100 is a possible equilibrium. But if a single worker leaves the market, the wage will rise to 100, and if a single employer withdraws, the wage will fall to 50. This ability of a single trader to affect the price arises because of the lumpiness of the article traded (here a worker's labour for a given period). Once a worker can work for two masters, the withdrawal of one worker in a thousand will reduce the available hours of work per day to each employer by only 8/1000 hours or 4.8 minutes per day, with only negligible influence upon the wage rate. Alternatively, a distribution of wage offers and demands would also eliminate the indeterminacy and market power.

Edgeworth's analysis was limited to competition within a market, and it was left to John Bates Clark to emphasize the need for mobility of resources if the return on each resource was to be equalized in every use.

> . . .there is an ideal arrangement of the elements of society, to which the force of competition, acting on individual men, would make the society conform. The producing organism actually shapes itself about his model, and at no time does it vary greatly from it . . . We must use assumptions boldly and advisedly, make labour and capital absolutely mobile, and letting competition work in ideal perfection. (Clark 1899, pp. 68, 71)

Perfect and free mobility of resources is of course an even more extreme assumption than the other conditions required for perfect competition because there is less reason to believe that free movement of resources is even approached in the real economy. Nor is the assumption of perfect mobility necessary to eliminate monopoly power in a market: in the Victorian age, the price of wheat of Iowa was set in Liverpool even though transportation costs were substantial. The assumption is usually necessary to attain strict equality in the price of a good at every point (the law of one price), although even this is not strictly true (as in the factor price equalization theorem). Clark also demanded that the economy be stationary for perfect competition, a condition we shall return to later.

All the elements of a concept of perfect competition were in place by 1900, and this concept increasingly became the standard model of economic theory thereafter. The most influential statement of the conditions for perfect competition was made by Frank H. Knight in his doctoral dissertation, *Risk, Uncertainty and Profit* (1921). The conditions were stated in extreme form; for example, 'There must be perfect, continuous, costless intercommunication between all individual members of the society' (Knight 1921, p. 78) – so Jones in Seattle would know the price of potatoes and be able costlessly to ship to Smith in Miami a bushel of potatoes at every moment of time.

Of course these conditions are not *necessary*, but only sufficient, to achieve the competitive equilibrium. For example, if even a considerable fraction of buyers knows that seller A is charging more than B for a given commodity, their patronage may be quite enough to force A to reduce his price to that of B. Nor are the various conditions independent of one another: for example, if it is very cheap for either a commodity or its buyers or sellers to move between two places, that will insure that the prices in the two places will be widely known.

Along with the development of the concept of competition as a standard component of the theory of prices and the allocation of resources, it acquired a growing role as the criterion by which to judge the efficiency of actual markets. Adam Smith had already advanced the proposition that output was maximized in a private enterprise economy with competition. If each owner of a

resource maximized the return from his resources, then (in the absence of 'external' effects of one person's actions on others) aggregate output would be maximized. This theorem (labelled 'on maximum satisfaction') was developed and qualified by Léon Walras (1874), Alfred Marshall (1980), Pareto (1895–6, 1907), Pigou (1912) and a host of modern economists.

Competition is much too central a concept in economics to remain unaffected when economists change their interests or analytical methods. We may illustrate this fact by the problem of economic change.

In a regime of change, of growing population and capital or innovations or new consumer demands, the problem of defining competition is much more difficult than it is for the stationary economy. Unless the change is predictable with precision, knowledge must necessarily be incomplete and errors and lags in adaptation to new conditions can be large. For this reason, indeed, J.B. Clark believed that perfect competition was achievable only in the stationary economy.

Even short-run changes in market price raise the question: is the change in price initiated by a particular seller or buyer, and if so, is this trader not facing a negatively sloping demand curve or a positively sloping supply curve? The infinitely elastic supply and demand curves of perfectly competitive equilibrium seem inapplicable to periods of changing market conditions. Some economists nevertheless retain the condition that individual traders cannot influence price by introducing a hypothetical auctioneer who announces price changes.

A partial adaptation of the competitive concept to change is made by making it a long-run equilibrium concept. Even if resources are not costlessly mobile and even if entrepreneurs do not have perfect foresight, one can analyse the rate of approach of returns on resources to equality. If an industry experiences a once-for-all large change, it could be in competitive equilibrium before and after the change, and the equilibria could be studied by competitive theory (comparative statics).

This adaptation did not satisfy Joseph Schumpeter, who believed that incessant change in products and production methods was the very essence of competitive capitalism. He argued that the displacing of one product or method by another, a process which he called creative destruction, made the concept of perfect competition irrelevant to either positive analysis or welfare judgements. If the monopoly that reduced output, compared to competition, by 10 per cent in one year, increased output by 100 per cent over the next two decades, then monopoly might be preferred to stagnant competition.

It is crucial to this argument that monopoly provides large, though temporary, rewards to successful innovators but competition does not:

> But perfectly free entry into a *new* field may make it impossible to enter it at all. The introduction of new methods of production and new commodities is hardly conceivable with perfect – and perfectly prompt – competition from the start. And this means that the bulk of what we call economic progress is incompatible with it. As a matter of fact, perfect competition is and always has been temporarily suspended whenever anything new is being introduced – automatically or by measures devised for that purpose – even in otherwise perfectly competitive conditions. (Schumpeter 1942, pp. 104–5)

Schumpeter relies on instantaneous rivalry to eliminate the incentives to innovation under competition, and the conclusion would not hold if competition is defined in terms of long-run equilibrium.

Nevertheless the issue is not disposed of so easily. If change is continuous rather than sporadic, long-run equilibria will never be fully achieved. Several economists have emphasized that alterations in the concept of competition are called for in periods of historical change. Kirzner has emphasized the role of entrepreneurial rivalry in competition, whereas such rivalry is nonexistent in a perfectly competitive equilibrium. Demsetz has proposed a concept of laissez-faire competition, in which freedom of resources to move into any use is the central element. Such realistic reversions to the competitive concept of the classical economists have not been systematically formalized into theoretical models.

The concept of perfect competition, or indeed any theoretically precise concept of competition,

will not be met by the actual condition of competition in any industry. John Maurice Clark made the most influential effort to create a concept of 'workable competition' which would serve as a working rule for public policies which seek to preserve or increase competition.

Clark emphasized the fact that if one requisite of perfect competition is absent, it may be desirable that a second requisite also be unfulfilled. For example, with instantaneous mobility but imperfect knowledge, members of an occupation would keep shifting back and forth between two cities, always overshooting the amount of migration which would equalize wage rates. This propensity to overshoot equilibrium would be corrected with less mobility of labour. This problem was later formalized as the theory of the 'second best'.

The essence of the concept of workable competition was the belief that 'long- run curves, both of cost and of demand, are much flatter than short-run curves, and much flatter than the curves which are commonly used in the diagrams of theorists' (J.M. Clark 1940, p. 460). This correct and sensible view led to a proliferation of studies, usually in doctoral dissertations, of individual industries, in which the workableness of competition in each industry was appraised. Unfortunately there were no objective criteria to guide these judgements, and there was no evidence that the studies were accepted by the governmental agencies which administered competitive policies.

The popularity of the concept of perfect competition in theoretical economics is as great today as it has ever been. The concept is equally popular as first approximation in the more concrete studies of markets and industries that comprise the field of 'industrial organization' (applied microeconomics). The limitations of the concept in dealing with conditions of persistent and imperfectly predicted change will not be removed until economics possesses a developed theory of change. Even within a stationary economic setting the concept is being deepened by mathematical economists (see Mas-Colell 1982). Meanwhile the central elements of competition – the freedom of traders to use their resources where they will, and exchange them at any price they wish – will continue to play a major role in the economics of an enterprise economy.

Competition and Efficiency

John C. Panzar

The association between economic efficiency and competition goes back at least as far as Adam Smith's 'invisible hand' metaphor. Indeed, a goodly portion of the vast body of subsequent work in value theory has dealt with the normative issues arising from the workings of the competitive economy. Thus any short essay on the topic must be somewhat idiosyncratic, focusing upon the points which are of greatest interest to the author. Therefore, I shall limit my attention to the properties of the (static, partial equilibrium) *economic model* of perfect competition and how its use has recently been extended to add to our understanding of a larger range of real world markets. I must leave to others the tasks of sorting out the importance of competition in, for example, the Schumpeterian process of 'creative destruction', the aggregation and transmission of society's stock of information, or the evolutionary progress of technological advance. Fortunately for my purposes, the historical development of the competitive model has been thoroughly analysed by Stigler (1957). The formulation of the model, as we know it today, was completed in the work of Knight (1921). It is interesting to note that the last refinement to be added was the free mobility of resources across industries: i.e. the entry and exist of firms. In his insightful concluding section, Stigler points out that competition can flourish *within* a market without this last ingredient. (Consider an agricultural market with Ricardian rents.) He suggested that the term 'market competition' be used to describe such situations, and that the term 'industrial competition' be applied when mobility across industries is present. The work that I shall discuss deals with the converse possibility: perfectly contestable markets, situations in which competition may not necessarily exist within a particular market, but firms (and resources) are assumed to be perfectly mobile across industries.

The role of entry and exit in assuring the equalization of returns across markets is not logically limited those cases in which it is technologically feasible for the market to be populated by a large number of firms, each capable of achieving an efficient scale of operation. It may be expected that the lure of profits might serve to make relevant certain aspects of competitive theory even under conditions of 'natural monopoly'. The most striking practical illustration of this point was the recent deregulation of airlines in the United States. This took place, in part, because the free mobility of resources (aircraft) across markets led policy makers to believe that satisfactory economic performance could be achieved without the stultifying effects of economic regulation. This, despite the fact that most city-pair airline markets are natural monopolies and none can be expected to support the large numbers of firms required by the perfectly competitive model. Thus the need to extend at least part of the competitive paradigm to incorporate such cases had become apparent.

In a classic article, Demsetz (1968) set forth one way to break the commonly perceived link between monopoly provision of certain increasing returns services and monopoly conduct on the part of the firm providing the service at any point in time. By pointing out that the impossibility of competition within the market need not preclude effective competition *for the market*, Demsetz raised a fundamental challenge to the conventional wisdom that the only effective ways to deal with a technological natural monopoly were through economic regulation or public enterprise.

Demsetz chose to elaborate this idea in the context of a franchise bidding scheme, in which the franchise was to be awarded, not to the firm offering the greatest lump sum payment to the municipal coffers, but to the firm offering to

serve the market at the lowest price. Subsequent authors have criticized this as a policy proposal, focusing on the problems raised by considerations of sunk costs and incomplete contracts, from which Demsetz explicitly sought to abstract. However, there is another sense in which the franchise bidding example may have been an unfortunate expository choice. Because it introduced a new institution between the firm and the market – the franchise auctioneer – this illustration may have obscured the link between the analysis of competition for the market and the earlier notion of the role of free entry and exit in ensuring effective industrial competition. Furthermore, Demsetz's simple bidding scheme cannot handle the realistic cases in which the monopolist produces two or more technologically related services.

The theory of contestable markets developed by Baumol et al. (1982) is most usefully viewed as an attempt to extend the neoclassical (partial equilibrium) theory of long-run competitive equilibrium to the case of increasing returns to scale. In so doing, they developed a model which achieved the Demsetz solution to the monopoly problem as the result of a market equilibrium process. This extension was accomplished by emphasizing the role played by potential entry in characterizing the role defining properties of long-run competitive equilibrium. To see this reinterpretation most clearly, the following definitions are necessary:

Definition 1 A Feasible Industry Configuration (FIC) is a collection of firms, $i = 1, \ldots, m$ output vectors for each, $y^1, \ldots, y^m$; and a market price vector p such that each firm earns non-negative profits and the total quantity supplied equals the quantity demanded; i.e. $py^i - C(y^i) \geq 0$, for all $i = 1, \ldots, m$ and $\sum y^i = D(p)$, where C is the (multiproduct) minimum cost function and D the market demand function.

Feasibility surely reflects the minimal conditions one would expect to prevail in long-run industry equilibrium in a private enterprise economy: All firms must earn non-negative profits and the total quantity supplied by firms equals the amount demanded by consumers at the market price. While feasibility requires financial viability, it does not preclude the positive profits which may attract entry. Therefore, the neoclassical notion of long-run competitive equilibrium must encompass some additional restrictions. More specifically,

Definition 2 A long-run competitive equilibrium is any FIC which also has the property that $py - c(y) \leq 0$ for all y.

While this characterization of long-run competitive equilibrium may be unfamiliar, it is equivalent to the standard notion of price taking firms earning zero economic profits by equating marginal cost to price. (To see this, note that since profits are nonpositive for all output levels, the fact that $py^1 - C(y^i) \geq 0$ means that output level y^i maximizes the ith firm's profits. This, in turn, implies that $MC(y^i) = p$ if firm i is producing.)

Characterizing competitive equilibrium via Definitions 1 and 2 has the advantage of focusing attention on the role played by potential entry. The strictures of Definition 2 can be interpreted to mean that the firms in an industry in long-run competitive equilibrium act as if they were policed by potential entrants prepared to enter the market in pursuit of any profit opportunity calculated at current market prices. While this lack of attention to the possibility of retailatory price responses by rivals reflects the noncooperative spirit of the competitive paradigm, it ignores the response of consumers to a change in the market price. Therefore it is useful to consider making potential entrants 'less optimistic' in the following sense:

Definition 3 A Sustainable Industry Configuration (SIC) is any FIC which also satisfies the condition that $p^e y^e - C(y^e) \leq 0$ for all $p^e \leq p$ and $y^e \leq D(p^e)$.

Thus firms in a SIC behave as if the market were policed by potential entrants that calculate the profitability of entry under the assumption that incumbent firms' prices remained unchanged, but that do take account of the reality that consumers can be induced to purchase a larger quantity only at a lower price. Put another way, an FIC is also an SIC when no potential

entrant can anticipate earning a positive profit by quoting a price at or below that prevailing in the market and serving all or a part of the resulting demand. The following semantic clarification completes the characterization of a contestable market:

Definition 4 A perfectly contestable market is one in which perfectly free entry and exit ensure that the only possible long-run equilibria are SICs.

An immediate implication of Definitions 1, 2, 3, and 4 is:

Proposition 1 Any long-run competitive equilibrium is an SIC, but not conversely. Thus all perfectly competitive markets are perfectly contestable, but not all perfectly contestable markets are perfectly competitive.

The proof follows from the fact that the conditions which an FIC must satisfy in order to be a long-run competitive equilibrium are stronger than those required of an SIC. Thus a long-run competitive equilibrium is, by construction, an SIC. To see that the converse is not true, consider the case in which the average costs of production fall throughout the relevant range; i.e. at least as far as the intersection of the average cost curve and the market demand curve. The point of intersection, the Demsetz outcome, characterizes a sustainable industry configuration, since profits are non-positive and no point on or below the demand curve can yield non-negative profits at a lower price. However this outcome is clearly not a long-run competitive equilibrium because price is equal to average cost which, by hypothesis, is strictly greater than marginal cost. The above demonstration points out the fact that the concept of contestable markets can be applied beyond the large-numbers case of perfect competition. However it also raises questions about the efficiency properties of such markets. The fact that equilibrium may involve a price greater than marginal cost means that the First Best optimality properties of the competitive model need no longer apply. What efficiency properties, then, *can* be associated with equilibria in contestable markets? In the case of single product markets it is intuitively clear (and straightforward to prove) that, when they exist, sustainable industry configurations are solutions to the Second Best optimization problem: maximize welfare (as measured, for example, by the sum of producers' and consumers' surpluses) subject to the constraint that firms earn non-negative profits. Clearly, when increasing returns to scale render marginal cost pricing unprofitable, the best that can be done, in the absence of lump sum transfers and discriminatory or non-linear pricing, is to set price equal to average cost.

However, even this level of performance can no longer be guaranteeed once one moves to the realistic realm of multiple products. For example, a monopolist producing two or more products can, in general, find an infinite number of price combinations which will yield it exactly zero economic profits. Some of these prices and resulting market demand quantities may represent SICs. Call this set *P*. If the underlying cost and demand functions are sufficiently well-behaved, there will exist a unique constrained welfare maximizing price vector p^*. The most desirable efficiency result would be for the set P to consist of the single element p^*. Unfortunately, it is easy to construct examples in which P does not contain p^*, as well as cases in which P is empty. What efficiency properties does this generalized process of industrial competition possess when extended beyond the realm of perfect competition? The results that pertain generally lie entirely on the cost side.

Proposition 2 In any SIC, the industry's output is divided among the firms in a way that minimizes total industry costs.

The proof is by contradiction. Consider an initial SIC composed of m firms producing output vectors, $y^1, \ldots, y^m$, at market prices p. Suppose, contrary to hypothesis, that there exists an alternative group of k firms with output vectors, $z^1, \ldots, z^k$, that could produce the current industry output at a lower total cost. That is $\sum_j z^j = D(p) = \sum_i y^i$, but $\sum_j C(z^j) < \sum_i C(y^i)$. Then the new group, in total, would earn positive economic profits at the initial price p. This is true because, by hypothesis, total revenues would be equal, but total costs would be lower for the alternative group, while the initial

group of firms must have been earning non-negative profits. Therefore at least one firm, say firm j, in the alternative group would anticipate earning strictly positive profits at the price vector p. But then there exists an entry plan $p^e = p \leq p$ and $y^e = z^j \leq D(p^e)$ such that $p^e y^e - C(y^e) > 0$, which contradicts the hypothesis that the initial group of firms constituted a SIC.

Additional efficiency results for contestable markets are presented in chapter 11 of Baumol, Panzar and Willig. Here, I shall mention specifically a class of results which are relevant only in the multiproduct context. One implication of the fact that equilibrium in a contestable market presents no profit opportunities for potential entrants is that no subset of services of a multiproduct enterprise can generate revenues in excess of the cost of providing them alone. Thus, equilibrium in perfectly contestable markets cannot involve one gorup of services subsidizing another. Whether or not this property is a desirable efficiency result is unclear. Consider, for example, a situation in which a monopoly firm uses common facilities to produce two services, one of which has a very elastic demand curve while that of the other is very inelastic. Maximizing total surplus subject to a break-even constraint leads to the well-known inverse elasticity rule: the markup of price over marginal cost is greater for services whose demand is least elastic. However, this pricing policy may easily lead to revenues from the inelastic service in excess of the cost of providing it alone. Such an outcome would not be an SIC and could not persist in a perfectly contestable market. Thus while the mobility of firms and resources can, even without the presence of market competition, ensure productive efficiency, it cannot in general guarantee that an optimal relationship of output prices in a multiproduct industry will prevail outside the perfectly competitive realm.

Competition and Selection

Sidney G. Winter

Abstract

The claim that a business firm must maximize profit if it is to survive serves as an informal statement of the common conclusion of a class of theorems characterizing explicit models of economic selection processes. Such models, by making explicit the strong assumptions needed to generate this sort of result, are the basis for a critique of standard economic theory which relies on competitive equilibrium. Models of Schumpeterian competition, emphasizing the centrality of innovation, plainly provide a much better description of the world we live in than do models of static equilibrium.

Under competitive conditions, a business firm must maximize profit if it is to survive – or so it is often claimed. This purported analogue of biological natural selection has had substantial influence in economic thinking, and the proposition remains influential today. In general, its role has been to serve as an informal auxiliary defence, or crutch, for standard theoretical approaches based on optimization and equilibrium. It appeared explicitly in this role in a provocative passage in Milton Friedman's famous essay on methodology (Friedman 1953, ch. 1), and it seems that many economists are familiar with it in this context only.

There is, however, an alternative role that the proposition can and does play. It serves as an informal statement of the common conclusion of a class of theorems characterizing explicit models of economic selection processes. A model in this class posits, first, a range of possible behaviours for the firm. This range must obviously extend beyond the realm of profit maximization if the conclusion of the argument is to be non-trivial, and it must include behaviour that is appropriately termed 'profit maximizing' if the conclusion is to be logically attainable at all. The model must also characterize a particular dynamic process that in some way captures the general idea that profitable firms tend to survive and grow, while unprofitable ones tend to decline and fail. A stationary position of such a process is a 'selection equilibrium'.

Models of this type occupy an important but non-central position in evolutionary economic theory (Nelson and Winter 1982). They establish that the equilibria of standard competitive theory can indeed be 'mimicked' (in several different senses) by the equilibria of selection models. More importantly, by making explicit the strong assumptions that apparently are required to generate this sort of result, they are the basis for a critique of its generality and an appraisal of the strength of the crutch on which standard theory leans. They also provide a helpful entry-way to the much broader class of evolutionary models in which mimicry results fail to hold. This entry-way has the convenient feature that the return path to standard theory is well marked; the sense in which evolutionary theory subsumes portions of standard theory becomes clear.

The concept of competition need not, of course, be considered only in the context of perfectly competitive equilibrium. In a broader sense of the term, any nontrivial selection model in which the 'fit' prosper and the 'unfit' do not is a model of a 'competitive' process. The process need not have a static equilibrium, or any equilibrium, and it may easily lead to results that are clearly non-competitive by the standards of industrial organization economics.

The remainder of this essay first considers in more detail the theoretical links between selection processes and competitive equilibrium outcomes. It then examines a more interesting and less well-explored area that involves selection and, in a broad sense, competition; Schumpeterian competition.

Competitive Equilibrium as a Selection Outcome

The intention here is to describe the heuristic basis of existing examples of this type of theorem, or, alternatively, to describe the basic recipe from which an obviously large class of broadly similar results could be produced. There may be other basic recipes, as yet unknown. There certainly are ways to ignore individual instructions of the recipe and yet preserve the result, though at the cost of delicately contrived adjustments in other assumptions.

(To avoid confusion, it should be noted at the outset that the word 'equilibrium' is used in two different senses in this discussion, the 'no incentives to change behaviour' sense employed in economic theory and the 'stationary position of a dynamic process' sense that is common outside of

economics. The point of the discussion is, in fact, to relate these two equilibrium ideas in a particular way.)

(1) Constant returns to scale must prevail in the specific sense that the supply and demand functions of an individual firm at any particular time are expressible as the scale (or 'capacity') of that firm at that time multiplied by functions depending on prices, but not directly on scale or time. Increasing returns to scale must be excluded for familiar reasons. Decreasing returns must be excluded because they will in general give rise to equilibrium 'entrepreneurial rents' which could be partially dissipated by departures from maximization without threatening the survival of the firm. Thus, for example, the U-shaped long run average cost curve of textbook competitive theory does not provide a context in which selection necessarily mimics standard theory if competitive equilibrium would require some firms to be on the upward sloping portion of the curve.

(2) Firms must increase scale when profitable and decrease scale (or go out of business entirely) when unprofitable. Alternatively, profitability of a particular firm must lead to entry by perfect imitators of that firm's actions. In the absence of such assumptions, it is plain that there will in general be equilibria with non-zero profit levels, which under assumption (1) cannot mimic the competitive result. While the 'decline or fail' assumption is a plausible reflection of long-run breakeven constraints characteristic of actual capitalist institutions, no such realistic force attaches to the requirement that profitability lead to expansion. If firms do not pursue profits in the long-run sense of expanding in response to positive profitability, stationary positions may involve positive profits. Such stationary positions fail to mimic competitive equilibria for that reason alone (given constant returns), but they also introduce once again the possibility that the short-run behavioural responses of surviving firms may dissipate some of the positive profit that is potentially achievable at selection equilibrium scale.

In standard theory, expansion in response to profitability may be seen as an aspect of the firm's profit-seeking on the assumption that it regards prices as unaffected by its capacity decisions. In turn, this ordinarily requires that the firm in question be but one of an indeterminately large number of firms that all have access to the same technological and organizational possibilities.

While the assumption that firms have identical production sets and behavioural rules is common and appears inoffensive in orthodox theorizing, it is very much at odds with evolutionary theory. The orthodox view comes down to the assertion that all productive knowledge is freely available to one and all – perhaps it is all in the public library. By contrast, evolutionary theory emphasizes the role of firms as highly individualized repositories of productive knowledge, not all of which is articulable. From the evolutionary perspective, the fact that mimicry theorems rely on assumptions of unimpaired access to a public knowledge pool is by itself sufficient to make it clear that the selection argument can provide only a weak and shaky crutch for standard competitive theory.

(3) A firm that is breaking even with a positive output at prevailing prices must not alter its behaviour; a potential entrant that would only break even at prevailing prices must not enter. This assumption is needed to assure that the competitive equilibrium position is in fact a stationary position of the selection process.

Models of natural selection in biology do not typically involve this sort of assumption, but neither do they conclude that only the fittest genotypes survive – the biological analogue of the proposition discussed here. Rather, they show how constant gene frequencies come to prevail as the selection forces that tend to eliminate diversity come into balance with mutation forces that constantly renew it. A strictly analogous treatment of economic selection would be much more appealing than the sort of result discussed here.

It would admit that occasional disruptions may arise from random behavioural change, or from over-optimistic entrants. Thus, potentially at least, it could better serve the purpose of establishing the point that the results of standard competitive theory are in some sense robust with respect to its behavioural assumptions. Unfortunately, standard theory offers no clue as to what this sense might be. It is plain that the adjustment processes of the system are centrally involved, and there is no behaviourally plausible theory of adjustment that is the dynamic counterpart in the disciplinary paradigm of static competitive equilibrium theory.

Within the limits defined by the requirement for a strictly static competitive outcome, the most plausible approach combines the idea of characterizing the firms in the selection process by their 'rules of behaviour' – an idea advanced in a seminal paper by Armen Alchian (1950) – with Herbert Simon's idea of satisficing (1955). In the simplest version, each firm simply adheres unswervingly to its own deterministic behavioural rule (or 'routine', in the language of Nelson and Winter 1982). Such a rule subsumes or implies the firm's supply and demand functions, and given the conditions set forth in (1) and (2) above, a constant environment evokes a constant response. Satisficing may be introduced as a complication of this picture by an assumption that a firm that sustains losses over a period of time will search for a better behavioural rule; this adds behavioural plausibility to the adjustment process but does not introduce the possibility that random rule change might disrupt an otherwise stationary competitive equilibrium position.

(4) The final requirement can be succinctly but inadequately stated as 'some firms must actually be profit maximizers'. Although this formulation does adequately cover some simple cases, it does not suggest the depth and subtlety of the issues involved.

Two points deserve particular emphasis here. The first is the distinction between profit maximizing *rules of behaviour* (functions) and profit maximizing *actions.* In general, a selection equilibrium that mimics a particular competitive equilibrium must clearly be one in which some firms take actions that are profit maximizing in that competitive equilibrium, and in this sense are profit maximizers. But this observation does not imply that the survivors in the selection equilibrium possess maximizing *rules*, and in general it is not necessary that survivors be maximizers in this stronger sense. (Proof: Consider a competitive equilibrium with constant returns to scale. Restrict the firms' supply and demand functions to be constant up to a scale factor at the values taken in the given equilibrium. Embed this static equilibrium in a dynamic adjustment system in which firms' scales of output respond to profitability in accordance with assumption (2). Then the given competitive equilibrium becomes a selection equilibrium – since the only techniques in use make zero profit – but the firms are not profit maximizers in the stronger sense.)

The second point extends the first. The notion of profit maximizing behavioural rules itself rests on the conceptual foundation of a production set or function that is regarded as a given. In evolutionary theory, however, it is the rules themselves that are regarded as data and as logically antecedent to the values (actions) they yield in particular environments. Thus, in this context, a problem arises in interpreting the basic idea of a selection equilibrium mimicking a standard competitive one: there is no obvious set of 'possibilities' to which one should have reference.

The most helpful approach here emphasizes internal consistency. Assumptions about the structure of what is 'possible' can be invoked without the additional assumption that there is a given set of possibilities – for example, additivity and divisibility may be assumed without implying that the set of techniques to which these axioms apply is a given datum of the system. Such an approach provides a basis for discussing whether a particular selection equilibrium is legitimately *interpretable* as a competitive equilibrium given the other assumptions in force. Along this path one can explore a rich variety of selection equilibrium situations that may be thought of as competitive equilibria. Precisely because the variety is so rich, to know only that an outcome is interpretable in this fashion is to know very little about it.

In the light of formal analysis of selection models of the sort described above, how strong is the crutch that selection provides to standard theory? For many analytical purposes, it is a crucial weakness that the crutch relates only to equilibrium actions and not to behavioural rules; it is from the knowledge that the rules are maximizing that the results of comparative statics derive. A selection system disturbed by a parameter change from a 'mimicking' equilibrium does not necessarily go to a new 'mimicking' equilibrium, let alone to one that is consistent, in standard theoretical terms, with the information revealed in the original equilibrium. More fundamentally, selection considerations cannot compensate for the inadequacies of standard theory that arise from the basic assumption that production possibilities are given data of the system.

Schumpeterian Competition

In two great works and in many other writings, Joseph Schumpeter proclaimed the central importance of innovative activity in the development of capitalism. His early book, *The Theory of Economic Development,* focused on the role and contribution of the individual entrepreneur. From today's perspective the work remains enormously insightful and provocative but may seem dated; the image of the late 19th-century captains of industry lurks implicitly in the abstract account of the entrepreneur. The late work, *Capitalism, Socialism and Democracy*, is likewise insightful, provocative and a bit anachronistic. In this case, the anachronism derives from the predictions of a future in which the innovative process is bureaucratized, the role of the individual entrepreneur is fully usurped by large organizations, and the sociopolitical foundations of capitalism are thereby undercut. Present reality does not correspond closely to Schumpeter's predictions, and it seems increasingly clear that he greatly underestimated the seriousness of the incentive problems that arise within large organizations, whether capitalist corporations or socialist states.

Substantial literatures have accumulated around a number of specific issues, hypotheses and predictions put forward in Schumpeter's various writings. Regardless of the verdicts ultimately rendered on particular points, everyday observation repeatedly confirms the appropriateness of his emphasis on the centrality of innovation in contemporary capitalism. It confirms, likewise, the inappropriateness of the continuing tendency of the economics discipline to sequester topics related to technological change in subsectors of various specialized fields, remote from the theoretical core.

The purpose of the present discussion is to assess the relationships of selection and competition from a Schumpeterian viewpoint, that is, to extend the discussion above by considering what difference it makes if firms are engaged in inventing, discovering and exploring new ways of doing things. Plainly, one difference it makes is that 'competition' must now be understood in the broad sense that admits a number of additional dimensions to the competitive process, along with price-guided output determination. In particular, costly efforts to innovate, to imitate the innovations of others, and to appropriate the gains from innovation are added to the firm's competitive repertoire.

Selection now operates at two related levels. The organizational routines governing the use made of existing products and processes in every firm interact through the market place, and the market distributes rewards and punishments to the contenders. These same rewards and punishments are also entries on the market's scorecard for the higher level routines from which new products and processes derive – routines involving, for example, expenditure levels on innovative and imitative R&D efforts. Over the longer term, selection forces favour the firms that achieve a favourable balance between the rents captured from successive rounds of innovation and the costs of the R&D efforts that yield these innovations.

In formal models constructed along these lines, it is easy to see how various extreme cases turn out. One class of cases formalizes the cautionary tale told by Schumpeter (1950, p. 105), in which competition that is 'perfect – and perfectly prompt' makes the innovative role non-viable.

Sufficiently high costs of innovation and low costs of imitation (including costs of surmounting any institutional barriers such as patents) will lead to the eventual suppression of all firms that continue to attempt innovation, and the system will settle into a static equilibrium. (The character of this equilibrium may, however, depend on initial conditions and on random events along the evolutionary path; the production set ultimately arrived at is an endogenous feature of the process.) One can also construct model examples to illustrate the cautionary message 'innovate or die', the principal requirement being simply a reversal of the cost conditions stated above.

With the exception of some extreme or highly simplified cases, models of Schumpeterian competition describe complex stochastic processes that are not easily explored with analytical methods. Of course, the activity of writing down a specific formal model is often informative by itself in the sense that it illuminates basic conceptual issues and poses key questions about how complex features of economic reality can usefully be approximated by a model. Some additional insight can then be obtained using simulation methods to explore specific cases (Nelson and Winter 1982, Part V; Winter 1984). One of the most significant benefits from simulation is the occasional discovery of mechanisms at work that are retrospectively 'obvious' and general features of the model.

The discussion that follows pulls together a number of these different sorts of insights, emphasizing in particular some issues that do not arise in the related theoretical literature that explores various Schumpeterian themes using neoclassical techniques (For the most part these neoclassical studies explore stylized situations involving a single possible innovation, and thus do not address issues relating to the cumulative consequences of dynamic Schumpeterian competition. See Kamien and Schwartz (1981) and Dasgupta (1985) for references and perspectives on this literature.)

A fundamental constituent of any dynamic model of Schumpeterian competition is a model of technological opportunity. Such a model establishes the linkage between the resources that model firms apply to innovative effort and their innovative achievements. The long run behaviour of the model as a whole depends critically on the answers provided for a set of key questions relating to technological opportunity. Does the individual firm face diminishing returns in innovative achievement as it applies additional resources over a short period of time? If so, from what ' fixed factors' does the diminishing returns effect arise, and to what extent are these factors subject to change over time either by the firm's own efforts or by other mechanisms? Are selection forces to be studied in a context in which technological opportunity presents more or less the 'same problem' for R&D policy over an extended period, or is the evolutionary sorting out of different policies for the firm a process that proceeds concurrently with historical change in the criteria that govern the sorting?

Technological opportunity is said to be *constant* if R&D activity amounts to a search of an unchanging set of possibilities – in effect, there is a meta-production set or meta-production function that describes what is ultimately possible. *Increasing* technological opportunity means that possibilities are being expanded over time by causal factors exogenous to the R&D efforts in question – implying that, given a level of technological achievement and a level of R&D effort, the effort will be more productive of innovative results if applied later. With constant technological opportunity, returns to R&D effort must eventually be decreasing, approaching zero near the boundary of the fixed set of possibilities.

It is all too obvious that it may be very difficult to develop an empirical basis for modelling technological opportunity in an applied analysis of a particular firm, industry or national economy. There is no easy escape from the conundrum that observed innovative performance reflects both opportunity and endogenously determined effort, not to mention the fact that neither performance nor effort is itself easily measured or the even more basic question of whether analysis of the past can illuminate the future. These difficulties in operationalizing the concept of technological opportunity do not, unfortunately, in any way diminish its critical role in Schumpeterian competition.

The evolutionary analysis of Schumpeterian competition has not, thus far, produced any counterpart for the sorts of mimicry theorems that can be proved for static equilibria. That is, there is no model in which it can be shown that selection forces, alone or in conjunction with adaptive behavioural rules, drive the system asymptotically to a path on which surviving firms might be said to have solved the remaining portion of the dynamic optimization problem with which the model situation confronts them – except in the cases where the asymptotic situation is a static equilibrium with zero R&D. The list of identified obstacles to a non-trivial positive result is sufficiently long, and the obstacles are sufficiently formidable, so as to constitute something akin to an impossibility theorem. It seems extremely unlikely that a positive result can be established within the confines of an evolutionary approach – that is, without endowing the model firms with a great deal of correct information about the structure of the total system in which they are embedded.

The most formidable obstacle of all derives from the direct clash between the future-oriented character of a dynamic optimization and the fact that selection and adaptation processes reflect the experience of the past. If firms cannot 'see' the path that technological opportunity will follow in the future, if their decisions can only reflect past experience and inferences drawn therefrom, then in general they cannot position themselves optimally for the future. They might conceivably do so if the development of technological opportunity were simple enough to validate simple inference schemes. Such simplicity does not seem descriptively plausible; who is to say that it is implausible that in a particular case technological opportunity might be constant, or exponentially increasing, or following a logistic, or some stochastic variant of any of these? And without some restriction on the structural possibilities, how are model firms to make inferences to guide their R&D policies?

This obstacle is not featured prominently in the simulations reported by Nelson and Winter, which are largely confined to very tame and stylized technological regimes in which opportunity is summarized by a single exponentially increasing variable, called 'latent productivity'. Such an environment, reminiscent in some ways of neoclassical growth theory, seems at first glance to be a promising one for the derivation of a balanced growth outcome in which actual and latent productivity are rising at the same rate, the problem facing the firms is in a sense constant, and selection and adaptation might bring surviving firm R&D policies to optimal values.

In fact, such a result remains remote even under the very strong assumption just described. Demand conditions for the product of the industry (or the economy) affect the long run dynamics, and in this area also assumptions must be delicately contrived to avoid excluding a balanced growth outcome. For example, consider an industry model with constant demand in which demand is (plausibly) less than unit elastic at low prices. Then, cost reduction continued indefinitely would drive sales revenue to zero. Zero sales revenue will not cover the cost of continuing advance. What is involved here is a reflection of the basic economics of information; costs of discovery are independent of the size of the realm application, and on the assumption stated the economic significance of that realm is dwindling to nothing. The implication is that demand conditions may check progress even if technological opportunity is continually expanding. Indeed, this may well be the pattern that is typically realistic for any narrowly defined sector.

This difficulty too can be dispatched by an appropriately chosen assumption. Beyond it lie some further problems. A model that acknowledges the partially stochastic nature of innovative success will display gradually increasing concentration (Phillips 1971), unless some opposing tendency is present. A good candidate for an opposing tendency is the actual exercise of market power that has been acquired by chance (Nelson and Winter 1982, ch. 13). But this market power can, presumably, also shelter various departures from present value maximization, including departures from dynamically optimal R&D policy.

To reiterate, the quest for mimicry theorems in the context of Schumpeterian competition seems foredoomed to failure. Since models of

Schumpeterian competition plainly provide a much better description of the world we live in than do models of static equilibrium, the overall conclusion with regard to the strength of the selection crutch is distinctly more negative than the conclusion for static models alone. Assumptions that firms maximize profit or present value will have to stand on their own, at least until somebody invents a better crutch for them. In the meantime, it will continue to be the case that predictions based on these assumptions are sometimes sound and sometimes silly, and standard theory does not offer a means of discriminating between the cases. More direct attention should be paid to the mechanisms of selection, adaptation and learning, which among them probably account for as much sense as economists have actually observed in economic reality, and also leave room for a lot of readily observable nonsense.

Competition in International Trade

D. K. Stout

In international markets the equivalent of the owned assets and the skills of individuals and firms in internal markets is the difference in relative national resource endowments. In elementary theory, the effects of international competition are defined by comparison with an initial state of no trade. The typical question addressed is 'What will happen if trade is opened up?' On this view, international competition 'causes' trade because of the differences there would be, in the absence of trade, in the relative costs of production of pairs of goods in two countries. And the effect of international competition, and the ensuing trade, is to have ironed out some of these differences and to have increased in the process the aggregate equilibrium output of each good.

In each country, initially, the cheaper good is the one whose production technology calls for a lot of the input that is relatively plentiful there. When trade is opened up, the producers of the dearer commodity in each country face competition from the country better suited to produce it. Through international competition, differences in the relative scarcity (and cost) of labour, land and capital and consequent differences in the ratio of the price of, say, food to the price of, say, machinery are lessened. With the growth of multinational companies (MNCs), choices are made between competing by offering products (i.e. by exporting) and by licensing domestic producers overseas or setting up subsidiary companies to produce and market on the spot. These choices depend upon the importance of economies of scale in production; transport costs; the costs of transferring capital, technology and management; and upon the restrictions imposed by governments upon the free movement of goods: that is, tariffs, import quotas and other barriers.

If all industries were subject to diminishing returns and perfect competition ruled, with homogeneous products, differences in the factor

endowments of two countries starting to compete would lead to specialization up to the point where, at the margin, the relative costs of each pair of goods were the same in each country. In fact, with increasing returns to scale, equal relative marginal costs are no guarantee of equilibrium. Competitive advantage may accrue to an industry in the country where home demand expands and is protected for a time, so that relative costs fall as output increases. This so-called 'infant industry' case is still the most striking illustration of the inadequacy of simple static theorems about the effects of international competition upon trade flows.

The account of trade flows due to Heckscher and Ohlin (namely that it depends on differing input requirements for different goods and differing input endowments in different countries) remains the most important observation about international competitive advantage.

This model of specialization through trade can be modified to cope quite well with such market imperfections as transport and other transaction costs, limited information, a degree of imperfect competition in factor markets and limited trade barriers. It becomes seriously strained however when one tries to use it to explain the results of international competition in the world of many traders and many commodities. The number of separate 'factors of production' has to be increased to equal the number of traded commodities and defined to suit the observed trade flows. Competitive advantage became something 'revealed', rather than predictable by taking a census of resources. Cheap US skilled labour might be redefined as capital; but since physical capital was also cheap in the US the paradox which Leontief observed – that the US tended to import capital-intensive goods and export labour-intensive – could not be resolved this way.

On another view, out of which grew an alternative and more robust model of international competition, high technology was regarded as complementary to (skilled) labour explaining the bias of US trade. But a theory which relied first on separating factors of production but then required them to be lumped together is not a good theory. Furthermore, competitive advantages were found to be continuously changing in ways that could not be predicted by counting heads or hectares.

In the 1950s and 1960s, when industrial international competition became much more open and many countries were newly industrializing, trade both ways in different variants of the same products grew prodigiously. It has become clear that international competition drives intraindustry trade in imperfectly competitive differentiated markets; that in very many markets today's net exporter is tomorrow's importer; and that international competition involves the international transfer of capital and knowhow as well as of goods.

Something is needed then to supplement the explanation of broad directions of trade advantage in terms of fixed differences in factor endowments and given technology. There has arisen a less determinate, more detailed account of disequilibrium change in trade flows under conditions of imperfect competition. This account makes it clear how international competition leads to two-way flows of trade within the same industry. Where there are economies of scale in each of eight plants, four in each country, producing four variants of one product, a likely outcome is that four of the eight will survive, perhaps two in each country, and in each country the loyal customers of each type will import or buy at home accordingly. *Net* trade flows might be zero but gross trade might be half of total consumption. Or two countries, one rich and one poor, might have developed at home (through domestic competition) lower relative costs in the 'superior' variant in the richer country and in the 'down-market' variant in the poorer country. As trade becomes easier, with cheaper transport and communications or lower tariff barriers, the poor country exports its variant to the poorer consumers in the richer country and vice versa. As incomes grow in both countries, demand in both will shift more and more towards the rich country's variant, and the poorer country loses overall market share.

Where the pressures of competition are leading to successive shifts in state-of-the-art technology in a discontinuous way, competitive advantage may move from the technological leader nation to the fast followers as they acquire this

technology; and back to the leader again with the next major breakthrough, as has been observed in industries as different as radio receivers and textiles.

These models of changing comparative advantage owe much to Joseph Schumpeter. They focus upon the temporary monopoly advantages that accrue to the innovator, extended sometimes by patent protection and economies of scale.

As the technology gap is closed by imitators competing away the monopoly profits, the technological leader nation, like Schumpeter's individual innovator, jumps to new dry steppingstones in today's 'sunrise' industries. The technology gap is moved but kept open.

Whenever this evolution involves new products, it becomes closely linked to a now well-established view of the development of product markets: namely, that products move through a life cycle of youthful growth as comparative luxuries; into explosive growth as they are mass-produced and become available to poorer consumers; into maturity, stagnation and sometimes death as they are superseded by a more efficient or desirable way of satisfying the same underlying needs. As products move through their life cycles, international competitive advantage will tend to shift from developed technological leader economies to newer or poorer industrializing economies, particularly those with large domestic markets allowing home-grown scale economies.

Technology gap and product life-cycle theories do not explain why some economies lead and others follow. The underlying point is that industrial leadership creates a kind of human and physical capital infrastructure, usually reflected in vigorous R&D. This intellectual property is partly external to the individual competitors in the leader economies and acts as a catalyst for new processes and products. There is a virtuous circle at work so long as resources can move freely from yesterday's staples to tomorrow's winners. When structural adaptation is slow, international competition can remove a historical leadership position from an economy whose high relative wages then prevent it from competing later in the cycle with newly-industrializing fast-followers. The UK is an economy, open to fierce international competition, which has lost its place in this way and is rapidly de-industrializing.

The typical market in international trade nowadays is one in which there is a small number of firms each with a strong home base but competing in each other's markets and in third markets. Price cuts are typically quickly matched, so oligopolists compete (and try to secure their segment of the market) by differentiating their products. Cars, clothes and computers are therefore both imported and exported as international competition drives individual producers to specialize.

Much of the most recent work on international competition examines how trade develops under conditions of imperfect competition. Intra-industry trade flows are affected by increasing returns to scale in individual product lines, by product differentiation, by competition in *non-price* terms (design, reliability, durability, variety, packaging, servicing, distribution, delivery speed, advertising) and by the scope for vertically integrated corporations to choose the separate locations of the different stages of production of the final product.

With intra-industry trade specialization, the threat of re-entry into each other's specialisms, as well as the possibilities of new entry, limit monopoly power. Other things being equal, entry is easier where world demand is growing fast and when the background technology is changing fast. Trade under conditions of imperfect competition tends to lead to increasing 'narrow market' specialization but decreasing 'wide market' monopoly power, together with lower costs and equal or greater breadth of consumer choice.

Two final international competition issues are important: the occasionally perverse effects of increased price competitiveness through currency depreciation; and the effect upon trade flows of the competitive options open to MNCs.

Suppose, through successive devaluations, one country's relative unit labour costs fall. (Relative unit labour costs are a better measure of price competitiveness than relative export prices because the latter catch only actual transactions, not lost orders.) The benefit to its trade in manufactures may be short-lived. Orders will come in at

the most price-sensitive end of each of its industrial markets. Since this is usually the less sophisticated end, the nation's industries tend to become less competitive in *non-price* terms: to be impelled to specialize in those product versions whose demand grows least fast as incomes grow. In the longer run, scale economies (and overall market share) may be lost. Paradoxically, devaluation may have its best chance of increasing trade competitiveness when *domestic* competition is limited, so that home currency prices can be raised in price-inelastic markets, and the higher margins be used to overcome *non-price* disadvantages in world markets.

Large firms can move technology, capital and management skills, as well as goods, and change domestic factor supplies by training. International competition drives firms to look for the lowest cost way of creating value-added. It is often cheaper for a MNC to transfer key inputs than to ship final products. Exporting, licensing, local assembly or packaging, joint ventures with local producers, and complete local production and marketing are alternative modes of international competition. Each mode has private benefits and costs. The choice between them is affected by the expected reactions of competitors and by the policies of the consumer governments. Protection, and its threat, and dramatic improvements in communications in recent years have led to a large increase in international competition between local subsidiaries of MNCs and an increase in the proportion of trade in intermediate goods within vertically integrated firms. The overall volume of trade is nowadays a poor measure of the importance or strength of international competition.

Competition Policy

Alan Hughes

The content and direction of competition policy is inevitably conditioned by the domestic structure and international relations of the economy in which the policy is applied. Since my discussion, although theoretical, is essentially concrete, I will direct my analysis to the case of competition policy in the UK. However, the argument may readily be generalized to other economies.

Economic Efficiency

In the postwar period there have been considerable changes in the industrial structure and performance of the UK economy. In general, these changes have been associated with a decline in international competitiveness across broad areas of manufacturing industry, and a more concentrated structure of output in the hands of fewer, major, domestic producers in many manufacturing and non-manufacturing sectors. The increased exposure of the UK to international competition following entry to the EEC, and the more general progressive liberalization of international trade in the world economy, have been associated, in this country, with the development of substantial structural unemployment, surplus capacity, and an inability to match, by exports, the increased penetration of domestic markets by foreign producers.

The policy response to these changes has involved a constant interplay between macroeconomic demand management on the one hand, and interventionist, cooperative and competitive supply side strategies on the other. As one industrial policy weapon, on the supply side, the regulation of competition has evolved gradually in the postwar years in response to the accumulation of evidence about the effects of particular types of market behaviour upon the amount, quality and price of output supplied, and upon the responsiveness of supply to changing domestic and international demand patterns. This evolution has occurred against a background of other supply side industrial policies, in particular planning and cooperative initiatives, and policies towards price and profit margin controls. Any discussion of the appropriate current, and future, stance of competition policy must therefore be carried out in the context of specific assumptions about the objectives and form of industrial policy; and about the form of overall economic strategy, in particular about policies towards the balance of payments and international trade.

In an open economy we may define the role of industrial policy to be the maintenance of efficient production of output. By efficiency in this sense we mean that the economy must be able to meet the demands for goods and services of consumers at home, as well as sell enough of its products abroad to pay for the nation's import requirements subject to the constraint that this objective is fulfilled at socially acceptable levels of output, employment and the exchange rate (Singh 1977).

It will be assumed that the role of competition policy within this framework must be to regulate economic behaviour to assist in the achievement of the efficiency objective. In more operational terms we shall interpret this to mean that competitive behaviour should be so regulated as to ensure the production, currently and in the future, of internationally tradeable output of a sufficiently high quality and at a sufficiently low cost and price to compete effectively with international suppliers at home and abroad, along with least-cost production of those non-tradeable elements of domestic consumption. This means that the competitive process must so far as is possible allocate sufficient inputs, including investment, to those uses necessary to achieve those objectives, and ensure operation at lowest possible cost. To the extent that certain forms of competitive behaviour are not compatible with the achievement of the appropriate levels and allocations of investment, employment and output, and hinder the achievement of the overall efficiency objective, then competition policy must be sufficiently flexible to accommodate non-competitive behaviour shown to be necessary for this.

I am therefore abstracting throughout from arguments in favour of a competition policy based on the notion of competitive behaviour as a 'good thing' *in itself*, irrespective of its implications in terms of an overall economic efficiency objective. Such arguments may be considered by some to be of overriding importance. It must, however, be recognized that they are based on political, philosophical or moral grounds, and are not in themselves susceptible to positive economic analysis.

Competitive and Competition Policy

In order to distinguish competitive and non-competitive behaviour, and to consider the

link between market behaviour and some notion of economic efficiency we obviously need to define a concept of competition. The best-developed notion of competition in formal economic analysis is that inherent in the state of affairs known as perfect competition. It is easy to show that, under certain very restrictive conditions, perfect competition will lead to economic efficiency in the traditional Pareto sense in which resources are so allocated that no one can be made better off without someone else being made worse off. Unfortunately, both the notion of perfect competition and the related Pareto efficiency criterion are too restrictive to serve as useful foundations for the analysis of competition policy. The state of affairs embodied in perfect competition assumes away nearly all those aspects of business behaviour with which competition policy is concerned (such as rivalry in terms of price setting, innovation in products and processes, and advertising) and ignores the static welfare gains to be had by improving the internal organization of enterprises, in favour of an analysis concentrating exclusively on the gains to be had by reallocating resources between perfectly internally efficient producers. Moreover, even within its own restricted ambit, it yields few helpful decision rules for an imperfect world to adopt since it is unfortunately the case that if the conditions necessary for perfect competition are unavoidably absent in any single market then nothing can be said in general about the correct behaviour to be followed in the rest of the economy. In particular, it does not follow, for example, that the perfectly competitive partial equilibrium solution of setting prices equal to marginal cost, so that normal profits are earned in all sectors but the affected one, is the next best solution to setting prices equal to marginal cost everywhere. This 'problem of the second best' means that appropriate pricing rules can only be derived after a piecemeal approach to individual cases in which the input–output links with the distorted sectors are examined in order to gauge in which direction, and to what extent, price should diverge from marginal cost. The Pareto efficiency criterion is, of course, limited because of its inability to deal with those economic changes which involve alterations in the distribution of income. It is inevitable that the achievement of the kind of efficiency we have described above as the objective of UK economic policy will involve changes in the distribution of income. It not least between different industrial nations, and between sectors of the domestic economy. For all these reasons we have preferred to adopt another approach to competition to use in relation to our efficiency criterion set out earlier.

This approach analyses competition, not as a state of affairs, but as a dynamic process linking structural change with market behaviour. Competition is taken to mean that range of activities aimed at meeting the objectives of one producer at the expense of others, and is thus defined in the business sense of the word, as a process involving rivalry between producers. Competitive rivalry takes both the form of contests within existing markets, and the form of potential entry into new areas when prospective returns appear relatively attractive. It includes rivalry in terms of price, but also in terms of altered or improved techniques of production or products, and in terms of the provision of information to consumers about products. All these forms of rivalry have consequences for the level and rate of growth of the technical efficiency of production and standards of consumption, for the allocation of resources between industries, and for the evolution of the structures of markets themselves.

There are a number of theories from which we may choose, which involve notions of competition as a dynamic process. The best known are those of Marx (1867–94), Schumpeter (1942), Downie (1958) and Clark (1961). This entry is based on the characterization of the competitive process by Downie. This is because he provides in a relatively simple manner, an analysis which is both more precise for our purposes than Clark, and avoids the complications imposed by the richer, more cosmic, implications of the Marxian and Schumpeterian analyses of capitalism. Moreover, the Downie model includes the main beneficial effects usually claimed to follow from competitive rivalry, in terms of cost efficiency, resource allocation, and technical progress, whilst emphasizing the possible structural changes flowing from competition which may change its

nature and effects. We can then, following Downie, sketch an outline of a simple competitive process in a given market and consider its efficiency implications.

In any market we may expect that firms with the lowest cost structure (inherited from the past). will for any given market price have the highest profits to finance expansion. In their own pricing policy, firms are expected to set a price which promises to attract customers and provide sufficient retained profits to finance the capacity necessary to serve them in a balanced manner. In this way, within markets, relatively low costs will be associated with relatively fast growth, and a competitive transfer of market shares from the less to the more efficient will occur. Moreover, this transfer mechanism may have a feedback effect on efficiency in the sense that the previously less efficient will be threatened with an ever-diminishing share of the market unless they can improve their cost position, for instance by introducing more recent innovations in production technique.

The transfer and innovation mechanisms within markets thus have beneficial effects, both upon allocative efficiency, by transferring output and resources to the currently most efficient producers, and upon technical progressiveness, by encouraging the introduction of the least-cost techniques available. The outcome of this competitive process, however, in terms of the changing allocation of output between different firms over time, and the impact of this upon competitive behaviour itself, will depend ultimately on the answer to a number of empirical questions about the relationship between past and future efficiency, and company size and performance. If past success is repeated, and resulting gains in relative size offer efficiency advantages in themselves, through economies of scale or enhanced innovative ability, then particular markets may come to be dominated by ever fewer, ever larger, firms as a result of the transfer mechanism, whilst the innovative mechanism, acting as a spur for past losers to improve performance, may not be powerful enough to offset this tendency. Past failure may raise the desire, but inhibit the ability, to recover. Innovation in process or product may be expensive, and low profits, or relatively small scale, may limit the power of losers to respond actively enough to prevent the transfer mechanism from leading to the concentration of ever more output in fewer hands. Thus, in the absence of revival the end product of the competitive process may be domination of the market by the single producer whose efficiency in the past has outstripped all rivals.

However, before this stage is reached, the private gains from collusion between remaining producers may become apparent, since it can offer both lower costs of competition and a higher market price. The costs of adding to the stock of goodwill accumulated by past advertising can be reduced, and the necessity to indulge in competitive process and product innovation is modified. Moreover, collusion can offer the leading firms higher margins by concerted pricing policies, at least in the short run, and possibly in the long run too, if the scales of production and advertising created by the competitive process itself form effective barriers to entry. Thus the competitive process seems to end inevitably in dominant-firm monopolistic or oligopolistic structures, and in the suppression of the process itself. This reduces the pressure to increase the level of efficiency through time and, in the case of collusion, to reduce the dispersion of efficiency. Market price is higher, and to some extent output is lower than it might otherwise be. High-cost plants and firms can remain in production at the higher market price and the incentive to improve products and production methods falls. Thus, both levels and rates of growth of efficiency in any market may be worsened by the cessation of the competitive process in structural conditions which may themselves limit the chances of substantial new entry.

In terms of this analysis the objective of competition policy would appear to be the identification and regulation of those structures, restrictions on entry and kinds of behaviour which arrest the competitive process, and produce the efficiency losses described above. This clearly poses problems of establishing links between structure and behaviour, of specifying behaviour inimical to the competitive process and of establishing the existence of markets where the competitive process has atrophied, and where it appears that efficiency

gains are possible. In the case of an open economy such as the United Kingdom the relevant markets, and standards of comparison for efficiency, are international in character, and we must recognize that in many industries the degree of concentration of purely domestic producers will be of little use in assessing the fierceness of the transfer mechanism, because of the importance of foreign competition.

However, more fundamental problems have also to be recognized. It may be that a competitive process of the kind outlined above may not be the only, or the most efficient, means of achieving the same ends, either before or after the stage is reached at which the possibilities of market dominance or collusion arise. Thus, we must consider planned or cooperative solutions to the problem of raising efficiency. Moreover, there is no guarantee that the end result of the competitive process itself, in terms of the levels and rates of change of operating efficiency of producers, and their distribution between activities, will, for any individual country, necessarily meet the overall efficiency objective outlined earlier, in terms of output, inflation, employment and international trade performance targets. There is then, for both the above reasons, the possibility of conflict, in industrial policy *methods*, between the promotion of arm's-length competitive behaviour through competition policy, and the possible reduction in such behaviour encouraged by other aspects of government policy in pursuit, for instance, of industrial strategy. The possibility of conflict is most obvious in relation to restrictive trade practices, but is also present in the creation or encouragement of domestic dominant-firm positions through government-sponsored mergers or rationalization schemes (NEDO 1978).

These conclusions run in some cases contrary to the majority of recent academic argument in this area, where increasing emphasis has been paid to the claimed welfare losses due to merger, increased monopoly power, and restrictive trade practices. However, in the context of current UK industrial performance and within the current overall economic policy framework a detailed scrutiny of the current evidence for the UK yields no foundation for a generally more aggressive approach towards large-firm dominance than the current legislation already adopts. This is not to deny that competition policy is necessary, but to assert that an *appropriate* competition policy must be designed in the light of existing economic conditions; of the evidence of the effects of various forms of market structure and behaviour; and of the overall objectives of economic policy.

The essence of Austrian economics is its emphasis on the ongoing economic process as opposed to the equilibrium analysis of neoclassical theory. Austrian concepts of competition reflect this emphasis. Indeed, one of the central challenges by Austrians to the neoclassical model, and a common denominator of virtually all Austrian economics, is the rejection of the concept of perfect competition. In this respect, a number of economists who cannot be considered Austrian in all aspects of their work, share, nonetheless, the Austrian emphasis on actual market activities and processes – for example, Joseph Schumpeter (1942), J.M. Clark (1961), Fritz Machlup (1942) and others.

When the concept of competition entered economics at the hands of Adam Smith and his predecessors, it was not clearly defined, but it generally meant entry by firms into profitable industries (or exit from unprofitable ones) and the raising or lowering of price by existing firms according to market conditions. There was little recognition, and virtually no analysis, of entrepreneurship as it might be reflected in these and other forms of competition, but there was a recognition that business firms do in most situations have some control over market prices, with the degree of control varying inversely with the number of firms in the industry. These basic ideas, expanded and supplemented, are generally compatible with most modern Austrian analysis.

What is objectionable to Austrian economists is the neoclassical concept of perfect competition, developed during the 19th and early 20th centuries. The development began with Cournot (1838), whose concern it was to specify as rigorously as possible the *effects* of competition, after the *process* of competition had reached its limits. His conceptualization of this situation was a market structure in which the output of any one firm could be subtracted from total industry output with no discernible effect on price. Later contributions by Jevons, Edgeworth, J.B. Clark and Frank Knight led to the model of perfect competition as we know it today (Stigler 1957; McNulty 1967).

The trouble with the concept from the Austrian point of view, as Hayek has emphasized, is that it describes an equilibrium situation but says nothing about the competitive process which led to that equilibrium. Indeed, it robs the firm of all business activities which might reasonably be associated with the verb 'to compete' (von Hayek 1948). Thus, firms in the perfectly competitive model do not raise or lower prices, differentiate their products, advertise, try to change their cost structures relative to their competitors, or do any of the other things done by business firms in a dynamic economic system. This was precisely the reason why Schumpeter insisted on the irrelevance of the concept of perfect competition to an understanding of the capitalist process.

For Schumpeter, any realistic analysis of competition would require a shift in analytical focus from the question of how the economy allocates resources efficiently to that of how it creates and destroys them. The entrepreneur, a neglected figure in classical and neoclassical economics, is the central figure in the Schumpeterian analytical framework. The entrepreneur plays a disequilibrating role in the market process by interrupting the 'circular flow' of economic life, that is, the ongoing production of existing goods and services under existing technologies and methods of production and organization. He does this by innovating – that is, by introducing the new product, the new market, the new technology, the new source of raw materials and other factor inputs, the new type of industrial organization, and so on. The result is a concept of competition grounded in cost and quality advantages which Schumpeter felt is much more important than the price competition of traditional theory and is the basis of the 'creative destruction' of the capitalist economic process. It produces an internal efficiency within the business firm, the importance of which for economic welfare is far greater, Schumpeter argued, than the allocative efficiency of traditional economic theory (Schumpeter 1942).

His emphasis on the advantages of the firm's internal efficiency led Schumpeter to a greater tolerance for large-scale business organizations, even for those enjoying some degree of monopoly power, than was typical of many more traditional theorists of his time. This is a not uncommon

characteristic of Austrian economics. Hayek, for example, makes the distinction between entrenched monopoly, with its probable higher-than-necessary costs, and a monopoly based on superior efficiency which does relatively little harm since in all probability it will disappear, or be forced to adjust to market conditions, as soon as another firm becomes more efficient in providing the same or a similar good or service (von Hayek 1948). And that is precisely Schumpeter's point. The ground under even large-scale enterprise is constantly shaking as a result of the competitive threat from the new firm, the new management, or the new idea. Schumpeter's competitive analysis was less a defence of monopoly power than of certain business activities which were judged to be monopolistic only from the comparative standpoint of the model of perfect competition. He insisted that the quality of a firm's entrepreneurship was of far greater significance than its mere size.

The leading contemporary Austrian theorist of competition is Israel Kirzner (1973). Kirzner's approach draws on the analysis of market processes and the concept of 'human action' developed earlier by Ludwig von Mises. For von Mises, entrepreneurship is human action in the market which successfully directs the flow of resources toward the fulfillment of consumer wants (von Mises 1949). Kirzner's more fully developed theory of competition is based on the idea that the means – end nexus of economic life is not given but is itself subject to creative human action. This creative role Kirzner defines as entrepreneurship, and it is essentially the ability to detect new but desired human wants, as well as new resources, techniques, or other ways through which to satisfy them. Whether he discovers new wants or new means of satisfying old ones, the Kirznerian entrepreneur is the one who sees and exploits what others fail to notice – the profit opportunities inherent in any situation in which the prices of factor inputs fall short of the price of the final product.

There is a difference between Kirzner's theory of entrepreneurship and that of Schumpeter. Schumpeter's entrepreneur is a disequilibrating force in the economic system; he initiates economic change. Kirzner's entrepreneur plays an equilibrating role; the changes he brings about are responses to the mistaken decisions and missed opportunities he detects in the market. Unlike Schumpeter's entrepreneur, he is not so much the creator of his own opportunities as a responder to the hitherto unnoticed opportunities that already exist in the market. Thus, in the competitive market process, the Schumpeterian and Kirznerian entrepreneurs may complement each other – the one creating change, the other responding to it.

Austrian dissatisfaction with the perfectly competitive model extends to the theories of imperfect and monopolistic competition. Hayek's and Kirzner's criticisms are the same as of perfect competition, namely, that the analysis is limited to an equilibrium situation in which the underlying data are assumed to be adjusted to each other, whereas the relevant problem is the process through which adjustment occurs. Schumpeter criticized monopolistic competition for its continued acceptance of an unvarying economic structure and forms of industrial organization. Nonetheless, the incorporation into economic theory of quality competition and sales efforts, complementing the traditional and limited focus on price competition, as well as the efforts on the part of some industrial organization specialists and institutional economists to analyse and explain actual market processes, are developments that are generally within the Austrian tradition.

Only through the principle of competition has political economy any pretension to the character of a science. So far as rents, profits, wages, prices, are determined by competition, laws may be assigned for them. Assume competition to be their exclusive regulator, principles of broad generality and scientific precision may be laid down, according to which they will be regulated. (Mill 1848, p. 242)

In all versions of economic theory 'competition', variously defined, is a central organizing concept. Yet the relationship between different definitions of competition and differences in the theory of value have not been fully appreciated. In particular, the characteristics of 'perfect' competition (notably the conditions which ensure price-taking) are often read back, illegitimately, into classical discussions of competition.

The mechanisms which determine the economic behaviour of industrial capitalism are not self-evident. As a form of economy in which production and distribution proceed by means of a generalized process of exchange (in particular by the sale and purchase of labour), it possesses no obvious direct mechanisms of economic and social coordination. Yet, in so far as these operations constitute a system, they must be endowed with some degree of regularity, the causal foundations of which may be revealed by analysis. The first steps in economic investigation which accompanied the beginnings of industrial capitalism consisted of a variety of attempts to identify such regularities, often by means of detailed description and enumeration, as in the works of Sir William Petty, and hence to establish the dominant causes underlying the behaviour of markets. But what was required was not simply the description and classification which precedes analysis, but abstraction, the transcendence of political arithmetic (Smith 1776, p. 501).

The culmination of the search for a coherent abstract characterization of markets, and hence the foundation of modern economic analysis, is to be found in Chapter 7 of Book I of Adam Smith's *Wealth of Nations* – 'Of the Natural and Market Price of Commodities'. In this chapter Smith presented the first satisfactory formulation of the regularity inherent in price formation. The idea, partially developed earlier by Cantillon, and by Turgot in his discussion of the circulation of money, was that

> There is in every society . . . an ordinary or average rate of both wages and profits . . . When the price of any commodity is neither more nor less than what is sufficient to pay the rent of land, the wages of labour, and the profits of stock employed . . . according to their natural rates, the commodity is then sold for what may be called its natural price.

and that

> The natural price . . . is, as it were, the central price, to which the prices of all commodities are continually gravitating. Different accidents may sometimes keep them suspended a good deal above it, and sometimes force them down somewhat below

> it. But whatever may be the obstacles which hinder them from settling in this center of repose and continuance, they are continually tending towards it. (Smith 1776, p. 65)

Thus the natural price encapsulates the persistent element in economic behaviour. And that persistence derives from the ubiquitous force of competition: or, as Smith put it, the condition of 'perfect liberty' in which 'the whole of the advantages and disadvantages of the different employments of labour and stock must … be either perfectly equal or continually tending to equality' (p. 111), for the natural price is 'the price of free competition' (p. 68).

The relationship between competition and the establishment of what Petty called 'intrinsic value' had been discussed in the works of Petty, Boisguillebert, Cantillon and Harris as the outcome of rival bargaining in price formation, competition being the greater when the number of bargainers was such that none has a direct influence on price. Quesnay expressed the formation of competitive prices as being 'independent of mens' will … far from being an arbitrary value or a value which is established by agreement between the contracting parties' (in Meek 1962, p. 90), but he did not relate the *organization of production* to the formation of prices in competitive markets. Consideration of that relationship required the development of a general conception of the role of capital, and with it the notion of a general rate of profit formed by the competitive disposition of capital between alternative investments (Vaggi 1987).

A significant step in this direction was made by Turgot, who both conceived of the process of production as part of the circulation of money:

> We see … how the cultivation of land, manufactures of all kinds, and all branches of commerce depend upon a mass of capitals, or movable accumulated wealth, which, having been first advanced by the entrepreneurs in each of these different classes of work, must return to them every year with a regular profit … It is this continual advance and return of capitals which constitutes *what ought to be called the circulation of money.* (Turgot 1973, p. 148)

and saw that the structure of investments would tend to be that which yielded a uniform rate of profit:

> It is obvious that the annual products which can be derived from capitals invested in these different employments are mutually limited by one another, and that all are relative to the existing rate of interest on money. (Turgot 1973, p. 70)

However, Turgot neither related the determination of the rate of profit to production in general – he accepted the Physiocratic idea that the incomes of the industrial and commercial classes were 'paid' by agriculture – nor developed the conceptual framework which linked the formation of prices and of the rate of profit to the overall organization of the economy. These were to be Smith's achievements:

> If … the quantity brought to market should at any time fall short of the effectual demand, some of the component parts of its price must rise above their natural rate. If it is rent, the interest of all other landlords will naturally prompt them to prepare more land for the raising of this commodity; if it is wages or profit, the interest of all other labourers and dealers will soon prompt them to employ more labour and stock in preparing and bringing it to market. The quantity brought thither will soon be sufficient to supply the effectual demand. All the different parts of its price will soon sink to their natural rate, and the whole price to its natural price. (Smith 1776, p. 65)

So in a competitive market there will be a tendency for the actual prices (or 'market prices' as Smith called them) to be relatively high when the quantity brought to market is less than the effectual demand (the quantity that would be bought at the natural price) and relatively low when the quantity brought to market exceeds the effectual demand. This working of competition was known as the 'Law of Supply and Demand'. The working of competition which constitutes the 'Law' do not identify the phenomena which *determine* natural prices. The 'Law' of supply and demand should not be confused with supply and demand 'theory', that is, the neoclassical theory of price determination which was to be developed one hundred years later. Nor should Smith's discussion of the tendencies of concrete market prices be confused with supply and demand function, which are loci of equilibrium prices.

Adam Smith's conception of 'perfect liberty' consists of the mobility of labour and stock between different uses – the mobility that is

necessary for the establishment of 'an ordinary or average rate both of wages and profits' and hence for the gravitation of market prices toward natural prices. Smith identifies four reasons why market prices may deviate 'for a long time together' above natural price, creating differentials in the rate of profit, all of which involve restriction of mobility:

(a) Extra demand can be 'concealed', though 'secrets of this kind . . . can seldom be long kept';
(b) Secret technical advantages;
(c) 'A monopoly granted either to an individual or a trading company';
(d) 'Exclusive privileges of corporation, statutes of apprenticeship, and all those laws which restrain, in particular employments, the competition to a smaller number than might otherwise go into them'.

For Smith there is some similarity in the forces acting on wages and profits which derives from his conceiving of the capitalist as personally involved in the prosecution of a particular trade or business. So the rate of profit, like the rate of wages, may be differentiated between sectors by 'the agreeableness of disagreeableness of the business', even though 'the average and ordinary rates of profit in the different employments of stock should be more nearly upon a level than the pecuniary wages of the different sorts of labour' (1776, p. 124). Landlords, capitalists and workers are all active agents of mobility. In Ricardo's discussion the emphasis shifted towards the distinctive role of capital:

> It is, then, the desire, which every capitalist has, of diverting his funds from a less to a more profitable employment, that prevents the market price of commodities from continuing for any length of time either much above, or much below their natural price. (Ricardo 1817, p. 91)

Ricardo used the term 'monopoly price' to refer to commodities 'the value of which is determined by their scarcity alone', such as paintings, rare books and rare wines (1817 pp. 249–51) which have 'acquired a fanciful value', and he argued that for 'Commodities which are monopolised, either by an individual, or by a company . . . their price has no necessary connexion with their natural value' (p. 385). His analysis of value and distribution is accordingly confined to 'By far the greatest part of those goods which are the object of desire . . . such commodities only as can be increased in quantity by the exertion of human labour, and on the production of which competition operates without restraint' (p. 12).

For Marx competition is synonymous with the generalization of capitalist relations of production. Competition is thus related to the rise to dominance of the capitalist mode of production.

> While free competition has dissolved the barriers of earlier relations and modes of production, it is necessary to observe first of all that the things which were a barrier to it were the inherent limits of earlier modes of production, within which they spontaneously developed and moved. These limits became barriers only after the forces of production and the relations of intercourse had developed sufficiently to enable capital as such to emerge as the dominant principle of production. The limits which it tore down were barriers to its motion, its development and realization. It is by no means the case that it thereby suspended all limits, nor all barriers, but rather only the limits not corresponding to it . . . Free competition is the real development of capital. (Marx 1973, pp. 649–50)

And as capitalism itself develops so does competition:

> On the one hand . . . [capital] creates means by which to overcome obstacles that spring from the nature of production itself, and on the other hand, with the development of the mode of production peculiar to itself, it eliminates all the legal and extra-economic impediments to its freedom of movement in the different spheres of production. Above all it overturns all the legal or traditional barriers that would prevent it from buying this or that kind of labour-power as it sees fit, or from appropriating this or that kind of labour. (Marx 1867, p. 1013)

The concentration of capital (increasing unit size of firms) and, in particular, the centralization of capital (cohesion of existing capitals) destroys and *recreates* competition. Competition is one of the most powerful 'levers of centralization', and

> The centralization of capitals, or the process of their attraction, becomes more intense in proportion as the specifically capitalist mode of production develops along with accumulation. In its turn

> centralization becomes one of the greatest levers of its development. (Marx 1867, p. 778n)

Like Smith and Ricardo, Marx, relates the development of competition to the establishment of the general rate of profit:

> What competition, first in a single sphere, achieves is a single market value and market price derived from the individual values of commodities. And it is competition of capitals in various spheres, which first brings out the price of production equalising the rates of profit in the different spheres. The latter process requires a higher stage of capitalist production than the previous one. (Marx 1894, p. 180)

It is in his conception of the circuit of capital that Marx best portrays capitalist competition. The image is one of capital as a homogeneous mass of value (money) seeking its maximum return. Profits are created by embodying capital in the process of production, the commodity outputs of which must be realized, that is, returned to the homogeneous money form to be reinvested. Competition is thus characteristic of the capitalist mode of accumulation; mobility and restructuring are two aspects of the same phenomenon.

Marx's general conception of capital as a system corroborates Quesnay's notion of an economy operating 'independent of men's will'. This does not mean that there may not be circumstances in which individual capitals exercise some control in particular markets – indeed, such limitations may be necessary for the accumulation process to proceed in certain lines. Capital removes only those barriers which *limit* its accumulation. The market control exercised in some lines of modern industry is not necessarily a limitation but may be a prerequisite of production on an extended scale. Aggregate capital flows discipline the actions of individual capitals, and hence endow the system with the regularity manifest in the perpetual tendency, successfully contradicted and recreated, towards a general rate of profit and associated prices.

Competition not only establishes the object of analysis, natural prices and the general rate of profit, but makes meaningful analysis possible, since it allows the operations of the capitalist economy to be characterized in a manner which permits theoretical statements of general validity to be made about them.

Theory proceeds by the extraction from reality of those forces which are believed to be dominant and persistent, and the formation of those elements into a formal system, the solution of which is to determine the magnitude or state of the variables under consideration. It is obvious that the solution will not, except by a fluke, correspond to the actual magnitudes of the variables ruling at any one time, for these will be the outcome not solely of the elements grouped under the heading 'dominant and persistent', but also of the myriad of other forces excluded from the analysis as transitory, peculiar or specific (lacking general significance) which may, at any moment, exert a more or less powerful effect. Nonetheless, the practice of analysis embodies the assumption that the forces comprising the theory *are* dominant, and that the determined magnitudes will, on average, tend to be established. In any satisfactory analytical scheme these magnitudes must be centres of gravitation, capturing the essential character of the phenomena under consideration.

The importance of Smith's use of competition is now apparent. Theory cannot exist in a vacuum. Simply labelling forces dominant is not enough. These forces must operate through a process which establishes their dominance and through which the 'law-governed' nature of the system is manifest. That process is competition, which both enforces and expresses the attempt of individual capitals to maximize profits. Thus important aspects of the behaviour of a capitalist market economy may be captured at a sufficient level of generality to permit the formulation of general causal statements, that is, to permit analysis. Without this step, which constitutes the establishment of what was called above the *method* of analysis, it would have been impossible to develop any general form of economic *theory*.

The classical theory of value and distribution may be shown to provide a logically coherent explanation of the determination of the general rate of profit and hence of natural prices (prices of production) taking as data (see Sraffa 1960):

(a) The size and composition of social output;
(b) The technique in use; and
(c) The real wage.

The classical achievement is thus composed of two independent elements: (*a*) the characterization of the object of the theory of value; and (*b*) the provision of a theory for the determination of that object. Underlying the former is the concept of gravitation imposed by competition, and underlying the latter the concept of gravitation inherent in theoretical abstraction. Any alternative system must not simply provide a different theory but also achieve a similar congruence with the traditional method.

The development in the final quarter of the 19th century of what was to become known as the neoclassical theory of value and distribution was an attempt to provide an alternative to a classical theory embroiled in the logical difficulties inherent in the labour theory of value and sullied by unsavoury associations with radicalism and Marxism. But despite the dramatic change in theory that was to be heralded by the works of Jevons, Menger and Walras, the method of analysis which characterized the object the theory was to explain stayed fundamentally the same; the new theory was an alternative explanation of the same phenomena. Marshall labelled natural prices 'long-run normal prices', and declared that, as far as his discussion of value was concerned 'the present volume is chiefly concerned … with the normal relations of wages, profits, prices etc., for rather long periods' (1920, p. 315). The same continuity of method may be found in the work of Walras (1874–7, pp. 224, 380), Jevons (1871, pp. 86, 135–6), Böhm-Bawerk (1899, p. 380) and Wicksell (1934, p. 97).

Nonetheless, the structure of neoclassical theory is such that a different notion of competition is required. The classical emphasis on mobility must be supplemented by a precise definition of the relationships presumed to exist between individual agents. The fundamental concept of 'perfect' competition, for example, encompasses the idea that the influence of each individual participant in the economy is 'negligible', which in turn leads to the idea of an economy with infinitely many participants (Aumann 1964). Such formulations are entirely absent from the classical conception of competition, since the classical theory is not constructed around individual constrained utility maximization.

Competition: Marxian Conceptions

Willi Semmler

In the works of the classical economists such as Smith (1776) and Ricardo (1817), competition was identified as a central concept in economic theory. Free competition was regarded as the

organizing and equilibrating force in an exchange society, bringing about natural prices as centres of gravity for market prices through capital flows from areas with low rates of returns to areas with high rates. Yet compared with the theory of perfect competition, classical free competition was defined more in terms of economic behaviour than of market structure (Stigler 1957; McNulty 1968; Eatwell 1982). Marx's concept of competition, rooted in the classical theory of free competition, also refers to the behavioural activities of the capitalist firm. Marx, however, more than the classics, cast serious doubts on the stability properties of the competitive process, and he conceptualized competition as inter-firm dynamics carried out through reorganization of the firm and technical change. In this it somewhat resembles the modern theory of oligopolistic rivalry (Friedman 1982) and Schumpeter's notion of competition as a process of 'creative destruction' (1943).

The Dynamics of Competition in Marx

The marxian concept of competition though already adumbrated in his early writings (1847, 1857/8) is systematically developed in his later work (1861/3, 1867, 1893, 1894). It is derived from his theory of the behaviour of the capitalist firm (Kuruma 1973). The driving force for economic change and growth is the goal of the capitalist firm to grow and to expand ('the self-expansion of capital'). From the inter-firm dynamics results economic evolution, accumulation and growth, but also the downfall of old firms and the centralization of capital (Marx 1867, ch. 25) by which the competition and rivalry become fiercer. Firms are not conceived as powerless economic agents adjusting passively toward parametrically given techniques, prices and quantities but as actively seeking the reorganization of production and market activities in the context of rivals' possible reactions. Firms also are not seen as price takers but rather as price-setting firms with their market shares adjusting through the reaction of the rivals or as quantity-setting firms (Marx 1894, ch. 10) with prices and profits determined through market interactions. Price differentiation even for homogeneous products is assumed to exist under disequilibrium conditions (Marx 1894, ch. 10). Monopoly firms are considered exceptional cases as 'temporary monopolies' (Marx 1894, p. 178) when the demand exceeds supply for a considerable period or as 'natural monopolies' (Marx 1894, p. 861) when there is ownership of land or natural resources (Marx 1894, pp. 178, 861).

In production activities, the reorganization of the firm and technical change are seen as the main weapons of competition (Marx 1867, pp. 623). The goal of the firm is to capture a transient surplus profit and to transform it into long-run growth potentials, leading to disequilibria and imbalances through irreversible technical change and innovation, taking place not in time-continuous form but in discrete steps. Moreover, competition through technical change results not in the existence of one optimal technique but in the coexistence of multiple techniques, and the weighted average technique is – excluding some exceptional cases such as decreasing returns to scale and rent – considered the regulating technique determining the long-run normal price (Marx 1894, ch. 10).

Contrary to those forces generating disequilibria and imbalances through inter-firm dynamics competition is also conceived as a balancing force. Capital as a homogeneous fund (money capital) seeks its maximum return by flowing between sectors ('competition between industries', Marx 1894, ch. 10). Free mobility of labour and capital, no artificial or natural barriers for its entry or exit and sufficiently widespread knowledge of fields of investment are considered preconditions for the free flow of funds. In Marx (1894, ch. 10) as in Smith (1776, ch. 7), and Ricardo (1817, ch. 4) a dynamical process is conceived in which capital funds flow into industries with high rates of return away from industries with low rates of return. Thus the relative output proportions in industries will change, creating imbalances of supply and demand. These, in turn, cause relative market prices and profit rates to change, tending to establish for the economic system long-run prices of production as centres of

gravity for market prices. Yet the stability properties of such a dynamic process were not demonstrated rigorously. The arguments were put forward intuitively by analogy with Newton's theory of the planetary system that profit rates fluctuate or oscillate within a bounded interval and actual prices gravitate around their long-run production prices. Differentials of profit rates between industries and firms were expected to exist for a shorter or longer period due to disequilibrium dynamics and due to speed and ease of adjustment varying from one industry to another (Marx 1894, p. 208). Though Marx anticipated possible institutional and structural changes, due to 'concentration and centralization of capital', he did not, however, assume that inter-firm and inter-industry competition would become less severe with the evolution of capitalism.

Post-Marxian Theory

In the post-marxian theory since Hilferding (1910) the elimination of competition and the delay and disruption of the formation of a general profit rate through monopolization became the main theoretical concern. Three causes are posited as reasons for monopolization: industrial concentration, increasing constraints for the mobility of capital (in particular due to high proportion of fixed capital in total capital outlay), and collusion (cooperative behaviour and cartels). In this view these three causes result in monopoly prices and the persistence of differential profit rates between industries and size classes of firms (Sweezy 1942). For those theories, the large firms are conceived as economic units endowed with discretionary price setting power determining their own environment (Kalecki 1938, 1943; Sweezy 1939, 1942; Baran and Sweezy 1966; Eichner 1976). Here the ideas of mark-up pricing, target rate of return pricing and entry-preventing pricing have replaced the classical and marxian theory of production prices (natural prices, prices of production).

Given this general trend in post-marxian theory there are, however, many differences among theorists regarding (i) the causes of the monopolization; (ii) the determination of the mark-ups and the rates of return; (iii) the different role of inverse demand function and quantity reactions in their theory of price setting firms; (iv) the impact of the rise of oligopolies and firms size on technical change; and (v) the impact of large oligopoly firms on the stability of the economic system (increasing stability or instability with stagnation tendencies). Yet in spite of these differences, post-marxian theory is influenced by the theory of imperfect competition arising in the 1930s, and competition is thus identified more with market structure than with rival behaviour. Moreover, the theory of mark-up pricing was built more on a partial equilibrium view and thus not well-founded in an interdependent economic system. Though in the writings of some of the post-Marxian scholars the existence of large oligopoly firms does not preclude rivalry and competition (in particular concerning technical change, see Baran and Sweezy 1966, ch. 3), post-marxian writers seemed to have considered the theory of imperfect competition a more adequate framework for their analysis of advanced capitalism.

Recent Discussions

In recent discussions there is a certain revival of the concepts of competition of the classics and Marx, in particular concerning the role of competition for (1) industrial and corporate price and profit determination; (2) technical change and innovation; and (3) the formation of a general rate of profit.

1. In new contributions attempts have been made to elaborate a theory of mark-up pricing for large corporations in the context of a dynamic theory of competition and long-run prices of production. In this context the economic behaviour of large corporations is explained more in terms of change of the production processes and the organization of the firm and less in terms of a change of market structures (Clifton 1977, 1983; Semmler 1984a) as was

attempted by post-marxian theory. According to this new view, mark-up and target rate of return pricing have their origin not in new market structures but in the rise of a new type of firm: the multi-plant and multi-product corporations and their new financial management techniques. Though there is, as the theory of mark-up pricing predicts, sufficient empirical evidence of differential profit rates among industries and size classes of firms – depending, however, also on the time-period and the measure chosen for the rate of profit – it has not been sufficiently demonstrated that these differentials stem from imperfect market structures or from a disequilibrium dynamics. In addition, the empirically observed mark-up, target rate of return, and entry-preventing pricing, originally developed by large corporations in the 1920s, can be made consistent with a concept of long period prices of production. Since, however, large corporations are no longer single product firms, it is more appropriate to apply the theory of joint production to the economic behaviour of large corporations (Semmler 1984a). On this basis fruitful attempts have been made to analyse the dynamics of competition, mark-ups, and rates of return on the basis of an interdependent system of prices and outputs.

2. The theory of technical change in marxian economics has recently been given a firmer foundation in the theory of competition (Okishio 1961; Shaikh 1978; Roemer 1979). In this discussion, the marxian statement (Marx 1867, ch. 12; 1894, ch. 15) that under competitive pressure individual firms will implement technical change and innovations and capture a transient surplus profit, but that the diffusion of techniques will entail a falling general profit rate, was debated anew with the tools of mathematical economics. The Okishio theorem seemed to invalidate this statement, since it implies that the capitalist firm in competition will always choose a cost minimizing technique that raises the individual as well as the general profit rate (Okishio 1961). This Okishio result was disputed by Shaikh (1978) and extended by Roemer (1979). The latter extended the Okishio result to a production price model including fixed capital. In the debate, however, it became clear that the Okishio result holds only under the conditions of perfect competition with perfect information about the current and future cash flow and capital cost of an innovation where rivals' reactions either do not occur or can be foreseen (Semmler 1984b). In the context of the dynamics of competition as conceived by Marx – and also in the Schumpeterian tradition – due to unforeseen rivals' reactions certainty concerning future technology and markets cannot be expected when firms choose or are forced to choose a technique through competition. Thus the theory of perfect competition does not seem to be applicable as a framework in this context. But choice of techniques with market and technological uncertainties due to unforeseen rivals' reactions is by its nature difficult to model appropriately and thus more precise results are not yet available.
3. In post-marxian theories the competitive formation of a general profit rate was either taken for granted or completely disputed (as in the tradition since Hilferding). Recently, however, it became clear that if it cannot be established theoretically how profit rate differentials are dynamically equalized through the forces of competition then the concept of prices of production would become empirically irrelevant. In order to solve this problem, many scholars have begun to formalize Marx's conceptualization of competition by means of dynamical systems with price and quantity changes over time. Nikaido (1983) presented results on the dynamic equalization of profit rates and the stability properties of prices of production showing that in general they are not even locally stable. In subsequent discussion, however, it was shown by Duménil and Lévy (1984), Steedman (1984), and Flaschel and Semmler (1987) that better results may be obtained if the dynamics of competition are formalized as indicated above. For an *n*-sector

model, a dynamics which includes changes not only in prices but also in production levels can be formulated as follows:

$$\dot{x}_i = d_i\left[r(p,x)_i - \overline{r}(p,x)\right] \tag{1}$$

and

$$\dot{p}_i = k_i\left[\overline{D}(p,x)_i = S(p,x)_i\right] \tag{2}$$

where $\overline{D}(p,x)$ is the average or expected demand for an industry i for a growing economic system, $S(p,x)_i$ the industry's supply, $r(p, x)_i$ the industry's profit rate, $\overline{r}(p,x)$ the average profit rate and $\dot{p}_x$, $\dot{x}_i$ the time rate of change of prices and outputs. This dynamical process of competition refers to capital flows across industries according to differential profit rates (and changes in respective production levels) as well as to changes in prices due to imbalances in supply and demand. The results obtained in recently published articles on this process range from the demonstration of complete instability of the dynamic equalization of profit rates (Nikaido 1983) to the demonstration that prices of production are at least locally stable (Duménil and Lévy 1984). It can also be demonstrated (by utilizing a proper Lyapunov function) that prices, outputs, and profit rates are fluctuating or oscillating within boundaries (Flaschel and Semmler 1987). Most of these attempts, however, refer only to a circulating capital model when the inter-industry competitive process is analysed, and the demonstrated results depend on the type of formalization, the reaction coefficients as well as on additional stabilizing forces (such as substitution in capitalist consumption, rate of change of inventories or rate of change of profit rate differentials). Models of inter-industry competition including fixed capital, returns to scale, or multiple techniques are still rare.

Competitive Market Processes

J. A. Clifton

1. Do fully competitive price signals from intense rivalry in the market justify the moral sentiment of laissez-faire? On grounds of distributive justice among risk-takers, the answer has generally been 'yes' throughout the history of economic analysis.

   In considerations of optimum economic efficiency, however, the answer seems to have become more difficult over the course of development. The cheapening of commodities witnessed by the classical economists is the most virtuous example of efficient competitive market processes in which the distribution of returns tends to be equalized. Against the theoretical standard of perfect competition, non-price forms of competition came to be viewed in the 1930s as second-class virtues – imperfectly or monopolistically competitive practices.

   Questions of intervention on grounds of allocative inefficiency have continued to hinge on the existence of classical monopoly profits. By the 1970s, the weight of empirical evidence and the acknowledged fact of intensified global competition served to eliminate the credibility of the market concentration doctrine derived from perfect and imperfect competition (see Demsetz 1973, 1982).

   At a more fundamental level, Joan Robinson was persuaded to abandon imperfect competition in favour of trying to more fully develop a classical line of analysis only partially worked out by the classical economists and largely ignored ever since (see Clifton 1977).

   Yet, after a decade of deregulation and the strongest sentimentality to let the free market reign, evidence of static and dynamic inefficiencies in industry is accumulating (*Business* Week 1986). Has the sheer intensity of competition in the rate of economic change and the pace of economic life become so severe as to hinder economic efficiency even under the strongest possible tendencies to equalized returns in the market? Competition, however complex and full of discontinuities, is still evident as a systematic and general force in the empirically observed fact that accounting rates of return across firms and industries tend toward uniformity over time.

   This dynamic tendency is stronger among larger than smaller firms and is stronger today than a century ago (see Singh and Whittington 1968 chapter 6; Brozen 1970, 1971, 1982, pp. 239–40). But it is not explained by the neoclassical theory of perfect competition, which requires atomism of independent agents under static premises of maximization. It is not explained by imperfect or monopolistic competition for stable positions of some degree of monopoly power are less and less in evidence all the time. Yet this dynamic tendency is not associated with any optimum or unique state of industrial efficiency, as under perfect competition. Finally, the intensity of competitive

rivalry that leads to this tendency cannot be measured by neoclassical standards – the number of firms in a market. It exists primarily under market conditions of concentrated oligopoly.

It seems pointless to try to reconstitute the general theory of competitive value by still more a priori game theorizing which only adds to the false perception of indeterminacy and lack of systematic generality in 'price behaviour' under contemporary market conditions. A recent alternative has been to apply game theory to perfect competition (see Mas-Colell 1980). What used to be a static state of affairs distinguished by the absence of any and all rivalry is now a non-cooperative equilibrium, independent of the number of agents, that may entail dynamic strategies of M periods contingent on past histories.

This re-introduces the long forgotten classical principle that interdependent, dynamic rivalries are what lead to the tendency toward uniformity in returns across the price system. A possible virtue of the approach is that not all games need have positive sum outcomes, so the question of competitive rivalry and economic efficiency is left open, not closed as in the pure neoclassical doctrine of perfect competition.

With all the intellectual baggage imposed by perfect and imperfect competition, however, is it not preferable to start fresh by examining and explaining in classical price–theoretic terms that systematic empirical tendency toward uniformity in returns? The first point is that the institutional conditions for free capital mobility in the industrial context of fixed capital have developed gradually and progressively over the course of economic development during the past two hundred years. They are to be found in the first instance not in the atomistic enterprise but in the evolution of the organizational structure and competitive strategies of today's representative firm, the industrially and geographically diversified, publicly held corporation. Top management in industry has increasingly assumed the role once reserved for bankers in day-to-day affairs, moving capital from areas of lower to areas of higher returns.

When finance is committed to industry as fixed capital, it is at once immobilized for its economic life. It does not have the character of putty which enables it to be moulded for any use promising today's highest return in the market. The greatest barriers to capital mobility existed for the single factory enterprise which typified organizational structures in the United States in the 1840s. Railroad firms created the first degree of capital mobility directly within the enterprise by pioneering the coordinated, multi-unit organization. From the 1890s on, a degree of capital mobility across industries was added by integrated manufacturing companies and by mass retailers. Truly diversified industrial corporations began appearing in the 1920s and by the 1930s, mass retailers were national in scope (see Chandler 1977, for a definitive history).

Beyond these structural elements in the development of capital mobility in the firm, the number of competitive strategies available to it from economies of large-scale organization and the intensity of the search for competitive advantage available from large budgets and staffs have also increased. Product innovations from a permanent R&D staff, advertising campaigns, takeovers and divestitures, together with price and credit competition give the firm added flexibility in responding to changes in market conditions and in initiating them.

Free capital mobility is not synonymous with the ability of atomistic firms or individual agents to move freely throughout the economy, whatever utopian analogies with a system of perfect liberty and individual freedom that may conjure up. What matters is the freedom of capital, however organized, so to move. As theoretical constructs, perfect and imperfect competition left a vision of capitalist development that is at complete odds with the actual historical development of conditions of free capital mobility. In this view, which is also espoused by many non-neoclassical economists, barriers to free capital mobility have

grown with the evolution of large corporations, and the system has become less competitive, not more competitive.

Even beyond considerations of corporate organization and strategy, free capital mobility is nowhere more fully developed in history than in the institutions of today's capital markets. Ever more integrated on a world scale, ever more innovative in the range of 'products' and services offered, the large firms which dominate these markets have such powerful and all-encompassing information networks as to approximate the economic assumption of perfect information in the short run, if not rational expectations in the long run.

The acceptance of market processes in ever more spheres of human existence beyond basic needs is a third sense in which free capital mobility is more highly developed today. Scale economies in automobile production are not barriers to entry into new fields of endeavour like the child care industry. Finally, with the growth of labour-intensive services as a proportion of the economy, more businesses take on the characteristics of merchant capital once again in history since even learned human capital is more malleable than fixed stock.

2. Beyond considerations of free capital mobility in explaining the uniformity in returns are other key issues that fall outside the scope of perfect and imperfect competition, whether or not amalgamated with game theory.

If today's oligopolistic firms are the slaves of the market as never before in history, in what sense are they 'pure price takers'? Such corporations are entirely unable to dictate their ex post rate of return in the market, whatever their ex ante pricing behaviour. It is with the ex post rate of return that the theory of competitive price is concerned, and that will be determined by many forms and intensities of competitive behaviour in the market, of which a suggested mark-up ex ante is only one. Partial equilibrium mark-up theories have never comprehended the difference between ex ante and ex post and err in believing ex ante pricing discretion implies some degree of ex-post monopoly power.

The very interdependence in decision-making between oligopolistic firms is what causes that ebb and flow of business and profits across firms, industries and markets so as to render the ex post rate of return fully competitive and beyond the control of the individual firm. Unfortunately, game theory was used for decades to deny the generality of contemporary competitive behaviour rather than to explain its most systematic feature in the convergence of accounting rates of return over the long run.

A virtue of the neoclassical theory of perfect competition was to provide a readily quantifiable means of measuring the intensity of competition – by the number of firms in a market. In consideration of non-price forms of competition, this precision in economic theory became lost, appearing in lieu of theory as an industrial organization 'paradigm' of market structure *and* conduct *and* performance. Can quantitative precision be resurrected in a general theory of competitive value for the modern age?

Observation tells us that the intensity of rivalry in contemporary markets can be measured by the *frequency* and *voracity* of changes in market conditions – the sum total of strategic moves and countermoves made by firms in that market per unit of time. The common denominator among all types of competition is to what measured degree does the action move business and profits from one sphere to another or one firm to another.

There is a clear analogy to perfect competition that can be made here. Were oligopolists in a market limited to the type of action an atomistic firm entering that market could take, pure price taking behaviour would emerge as the frequency of such strategic moves and countermoves increased without limit. Price for a homogeneous good would be bid down to its normal competitive minimum not by unlimited entry by one small firm after another, but by an unlimited number of atomistic-like strategic moves by the competing oligopolists.

Game theory to date appears to have overlooked the primacy of numbers of actions in

the marketplace over numbers of actors in resurrecting the general theory of competitive value, on measuring the intensity of competition as the frequency of strategic moves and countermoves in the first instance.

Of course, large firms are not restricted to atomistic competition. Cut-rate 'two percent' financing by General Motors Corporation in August 1986 was a competitive move that had the potential to draw a great amount of business and profits away from other firms. For that reason, this voracious move was imitated quickly by Ford and Chrysler.

Competition in the personal computer market has been intense not only because of voracious price breaks from time to time, but because the frequency of changes in market conditions has been enormous from real and cosmetic innovations in hardware and software. The frequency of competition among the commercial television networks in changing the time slots of programmes has at times approached the irrational from the consumer's standpoint.

3. When market processes are intensely competitive in the frequency, voracity or complexity of strategic moves and countermoves applied, what will be the nature of decisionmaking by the individual firm? Does active rivalry in the market necessarily mean 'maximizing behaviour', optimally efficient performance from decision-making at the margin?

One strong clue to the answer is the rejection of the marginal method *and* the assumption of constant returns to scale in recent classical general equilibrium models of competitive price determination (see Sraffa 1960). If maximizing behaviour underlies the classical approach, it certainly is not of pure neoclassical vintage, for decision-making at the margin requires marginal units which, according to Sraffa, are 'nowhere to be found' in the pure classical theory of competitive value.

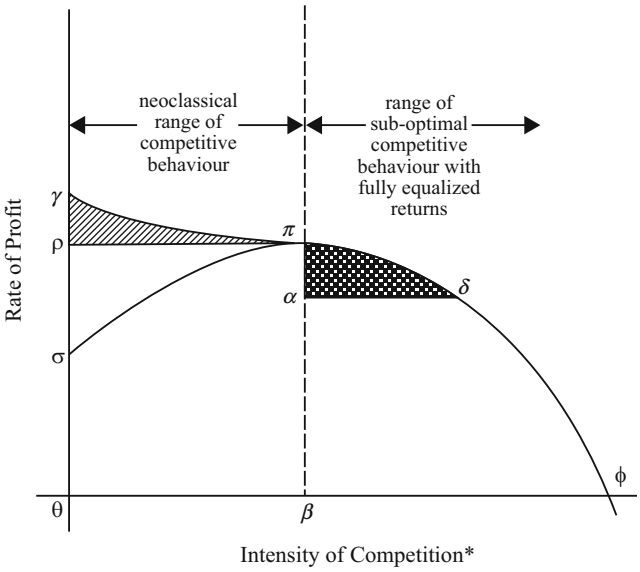
Nor is any notion of maximization or optimal efficiency to be found in the statement of technology or 'production function' of the pure classical system. The technology is not specified by input–output coefficients, which imply minimum input per unit of output. Only viability conditions for each industry at a given scale of output are listed. Viability is not the same thing as optimum efficiency in the use of a technique of production, whether under conditions of simple reproduction or the production of a surplus.

The entirely unsophisticated requirements for specifying technology in the classical determination of competitive value is an advantage, because it formally leaves open the question of whether fully competitive price behaviour in ongoing market processes is always efficient.

The empirically observed tendency of accounting rates of return to converge in the long run seems more assuredly decision-making by oligopolists where the intensity of competitive behaviour is asymmetric around a normal or average rate of profit. Whether from creditor or stockholder admonition, team pride or the threat of takeover, firms whose performance is below the normal rate of return are under stronger pressure to improve profitability than those whose performance is above the norm (see Cyert and March 1956).

Further, the attributes of intensely competitive market processes cause decision-making by the firm facing such discontinuities and complexities in its external environment to be the kind of 'bounded rationality' highlighted in the administrative theories of decision-making for different reasons related to the internal characteristics of large organizations (see Simon 1945).

The paradox of how 'maximum' effort or greater and greater rivalry directed through market processes can result in sub-optimal outcomes is precisely the question the business world, especially in America, seems to be asking itself today (see President's Commission 1985). While associated with even stronger and faster movements to capture new markets or eliminate excess profitability than less intensely competitive behaviour in bygone eras, classifying it as 'maximizing behaviour' or 'satisficing' can only lead to confusion. The



Competitive Market Processes,
Fig. 1 Efficiency and Inefficiency in Competitive Resource Allocation *For neoclassical theory, this axis measures the number of competitors, where the limit, represented by the vertical dashed line, is the familiar large numbers case of atomistic or perfect competition. For classical theory, the axis measures the frequency and magnitude of changes in market conditions. There is no limit to the intensity of such competitive behaviour

former implies efficiency where no such implication is warranted a priori, while the latter implies an absence of highly energetic behaviour from constantly striving, an implication at complete odds with the facts. A more neutral term like 'competitive behaviour' seems preferable.

4. If fully competitive price signals can exist under different degrees of industrial efficiency, then the moral sentiment of laissez-faire is not so readily justified in a competitive free enterprise system. Welfare economics must focus on competition as both virtue and vice, rather than competition as virtue and monopoly as vice, as in the past fifty years. Consider Fig. 1, which relates the intensity of competition to the degree of economic efficiency. In modern economic doctrine there are three unambiguous situations: pure monopoly (point γ), perfect competition (point π) and the long run shutdown point beyond which a firm cannot cover its total costs (point θ).

In the context of a single industry, ruinous competition is rightly viewed as self-correcting by market forces. Therefore, the entire scope of economic investigation is believed to have been between θ and β. The curve $\sigma\,\pi$ expresses the sentiment that the more competition the better for efficiency as measured by the rate of return. The curve $\gamma\,\pi$ expresses the proposition that the more competition, the lower the degree of monopoly, and the stronger the tendency toward uniformity in returns around a normal rate of profit ρ. All inefficiency is due to the absence of competition in sufficient degree, and may be measured as social welfare losses like the area $\gamma\,\sigma\,\pi$.

The principle justification for laissez-faire through history has been that 'competition without limit' must always enhance the general welfare by improving static or dynamic efficiencies, as expressed in the positive slope of $\sigma\pi$. Competition in effect can never become so intense, or of a character or complexity, that it pushes a market or an economic system beyond point π in the long run. In neoclassical theory, this is expressed as an increase in the number of firms without limit tending to produce a state of perfect competition.

Yet once we admit that ruinous competition has existed in history, is there no range of sub-optimal competitive behaviour between π and φ? Competition that is sufficiently intense to bid away all excess profits, but too intense to maximize efficiency and the general welfare? Fully competitive market processes that lead to sub-optimal outcomes – zero sum or even negative sum games?

If and only if such business practices are isolated in one or a few markets will they be self-correcting by the market. If they are, or have become, systemic throughout the economy, there is no reason to believe they will be self-regulating in the market in a way which leads to movement from a position like δ to the unique point of optimum efficiency associated with equality of returns, π.

I submit that today's general competitive equilibrium in resource allocation lies at a point like δ and that the free enterprise system in an atmosphere of laissez-faire is experiencing social welfare losses of the form $\pi \propto \delta$, not of the form $\pi \rho \gamma$ from monopolistic distortions.

There is no distortion in price signals associated with contemporary social welfare losses. They exist in a climate of intensely competitive market processes where the tendency toward equality of returns is stronger, not weaker. The real issue is becoming whether all this incessant change still represents a Schumpeterian process of creative destruction or an inefficient process of 'destructive creations'.

Free capital mobility has become so highly developed in financial markets and top management behaviour in corporations that it has led to the virtual collapse of the long period in setting aspiration levels for the rate of return on real capital formation in industry. This increase in the intensity of competition is generating an ongoing bias against efficiency-enhancing forms of strategic corporate behaviour in favour of stop-gap or crisis management forms of competition such as 'asset juggling', which does not affect the quality of products or the efficiency with which they are produced, distributed and sold.

The rate of change in and complexity of market conditions to which the firm must respond strategically has accelerated, not only in product and input markets, but also in economic policy variables here and abroad. The intensity of these competitive pressures is leading to the creation of corporate cultures that are very risk averse, and to decision-making of strictly bounded rationality that, however energetic, can hardly be called 'maximizing behaviour'.

The growing inability to protect positions of differential rent or supra-normal profits for a period necessary to sustain some of the most productive forms of risk-taking entrepreneurial behaviour is caused by the very intensity of competition in contemporary market processes. The crowding out of these Schumpeterian forms of dynamically efficient market processes is a third social welfare loss that exists in today's laissez-faire atmosphere.

The capitalization of finance on pure finance rather than real asset creation has become almost an epidemic of market processes that are of dubious value to the general welfare and that, moreover, increase the cost of capital for productive uses. For example, the increase in takeover divestiture type activities is associated with the creation of a distinct market for corporate control which simply changes the distribution of ownership and/or control of existing productive assets.

5. All seem to be agreed that competition has become more intense in recent decades and especially in recent years. I continue to maintain, as well, that there has been a secular increase in the intensity and complexity of competition over the course of capitalist development and that the free enterprise system continues to develop fundamentally along the lines of ever greater capital mobility.

   But it is also my contention that over the course of capitalist development and especially evident in recent years in America, the intensity of competition has become so great as to hinder industrial efficiency. Change for the sake of change rather than for economic and social progress. Competition, that engine of prosperity that has propelled us forward for two centuries, now seems to be of a character that it is holding us back.

This suggests a very different role for economic doctrine and public policy than either laissez-faire or the regulation of monopolistically competitive practices. It implies that intervention in the market which reduces the intensity or scope of certain

fully competitive practices will not inexorably lead to protected positions of monopoly or associated inefficiencies. Intervention may in all probability enhance economic growth or improve statical resource allocation while fully maintaining that attribute of distributive justice among risk-takers, insofar as the equality of returns is concerned, that is the hallmark of capitalism and freedom.

Computation of General Equilibria

Herbert E. Scarf

Abstract

The Walrasian model of economic equilibrium is a generalization to the entire economy of the basic notion that prices move to levels that equilibrate supply and demand. Although the model avoids some factors of economic significance, it is extremely useful in helping us evaluate the effects of changes in economic policy or the economic environment. A moderately realistic model designed to illustrate a significant economic issue typically involves a large system of highly nonlinear equations and inequalities. Existence of a solution is demonstrated by non-constructive fixed point theorems. The explicit numerical solution of such a model requires sophisticated computational techniques.

The general equilibrium model, as elaborated by Walras and his successors, is one of the most comprehensive and ambitious formulations in the current body of economic theory. The basic ingredients with which the Walrasian model is constructed are remarkably spare: a specification of the asset ownership and preferences for goods and services of the consuming units in the

economy, and a description of the current state of productive knowledge possessed by each of the firms engaged in manufacturing or in the provision of services. The model then yields a complete determination of the course of prices and interest rates over time, levels of output and the choice of techniques by each firm, and the distribution of income and patterns of saving for each consumer.

The Walrasian model is essentially a generalization, to the entire economy and to all markets simultaneously, of the ancient and elementary notion that prices move to levels which equilibrate supply and demand. No intellectual construction of this scope, designed to address basic questions in a subject as complex and elusive as economics, can be described as simply true of false – in the sense in which these terms are used in mathematics or perhaps in the physical sciences. The assertions of economic theory are not susceptible to crisp and immediate experimental verification. Moreover, the Walrasian model disregards obvious aspects of human motivation which are of the greatest economic significance and which cannot be addressed in the language of our subject: economic theory is mute about our affective lives, about our opposing needs for community and individual assertion, and about the non-pecuniary determinants of entrepreneurial energy.

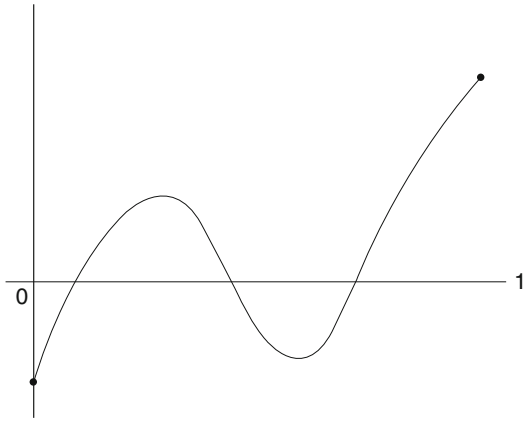
There are, in addition, aspects of economic reality which are capable of being described in the framework of the Walrasian model but which must be assumed away in order for the model to yield a determinate outcome. Uncertainty about the future is an ever-present fact of economic life, and yet the complete set of markets for contingent commodities required by the Arrow–Debreu treatment of uncertainty is not available in practice. Economies of scale in production are a central feature in the rise of the large manufacturing entities which dominate modern economic activity; their incorporation into the Walrasian model requires the introduction of non-convex production possibility sets for which the competitive equilibrium will typically fail to exist.

In spite of its many shortcomings, the Walrasian model – if used with tact and circumspection – is an important conceptual framework for evaluating the consequences of changes in economic policy or in the environment in which the economy finds itself. The effects of a major shock to the economy of the United States – such as the four-fold increase in the price of imported oil which occurred in late 1973 – can be studied by contrasting equilibrium prices, real wages and the choice of productive techniques both before and after the event in question. Generations of economists have used the Walrasian model to analyse the terms of trade, the impact of customs unions, changes in tariffs and a variety of other issues in the theory of International Trade. And much of the literature in the field of Public Finance is based on the assumption that the competitive model is an adequate description of economic reality.

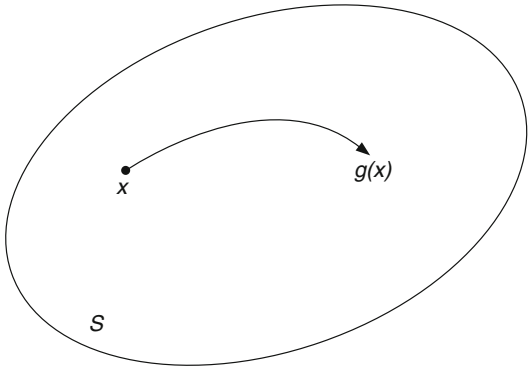
In these discussions the analysis is frequently conducted in terms of simple geometrical diagrams whose use places a severe restriction on the number of consumers, commodities and productive sectors that can be considered. This is in contrast to formal mathematical treatments of the Walrasian model, which permit an extraordinary generality in the elaboration of the model at the expense of immediate geometrical visualization. Unfortunately, however, it is only under the most severe assumptions that mathematical analysis will be capable of providing unambiguous answers concerning the direction and magnitude of the changes in significant economic variables, when the system is perturbed in a substantial fashion. In order for a comparative analysis to be carried out in a multi-sector framework it is necessary to employ computational techniques for the explicit numerical solution of the highly non-linear system of equations and inequalities which represent the general Walrasian model.

The Use of Fixed-Point Theorems in Equilibrium Analysis

One of the triumphs of mathematical reasoning in economic theory has been the demonstration of the existence of a solution for the general equilibrium model of an economy, under relatively mild assumptions on the preferences of consumers and the nature of production possibility sets (see



Computation of General Equilibria, Fig. 1



Computation of General Equilibria, Fig. 2

Debreu 1982). The arguments for the existence of equilibrium prices inevitably make use of Brouwer's fixed-point theorem, or one of its many variants, and any effective numerical procedure for the computation of equilibrium prices must therefore be capable of computing the fixed points whose existence is asserted by this mathematical statement.

Brouwer's fixed-point theorem, enunciated by the distinguished Dutch mathematician L.E.J. Brouwer in 1912, is the generalization to higher dimensions of the elementary observation that a continuous function of a single variable which has two distinct signs at the two endpoints of the unit interval, must vanish at some intermediary point. In Brouwer's Theorem the unit interval is replaced by an arbitrary closed, bounded convex set S in R^n, and the continuous function is replaced by a continuous mapping of the set S into itself: $x \rightarrow g(x)$ Brouwer's Theorem then asserts the existence of at least one point x which is mapped into itself under the mapping; that is, apoint x for which $x = g(x)$.To see how this conclusion is used in solving the existence problem let us begin by specifying, in mathematical form, the basic ingredients of the Walrasian model (Fig. 1).

The typical consumer is assumed to have a preference order for, say, the non- negative commodity bundles $x = (x_1,x_2,\ldots,x_n)$ in R^n; the preference ordering is described either by a specific utility function $u(x_1,x_2,\ldots,x_n)$ or by means of an abstract representation of preferences. The consumer will also possess, prior to production and trade, a vector of initial assets $w=(w_1,w_2,\ldots,w_n)$. When a non- negative price vector $p= (p_1,p_2,\ldots, p_n)$ is announced the consumer's income will be $I = p \cdot w$ and his demands will be obtained by maximizing preferences subject to the budget constraint $p \cdot x \leq p \cdot w$. If the preferences satisfy sufficient regularity assumptions, the consumer's demand functions $x(p)$ will be single-valued functions of p, continuous (except possibly when some of the individual prices are zero), homogeneous of degree zero and will satisfy the budget constraint $p \cdot x(p) = p \cdot w$ (Fig. 2).

The market demands are obtained by aggregating over individual demand functions and, as such, will inherit the properties described above. The market *excess* demand functions, which I shall denote by $f(p)$, arise by subtracting the supply of assets owned by all consumers from the demand functions themselves. It is these functions which are required for a complete specification of the consumer side of the economy in the general equilibrium model: they may be obtained either by the aggregation of individual demand functions – as we have just described – or they may be directly estimated from econometric data. The following properties will hold, either as a logical conclusion or by assumption:

1. $f(p)$ is homogeneous of degree zero.
2. $f(p)$ is continuous in the interior of the positive orthant.
3. $f(p)$ satisfies the Walras Law $p \cdot f(p)=0$.

The first of these properties permits us to normalize prices in any one of several ways; for example, $\Sigma pj = 1$ or $\sum p_j^2 = 1$. Given either of these normalizations, I personally do not find it offensive to extend the property of continuity to the boundary, even though there are elementary examples of utility functions, such as the Cobb–Douglas function, for which this would not be correct.

The production side of the economy requires for its description a complete specification of the current state of technical knowledge about the methods of transforming inputs into outputs – with commodities differentiated according to their location and the time of their availability. This can be done by means of production functions, an input/output table with substitution possibilities and several scarce factors rather than labour alone, or by a general activity analysis model:

$$\mathrm{A} = \begin{bmatrix} -1 & 0 & \dots & 0 & a_{1,n+1} & a_{1,k} \\ 0 & -1 & & 0 & a_{2,n+1} & a_{2,k} \\ \vdots & \vdots & & \vdots & \vdots & \vdots \\ 0 & 0 & & -1 & a_{n,n+1} & a_{n,k} \end{bmatrix}$$

Each column of A describes a particular productive process, with inputs represented by non-negative entries and outputs by positive entries. The activities are assumed capable of being used simultaneously and at arbitrary non-negative levels $x = (x_1,x_2,\dots,x_k)$; the net production plan is then $y = \mathrm{A}x$ (Fig. 3).

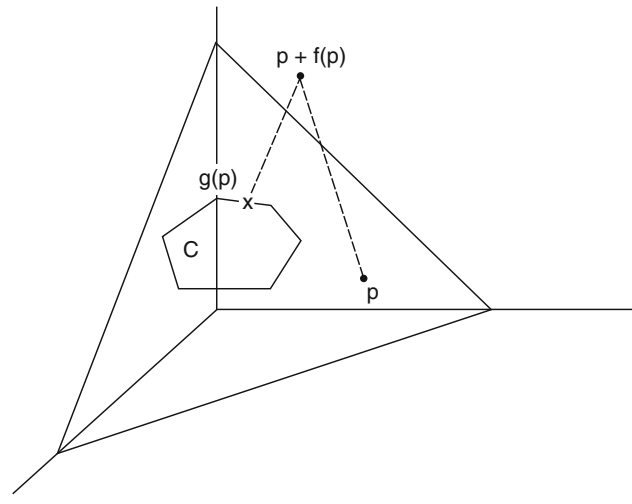
With this formulation, a competitive equilibrium is defined by a non-negative vector of prices $p = (p_1,p_2,\dots,p_n)$ and a non-negative vector of activity levels $x = (x_1,x_2,\dots x_k)$ satisfying the following conditions:

1. $f(p) = \mathrm{A}x$,
2. $p\mathrm{A} \leq 0$.

The first condition states that supply and demand are equal in all markets, and the second that there are not opportunities for positive profits when the profitability of each activity is evaluated at the equilibrium prices. Taken in conjunction with the Walras's Law, these conditions imply that those activities which are used at a positive level in the equilibrium solution make a profit of zero.

Given the assumption of continuous and single-valued excess demand functions and the description of the production possibility set by means of an activity analysis model, the following rather direct application of Brouwer's Theorem is sufficient to demonstrate the existence of a equilibrium solution. Under weaker assumptions on the model, variants such as Kakutani's Fixed-Point Theorem may be required.

Computation of General Equilibria, Fig. 3



Let prices be normalized so as to lie on the unit simplex $S = \{p = (p_1,p_2,\ldots,p_n) | p_i \geq 0, \sum pi = 1\}$. The set of prices p for which $pA \leq 0$ is termed the *dual* cone of the production possibility set generated by the activity matrix A. Its intersection with the unit simplex is a convex polyhedron C consisting of those normalized prices which yield a profit less than or equal to zero for all activities.

We construct a continuous mapping of S into itself as follows: for each p in S consider the point $p + f(p)$; a point which is generally not on the unit simplex itself. We then define $g(p)$ – the image of p under the mapping – to be that point in C which is closest, in the sense of Euclidean distance, to $p + f(p)$. It is then an elementary application of the Kuhn–Tucker Theorem to show that a fixed point of this mapping is, indeed, an equilibrium price vector.

The Equilibrium Model as a Tool for Policy Evaluation

Brouwer's original proof of his theorem was not only difficult mathematically, but it was decidedly non-constructive; it offered no method for effectively computing a fixed point of the mapping. Brouwer did, in fact, reject his own argument during the later 'intuitionist' phase of his career, in which he proclaimed the acceptability of only those mathematical conclusions obtained by constructive procedures. In spite of the many simplifications in the proof of Brouwer's Theorem offered during the subsequent half-century, it was not until the mid-1960s that constructive methods for approximating fixed points of a continuous mapping finally made their appearance on the scene (Scarf 1967) – aided by the development of the modern electronic computer and by the rapid methodological advances in the discipline of operations research.

In the early decades of this century, the question of the explicit numerical solution of the general equilibrium model was an active topic of discussion – not by numerical analysts – but rather by economists concerned with the techniques of economic planning in a socialist economy. The issue was raised in the remarkable paper published by Enrico Barone in 1908, entitled 'The Ministry of Production in a Socialist Economy'. Barone, and subsequently Oskar Lange (1936), accepted the Walrasian model – with suitable transfers of income – as an adequate description of ideal economic activity in an economy in which the means of production were collectively owned. In the absence of markets, prices, levels of output and the choice of productive techniques were to be obtained by an explicit numerical solution of the Walrasian system. A key feature of Barone's analysis was the concept of the 'technical coefficients of production' – the input/output coefficients associated with those activities in use at equilibrium. Barone's contention was that the equilibrium could be found – by an extremely laborious calculation which might indeed claim a significant share of the national product – only if the correct activities were known in advance. For Barone, rational economic calculation in a socialist economy was defeated by the many opportunities for substitution in production: the particular activities in use at equilibrium would be impossible to determine by a prior computation. It is instructive to quote Barone on this point.

> The determination of the coefficients economically most advantageous can only be done in an *experimental* way: and not on a *small scale*, as could be done in a laboratory; but with experiments on a *very large scale*, because often the advantage of the variation has its origin precisely in a new and greater dimension of the undertaking. Experiments may be successful in the sense that they may lead to a lower cost combination of factors; or they may be unsuccessful, in which case the particular organization may not be copied and repeated and others will be preferred, which *experimentally* have given a better result.
>
> The Ministry of Production could not do without these experiments for the determination of the *economically* most advantageous technical coefficients if it would realize the condition of the minimum cost of production which is *essential* for the attainment of the maximum collective welfare.
>
> It is on this account that the equations of the equilibrium with the maximum collective welfare are not soluble *a priori*, on paper.

An Elementary Algorithm

Barone's negative conclusion is certainly valid if the full production possibility set, including all of

the possibilities for substitution in production, is not known to the central planner. In this event, numerical calculation is impossible, and Lange's suggestion, made some 20 years later, may be appropriate: the problem can be turned on its head and the market, itself, can be used as a mechanism of discovery as well as a giant analogue computer. But if the production possibility set can be explicitly constructed, substitution – in and of itself – does not seem to me to be a severe impediment to numerical computation.

At the present moment, some 20 years after the introduction and continued refinement of fixed-point computational techniques, I have in my possession a small floppy disk with a computer program which will routinely solve – on a personal computer – for equilibrium prices and activity levels in a Walrasian model in which the number of variables is on the order of 100. (The authors of the program suggest that examples with 300 variables can be accommodated on a mainframe computer.) Substantial possibilities of substitution, if known in advance, offer no difficulty to the successful functioning of this algorithm. In my opinion, the modern restatement of Barone's problem is rather that even 300 variables are extremely small in number in contrast to the millions of prices and activity levels implicit in his account. The computer, while expanding our capabilities immeasurably, has taught us a severe lesson about the role of mathematical reasoning in economic practice and forced us to shift our point of view dramatically from that held by our predecessors. We realize that our preoccupations are not with universal laws which describe economic phenomena with full and complete generality, but rather with intellectual formulations which are an imperfect representation of a complex and elusive reality. The application of general equilibrium theory to economic planning, and more generally to the evaluation of the consequences of changes in economic policy, must be based on highly aggregated models whose conclusions are at best tentative guides to action.

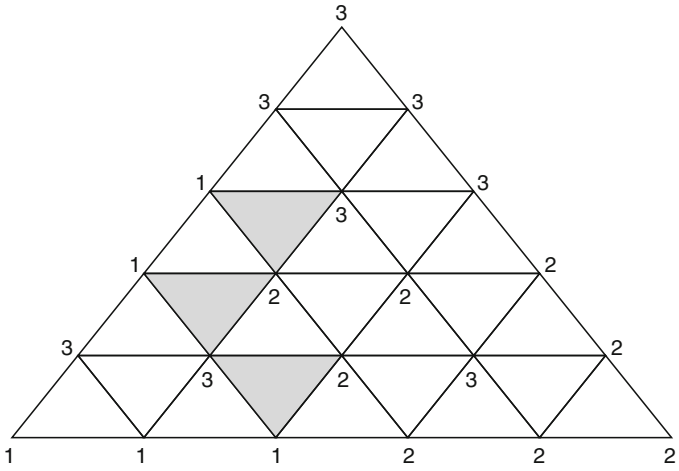
An exercise in comparative statics is begun by constructing a general equilibrium model whose solution reflects the economic situation existing prior to the proposed policy change. The number of parameters required to describe demand functions, initial endowments and the production possibility set is considerable, and in practice the constraint of reproducing the current equilibrium must be augumented by a variety of additional statistical estimates in order to specify the model. The limitations of data in the form required by the Walrasian model inevitably make this estimation procedure less than fully satisfactory.

The second step in the exercise is to calculate the solution after the proposed policy changes are explicitly introduced into the model. In some cases the policy variables being studied can be directly incorporated as parameters in the equations whose solution yields the equilibrium values; if the changes are small, their effects on the solution may be obtained by differentiating these equations and solving the resulting linear system for the corresponding changes in the equilibrium values themselves. This approach was adopted by Leif Johansen (1960) and by Arnold Harberger (1962) in his study of the incidence of a tax on corporate profits. The use of this method in policy analysis continues in Norway, and it forms the basis of the amibitious programme carried out by Peter Dixon and his collaborators in Australia (1982). If, on the other hand, the policy changes are large, the equilibrium position may be shifted substantially, and its determination may require the use of more sophisticated computational methods.

Fixed-point algorithms can be divided into two major classes: those based on the elements of differential topology, surveyed by Smale (1981), and those which are combinatorial in nature. The most elementary of the combinatorial algorithms for approximating a fixed point of a continuous mapping of the unitsimplex $S = \{(x = (x_1, x_2, \ldots, x_n) | x_i \geq 0, \sum x_i = 1\}$ begins by dividing the simplex into a large number of small subsimplices as illustrated in Fig. 4. In our notation the simplex is of dimension $n-1$ and has faces of dimension $n-2, \ldots, 1$. It is a requirement of the subdivision that the intersection of any two of the subsimplices is either empty or a full lower dimensional face of both of them.

Each vertex of the subdivision will have associated with it an integer label selected from the set

Computation of General Equilibria, Fig. 4



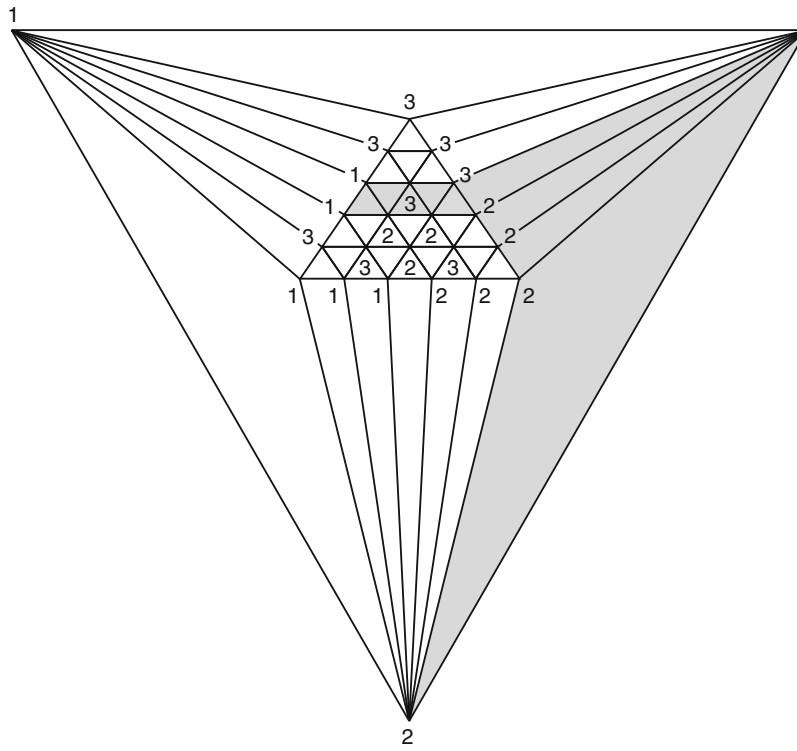
(1, 2,. . ., *n*). When the method is applied to the determination of a fixed point of a particular mapping, the labels associated with a vertex will depend on the mapping evaluated at that point. For the moment, however, the association will be arbitrary aside from the requirement that a vertex on the boundary of the simplex will have a label *i* only if the *i*th coordinate of that vertex is positive.

The remarkable combinatorial lemma demonstrated by Emanuel Sperner (1928) in his doctoral thesis is that at least one subsimplex must have all of its vertices differently labelled. Assuming this result to be correct, let us consider a mapping of the simplex in which the image of the vector $x = (x_1,\ldots,xn)$ is $f(x) = [f_1(x),\ldots, f_n(x)]$. The requirement that the image be on the simplex implies that $f_i(x) \geq 0$ and that $\sum fi(x) = 1$. It follows that for every vertex of the subdivision *v*, unless *v* is a fixed point of the mapping, there will be a least one index *i* for which $fi(v) - vi < 0$. If we select such an index to be the label associated with the vertex *v*, then the assumptions of Sperner's Lemma are clearly satisfied, and the conclusion asserts the existence of a simplex whose vertices are distinctly labelled.

If the simplicial subdivision is very fine, the vertices of this sub-simplex are all close together; at each vertex a different coordinate is decreasing under the mapping, and by continuity every point in the small subsimplex will have the property that each coordinate is not increasing very much under the mapping. Since the sum of the coordinate changes is by definition zero, the image of any point in the completely labelled subsimplex will be close to itself, and such a point will therefore serve as an approximate fixed point of the mapping. A formal proof of Brouwer's Theorem requires us to construct a sequence of finer and finer subdivisions, to find, for each subdivision, a completely labelled simplex, and to select a convergent sequence of these simplices tending to a fixed point of the mapping.

Sperner's Lemma may be applied to the equilibrium problem directly. For simplicity, consider the model of exchange in which the market excess demand functions are given by $g(p)$, with p on the unit price simplex. As before, we subdivide the simplex and associate an integer label from the set (1,. . ., *n*) with each vertex *v* of the subdivision, according to the following rule: the label *i* is to be selected from the set of those indices of which $g_i(p) \leq 0$. It is an elementary consequence of Walras's Law that a selection can be made which is consistent with the assumptions of Sperner's Lemma, and there will therefore be a subsimplex all of whose vertices bear distinct labels. By virtue of the particular labelling rule, any point in such a completely labelled simplex will be an approximate equilibrium price vector in the sense that all excess demands, at this price, will be either negative or, if positive, very small.

Computation of General Equilibria, Fig. 5



Sperner's original proof of his combinatorial lemma was not constructive; it was based on an inductive argument which required a complete enumeration of all completely labelled simplices for a series of lower dimensional problems. In order to develop an effective numerical algorithm for the determination of such a simplex let us begin by embedding the unit simplex, and its subsimplices, in a larger simplex T, as in Fig. 5. The larger simplex is subdivided by joining its n new vertices to those vertices of the original subdivision lying on the boundary of the unit simplex. The assumptions of Sperner's Lemma permit the new vertices to be given distinct labels from the set $(1,\ldots, n)$, in such a way that no additional completely labelled simplices are generated. For concreteness, let the new vertex receiving the label i be denoted by v^i.

We begin our search for a completely labelled simplex by considering the simplex with vertices $v^2,\ldots, v^n$ and one additional vertex, say v^*. If v^* has the label 1, this simplex is completely labelled and our search terminates; otherwise we move to an adjacent simplex by removing the vertex whose label agrees with that of v^* and replacing it with that unique other vertex yielding a simplex in the subdivision. As the process continues, we are, at each step, at a simplex whose vertices bear the labels $2,\ldots,n$, with a single one of these labels appearing on a pair of vertices. Precisely two $n-2$ dimensional faces have a complete set of labels $2,\ldots,n$. The simplex has been entered through one of these faces; the algorithm proceeds by exiting through the other such face.

The argument first introduced by Lemke (1965) in his study of two person non- zero sum games was carried over by Scarf (1967) to show that the above algorithm never returns to a simplex previously visited and never requires a move outside of T. Since the number of simplices is finite, the algorithm must terminate, and termination can only occur when a completely labelled simplex is reached.

Improvements in the Algorithm

The algorithm can easily be programmed for a computer, and it provides the most elementary numerical procedure for approximating fixed points of a continuous mapping and equilibrium prices for the Walrasian model. Since its introduction in 1967, the algorithm, in this particular form, has been applied to a great number of examples of moderate size, and it performs sufficiently well in practice to conclude that the numerical determination of equilibrium prices is a feasible undertaking. The algorithm does, however, have some obvious drawbacks which must be overcome to make it available for problems of significant size. For example, the information which yields the labelling of the vertices, and therefore the path taken by the algorithm, is simply the index of a coordinate which happens to be decreasing when the mapping is evaluated at the vertex. More recent algorithms make use of the full set of coordinates of the image of the vertex instead of a single summary statistic.

Second, this primitive algorithm is always initiated at the boundary of the simplex. If the approximation is not sufficiently good, the grid size must be refined, and a recalculation, which makes no use of previous information, must be performed. It is of the greatest importance to be able to initiate the algorithm at an arbitrary interior point of the simplex selected as our best a priori estimate of the answer.

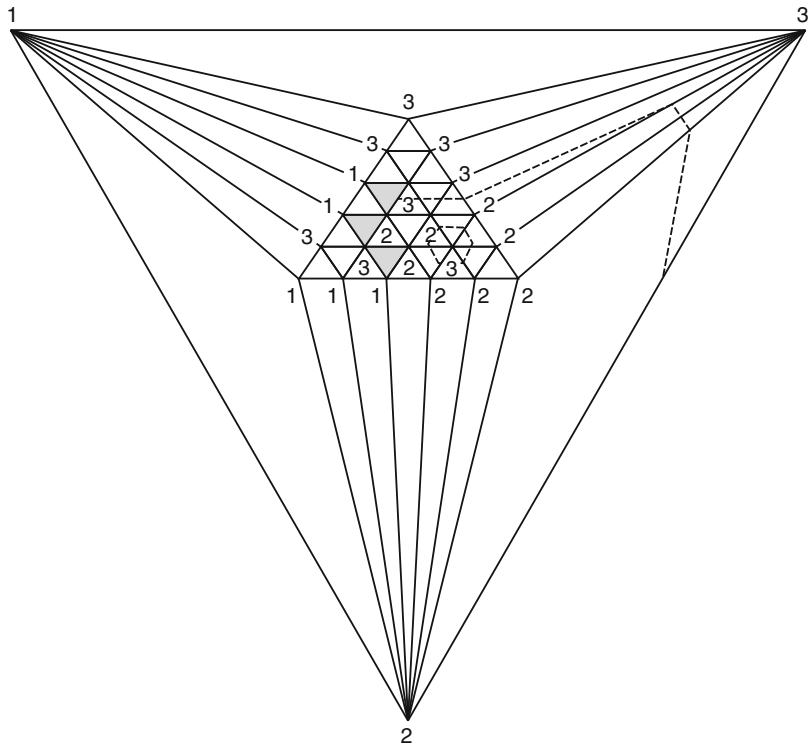
The following geometrical setting (Eaves and Scarf 1976) for the elementary algorithm suggests the form these improvements can take. Let us construct a piecewise linear mapping, $h(x)$, of T into itself as follows: for each vertex v in the subdivision let $h(v)=v^i$, where i is the label associated with v. We then complete the mapping by requiring h to be linear in each simplex of the subdivision. The mapping is clearly continuous on T and maps every boundary point of T into itself. Moreover, every subsimplex in the subdivision whose vertices are not completely labelled is mapped, by h, into the boundary of T. If none of the simplices were completely labelled, this construction would yield a most improbable conclusion: a continuous mapping of T into itself which is the identity on the boundary and which maps the entire simplex into the boundary. That such a mapping cannot exist is known as the Non-Retraction Theorem, an assertion which is, in fact, equivalent to Brouwer's Theorem. The impossibility of such a mapping reinforces our conclusion that a completely labelled simplex does exist.

Select a point c interior to one of the boundary faces of T and consider the set of points which map into c; that is, the set of x for which $h(x)=c$. As Fig. 6 indicates, this set contains a piecewise linear path beginning at the point c, and transversing precisely those simplices encountered in our elementary algorithm. There are however, other parts of the set $\{x|h(x)=c\}$: closed loops which do not touch the boundary of T and other piecewise linear paths connecting a pair of completely labelled simplices. Stated somewhat informally, the general conclusion, of which this is an example, is that the inverse image of a particular point, under a piecewise linear mapping from an n dimensional set to an $n-1$ dimensional set, consists of a finite union of interior loops, and paths which join two boundary points (see Milnor 1965, for the differentiable version).

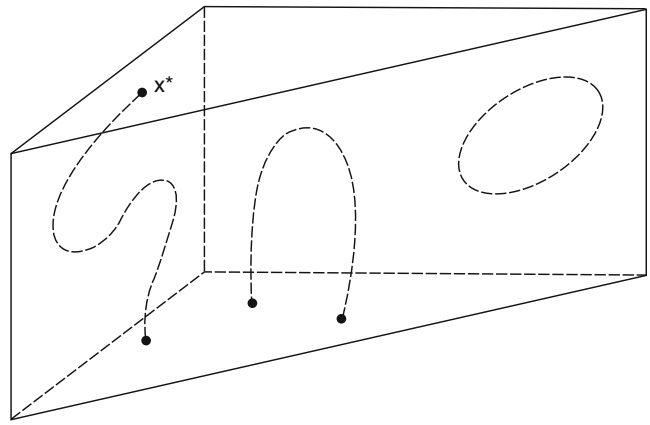
To see how this observation can be used, consider the product of the unit simplex S and the closed unit interval [0, 1]; that is, the set of points (x, t) with x in S and $0 \leq t \leq 1$, as in Fig. 7. Extend the mapping from the unit simplex to this large set by defining $F(x,t)=(1-t)\,f(x)+tx^*$, with x^* a preselected point on the simplex, taken to be an estimate of the true fixed point. The set of points for which $F(x,t)-x=0$ is, by our general conclusion, a finite union of paths and loops. Precisely one of these paths intersects the upper boundary of the enlarged set. If the path is followed, its other endpoint must lie in the face $t=0$ and yield a fixed point of the original mapping.

The path leading to the fixed point can be followed on the computer in several ways. We can, for example, introduce a simplicial decomposition of the set $S \times [0, 1]$ and approximate F by a piecewise linear mapping agreeing with F on the vertices of the subdivision. Following the path then involves the same type of calculation we have become accustomed to in carrying out linear programming pivot steps. There are a great many variations in the mode of simplicial subdivision

Computation of General Equilibria, Fig. 6



Computation of General Equilibria, Fig. 7



leading to substantial improvements in the efficiency of our original fixed-point algorithm (Eaves 1972; Merrill 1971; van der Laan and Talman 1979).

An alternative procedure, adopted by Kellogg et al. (1976) and Smale (1976), is to impose sufficient regularity conditions on the underlying mapping so that differentiation of $F(x,t)-x = 0$ yields a set of differential equations for the path joining x^* to the fixed point on $t = 0$. This leads to a variant of Newton's method which is global in the sense that it need not be initiated in the vicinity of the correct answer. But, whichever of these alternatives we select, the numerical

difficulties in computing equilibrium prices can be overcome for all problems of reasonable size.

Applied General Equilibrium Analysis

During the last 15 years, the field of Applied General Equilibrium Analysis has grown considerably; instead of the few tentative examples illustrating our ability to solve general equilibrium problems, we have seen the construction of a large number of models of substantial size designed to illuminate specific policy issues. The number of books and papers which have appeared in the field is far too large for a complete enumeration in this essay, and I shall mention only a few public ations which may be consulted to obtain an indication of the diversity of this activity. The paper by Shoven and Whalley (1984) in the *Journal of Economic Literature* is a survey of applied general equilibrium models in the fields of taxation and international trade constructed by these authors and their colleagues. The volume by Adelman and Robinson (1978) is concerned with the application of general equilibrium analysis to problems of economic development. Whalley (1985) has written on trade liberalization, and Ballard et al. (1985) on the evaluation of tax policy. Jorgenson (Hudson and Jorgenson 1974) and Manne (1976) have made extensive applications of this methodology to energy policy, and Ginsburg and Waelbroeck (1981) provide a refreshing discussion of alternative computational procedures applied to a model of international trade involving over 200 commodities. The volume edited by Scarf and Shoven (1985) contains a collection of papers presented at one of an annual series of workshops in which both applied and theoretical topics of interest to researchers in the field of Applied General Equilibrium Analysis are discussed.

Computation of General Equilibria (New Developments)

Felix Kubler

Abstract

In this article, I review two recent developments in the theory of computation of general equilibria. First, following Brown et al. (1996) several papers have developed globally convergent algorithms for the computation of general equilibria in models with incomplete asset markets. I review some of the developments in that area. Second, new developments in computational algebraic geometry lead to algorithms to compute effectively all equilibria of systems of polynomial equations. I point out some applications of these algorithms to general equilibrium theory.

Introduction

After Scarf (1967) showed that there exist globally convergent (and effectively applicable) algorithms to compute economic equilibria, there is now a class of computable applied models which are routinely used to evaluate the economic consequences of different taxes and tariff structures (see, for example, Shoven and Whalley 1992). Research on efficient algorithms for the computation of general equilibria in these models largely took place outside of economics.

A large literature in numerical analysis has developed algorithms that are much faster than Scarf's original method and that can be used for large-scale applications. Efficient iterative schemes, mostly based on global Newton methods, now allow applied researchers to solve for competitive equilibria in models with hundreds of commodities and agents (see, for example, Ferris and Pang 1997).

Recently, there has been substantial research in theoretical computer science on the development of polynomial time algorithms for the computation of general equilibria. For most existing methods, the number of operations needed to approximate equilibria within a fixed precision ε grows exponentially in $1/\varepsilon$. Under restrictive assumptions on preferences, in models without production, researchers have developed algorithms to approximate equilibria 'in polynomial time', that is, the running time of the algorithm increases polynomially in the input parameters and in the precision with which equilibria are

computed. Codenotti et al. (2004) give an overview on recent developments along this line.

In this article I will not discuss any of these practical aspects of the solution of large-scale models. I will instead focus on the following two unrelated developments in the computation of general equilibria in economics.

1. The computation of equilibria in models with time, uncertainty and missing asset markets.
2. The computation of all equilibria and the relationship between exact and approximate equilibria in the standard Arrow–Debreu model.

Models with Asset Markets

Due to their essential static nature, standard computable general equilibrium models suffer from an oversimplified treatment of uncertainty. Agents either solve a static problem or have myopic expectations, and the model can therefore not explicitly incorporate investment and saving decisions. The general equilibrium model with incomplete asset markets (GEI model) provides a basic framework with several agents and several commodities to incorporate uncertainty and financial markets. See, for example, Magill and Qunizii (1996) for an overview of the literature. The computation of equilibria in these models is challenging because in some specifications equilibria fail to exist while in others they are often numerically unstable.

Kehoe and Prescott (1995) argue that real business cycle models provide an alternative way to extend computable general equilibrium to models with time and uncertainty. There is now a large literature on the computation of equilibria in dynamic stochastic economies. This is reviewed elsewhere in this dictionary; see approximate solutions to dynamic models (linear methods); see also Judd (1998).

In the standard GEI model there are two time periods (Kubler and Schmedders 2000, show how the problem of computation of equilibria in multi-period finance models can be essentially reduced to the two period case) and S possible states of the world in the second period. There are L perishable commodities available for trade at each state. There are H agents with endowments $e^h \in \mathbb{R}_+^{(S+1)L}$ and utility functions $u^h : \mathbb{R}_+^{(S+1)L} \to \mathbb{R}$. It is assumed throughout this article that utility functions are smooth in the sense of Debreu (1972) – that is, utility is C^2, strictly increasing, strictly quasi-concave, exhibits non-zero Gaussian curvature and indifference curves do not cut the axes.

There are J assets available for trade. In each state s, asset j pays a bundle of commodities $a_j(s) \in \mathbb{R}^L$. It is without loss of generality to assume that the $LS \times J$ matrix

$$A = \begin{pmatrix} a_1(1) & \dots & a_J(1) \\ \vdots & \ddots & \vdots \\ a_1(S) & \dots & a_J(S) \end{pmatrix}$$

has full rank J. Allowing assets to pay in different commodities is crucial when one wants to extend the model to several time periods and long-lived securities.

In the following, it will be useful to write commodity prices as

$$\begin{aligned} p &= (p(0), p(1), \dots, p(S)) \in \Delta^{(S+1)L-1} \\ &= \left\{ p \in \mathbb{R}_+^{(S+1)L} : \sum_i p_i = 1 \right\}, \end{aligned}$$

and the $S \times J$ asset payoff matrix (as a function of spot prices $p(1) \dots p(S)$), $R(p)$, as

$$R(p) = \begin{pmatrix} p(1) \cdot a_1(1) & \dots & p(1) \cdot a_J(1) \\ \vdots & \ddots & \vdots \\ p(S) \cdot a_1(S) & \dots & p(S) \cdot a_J(S) \end{pmatrix}.$$

In part of the discussion we assume an exogenous short-sale constraint, that is, there is a number $0 < K \leq \infty$ such that the two-norm of an agent's portfolio must always be less than or equal to K. One can then write an agent's aggregate excess demand function as the solution of his maximization problem in the GEI economy.

$$\begin{aligned} \left(z^h(p), \varphi^h(p)\right) &= \arg \max_{z \in \mathbb{R}^{L(S+1)}, \varphi \in \mathbb{R}^J} u\left(e^h + z\right) \text{ s.t.} p \cdot z \\ &= 0(p(1) \cdot z(1), \dots, p(S) \cdot z(S))^T \\ &= R(p) \cdot \varphi \| \varphi \| \leq K. \end{aligned}$$

A GEI equilibrium is a collection of prices, portfolios and a consumption allocation such that markets clear and each agent maximizes her utility, i.e. equilibrium prices p are characterized by $\sum_{h=1}^{H} z^h(p) = 0$.

In a slight idealization (see also the more precise definition in the next section), we assume that the maximization problem can be solved exactly and we define an ε-equilibrium as a price $\overline{p}$ such that

$$||\sum_{h=1}^{H} z^h(\overline{p})|| < \varepsilon.$$

A General Algorithm

Although generally $R(p)$ will have full rank J, there will be so-called 'bad prices' at which the rank of $R(p)$ drops. When there are no short sale constraints, that is, $K = \infty$, this leads to a discontinuity of excess demand. Scarf's algorithm fails: no matter how fine the simplicial subdivision, if the algorithm terminates at some $\overline{p}$, one cannot necessarily infer a bound on $\|z(\overline{p})\|$ and hence cannot find an ε-equilibrium.

Homotopy continuation methods (see Garcia and Zangwill 1981; Eaves 1972) turn out to be ideally suited for this numerical problem. In order to solve a system of equations $f(x) = 0, f: X \to Y$, the basic idea underlying homotopy methods is to find a smooth map $H : X \times [0, 1] \to Y$ with

$$H(x, 1) \equiv f(x) \text{ and } H(x, 0) \equiv g(x),$$

where $g : X \to Y$ has a known unique zero. The map H is called a smooth homotopy. In using homotopy methods it is crucial to set up the function, H, to ensure that there is a smooth path that connects $(x^s,0)$ with $g(x^s) = 0$ to some $(\overline{x}, 1)$ with $f(\overline{x}) = 1$.

Brown et al. (1996) develop a homotopy algorithm which can be shown to be globally convergent in that it finds an ε-equilibrium for any $\varepsilon > 0$ in a finite number of steps. Following the so-called Cass-trick, it is useful to introduce an unconstrained agent, that is, to define the first agent maximization problem as

$$z^u(p) = \arg\max_z u^1(e + z) \text{ s.t.} p \cdot z = 0,$$

and aggregate demand as $z(p) = z^u(p) + \sum_{h=2}^{H} z^h(p)$. Note that $\overline{p}$ is a GEI equilibrium (given that $K = \infty$) if and only if $z(p) = 0$. An ε-equilibrium is characterized by $\|z(p)\| < \varepsilon$.

Define the expenditure of the unconstrained agent y^u as

$$y^u = \big(p(1) \cdot z_1^u(p), \ldots, p(S) \cdot z_S^u(p)\big).$$

Define an extended payoff matrix $R^*(p)$ by

$$R * (p) = [R(p), y^u(p)]$$

and let $R^*_{-i}(p)$ be $R^*(p)$ with the i'th column deleted. For the constrained agents $h = 2, \ldots, H$ define

$$z^h\big(p, R^*_{-i}(p)\big) = \arg\max_{z,\varphi} u^h\big(e^h + z\big) \text{ s.t.} p \cdot z = 0$$

$$(p(1) \cdot z(1), \ldots, p(S) \cdot z(S))^T = R^*_{-i}(p) \cdot \varphi.$$

Now consider a family of homotopies, indexed by i

$$H_i(p, t, \theta) = \begin{pmatrix} z^u(p) + t\sum_{h=2}^{H} z^h\big(p, R^*_{-i}(p)\big) \\ R * (p)\theta \\ \theta \cdot \theta - 1 \end{pmatrix}.$$

To prove existence of a homotopy path, Brown et al. (1996) show that $\cup_{i=1}^{J+1} H_i^{-1}$ contains a smooth path connecting the starting point to a solution at $t = 1$.

While generically in endowments a homotopy path turns out to exist, the algorithm is hardly applicable in medium-sized problems, since the number of homotopies one has to consider can become quite large. An alternative is to focus on models with $K < \infty$ (or alternatively models with transaction costs) or to consider algorithms which might fail in a small class of problems but which are generally more efficient.

Short-Sale Constraints

In the presence of short-sale constraints, the excess demand function is continuous and equilibrium existence can be proven with Brouwer's theorem. Therefore, one could presumably use a version of Scarf's algorithm to compute equilibria in this case. However, while there are no new mathematical problems to be solved, the fact that the rank of the asset–payoff matrix can still collapse in equilibrium poses difficult numerical problems. Simple Newton method-based algorithms often do not work (see Kubler and Schmedders 2000) unless one has a starting point very close to the actual solution. It turns out that, just as in the problem without short-sale constraints, homotopy continuation methods can provide a basis for reliable algorithms.

Schmedders (1998) develops a homotopy algorithm which can be used to solve models with a large number of heterogeneous households and goods. The basic idea of his algorithm is to modify the agents' problem by introducing a homotopy parameter $t \in [0, 1]$ as follows.

$$\left(z^h(p,t),\varphi^h(p,t)\right) = \arg \max_{z\in\mathbb{R}^{L(S+1)},\varphi\in\mathbb{R}^J} u\left(e^h+z\right) - (1-t)\frac{1}{2}||\varphi||^2 \text{ s.t. } p\cdot z = 0(p(1)\cdot z(1),\ldots,p(S)\cdot z(S)) = R(p)\cdot\varphi||\varphi|| \le K.$$

Under the assumptions on utilities this is still a convex problem and the first order Kuhn–Tucker conditions are necessary and sufficient. Schmedders provides various examples that show that even for $K = \infty$ his algorithm, although not guaranteed to converge, performs well in practice.

For $K < \infty$, the Kuhn–Tucker inequalities can be converted into a system of equalities via a change of variables (see Garcia and Zangwill 1981, ch. 4). Kubler (2001), Herings and Schmedders (2006) and others subsequently used this idea to solve models with transaction costs, trading constraints and other market imperfections.

Of course, it is an important practical problem how to trace out a homotopy path numerically. See Watson (1979) for a theoretical algorithm. For a practical description of numerical homotopy path-following methods see Schmedders (2004).

Equilibria in Semi-algebraic Economies

While it is clear that sufficient assumptions for the global uniqueness of competitive equilibria are too restrictive to be applicable to models used in practice, it remains an open problem how serious a challenge the non-uniqueness of competitive equilibrium poses to applied equilibrium modelling. In the presence of multiple equilibria, comparative statics exercises become meaningless. Furthermore, even when for a given specification of the economy equilibrium is globally unique, as Richter and Wong (1999) point out, the possibility of multiple equilibria for close-by economies implies that it is generally impossible to compute prices and allocations that are close-by exact equilibrium prices and allocations (as opposed to computing prices at which aggregate excess demand is close to zero). In this section I argue that one can solve these problems by focusing on so-called 'semi-algebraic' economies.

While the arguments are also applicable to the GEI model, for simplicity, consider a standard Arrow–Debreu exchange economy, $\left(u^h, e^h\right)_{h=1}^H$. There are H agents trading L commodities. Each agent h has individual endowments $e^h \in \mathbb{R}^L_+$ and 'smooth preferences' characterized by an utility function $u^h : \mathbb{R}^L_+ \to \mathbb{R}$.

A Walrasian equilibrium is a collection of consumption vectors $\left(x^h\right)_{h=1}^H$ and prices $p \in \Delta^{L-1}$ such that

$$x^h \in \arg\max_{x\in\mathbb{R}^L_+} u^h(x) \text{ s.t.} p\cdot x \le p\cdot e^h \qquad (1)$$

$$\sum_{h=1}^H \left(x^h - e^h\right) = 0. \qquad (2)$$

An approximate (ε-) equilibrium consists of an allocation an prices such that

$$||u^h(x^h) - \left[\max_{x \in \mathbb{R}^L_+} u^h(x) \text{ s.t.} p \cdot x \leq p \cdot e^h\right]|| < \varepsilon \quad (3)$$

$$||\sum_{h=1}^{H} (x^h - e^h)|| < \varepsilon. \quad (4)$$

Given any $\varepsilon > 0$, Scarf's algorithm (as well as the more efficient algorithms used in practice) finds a p, x^h which constitute an ε-equilibrium.

This leaves open two important theoretical questions.

1. Can one relate the approximate equilibrium prices and allocations, to exact equilibria, that is, given a computed ε-equilibrium $(\overline{p}, (\overline{x}^h))$, does there exist a Walrasian equilibrium $\tilde{p}, (\tilde{x}^h)$ with $\|(\overline{p}, (\overline{x}^h)) - (\tilde{p}, (\tilde{x}^h))\|$ small? Can one find good bounds on this distance which tend to zero as $\varepsilon \to 0$?
2. Given an economy $(u^h, e^h)_{h=1}^H$ with N Walrasian equilibria $(p^h, (x^h)^n)_{n=1}^N$ and any $\delta > 0$, is it possible to approximate all N equilibria, that is, to find N ε-equilibria $(\tilde{p}^n, (\tilde{x}^h)^n)_{n=1}^N$ with $\|(p^n, (x^h)^n) - (\tilde{p}^n, (\tilde{x}^h)^n)\| < \delta$, for all $n = 1, \ldots, N$?

Clearly, the second problem is strictly more difficult to tackle than the first. Richter and Wong (1999) show that for general economies even the answer to the first question is negative. In order to obtain positive answers to both qsts, one needs to restrict possible preferences. One approach is to assume that better sets are semialgebraic sets. I will make the slightly more useful assumption that marginal utilities are semi-algebraic functions.

Semi-algebraic Economies

We assume that for each h, $D_x u^h(x)$ is a semi-algebraic function, that is, its graph $\{(x, y) \in \mathbb{R}^{2L}_+ : y = D_x u^h(x)\}$ is a finite union and intersection of sets of the form

$$\{(x, y) \in \mathbb{R}^{2L} : g(x, y) > 0\} \text{ or}$$
$$\{(x, y) \in \mathbb{R}^{2L} : f(x, y) = 0\}$$

for polynomials with real coefficients, f and g.

For practical purposes, the focus on semi-algebraic preferences is quite general. First note that Afriat's theorem implies that a finite set of observations on an individual's choices that can be rationalized by any utility function can also be rationalized by semi-algebraic preferences (in fact, Afriat's construction is piece-wise linear). Furthermore, note that the constant elasticity of substitution utility function which is often used in applied work is semi-algebraic if the elasticities of substitution are rational numbers.

It follows from the Tarski–Seidenberg theorem that for semi-algebraic economies the answers to both qsts above are positive, since the relevant statements can be written as first order sentences (see Basu et al. 2003). However, algorithmic quantifier elimination which needs to be used to answer general qsts in this framework is so computationally inefficient that for practical purposes this does not help towards solving the above qsts for interesting specifications of economies.

Nevertheless, given a semi-algebraic economy it is possible to find a system of polynomial equations $f(x) = 0, f: \mathbb{R}^{H(L+1)+L-1} \to \mathbb{R}^{H(L+1)+L-1}$, and finitely many inequalities $g^i(x) \geq 0$, $g^i : \mathbb{R}^{H(L+1)+L-1} \to \mathbb{R}^M$, $i = 1, \ldots, N < \infty$ such that p, (x^h) is a Walrasian equilibrium for the economy (u^h, e^h) if and only if there exist $\lambda^h \in \mathbb{R}_{++}$, $h = 1, \ldots, H$ such that for some $i = 1, \ldots, N$,

$$f(p, (x^h, \lambda^h)) = 0, g^i(p, (x^h, \lambda^h)) \geq 0.$$

Therefore, the problem of finding Walrasian equilibria reduces to finding the real roots of polynomial systems of equations and verifying polynomial inequalities (see Kubler and Schmedders 2006).

Having reduced the problem of finding Walrasian equilibria to finding roots of a polynomial system of equations, one can then answer the two qsts above affirmatively.

Question 1: Smale's Alpha Method

Smale's alpha method provides a simple sufficient conditions for approximate zeros to be close to exact zeros and can be viewed as an extension of the Newton–Kantarovich conditions. The following results are from Blum et al. (1998, ch. 8).

Let $D \subset \mathbb{R}^n$ be open and let $f : D \to \mathbb{R}^n$ be analytic. For $z \in D$, define $f^{(k)}(z)$ to be the k'th derivative of f at z. This is a multi-linear operator which maps k-tuples of vectors in D into $\mathbb{R}^n$. Define the norm of an operator A to be

$$\|A\| = \sup_{x \neq 0} \frac{\|Ax\|}{\|x\|}.$$

Suppose that the Jacobian of f at z, $f^{(1)}(z)$ is invertible and define

$$\gamma(z) = \sup_{k \geq 2} \left\| \frac{\left(f^{(1)}(z)\right)^{-1} f^{(k)}(z)}{k!} \right\|^{\frac{1}{(k-1)}}$$

and

$$\beta(z) = \left\| \left(f^{(1)}(z)\right)^{-1} f(z) \right\|.$$

Theorem 1 Given a $\overline{z} \in D$, suppose the ball of radius $\left(1 - \frac{\sqrt{2}}{2}\right)/\gamma(\overline{z})$ around $\overline{z}$ is contained in D and that

$$\beta(\overline{z})\gamma(\overline{z}) < 0.157.$$

Then there exists a $\tilde{z} \in D$ with

$$f(\tilde{z}) = 0 \text{ and } \|\overline{z} - \tilde{z}\| \leq 2\beta(\overline{z}).$$

While the theorem applies to any locally analytic function, the bound $\gamma(z)$ can in general only be obtained if the system is in fact polynomial. For this case, the bound can be computed fairly easily. Given an ε-equilibrium the result gives an immediate bound on the distance between the approximation and an exact Walrasian equilibrium, hence answering Question 1 above.

Question 2: Polynomial System Solving

In the following, I denote the collection of all polynomials in the variable $x_1, x_2, \ldots, x_n$ with coefficients in a field K by K $[x_1, \ldots, x_n]$. The for this survey relevant examples of K are the field of rational numbers $\mathbb{Q}$, the field of real numbers $\mathbb{R}$, and the field of complex numbers $\mathbb{C}$. Polynomials over the field of rational numbers are computationally convenient since modern computer algebra systems perform exact computations over the field $\mathbb{Q}$. Economic parameters are typically real numbers, and equations characterizing equilibria lie in $\mathbb{R}[x]$. The algorithms to compute all solutions to polynomial systems always compute all solutions in an algebraically closed field, in this case $\mathbb{C}[x]$.

Given a polynomial system of equations $f: \mathbb{C}^M \to \mathbb{C}^M$ there is now a variety of algorithm to approximate numerically all complex and real zeros of f. Sturmfels's monograph (2002) provides an excellent overview. In this survey I briefly mention two possible approaches, homotopy continuation methods and solution methods based on Gröbner bases.

At the writing of this article, both approaches are too inefficient to be applicable to large economic models, but they can be used for models with four or five households and four or five commodities. To find all equilibria for a given economy, homotopy methods seem slightly more efficient, while Gröbner bases allow for statements about entire classes of economies.

All Solution Homotopies

Solving polynomial systems numerically means computing approximations to all isolated solutions. Homotopy continuation methods can provide paths to all approximate solutions. There are well-known bounds on the maximal number of complex solutions of a polynomial system. The basic idea is to start at a generic polynomial system $g(x)$ whose number of roots is at least as large as the maximal number of solutions to $f(x) = 0$ and whose roots are all known. Then one needs to trace out all paths (in complex space) of the homotopy $H(x, t) = tg(x) + (1 - t)f(x)$, which do not diverge to infinity. Smale's alpha method can be applied along the path to ensure that the approximate solutions are close to real exact solutions (see Blum et al. 1998). It can be shown that all solutions to $f(x) = 0$ can be found in this manner.

Sommese and Wampler (2005) provide a detailed overview. Applications of these methods in economics have so far been largely restricted to game theory, but the method is also applicable to Walrasian equilibria.

Gröbner Basis

For given polynomials $f_1, \ldots, f_k$ in $\mathbb{Q}[x]$ the set

$$I = \left\{ \sum_{i=1}^{k} h_i f_i : h_i \in \mathbb{Q}[x] \right\} = \langle f_1, \ldots, f_k \rangle$$

is called the ideal generated by $f_1, \ldots, f_k$. It turns out that under conditions which can often be shown to hold in practice, the so-called 'reduced Gröbner basis' of this ideal, I, in the lexicographic term order has the shape

$$\mathcal{G} = \{x_1 - q_1(x_n), x_2 - q_2(x_n), \ldots, x_{n-1} - q_{n-1}(x_n), r(x_n)\}$$

where r is a polynomial of degree d and the q_i are polynomials of degree $d - 1$.

This basis can be computed exactly, using Buchberger's algorithm (recently, much more efficient versions of the basic algorithm have been developed; see for example Faugère 1999). The number of real solutions to the original system then equals the number of real solutions of the univariate polynomial $r(.)$ which can be determined exactly by Sturm's method (see Sturmfels 2002, for details). The roots of $r(.)$ can be approximated numerically with standard methods and the remaining solution to the original system is linear in these roots.

Kubler and Schmedders (2006) use the method to test for uniqueness of equilibria in semi-algebraic classes of economies.

Computational Methods in Econometrics

Vassilis A. Hajivassiliou

Abstract

The computational properties of an econometric method are fundamental determinants of its importance and practical usefulness, in conjunction with the method's statistical properties. Computational methods in econometrics are advanced through successfully combining ideas and methods in econometric theory, computer science, numerical analysis, and applied mathematics. The leading classes of computational methods particularly useful for econometrics are matrix computation, numerical optimization, sorting, numerical approximation and integration, and computer simulation. A computational approach that holds considerable promise for econometrics is parallel computation, either on a single computer with multiple processors, or on separate computers networked in an intranet or over the internet.

Introduction

In evaluating the importance and usefulness of particular econometric methods, it is customary to focus on the set of *statistical* properties that a method possesses – for example, unbiasedness, consistency, efficiency, asymptotic normality, and so on. It is crucial to stress, however, that meaningful comparisons cannot be completed without paying attention also to a method's *computational* properties. Indeed the practical value of an econometric method can be assessed only by examining the inevitable interplay between the two classes of properties, since a method with excellent statistical properties may be computationally infeasible and vice versa. Computational methods in econometrics are evolving over time to reflect the current technological boundaries as defined by available computer hardware and software capabilities at a particular period, and hence are inextricably linked with determining what the state of the art is in econometric methodology.

To give a brief illustration, roughly from the late 1950s until the early 1960s we had the 'Stone Age' of econometrics, when the most sophisticated computational instrument was the slide rule, which used two rulers on a logarithmic scale, one sliding into the other, to execute approximate multiplication and division. In this Stone Age, suitably named in honour of Sir Richard Stone, winner of the 1984 Nobel Prize in Economics, the brightest Ph.D. students at the University of Cambridge were toiling for days and days in back rooms using slide rules to calculate ordinary linear regressions, a task which nowadays can be achieved in a split second on modern personal computers.

The classic linear regression problem serves to illustrate the crucial interaction between statistical and computational considerations in comparing competing econometric methods. Given data of size S, with observations on a dependent variable denoted by $S \times 1$ vector y and corresponding observations on k explanatory factors denoted by $S \times k$ matrix X ($k < X$), the linear plane fitting exercise is defined by Gauss's minimum quadratic distance problem:

$$\begin{aligned}\widehat{\beta} = & \arg\min_b (y - Xb)'(y - Xb) \\ \times \equiv & \arg\min_b \sum_{s=1}^{S} \left(y_s - x_s' b\right)^2 \end{aligned} \quad (1)$$

where x_s' is the sth row of matrix X and b is a $k \times 1$ vector of real numbers defining the regression plane Xb. Under the assumption that X has full column rank k, the solution to this *ordinary least squares* minimization problem is the linear-in-y expression $\widehat{\beta} = (X'X)^{-1}X'y$, which only requires the matrix operations of multiplication and inversion. Suppose, however, that Gauss had chosen instead as his measure of distance the sum of absolute value of the deviations, and defined instead:

$$\tilde{\beta} = \text{rg} \min_b \sum_{s=1}^{S} |y_s - x_s' b| \quad (2)$$

The vector $\tilde{\beta}$ that solves the second minimization is known as the *least absolute deviations* (LAD) estimator and has no closed-form matrix expression. In fact, calculation of $\tilde{\beta}$ requires highly nonlinear operations for which computationally efficient algorithms were developed only in the 1970s. To give a concrete example, consider the *intercept-only* linear regression model where X is the $S \times 1$ vector of ones. Then the single $\widehat{\beta}$ coefficient that solves (1) is the sample mean of y, while $\tilde{\beta}$ that solves (2) is the sample *median* of y. The latter is orders of magnitude more difficult to compute than the former since it involves sorting y and finding the value in the middle, while the former simply adds all elements of y and divides by the sample size. Clearly, it could be quite misleading if $\widehat{\beta}$ and $\tilde{\beta}$ where compared solely in terms of statistical properties without any consideration of their substantially different computational requirements.

A second example in a similar vein is the following parametric estimation problem. Suppose a sample of size S is observed on a single variable y. It is believed that each observation y_s is drawn independently from the same uniform distribution on the interval $[\theta,c]$ where the lower value of the support is the single unknown parameter that needs to be estimated, while c is known. Two parametric estimation methods with particularly attractive statistical properties are the generalized method of moments (GMM) and the method of maximum likelihood (MLE). Indeed, for relatively large sample sizes these two methods are comparably attractive in terms of statistical properties, while they differ *drastically* in terms of computational requirements: the GMM solution is $\widehat{\theta}_{gmm} = \frac{2}{S}\sum_{s=1}^{S} y_s - c$, thus requiring only the simple calculation of the sample mean y, while the MLE involves the highly nonlinear operation of finding the minimum of the data vector y, $\widehat{\theta}_{mle} = min(y_1, \ldots, y_S)$.

In the following section we discuss in turn the leading classes of methods that are of particular importance in modern econometrics, while section "Parallel computation" introduces the concept of parallel processing and describes its current value and future promise in aiding dramatically econometric computation.

Computational Methods Important for Econometrics

The advancement of computational methods for econometrics relies on understanding the interplay between the disciplines of econometric theory, computer science, numerical analysis, and applied mathematics. In the five subsections below we discuss the leading classes of computational methods that have proven of great value to modern econometrics.

Matrix Computation and Specialized Languages

To start with the fundamental econometric framework of linear regression, the *sine qua non* of econometric computation is the ability to program and perform efficiently matrix operations. To this end, specialized matrix computer languages have

been developed which include Gauss and Matlab. Fundamental estimators of the linear regression coefficient vector β, like the OLS $(X'X)^{-1}X'y$ and its generalized least squares (GLS) variant $(X'\Omega^{-1}X)^{-1}X'\Omega^{-1}y$, are leading examples of the usefulness of such matrix languages, where the $S \times S$ matrix Ω is a positive definite, symmetric variance-covariance matrix of the disturbance vector $\varepsilon \equiv y - X\beta$. Matrix operations are useful even for nonlinear econometric methods discussed below, since a generally useful approach is to apply linearization approximations through the use of differentiation and Taylor's expansions.

In implementing econometric methods that involve matrix operations, special attention needs to be paid to the dimensionality of the various matrices, as well as to any special properties a matrix may posses, which can affect very substantially the feasibility and performance of the computational method to be adopted. Looking at the OLS and GLS formulae, we see three different matrices that require inversion: $X'X$, Ω, and $X'\Omega^{-1}X$. The first and the third are of dimension $k \times k$, while the second is $S \times S$. Since the number of regressors k is typically considerably smaller than the sample size S, the inversion of these matrices can involve vastly different burden in terms of total number of computer operations required as well as memory locations necessary for holding the information during those calculations. (For example, in panel data settings where multiple observations are observed in different time-periods for a cross-section of economic agents, it is not uncommon to have total sample sizes of 300,000 or more.) To this end, econometric analysts have focused on importing from numerical analysis matrix algorithms that are particularly efficient in handling sparse as opposed to dense matrices. By their very nature, sparse matrices exhibit a very high degree of compressibility and concomitantly lower memory requirements. See Drud (1977) for the use of sparse matrix techniques in econometrics. A matrix is called sparse if it is primarily populated by zeros, for example, the variance-covariance matrix of a disturbance vector following the moving-average-of-order-1 model:

$$\Omega_{ma1} = \sigma^2 \begin{pmatrix} 1 & \frac{\lambda}{1+\lambda^2} & 0 & \cdots & 0 \\ \frac{\lambda}{1+\lambda^2} & 1 & \frac{\lambda}{1+\lambda^2} & \ddots & \vdots \\ 0 & \frac{\lambda}{1+\lambda^2} & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & 1 & \frac{\lambda}{1+\lambda^2} \\ 0 & \cdots & 0 & \frac{\lambda}{1+\lambda^2} & 1 \end{pmatrix}$$

In contrast, a stationary autoregressive disturbance of order 1 has a dense variance-covariance matrix:

$$\Omega_{ar1} = \sigma^2 \begin{pmatrix} 1 & \gamma & \gamma^2 & \cdots & \gamma^{S-1} \\ \gamma & 1 & \gamma & \ddots & \vdots \\ \gamma^2 & \gamma & \ddots & \ddots & \gamma^2 \\ \vdots & \ddots & \ddots & 1 & \gamma \\ \gamma^{S-1} & \cdots & \gamma^2 & \gamma & 1 \end{pmatrix}$$

Other matrix algebra methods especially important in econometrics are the Cholesky factorization (see Golub 1969) of a positive definite matrix A into the product $A = R'R$ where R is an upper-triangular matrix, and the singular value decomposition that allows the calculation of pseudo-inverse of any matrix B which may be non-square, and if square, not positive definite (see Belsley 1974).

It is important to note that on occasion a brilliant theoretical development can simplify enormously the computational burden of econometric methods that, though possessing attractive statistical properties, were thought to be infeasible with existing computation technology in the absence of the theoretical development. A case in point is the GLS/MLE estimator for the one-factor random effects model proposed by Balestra and Nerlove (1966), which is of great importance in the analysis of linear panel data models. The standard formulation gives rise to the GLS formula

requiring the inversion of an equi-correlated variance covariance matrix Ω of dimension $S \times S$, where S is of the order of the product of the number of available observations in the cross-section dimension times the number available in the time dimension. For modern panel data-sets, this can exceed 300,000, thus making the calculation of Ω^{-1} infeasible even on today's supercomputers, let alone with the slide rules available in 1966. Fuller and Battese (1973), however, showed that the equi-correlated nature of the one-factor random effects model made calculation of the GLS estimator equivalent to an OLS problem, where the dependent variable $\tilde{y}$ and the regressors $\tilde{X}$ are simple linear combinations of the original data $y_{it}, x_{1it}, \ldots, x_{kit}$ and its time averages $\bar{y}_{it}, \bar{x}_{1it}, \ldots, \bar{x}_{kit}$ defined by $\bar{y}_{i.} \equiv \frac{1}{T}\sum_{t=1}^{T} y_{it}$ and $\tilde{y}_{it} \equiv y_{it} - \lambda \bar{y}_{i.}$, and analogously for the regressor variables. This realization allowed the calculation of the GLS estimator without the need for inverting the usually problematically large Ω matrix.

Another important case where a theoretical development in methodology led to a dramatic lowering of the computational burden and hence allowed the calculation of models that would otherwise have had to wait perhaps for decades for sufficient advancements in computer technology is the simulation-based inference for Limited Dependent Variable models, associated with the name of Daniel McFadden (1989). See section "Computer simulation" below, McFadden, Daniel and simulation-based estimation.

Optimization

Many econometric estimators with attractive statistical properties require the optimization of a (generally) nonlinear function of the form:

$$q \equiv \arg \max_{\theta} F(\theta; data) \tag{3}$$

over a vector of unknown parameters θ of dimension p, typically considerably larger than 1. Examples are: the method of maximum likelihood, minimum-distance (OLS, LAD, GMM), and other extremum estimators. (The need to optimize functions numerically is also important for certain problems in computational economics, for example, the problem of optimal control.) Algorithms for optimizing functions of many variables are a key component in the collection of tools for econometric computation. The suitability of a certain algorithm to a specific optimization econometric problem depends on the following classification:

1. *Algorithms that require the calculation of first and possibly second derivatives* Versus *algorithms that do not*. Clearly, if the function to be optimized is not twice continuously differentiable (as is the case with LAD) or even discontinuous (as is the case with the maximum score estimator for the semiparametric analysis of the binary response model – see Manski 1975), algorithms that require differentiability will not be suitable. The leading example of an algorithm not relying on derivatives is the nonlinear simplex method of Nelder and Meade (1965).
2. *Local* Versus *global algorithms*. Optimization algorithms of the first type (for example, Gauss-Newton, Newton-Raphson, and Berndt et al. (1974)) search for an optimum in the vicinity of the starting values fed into the algorithm. This strategy may not necessarily lead to a global optimum over the full set of parameter space. This is of particular importance if the function to be optimized has multiple local optima, where typically the estimator with the desirable statistical properties corresponds to locating the overall optimum of the function. In such cases, global optimization algorithms (for example, simulated annealing and genetic optimization algorithm) should be employed instead.

Special methods are necessary for constrained optimization, where a function must be maximized or minimized subject to a set of equality or inequality constraints. These problems, in general considerably more demanding than unconstrained optimization, can be handled through three main alternative approaches: interior, exterior and re-parameterization methods.

Comprehensive reviews of optimization methods in econometrics can be found in Goldfeld

and Quandt (1972), Quandt (1983), and Dennis and Schnabel (1984). These studies also discuss the related issue of the numerical approximation of derivatives and illustrate the fundamental link in terms of computation between optimization and the problem of solving linear and nonlinear equations. For similar methods used in economics, see numerical optimization methods in economics and nonlinear programming.

Sorting

Of special importance for computing the class of estimators known as robust or semiparametric methods is the ability to sort data rapidly and computationally efficiently. Such a need arises in the calculation of order statistics, for example, the sample median and sample minimum required by the first two estimation examples given above. The leading sorting algorithms, bubble-, heap- and quick-sort, have fundamentally different properties in terms of computation speed and memory requirements, in general depending on how close to being sorted the original data series happens to be. For a practical review of the leading sorting algorithms, see Press et al. (2001, ch. 8).

Numerical Approximation and Integration

Numerical approximation is necessary for any mathematical function that does not have a closed form solution, for example, exponential, natural logarithm and error functions. See Abramowitz and Stegun (1964) for an exhaustive study of mathematical functions and their efficient approximation. Judd (1996) focuses on numerical approximation methods particularly useful in economics and econometrics.

Numerical integration, also known as numerical quadrature, is a related approximation problem that is crucial to modern econometrics. There are two key fields of econometrics where integrals without a closed form must be evaluated numerically. The first is Bayesian inference where moments of posterior densities need to be evaluated, which take the form of high-dimensional integrals. See, inter alia, Zellner et al. (1988). The second main class is classical inference in limited dependent variable (LDV) models; for example, Hajivassiliou and Ruud (1994). See Geweke (1996) for an exhaustive review of numerical integration methods in computational economics and econometrics, and Davis and Rabinowitz (1984) for earlier results.

It is important to highlight a crucial difference between the numerical integration problems in Bayesian inference and those in classical inference for LDV models, which makes various integration-by-simulation algorithms be useful to one field and not the other: in the Bayesian case, typically a single or a few high-dimensional integrals have to be evaluated accurately. In contrast, in the classical LDV inference case, quite frequently hundreds of thousands of such integrals need to be approximated.

Computer Simulation

The need for efficient generation of pseudo-random numbers with good statistical properties on a computer appears very routinely in econometrics. Leading examples include:

- Statistical methods based on resampling, primarily the 'jackknife' and the 'bootstrap', as introduced by Efron (1982). These methods have proven of special value in improving the small sample properties of certain econometric estimators and test procedures, for example in reducing estimation bias. They are also used to approximate the small sample variance of estimators for which no closed form expressions can be derived.
- Evaluation of econometric estimators through Monte Carlo experiments, where hypothetical data-sets with certain characteristics are simulated repeatedly and the econometric estimators under study are calculated for each set. This allows the calculation of empirical (simulated) properties of the estimators, either to compare to theoretical mathematical calculations or because the latter are intractable.
- Calculation of frequency probabilities of possible outcomes in large-scale decision trees, for which the outcome probabilities are impossible to characterize theoretically.
- Sensitivity analyses and what-if studies, where an econometric model is 'run' on a computer under different scenarios of policy measures.

- Simulation-based Bayesian and classical inference, where integrals are approximated through computer simulation (known as Monte Carlo integration). Particularly important methods in this context are the following: frequency simulation; importance sampling; and Markov chain Monte Carlo methods (the leading exponents being Gibbs resampling and the Metropolis/Hastings algorithm). A related class of methods, known as variance-reduction simulation techniques, includes control variates and antithetics. See Geweke (1988) and Hajivassiliou et al. (1996) for reviews. See also simulation-based estimation.

Parallel Computation

Parallel processing, where a computation task is broken up and distributed across different computers, is a technique that can afford huge savings in terms of total time required for solving particularly difficult econometric problems. For example, the simulation-based estimators mentioned in the previous section exhibit the potential of significant computational benefits by calculating them on computers with massively parallel architectures, because the necessary calculations can be organized in essentially an independent pattern. An example of such a computer is the Connection Machine CM-5 at the National Center for Supercomputing Applications in Illinois with 1024 identical processors in a multiple-instruction/multiple-data (MIMDI) configuration. The benefits of such a parallel architecture on the problem of solving an econometric optimization classical estimator not involving simulation can also be substantial, since such estimators involve the evaluation of contributions to the criterion (for example, likelihood) function in the case of independently and identically distributed (i.i.d.) observations. Since typical applications in modern applied econometrics using cross-sectional and longitudinal data sets involve several thousands of i.i.d. observations, the potential benefits of parallel calculations of such estimators should be obvious. The benefits of a massively parallel computer architecture become even more pronounced in the case of simulation-based estimators. See Nagurney (1996) for a discussion of parallel computation in econometrics.

An alternative approach for parallel computation that does not involve a single computer with many processors has been developed recently and offers considerable promise for computational econometrics. Through the use of specialized computer languages, many separate computers are harnessed together over an organization's intranet or even over the internet, and an econometric computation task is distributed across them. The benefits of this approach depend critically on the relative burden of the overhead of communicating across the individual computers when organizing the splitting of the tasks and then collecting and processing the separate partial results. Such distributed parallel computation has the exciting potential of affording formidable super-computing powers to econometric researchers with only modest computer hardware.

Abstract

Commercial computing has grown to include an extraordinary range of economic undertakings. In any given era, computing markets are organized around platforms – a cluster of technically standardized components that buyers use together to make the wide range of applications. There has been an increasing secular trend in the number of firms that possess the necessary technical knowledge and commercial capabilities to bring to market some component or service. While general improvements in technical capabilities are readily apparent, it is quite difficult to calculate the productivity improvements arising from increased investment in and use of computing.

The commercial computing industry accounts for a large fraction of economic activity. From its military and research origins in the late 1940s, it spread into the commercial realm and has since grown to include an extraordinary range of economic undertakings. Many economists believe this expansion of applications for computing has been a driver of economic growth.

Computing aids the automated tracking of transactions, a function that finds use, for

example, in automating billing, managing the pricing of inventories of airline seating, and restocking retail outlets in a geographically dispersed organization. It also facilitates the coordination of information-intensive tasks, such as the dispatching of time-sensitive deliveries or emergency services. Computing also enables performance of advanced mathematical calculations, useful in such diverse activities as calculating interest on loans and generating estimates of underground geological deposits. Computer-aided precision also improves the efficiency of processes such as manufacturing metal shapes or the automation of communication switches, to name just two.

In any given era, computing markets are organized around platforms – a cluster of technically standardized components that buyers use together to make the aforementioned wide range of applications. Such platforms involve long-lived assets, both components sold in markets (that is, hardware and some software) and components made by buyers (that is, training and most software). Important computing platforms historically include the UNIVAC, the IBM 360 and its descendents, the Wang minicomputers, IBM AS/400, DEC VAX, Sun SPARC, Intel/Windows PC, Unix/Linux, and, after the mid-1990s, TCP/IP-based client–server platforms linked together.

Vendors tend to sell groups of compatible products under umbrella strategies aimed at the users of particular platforms. In the earliest eras of computing markets, the leading firms integrated all facets of computing and offered a supply of goods and services from a centralized source. In later eras, the largest and most popular platforms historically included many different computing, communications and peripheral equipment firms, software tool developers, application software writers, consultants, system integrators, distributors, user groups, news publications and service providers.

Until the early 1990s, most market segments were distinguished by the size of the tasks to be undertaken and by the technical sophistication of the typical user. Mainframes, minicomputers, workstations, and personal computers, in decreasing order, constituted different size-based market segments. Trained engineers or programmers made up the technical user base, while the commercial market was geared more towards administrators, secretaries and office assistants.

The most popular platform in the late 1980s and 1990s differed from the prominent platforms of earlier years. The personal computer (PC) began in the mid- 1970s as an object of curiosity among technically skilled hobbyists, but became a common office tool after the entry of IBM's design. Unlike prior computing platforms, this one has diffused into both home and business use. From the beginning, this platform involved thousands of large and small software developers, third-party peripheral equipment and card developers, and a few major players. In more recent experience, control over the standard has completely passed from IBM to Microsoft and Intel. Microsoft produces the Windows operating system and Intel produces the most commonly used microprocessor. For this reason the platform is often called Wintel.

The networking and internet revolution in the late 1990s is responsible for blurring once-familiar distinctions. These new technologies have made it feasible to build client–server systems within large enterprises and across ownership boundaries. It employs internet-based computing systems networked across potentially vast geographic distances, supporting the emergence of a 'network of networks'.

Despite frequent and sometimes dramatic technical improvements in specific areas of technology, many features of the most common platforms in use tend to persist or change very slowly. Many durable components make up platforms. And, though they lose their market value as they become obsolete in comparison with frontier products, they do not as quickly lose their ability to provide a flow of services to users. Consequently, new technology tends to be most successful when new components enhance and preserve the value of previous investments, a factor that creates demand for 'backward compatible' upgrades or improvements. It also creates a demand for support and service activities to reduce the costs of making the transition from old to new.

Control over changes to design and other aspects of technical standards shapes the backward compatibility for key components. Control of these decisions is coincident with platform leadership – determining the rate and direction of change in technical features of components around which other firms build their businesses. In each platform, it is very rare to observe more than a small number of firms acquiring leadership positions. Since such positions have been historically associated with high firm profitability, firms compete fiercely for market dominance in component categories where standards are essential. Not surprisingly, competitive behaviour affiliated with obtaining and retaining market leadership does occasionally receive attention from antitrust authorities.

Though innovative change in computing began well prior to the invention of the integrated circuit, in popular discussion advances in computing have become almost synonymous with advances in microprocessors. This is due to an observation by Gordon Moore, who co-founded and became chairman at Intel. In 1965 he foresaw a doubling of circuits per chip every two years. This prediction about the rate of technical advance later became known as 'Moore's law'. In fact, microprocessors and DRAMS have been doubling in capability every 18 months since the mid-1970s.

Moore's prediction pertained narrowly to integrated circuits. However, a similar pattern of improvement – though with variation in the rate – characterizes other electronic components that go into producing a computer or that are complementary with computing in many standard uses. This holds for disk drives, display screens, routing equipment, and data-transmission capacity, to name a few. Such widespread innovation creates opportunities for new entry and rearrangements in the conditions of supply.

Accordingly, there has been an increasing secular trend in the number of firms that possess the necessary technical knowledge and commercial capabilities to bring to market some component or service of value to computing users. This factor alone explains the increasing complexity of supply chains for the supply of most computing hardware and software products. It is also coincident with their increasing geographic reach. In addition, as in other manufacturing processes, the increasing use of sophisticated information technology helps coordinate design and production involving firms from many countries and continents.

While the spawning of new information technology businesses in North America has tended to be concentrated in a small number of locations, such as the Boston area and Santa Clara Valley (popularly known as Silicon Valley), every other facet of the supply chain for computing involves firms headquartered and operating in a much wider set of locations. In North America, these range from Seattle, Austin, Los Angeles, the greater New York area, Denver–Boulder, Washington DC, the North Carolina Research Triangle, Chicago, and virtually all major cities in the United States. The supply chain for many complementary components has also been associated with many firms in Western Europe and as well as in India, Israel, South Korea, Singapore, Taiwan and China. Even more widespread are computing service firms, which follow business and home users dispersed across the globe.

Despite this geographic dispersion since the 1950s, US companies have retained leadership in generating new platforms and commercializing frontier technologies in forms that most users find valuable. Part of this results from the persistence of platform leadership for a time within a segment. In addition, US firms have historically been ascendant whenever platform leadership has changed. However, this pattern seems likely to change in the 21st century, as non-US firms already have found leadership positions in producing components of many platforms and in related areas of electronics, such as consumer electronics, communication equipment and specialized software.

While general improvements in technical capabilities are readily apparent, it is quite difficult to calculate the productivity improvements arising from increased investment in and use of computing. There is no question that existing computing activities have become less expensive, while new capabilities have been achieved. This has allowed

economic actors to attain previously unobtainable outcomes. This shift in economic possibilities has generated a restructuring of organizational routines, market relationships, and other activities associated with the flow of goods, which inevitably improves the economy's ability to transform inputs into consumer welfare.

Yet altering the business use of computing can be slow. It often demands large adjustment costs and gradual learning about which organizational processes can best employ advances in computing. It can involve a reallocation of decision rights and discretion inside a large organization, especially when business units alter a wide array of intermediate routine processes (such as billing, account monitoring, and inventory management) or the coordination of services (such as the delivery of data for decision support). Moreover, the largest changes come from altering many complementary activities that respond to new and unanticipated opportunities, setting off new waves of invention. Each wave's productivity effect is interwoven with others.

Along with these improvements the boundaries of the 'computing market' have changed. A hardware-based definition for the computing market was barely adequate in the 1960s and is no longer adequate for economic analysis. However, there is no consensus about what alternative framing will be appropriate for understanding value creation, supplier behaviour, and user adoption in computing in the 21st century.

Computer Science and Game Theory

Joseph Y. Halpern

Abstract

Work at the intersection of computer science and game theory is briefly surveyed, with a focus on the work in computer science. In particular, the following topics are considered: various roles of computational complexity in game theory, including modelling bounded rationality, its role in mechanism design, and the problem of computing Nash equilibria; the *price of anarchy,* that is, the cost of using decentralizing solution to a problem; and interactions between distributed computing and game theory.

Keywords

Algorithmic knowledge; Algorithmic mechanism design; Bayesian networks; Bounded rationality; Byzantine agreement; Cheap talk;

Coalitions; Combinatorial auctions; Complexity theory; Computational complexity; Computer science and game theory; Distributed computing; Efficient representation of games; Game theory; Gibbard–Satterthwaite th; Implementing mediators; Interactive epistemology; k-resilient equilibrium; (k,t)-robust equilibrium; Learning; Mechanism design; Markov networks; Nash equilibrium; Price of anarchy; Prisoner's Dilemma; Regret; Strategic voting; Tit for tat; Voting

Introduction

There has been a remarkable increase in work at the interface of computer science and game theory in the past decade. Game theory forms a significant component of some major computer science conferences (see, for example, Kearns and Reiter 2005; Sandholm and Yokoo 2003); leading computer scientists are often invited to speak at major game theory conferences, such as the World Congress on Game Theory 2000 and 2004. In this article I survey some of the main themes of work in the area, with a focus on the work in computer science. Given the length constraints, make no attempt at being comprehensive, especially since other surveys are also available, including Halpern (2003), Linial (1994), Papadimitriou (2001), and a comprehensive survey book (Nisan et al. 2007).

The survey is organized as follows. I look at the various roles of computational complexity in game theory in section "Complexity Considerations", including its use in modelling bounded rationality, its role in mechanism design, and the problem of computing Nash equilibria. In section "The Price of Anarchy", I consider a game-theoretic problem that originated in the computer science literature, but should be of interest to the game theory community: computing the *price of anarchy,* that is, the cost of using a decentralizing solution to a problem. In section "Game Theory and Distributed Computing", I consider interactions between distributed computing and game theory. In section "Implementing Mediators", I consider the problem of implementing mediators, which has been studied extensively in both computer science and game theory. I conclude in section "Other Topics" with a discussion of a few other topics of interest.

Complexity Considerations

The influence of computer science in game theory has perhaps been most strongly felt through complexity theory. I consider some of the strands of this research here. There are a numerous basic texts on complexity theory that the reader can consult for more background on notions like NP-completeness and finite automata, including Hopcroft and Ullman (1979) and Papadimitriou (1994a).

Bounded Rationality

One way of capturing bounded rationality is in terms of agents who have limited computational power. In economics, this line of research goes back to the work of Neyman (1985) and Rubinstein (1986), who focused on finitely repeated Prisoner's Dilemma. In n-round finitely repeated Prisoner's Dilemma, there are 2^{2n-1} strategies (since a strategy is a function from histories to {cooperate, defect}, and there are clearly $2^n - 1$ histories of length $< n$). Finding a best response to a particular move can thus potentially be difficult. Clearly people do not find best responses by doing extensive computation. Rather, they typically rely on simple heuristics, such as 'tit for tat' (Axelrod 1984). Such heuristics can often be captured by finite automata; both Neyman and Rubinstein thus focus on finite automata playing repeated Prisoner's Dilemma. Two computer scientists, Papadimitriou and Yannakakis (1994), showed that if both players in an n-round Prisoner's Dilemma are finite automata with at least $2^n - 1$ states, then the only equilibrium is the one where they defect in every round. This result says that a finite automaton with exponentially many states

can compute best responses in Prisoner's Dilemma.

We can then model bounded rationality by restricting the number of states of the automaton. Neyman (1985) showed, roughly speaking, that if the two players in *n*-round Prisoner's Dilemma are modelled by finite automata with a number of states in the interval $[n^{1/k}, n^k]$ for some *k,* then collaboration can be approximated in equilibrium; more precisely, if the payoff for (cooperate, cooperate) is (3, 3) there is an equilibrium in the repeated game where the average payoff per round is greater than $3 - \frac{1}{k}$ for each player. Papadimitriou and Yannakakis (1994) sharpen this result by showing that if at least one of the players has fewer than $2^{c_\varepsilon n}$ states, where $c_\varepsilon = \frac{\varepsilon}{12(1+\varepsilon)}$, then for sufficiently large n, there is an equilibrium where each player's average payoff per round is greater than $3 - \varepsilon$. Thus, computational limitations can lead to cooperation in Prisoner's Dilemma.

There have been a number of other attempts to use complexity-theoretic ideas from computer science to model bounded rationality (see Rubinstein 1998, for some exs). However, it seems that there is much more work to be done here.

Computing Nash Equilibrium

Nash (1950) showed every finite game has a Nash equilibrium in mixed strategies. But how hard is it to actually find that equilibrium? On the positive side, there are well known algorithms for computing Nash equilibrium, going back to the classic Lemke–Howson (1964) algorithm, with a spate of recent improvements (see, for example, Govindan and Wilson 2003; Blum et al. 2003; Porter et al. 2004). Moreover, for certain classes of games (for example, symmetric games, Papadimitriou and Roughgarden 2005), there are known to be polynomial-time algorithms. On the negative side, many qsts about Nash equilibrium are known to be NP-hard. For example, Gilboa and Zemel (1989) showed that, for a game presented in normal form, deciding whether there exists a Nash equilibrium where each player gets a payoff of at least *r* is NP-complete. Interestingly, Gilboa and Zemel also show that computing whether there exists a *correlated* equilibrium (Aumann 1987) where each player gets a payoff of at least *r* is computable in polynomial time. In general, qsts regarding correlated equilibrium seem easier than the analogous qsts for Nash equilibrium; see Papadimitriou (2005) and Papadimitriou and Roughgarden (2005) for further examples. Chu and Halpern (2001) prove similar NP-completeness results if the game is represented in extensive form, even if all players have the same payoffs (a situation that arises frequently in computer science applications, where we can view the players as agents of some designer, and take the payoffs to be the designer's payoffs). Conitzer and Sandholm (2003) give a compendium of hardness results for various qsts regarding Nash equilibria.

Nevertheless, there is a sense in which it seems that the problem of finding a Nash equilibrium is easier than typical NP-complete problems, because every game is guaranteed to have a Nash equilibrium. By way of contrast, for a typical NP- complete problem like prptal satisfiability, whether or not a prptal formula is satisfiable is not known. Using this observation, it can be shown that if finding a Nash equilibrium is NP-complete, then NP = coNP. Recent work has in a sense completely characterized the complexity of finding a Nash equilibrium in normal-form games: it is a *PPAD-complete* problem (Chen and Deng 2006; Daskalis et al. 2006). PPAD stands for 'polynomial parity argument (directed case)'; see Papadimitriou (1994b) for a formal definition and examples of other PPAD problems. It is believed that PPAD-complete problems are not solvable in polynomial time, but are simpler than NP-complete problems, although this remains an open problem. See Papadimitriou (2007) for an overview of this work.

Algorithmic Mechanism Design

The problem of mechanism design is to design a game such that the agents playing the game, motivated only by self-interest, achieve the designer's goals. This problem has much in common with the standard computer science problem of designing protocols that satisfy certain specifications (for example, designing a distributed protocol that

achieves Byzantine agreement; see section "Game Theory and Distributed Computing"). Work on mechanism design has traditionally ignored computational concerns. But Kfir-Dahav et al. (2000) show that, even in simple settings, optimizing social welfare is NP-hard, so that perhaps the most common approach to designing mechanisms, applying the Vickrey–Groves–Clarke (VCG) procedure (Clarke 1971; Groves 1973; Vickrey 1961), is not going to work in large systems. We might hope that, even if we cannot compute an optimal mechanism, we might be able to compute a reasonable approximation to it. However, as Nisan and Ronen (2000, 2001) show, in general, replacing a VCG mechanism by an approximation does not preserve truthfulness. That is, even though truthfully revealing one's type is an optimal strategy in a VCG mechanism, it may no longer be optimal in an approximation. Following Nisan and Ronen's work, there has been a spate of papers either describing computationally tractable mechanisms or showing that no computationally tractable mechanism exists for a number of problems, ranging from task allocation (Archer and Tardos 2001; Nisan and Ronen 2001) to cost-sharing for multicast trees (Feigenbaum et al. 2000) (where the problem is to share the cost of sending, for example, a movie over a network among the agents who actually want the movie) to finding low-cost paths between nodes in a network (Archer and Tardos 2002).

The problem that has attracted perhaps the most attention is *combinatorial auctions*, where bidders can bid on bundles of items. This becomes of particular interest in situations where the value to a bidder of a bundle of goods cannot be determined by simply summing the value of each good in isolation. To take a simple example, the value of a pair of shoes is much higher than that of the individual shoes; perhaps more interestingly, an owner of radio stations may value having a licence in two adjacent cities more than the sum of the individual licences. Combinatorial auctions are of great interest in a variety of settings including spectrum auctions, airport time slots (that is, take-off and landing slots), and industrial procurement. There are many complexity-theoretic issues related to combinatorial auctions. For a detailed discussion and references see Cramton et al. (2006); I briefly discuss a few of the issues involved here.

Suppose that there are n items being auctioned. Simply for a bidder to communicate her bids to the auctioneer can take, in general, exponential time, since there are 2^n bundles. In many cases, we can identify a bid on a bundle with the bidder's valuation of the bundle. Thus, we can try to carefully design a bidding language in which a bidder can communicate her valuations succinctly. Simple information-theoretic arguments can be used to show that, for every bidding language, there will be valuations that will require length at least 2^n to express in that language. Thus, the best we can hope for is to design a language that can represent the 'interesting' bids succinctly. See Nisan (2006) for an overview of various bidding languages and their expressive power.

Given bids from each of the bidders in a combinatorial auction, the auctioneer would like to then determine the winners. More precisely, the auctioneer would like to allocate the m items in an auction so as to maximize his revenue. This problem, called the *winner determination problem*, is NP-complete in general, even in relatively simple classes of combinatorial auctions with only two bidders making rather restricted bids. Moreover, it is not even polynomial-time approximable, in the sense that there is no constant d and polynomial-time algorithm such that the algorithm produces an allocation that gives revenue that is at least 1/d of optimal. On the other hand, there are algorithms that provably find a good solution, seem to work well in practice, and, if they seem to be taking too long, can be terminated early, usually with a good feasible solution in hand. See Lehmann et al. (2006), for an overview of the results in this area.

In most mechanism design problems, computational complexity is seen as the enemy. There is one class of problems in which it may be a friend: voting. One problem with voting mechanisms is that of *manipulation* by voters. That is, voters may be tempted to vote strategically rather than ranking the candidates according to their true preferences, in the hope that the final outcome will be

more favourable. This situation arises frequently in practice; in the 2000 US presidential election, American voters who preferred Nader to Gore to Bush were encouraged to vote for Gore, rather than 'wasting' a vote on Nader. The classic Gibbard–Satterthwaite theorem (Gibbard 1973; Satterthwaite 1975) shows that, if there are at least three alternatives, then in any nondictatorial voting scheme (that is, one where it is *not* the case that one particular voter dictates the final outcome, irrespective of how the others vote), there are preferences under which an agent is better off voting strategically. The hope is that, by constructing the voting mechanism appropriately, it may be computationally intractable to find a manipulation that will be beneficial. While finding manipulations for the plurality protocol (the candidate with the most votes wins) is easy, there are well-known voting protocols for which manipulation is hard in the presence of three or more candidates. See Conitzer et al. (2007) for a summary of results and further pointers to the literature.

Communication Complexity

Most mechanisms in the economics literature are designed so that agents truthfully reveal their preferences. However, in some settings, revealing one's full preferences can require a prohibitive amount of communication. For example, in a combinatorial auction of m items, revealing one's full preferences may require revealing what one would be willing to pay for each of the $2^m - 1$ possible bundles of items. Even if $m = 30$, this requires revealing more than one billion numbers. This leads to an obvious qst: how much communication is required by various mechanisms? Formal work on this question in the economics community goes back to Hurwicz (1977) and Mount and Reiter (1974); their definitions focused on the dimension of the message space. Independently (and later), there was active work in computer science on *communication complexity*, the number of bits of communication needed for a set of n agents to compute the value of a function $f : x_{i=1}^{n}\Theta_i \rightarrow X$, where each agent i knows $\theta_i \in \Theta_i$ (Think of θ_i as representing agent i's type.) Recently there has been an explosion of work, leading to a better understanding of the communication complexity for many important economic allocation problems; see Segal (2006) for an overview. Two important themes in this work are understanding the role of price- based market mechanisms in solving allocation problems with minimal communication, and designing mechanisms that provide agents with incentives to communicate truthfully while having low communication requirements.

The Price of Anarchy

In a computer system, there are situations where we may have a choice between a centralized and a decentralized solution to a problem. By 'centralized' here, I mean that each agent in the system is told exactly what to do and must do so; in the decentralized solution, each agent tries to optimize his own selfish interests. Of course, centralization comes at a cost. For one thing, there is a problem of enforcement. For another, centralized solutions tend to be more vulnerable to failure. On the other hand, a centralized solution may be more socially beneficial. How much more beneficial can it be?

Koutsoupias and Papadimitriou (1999) formalized this question by considering the ratio of the social welfare of the centralized solution to the social welfare of the Nash equilibrium with the worst social welfare (assuming that the social welfare function is always positive). They called this ratio the *price of anarchy,* and proved a number of results regarding the price of anarchy for a scheduling problem on parallel machines. Since the original paper, the price of anarchy has been studied in many settings, including traffic routing (Roughgarden and Tardos 2002), facility location games (for example, where is the best place to put a factory) (Vetta 2002), and spectrum sharing (how should channels in a WiFi network be assigned) (Halldórsson et al. 2004).

To give a sense of the results, consider the traffic-routing context of Roughgarden and Tardos (2002). Suppose that the travel time on a road increases in a known way with the congestion on the road. The goal is to minimize the

average travel time for all drivers. Given a road network and a given traffic load, a centralized solution would tell each driver which road to take. For example, there could be a rule that cars with odd-numbered licence plates take road 1, while those with even-numbered plates take road 2, to minimize congestion on either road. Roughgarden and Tardos show that the price of anarchy is unbounded if the travel time can be a nonlinear function of the congestion. On the other hand, if it is linear, they show that the price of anarchy is at most 4/3.

The price of anarchy is but one way of computing the 'cost' of using a Nash equilibrium. Others have been considered in the computer science literature. For example, Tennenholtz (2002) compares the *safety level* of a game – the optimal amount that an agent can guarantee himself, independent of what the other agents do – to what the agent gets in a Nash equilibrium, and shows, for interesting classes of games, including load-balancing games and first-price auctions, that the ratio between the safety level and the Nash equilibrium is bounded. For example, in the case of first- price auctions, it is bounded by the constant e.

Game Theory and Distributed Computing

Distributed computing and game theory are interested in much the same problems: dealing with systems where there are many agents, facing uncertainty and having possibly different goals. In practice, however, there has been a significant difference in emphasis between the two areas. In distributed computing, the focus has been on problems such as fault tolerance, asynchrony, scalability, and proving correctness of algorithms; in game theory, the focus has been on strategic concerns. I discuss here some issues of common interest. Most of the discussion in the remainder of this section is taken from Halpern (2003).

To understand the relevance of fault tolerance and asynchrony, consider the *Byzantine agreement* problem, a paradigmatic problem in the distributed systems literature. In this problem, there are assumed to be n soldiers, up to t of which may be faulty (the t stands for *traitor*); n and t are assumed to be common knowledge. Each soldier starts with an initial preference, to either attack or retreat. (More precisely, there are two types of nonfaulty agents – those that prefer to attack, and those that prefer to retreat.) We want a protocol that guarantees that (1) all *nonfaulty* soldiers reach the same decision, and (2) if all the soldiers are nonfaulty and their initial preferences are identical, then the final decision agrees with their initial preferences. (The condition simply prevents the obvious trivial solutions, where the soldiers attack no matter what, or retreat no matter what.)

The problem was introduced by Pease et al. (1980), and has been studied in detail since then; Chor and Dwork (1989), Fischer (1983), and Linial (1994) provide overviews. Whether the Byzantine agreement problem is solvable depends in part on what types of failures are considered, on whether the system is *synchronous* or *asynchronous*, and on the ratio of n to t. Roughly speaking, a system is synchronous if there is a global clock and agents move in lockstep; a 'step' in the system corresponds to a tick of the clock. In an asynchronous system, there is no global clock. The agents in the system can run at arbitrary rates relative to each other. One step for agent 1 can correspond to an arbitrary number of steps for agent 2 and vice versa. Synchrony is an implicit assumption in essentially all games. Although it is certainly possible to model games where player 2 has no idea how many moves player 1 has taken when player 2 is called upon to move, it is not typical to focus on the effects of synchrony (and its lack) in games. On the other hand, in distributed systems, it is typically a major focus.

Suppose for now that we restrict to *crash failures*, where a faulty agent behaves according to the protocol, except that it might crash at some point, after which it sends no messages. In the round in which an agent fails, the agent may send only a subset of the messages that it is supposed to send according to its protocol. Further suppose that the system is synchronous. In this case, the following rather simple protocol achieves Byzantine agreement:

- In the first round, each agent tells every other agent its initial preference.
- For rounds 2 to $t + 1$, each agent tells every other agent everything it has heard in the previous round. Thus, for example, in round 3, agent 1 may tell agent 2 that it heard from agent 3 that its initial preference was to attack, and that it (agent 3) heard from agent 2 that its initial preference was to attack, and it heard from agent 4 that its initial preferences was to retreat, and so on. This means that messages get exponentially long, but it is not difficult to represent this information in a compact way so that the total communication is polynomial in n, the number of agents.
- At the end of round $t + 1$, if an agent has heard from any other agent (including itself) that its initial preference was to attack, it decides to attack; otherwise, it decides to retreat.

Why is this correct? Clearly, if all agents are correct and want to retreat (resp., attack), then the final decision will be to retreat (resp., attack), since that is the only preference that agents hear about (recall that for now we are considering only crash failures). It remains to show that if some agents prefer to attack and others to retreat, then all the nonfaulty agents reach the same final decision. So suppose that i and j are nonfaulty and i decides to attack. That means that i heard that some agent's initial preference was to attack. If it heard this first at some round $t' < t + 1$, then i will forward this message to j, who will receive it and thus also attack. On the other hand, suppose that i heard it first at round $t + 1$ in a message from i_{t+1}. Thus, this message must be of the form *'*i_t said at round t that... that i_2 said at round 2 that i_1 said at round 1 that its initial preference was to attack.' Moreover, the agents $i_1, \ldots, i_{t+1}$ must all be distinct. Indeed, it is easy to see that i_k must crash in round k before sending its message to i (but after sending its message to i_{k+1}), for $k = 1, \ldots, t$, for otherwise i must have gotten the message from i_k, contradicting the assumption that i first heard at round $t + 1$ that some agent's initial preference was to attack. Since at most t agents can crash, it follows that i_{t+1}, the agent that sent the message to i, is not faulty, and thus sends the message to j. Thus, j also decides to attack. A symmetric argument shows that if j decides to attack, then so does i.

It should be clear that the correctness of this protocol depends on both the assumptions made: crash failures and synchrony. Suppose instead that *Byzantine* failures are allowed, so that faulty agents can deviate in arbitrary ways from the protocol; they may 'lie', send deceiving messages, and collude to fool the nonfaulty agents in the most malicious ways. In this case, the protocol will not work at all. In fact, it is known that agreement can be reached in the presence of Byzantine failures iff $t < n/3$, that is, iff fewer than a third of the agents can be faulty (Pease et al. 1980). The effect of asynchrony is even more devastating: in an asynchronous system, it is impossible to reach agreement using a deterministic protocol even if $t = 1$ (so that there is at most one failure) and only crash failures are allowed (Fischer et al. 1985). The problem in the asynchronous setting is that if none of the agents have heard from, say, agent 1, they have no way of knowing whether agent 1 is faulty or just slow. Interestingly, there are randomized algorithms (that is, behavioural strategies) that achieve agreement with arbitrarily high probability in an asynchronous setting (Ben-Or 1983; Rabin 1983).

Byzantine agreement can be viewed as a game where, at each step, an agent can either send a message or decide to attack or retreat. It is essentially a game between two teams, the nonfaulty agents and the faulty agents, whose composition is unknown (at least by the correct agents). To model it as a game in the more traditional sense, we could imagine that the nonfaulty agents are playing against a new player, the 'adversary'. One of the adversary's moves is that of 'corrupting' an agent: changing its type from 'nonfaulty' to 'faulty.' Once an agent is corrupted, what the adversary can do depends on the failure type being considered. In the case of crash failures, the adversary can decide which of a corrupted agent's messages will be delivered in the round in which the agent is corrupted; however, it cannot modify the messages themselves. In the case of Byzantine failures, the adversary essentially gets to make the moves for agents that have been

corrupted; in particular, it can send arbitrary messages.

Why has the distributed systems literature not considered strategic behaviour in this game? Crash failures are used to model hardware and software failures; Byzantine failures are used to model random behaviour on the part of a system (for example, messages getting garbled in transit), software errors, and malicious adversaries (for example, hackers). With crash failures, it does not make sense to view the adversary's behaviour as strategic, since the adversary is not really viewed as having strategic interests. While it would certainly make sense, at least in principle, to consider the probability of failure (that is, the probability that the adversary corrupts an agent), this approach has by and large been avoided in the literature because it has proved difficult to characterize the probability distribution of failures over time. Computer components can perhaps be characterized as failing according to an exponential distribution (see Babaoglu 1987, for an analysis of Byzantine agreement in such a setting), but crash failures can be caused by things other than component failures (faulty software, for ex); these can be extremely difficult to characterize probabilistically. The problems are even worse when it comes to modelling random Byzantine behaviour.

With malicious Byzantine behaviour, it may well be reasonable to impute strategic behaviour to agents (or to an adversary controlling them). However, it is often difficult to characterize the payoffs of a malicious agent. The goals of the agents may vary from that of simply trying to delay a decision to that of causing disagreement. It is not clear what the appropriate payoffs should be for attaining these goals. Thus, the distributed systems literature has chosen to focus instead on algorithms that are guaranteed to satisfy the specification without making assumptions about the adversary's payoffs (or nature's probabilities, in the case of crash failures).

Recently, there has been some work on adding strategic concerns to standard problems in distributed computing; see, for example, Alvisi et al. (2005) and Halpern and Teague (2004). Moving in the other direction, there has also been some work on adding concerns of fault tolerance and asynchrony to standard problems in game theory; see, for example, Eliaz (2002), Monderer and Tennenholtz (1999a, b) and the definitions in the next section. This seems to be an area that is ripe for further developments. One such development is the subject of the next section.

C

Implementing Mediators

The question of whether a problem in a multiagent system that can be solved with a trusted mediator can be solved by just the agents in the system, without the mediator, has attracted a great deal of attention in both computer science (particularly in the cryptography community) and game theory. In cryptography, the focus on the problem has been on *secure multiparty computation.* Here it is assumed that each agent i has some private information x_i. Fix functions $f_1, \ldots, f_n$. The goal is to have agent i learn $f_i(x_1, \ldots, x_n)$ without learning anything about Xj for $j \neq i$ beyond what is revealed by the value off $(x_1 \ldots, x_n)$. With a trusted mediator, this is trivial: each agent i just gives the mediator its private value x_i the mediator then sends each agent i the value $f_i(x_1, \ldots, x_n)$. Work on multiparty computation (Goldreich et al. 1987; Shamir et al. 1981; Yao 1982) provides conditions under which this can be done. In game theory, the focus has been on whether an equilibrium in a game with a mediator can be implemented using what is called *cheap talk* – that is, just by players communicating among themselves (cf. Barany 1992; Ben-Porath 2003; Forges 1990; Gerardi 2004; Heller 2005; Urbano and Vila 2004). As suggested in the previous section, the focus in the computer science literature has been in doing multiparty computation in the presence of possibly malicious adversaries, who do everything they can to subvert the computation, while in the game theory literature the focus has been on strategic agents. In recent work, Abraham et al. (2006) and Abraham et al. (2007) considered deviations by both rational players, who have preferences and try to maximize them, and players who can viewed as malicious, although it is perhaps better to think

of them as rational players whose utilities are not known by the other players or mechanism designer. I briefly sketch their results here; the following discussion is taken from Abraham et al. (2007).

The idea of tolerating deviations by coalitions of players goes back to Aumann (1959); more recent refinements have been considered by Moreno and Wooders (1996). Aumann's definition is essentially the following.

Definition 1 *$\sigma^{\Rightarrow}$ is a k-resilient' equilibrium if, for all sets C of players with $|C| \leq k$, it is not the case that there exists a strategy $\tau^{\Rightarrow}$ such that $u_i(\tau^{\Rightarrow}{}_C, \sigma^{\Rightarrow}{}_{-C}) > u_i(\sigma^{\Rightarrow})$ for all $i \in$ C.*

As usual, the strategy $(\tau^{\Rightarrow}{}_C, \sigma^{\Rightarrow}{}_{-C})$ is the one where each player $i \in$ C plays τ_i and each player $i \notin C$ plays σ_i. As the prime notation suggests, this is not quite the definition we want to work with. The trouble with this definition is that it suggests that coalition members cannot communicate with each other during the game. Perhaps surprisingly, allowing communication can *prevent* certain equilibria (see Abraham et al. 2007, for an ex). Since we should expect coalition members to communicate, the following definition seems to capture a more reasonable notion of resilient equilibrium. Let the cheap-talk extension of a game Γ be, roughly speaking, the game where players are allowed to communicate among themselves in addition to performing the actions of Γ and the payoffs are just as in Γ.

Definition 2 $\sigma^{\Rightarrow}$ is a *k-resilient equilibrium* in a game Γ if $\sigma^{\Rightarrow}$ is a k-resilient' equilibrium in the cheap-talk extension of Γ (where we identify the strategy σ_t in the game Γ with the strategy in the cheap-talk game where player i never sends any messages beyond those sent according to σ_i).

A standard assumption in game theory is that utilities are (commonly) known; when we are given a game we are also given each player's utility. When players make decisions, they can take other players' utilities into account. However, in large systems it seems almost invariably the case that there will be some fraction of users who do not respond to incentives the way we expect. For example, in a peer-to-peer network like Kazaa or Gnutella, it would seem that no rational agent should share files. Whether or not you can get a file depends only on whether other people share files. Moreover, there are disincentives for sharing (the possibility of lawsuits, use of bandwidth, and so on). Nevertheless, people do share files. However, studies of the Gnutella network have shown almost 70 per cent of users share no files and nearly 50 per cent of responses are from the top one per cent of sharing hosts (Adar and Huberman 2000).

One reason that people might not respond as we expect is that they have utilities that are different from those we expect. Alternatively, the players may be irrational, or (if moves are made using a computer) they may be playing using a faulty computer and thus not able to make the move they would like, or they may not understand how to get the computer to make the move they would like. Whatever the reason, it seems important to design strategies that tolerate such unanticipated behaviours, so that the payoffs of the users with 'standard' utilities do not get affected by the nonstandard players using different strategies. This can be viewed as a way of adding fault tolerance to equilibrium notions.

Definition 3 A joint strategy $\sigma^{\Rightarrow}$ is *t-immune* if, for all T $\subseteq$ N with |T| $\leq$ t, all joint strategies $\tau^{\Rightarrow}$, and all $i \notin T$, we have $u_i(\sigma^{\Rightarrow}{}_{-T}, \tau^{\Rightarrow}{}_T) \geq u_i(\sigma^{\Rightarrow})$.

The notion of *t*-immunity and *k*-resilience address different concerns. For *t* immunity, we consider the payoffs of the players not in T, and require that they are not worse due to deviation; for resilience, we consider the payoffs of players in *C*, and require that they are not better due to deviation. It is natural to combine both notions. Given a game Γ, let Γ.be the game that is identical to Γ except that the players in *T* are fixed to playing strategy τ.

Definition 4 $\sigma^{\Rightarrow}$ is a (*k*, *t*) *-robust* equilibrium if $\sigma^{\Rightarrow}$ is t-immune and, for all T $\subseteq$ N such that $|T| \leq t$ and all joint strategies $\tau^{\Rightarrow}$, $\sigma^{\Rightarrow}{}_{-T}$ is a *k*-resilient strategy of $\Gamma_T^{\tau^{\Rightarrow}}$.

To state the results of Abraham et al. (2006) and (2007) on implementing mediators, three games need to be considered: an *underlying*

game Γ, an extension Γ_d of Γ with a mediator, and a cheap-talk extension Γ_{CT} of Γ. Assume that Γ is a *normal-form Bayesian game:* each player has a type from some type space with a known distribution over types, and the utilities of the agents depend on the types and actions taken. Roughly speaking, a cheap talk game *implements* a game with a mediator if it induces the same distribution over actions in the underlying game, for each type vector of the players. With this background, I can summarize the results of Abraham et al. (2006) and (2007).

- If $n > 3k + 3t$, a (k, t) -robust strategy $\sigma^{\Rightarrow}$ with a mediator can be implemented using cheap talk (that is, there is a (k, t)-robust strategy $\sigma^{\Rightarrow\prime}$ in a cheap talk game such that $\sigma^{\Rightarrow}$ and $\sigma^{\Rightarrow\prime}$ induce the same distribution over actions in the underlying game). Moreover, the implementation requires no knowledge of other agents' utilities, and the cheap talk protocol has bounded running time that does not depend on the utilities.
- If $n \leq 3k + 3t$, then, in general, mediators cannot be implemented using cheap talk without knowledge of other agents' utilities. Moreover, even if other agents' utilities are known, mediators cannot, in general, be implemented without having a $(k + t)$-punishment strategy (that is, a strategy that, if used by all but at most $(k + t)$ players, guarantees that every player gets a worse outcome than they do with the equilibrium strategy) nor with bounded running time.
- If $n > 2k + 3t$, then mediators can be implemented using cheap talk if there is a punishment strategy (and utilities are known) in finite expected running time that does not depend on the utilities.
- If $n \# 2k + 3t$ then mediators cannot, in general, be implemented, even if there is a punishment strategy and utilities are known.
- If $n > 2k + 2t$ and there are broadcast channels then, for all ε, mediators can be ε -implemented (intuitively, there is an implementation where players get utility within e of what they could get by deviating) using cheap talk, with bounded expected running time that does not depend on the utilities.
- If $n \leq 2k + 2t$, then mediators cannot, in general, be e-implemented, even with broadcast channels. Moreover, even assuming cryptography and polynomially bounded players, the expected running time of an implementation depends on the utility functions of the players and ε.
- If $n > k + 3$t, then, assuming cryptography and polynomially bounded players, mediators can be e-implemented using cheap talk, but if $n \# 2k + 2t$, then the running time depends on the utilities in the game and ε.
- If $n \leq k + 3t$, then even assuming cryptography, polynomially bounded players, and a $(k + t)$ -punishment strategy, mediators cannot, in general, be ε -implemented using cheap talk.
- If $n > k + t$, then, assuming cryptography, polynomially bounded players, and a public-key infrastructure (PKI), we can ε-implement a mediator.

The proof of these results makes heavy use of techniques from computer science. All the possibility results showing that mediators can be implemented use techniques from secure multiparty computation. The results showing that if $n \leq 3k + 3$t, then we cannot implement a mediator without knowing utilities, and that, even if utilities are known, a punishment strategy is required, use the fact that Byzantine agreement cannot be reached if $t < n/3$; the impossibility result for $n \leq 2k + 3t$ also uses a variant of Byzantine agreement.

A related line of work considers implementing mediators assuming stronger primitives (which cannot be implemented in computer networks); see Izmalkov et al. (2005) and Lepinski et al. (2004) for details.

Other Topics

There are many more areas of interaction between computer science than I have indicated in this brief survey. I briefly mention a few others here.

Interactive Epistemology

Since the publication of Aumann's (1976) seminal paper, there has been a great deal of activity in

trying to understand the role of knowledge in games, and providing epistemic analyses of solution concepts; see Battigalli and Bonanno (1999) for a survey. In computer science, there has been a parallel literature applying epistemic logic to reason about distributed computation. One focus of this work has been on characterizing the level of knowledge needed to solve certain problems. For example, to achieve Byzantine agreement common knowledge among the nonfaulty agents of an initial value is necessary and sufficient. More generally, in a precise sense, common knowledge is necessary and sufficient for coordination. Another focus has been on defining logics that capture the reasoning of resource-bounded agents. A number of approaches have been considered. Perhaps the most common considers logics for reasoning about *awareness*, where an agent may not be aware of certain concepts, and can know something only if he is aware of it. This topic has been explored in both computer science and game theory; see Dekel et al. (1998), Fagin and Halpern (1988), Halpern (2001), Halpern and Rêgo (2007), Heifetz et al. (2006), and Modica and Rustichini (1994, 1999) for some of the work in this active area. Another approach, so far considered only by computer scientists, involves *algorithmic knowledge*, which takes seriously the assumption that agents must explicitly compute what they know. See Fagin et al. (1995) for an overview of the work in epistemic logic in computer science.

Network Growth

If we view networks as being built by selfish players (who decide whether or not to build links), what will the resulting network look like? How does the growth of the network affect its functionality? For example, how easily will influence spread through the network? How easy is it to route traffic? See Fabrikant et al. (2003) and Kempe et al. (2003) for some recent computer science work in this burgeoning area.

Efficient Representation of Games

Game theory has typically focused on 'small' games, often two- or three-player games, that are easy to describe, such as Prisoner's Dilemma, in order to understand subtleties regarding basic issues such as rationality. To the extent that game theory is used to tackle larger, more practical problems, it will become important to find efficient techniques for describing and analysing games. By way of analogy, $2^n - 1$ numbers are needed to describe a probability distribution on a space characterized by n binary random variables. For $n = 100$ (not an unreasonable number in practical situations), it is impossible to write down the probability distribution in the obvious way, let alone do computations with it. The same issues will surely arise in large games. Computer scientists use graphical approaches, such as *Bayesian networks* and *Markov networks* (Pearl 1988), for representing and manipulating probability measures on large spaces. Similar techniques seem applicable to games; see, for example, Kearns et al. (2001), Koller and Milch (2001), and La Mura (2000) for specific approaches, and Kearns (2007) for a recent overview. Note that representation is also an issue when we consider the complexity of problems such as computing Nash or correlated equilibria. The complexity of a problem is a function of the size of the input, and the size of the input (which in this case is a description of the game) depends on how the input is represented.

Learning in Games

There has been a great deal of work in both computer science and game theory on learning to play well in different settings (see Fudenberg and Levine 1998, for an overview of the work in game theory). One line of research in computer science has involved learning to play optimally in a reinforcement-learning setting, where an agent interacts with an unknown (but fixed) environment. The agent then faces a fundamental tradeoff between *exploration* and *exploitation.* The question is how long it takes to learn to play well (to get a reward within some fixed ε of optimal); see Brafman and Tennenholtz (2002) and Kearns and Singh (1998) for the current state of the art. A related question is efficiently finding a strategy minimizes *regret* – that is, finding a strategy that is guaranteed to do not much worse than the best strategy would have done in hindsight (that is,

even knowing what the opponent would have done). See Blum and Mansour (2007) for a recent overview of work on this problem.

Computing in Mechanism Design

Tuomas Sandholm

Abstract

Computational issues are important in mechanism design, but have received insufficient research interest. This article briefly reviews some of the key ideas. I discuss computing by the *centre*, such as an auction server or vote aggregator, and computing by the *agents*, be they human or software. Limited computing hinders mechanism design in several ways, and presents deep strategic interactions between computing and incentives. On the bright side, novel algorithms and increasing computing power have enabled better mechanisms. Perhaps most interestingly, with computationally limited agents, one can implement mechanisms that would not be implementable among computationally unlimited agents.

Introduction

Computational issues in mechanism design are important, but have received insufficient research interest until recently. Limited computing hinders mechanism design in several ways, and presents deep strategic interactions between computing and incentives. On the bright side, novel algorithms and increasing computing power have enabled better mechanisms. Perhaps most interestingly, limited computing of the agents can be used as a tool to implement mechanisms that would not be implementable among computationally unlimited agents. This article briefly reviews some of the key ideas, with the goal of alerting the reader to the importance of these issues and hopefully spurring future research.

I will discuss computing by the *centre*, such as an auction server or vote aggregator, in Section "Computing by the Centre". Then, in Section "Computing by the Agents", I will address the *agents*' computing, be they human or software.

Computing by the Centre

Computing by the centre plays significant roles in mechanism design. In the following three subsections I will review three prominent directions.

Executing Expressive Mechanisms

As algorithms have advanced drastically and computing power has increased, it has become feasible to field mechanisms that were previously impractical. The most famous example is a *combinatorial auction* (*CA*). In a CA, there are multiple distinguishable items for sale, and the bidders can submit bids on self-selected packages of the items. (Sometimes each bidder is also allowed to submit exclusivity constraints of different forms among his bids.) This increase in the expressiveness of the bids drastically reduces the strategic complexity that bidders face. For one, it removes the exposure problems that bidders face when they have preferences over packages but in traditional auctions are allowed to submit bids on individual items only.

CAs shift the computational burden from the bidders to the centre. There is an associated gain because the centre has all the information in hand to optimize while in traditional auctions the bidders only have estimated projected (probabilistic) information about how others will bid. Thus CAs yield more efficient allocations.

On the downside, the centre's task of determining the winners in a CA (deciding which bids to accept so as to maximize the sum of the accepted bids'prices subject to not selling any item to more than one bid) is a complex combinatorial optimization problem, even without exclusivity constraints among bids. Three main approaches have been studied for solving it.

1. *Optimal winner determination using some form of tree search*. For a review, see Sandholm (2006). The advantage is that the bidding language is not restricted and the optimal solution is found. The downside is that no optimal winner determination algorithm can run in polynomial time in the size of the problem instance in the worst case, because the problem is $\mathcal{NP}$-complete (Rothkopf et al. 1998). ($\mathcal{NP}$-complete problems are problems for which the fastest known algorithms take exponential time in the size of the problem instance in the worst case. $\mathcal{P}$ is the class of easy problems solvable in polynomial time. The statement of winner determination not being solvable in polynomial time in the worst case relies on the usual assumption $\mathcal{P} \neq \mathcal{NP}$. This is an open question in complexity theory, but is widely believed to be true. If false, that would have sweeping implications throughout computer science.)
2. *Approximate winner determination*. The advantage is that many approximation algorithms run in polynomial time in the size of the instance even in the worst case. For reviews of such algorithms, see Sandholm (2002a) and Lehmann et al. (2006). (Other suboptimal algorithms do not have such time guarantees, such as local search, stochastic local search, simulated annealing, genetic algorithms and tabu search.) The downside is that the solution is sometimes far from optimal: no such algorithm can always find a solution that is within a factor

$$\min\left\{\#bids^{1-\varepsilon},\ items^{\frac{1}{2}-\varepsilon}\right\} \tag{1}$$

of optimal (Sandholm 2002a). (This assumes $\mathcal{LPP} \neq \mathcal{NP}$. It is widely believed that these two complexity classes are indeed unequal.) For example, with just nine items for sale, no such algorithm can extract even 33 per cent of the available revenue from the bids in the worst case. With 81 items, that drops to 11 per cent.
3. *Restricting the bidding language* so much that optimal (within the restricted language) winner determination can be conducted in worst-case polynomial time. For a review, see Müller (2006). For example, if each package bid is only allowed to include at most two items, then winners can be determined in worst-case polynomial time (Rothkopf et al. 1998). The downside is that bidders have to shoehorn their preferences into a restricted bidding language; this gives rise to similar problems as in non-combinatorial mechanisms for multi-item auctions: exposure problems, need to speculate how others will bid, inefficient allocation, and so on.

Truthful bidding can be made a dominant strategy by applying the *Vickrey–Clarke–Groves* (*VCG*) *mechanism* to a CA. Such incentive compatibility removes strategic complexity of the bidders. The mechanism works as follows. The optimal allocation is used, but the bidders do not pay their winning bids. Instead each bidder pays the amount of value he takes away from the others by taking some of the items. This value is measured as the difference between the others' winning bids' prices and what the others' winning bids' prices would have been had the agent not submitted any bids. This mechanism can be executed by determining the winners once overall, and once for each agent removed in turn. (This may be accomplishable with less computing. For example, in certain network auctions it can be done in the same asymptotic complexity as one winner determination – Hershberger and Suri 2001.)

Very few canonical CAs have found their way to practice. However, auctions with richer bid expressiveness forms (that are more natural in the given application and more concise) and that support expressiveness also by the bid taker have made a major breakthrough into practice (Sandholm 2007; Bichler et al. 2006). This is sometimes called *expressive commerce* to distinguish it from vanilla CAs. The widest area of application is currently industrial sourcing. Tens of billions of dollars worth of materials, transportation and services are being sourced annually using such mechanisms, yielding billions of dollars in efficiency improvements. The bidders' expressiveness forms include different forms of flexible package bids, conditional discounts, discount schedules, side constraints (such as capacity constraints), and often hundreds of cost drivers (for example, fixed costs, variable costs, transshipment costs and costs associated with changes). The item specifications can also be left partially open, and the bidders can specify some of the item attributes (delivery date, insurance terms, and so on). in alternate ways. The bid taker also specifies preferences and constraints. Winner determination then not only decides who wins what, but also automatically configures the items. In some of these events it also configures the supply chain several levels deep as a side effect. On the high end, such an auction can have tens of thousands of items (multiple units of each), millions of bids, and hundreds of thousands of side constraints. Expressive mechanisms have also been designed for settings beyond auctions, such as combinatorial exchanges, charity donations and settings with externalities.

Basically all of the fielded expressive auctions use the simple pay-your-winning-bids pricing rule. There are numerous important reasons why few, if any, use the VCG mechanism. It can lead to low revenue. It is vulnerable to collusion. Bidders would not tell the truth because they do not want to reveal their cost structures, which the auctioneer could exploit the next time the auction is conducted, and so on (Sandholm 2000; Rothkopf 2007).

Basically all of the fielded expressive auctions use tree search for winner determination. In practice, modern tree search algorithms for the problem scale to the large and winners can be determined optimally. If winner determination were not done optimally in a CA, the VCG mechanism can lose its truth-dominance property (Sandholm 2002b). In fact, any truthful suboptimal VCG-based mechanism for CAs is unreasonable in the sense that it sometimes does not allocate an item to a bidder even if he is the only bidder whose bids assign non-zero value to that item (Nisan and Ronen 2000).

Algorithmic Mechanism Design

Motivated by the worry that some instances of *NP*-hard problems may not be solvable within reasonable time, a common research direction in theory of computing is approximation algorithms. They trade off solution quality for a guarantee that even in the worst case, the algorithm runs in polynomial time in the size of the input.

Analogously, Nisan and Ronen (2001) proposed *algorithmic mechanism design*: designing approximately optimal mechanisms that take the centre a polynomial number of computing steps even in the worst case. However, this is more difficult than designing approximately optimal algorithms because the mechanism has to motivate the agents to tell the truth.

Lehmann et al. (2002) studied this for CAs with single-minded bidders (each bidder being only interested in one specific package of items). They present a fast greedy algorithm that guarantees a solution within a factor $\sqrt{\#items}$ of optimal. They show that the algorithm is not incentive compatible with VCG pricing, but is with their custom pricing scheme. They also identify sufficient conditions for any (approximate) mechanism to be incentive compatible (see also Kfir-Dahav et al. 2000). There has been substantial follow-on work on subclasses of single-minded CAs.

Lavi and Swamy (2005) developed a technique for a range of packing problems with which any k-approximation algorithm (that is, algorithm that guarantees that the solution is within a factor k of optimal) that also bounds the integrality gap of the linear programming (LP) relaxation of the problem by k can be used to construct a $k$approximation mechanism. The LP solution, scaled down by k, can be represented as a convex combination of integer solutions, and viewing this convex combination as specifying a probability distribution over integer solutions begets a VCG-based randomized mechanism that is truthful in expectation. For CAs with general valuations, this yields an $O\left(\sqrt{\#items}\right)$ -approximate mechanism.

In a different direction, several mechanisms have been proposed where the agents can help the centre find better outcomes. This is done either by giving the agents the information to do the centre's computing (Banks et al. 1989; Land et al. 2006; Parkes and Shneidman 2004), or by allowing the agents to change what they told the mechanism based on the mechanism's output and potentially also based on what other agents told the mechanism (Nisan and Ronen 2000). In VCG-based mechanisms, an agent benefits from lying only if the lie causes the mechanism to find an outcome that is better overall.

Automated Mechanism Design

Conitzer and Sandholm (2002) proposed the idea of *automated mechanism design*: having a computer, rather than a human, design the mechanism. Because human effort is eliminated, this enables custom design of mechanisms for every setting. The setting can be described by the agents' (discretized) type spaces, the designer's prior over types, the desired notion of incentive compatibility (for example, dominant strategies vs. Bayes–Nash implementation), the desired notion of participation constraints (for example, *ex interim*, *ex post* or none), whether payments are allowed, and whether the mechanism is allowed to use randomization.) This can yield better mechanisms for previously studied settings because the mechanism is designed for the specific setting rather than a class of settings. It can also be used for settings not previously studied in mechanism design.

For almost all natural (linear) objectives, all variants of the design problem are $\mathcal{NP}$-complete if the mechanism is not allowed to use randomization, but randomized mechanisms can be constructed for all these settings in polynomial time using linear programming. Custom algorithms have been developed for some problems in each of these two categories. (Even the latter category warrants research. While the linear programme is polynomial in the size of the input, the input itself can be exponential in the number of agents.) Structured representations of the problem can also make the design process drastically faster.

Beyond the general setting, automated mechanism design has been applied to specific settings, such as creating revenue-maximizing CAs (without the need to discretize types)–Likhodedov and Sandholm 2005 (a recognized problem that eludes analytical characterization; even the two-item case is open), reputation systems (Jurca and Faltings 2006), safe exchange mechanisms (Sandholm and Ferrandon 2000), and supply chain settings (Vorobeychik et al. 2006). Automated mechanism design software has recently also been adopted by several mechanism design theoreticians to speed up their research.

It turns out that even *multistage mechanisms* can be designed automatically (Sandholm et al. 2007). Furthermore, automated mechanism design has been applied to the design of *online mechanisms* (Hajiaghayi et al. 2007), that is,

mechanisms that execute while the world changes –for example, agents enter and exit the system.

Computing by the Agents

I will now move to discussing computing by the agents.

Mechanisms That Are Hard to Manipulate

This section demonstrates that one can use the fact that agents are computationally limited to achieve things that are not achievable via any mechanism among perfectly rational agents.

A seminal negative result, the *Gibbard–Satterthwaite th*, states that if there are three or more candidates, then in any non-dictatorial voting scheme there are candidate rankings of the other voters, and preferences of the agent, under which the agent is better off voting manipulatively than truthfully. One avenue around this impossibility is to construct desirable general non-dictatorial voting protocols under which *finding* a beneficial manipulation is prohibitively hard computationally.

There are two natural alternative goals of manipulation. In *constructive manipulation*, the manipulator tries to find an order of candidates that he can reveal so that his favourite candidate wins. In *destructive manipulation*, the manipulator tries to find an order of candidates that he can reveal so that his hated candidate does not win. These are special cases of the utility-theoretic notion of improving one's utility, so the hardness results, discussed below, carry over to the usual utility-theoretic setting.

Unfortunately, finding a constructive manipulation is easy (in $\mathcal{P}$) for the *plurality*, *Borda* and *maximin* voting rules (Bartholdi et al. 1989), which are commonly used. On the bright side, constructive manipulation of the *single transferable vote* (*STV*) protocol is $\mathcal{NP}$-hard (Bartholdi and Orlin 1991) (as is manipulation of the *second order Copeland* protocol (Bartholdi et al. 1989), but that hardness is driven solely by the tie-breaking rule). Even better, there is a systematic methodology for slightly tweaking voting protocols that are easy to manipulate, so that they become hard to manipulate (Conitzer and Sandholm 2003). Specifically, before the original protocol is executed, one pairwise elimination round is executed among the candidates, and only the winning candidates survive to the original protocol. This makes the protocols $\mathcal{NP}$-hard, # $\mathcal{P}$hard (#$\mathcal{P}$-hard problems are at least as hard as counting the number of solutions to a problem in $\mathcal{P}$), or even *PSPACE*-hard (*PSPACE*-hard problems are at least as hard as any problem that can be solved using a polynomial amount of memory) to manipulate constructively, depending on whether the schedule of the pre-round is determined before the votes are collected, randomly after the votes are collected, or the scheduling and the vote collecting are carefully interleaved, respectively.

All of the hardness results of the previous paragraph rely on both the number of voters and the number of candidates growing. The number of candidates can be large in some domains, for example when voting over task or resource allocations.

However, in other elections – such as presidential elections – the number of candidates is small. If the number of candidates is a constant, both constructive and destructive manipulation are easy (in $\mathcal{P}$), regardless of the number of voters (Conitzer et al. 2007). This holds even if the voters are weighted, or if a coalition of voters tries to manipulate. On the bright side, when a coalition of weighted voters tries to manipulate, complexity can arise even for a constant number of candidates: see Tables 1 and 2. Another lesson from that table is that randomizing over instantiations of the mechanism (such as schedules of a *cup*) can be used to make manipulation hard.

As usual in computer science, all the results mentioned above are worst-case hardness. Unfortunately, under weak assumptions on the preference distribution and voting rule, most instances of any voting rule are easy to manipulate (Conitzer and Sandholm 2006).

All of the hardness results discussed above hold even if the manipulators know the non-manipulators' votes exactly. Under weak

assumptions, if weighted coalitional manipulation with complete information about the others' votes is hard in some voting protocol, then individual unweighted manipulation is hard when there is uncertainty about the others' votes (Conitzer et al. 2007).

Non-Truth-Promoting Mechanisms

A challenging issue is that even if it is prohibitively hard to find a beneficial manipulation, the agents might not tell the truth. For example, an agent might take a chance that he will do better with a lie. The following result shows that, nevertheless, mechanism design can be improved by making the agents face complexity. (This is one reason why computational issues can render the *revelation principle* inapplicable. One of the things the principle says is that for any non-truth-promoting mechanism it is possible to construct an incentive-compatible mechanism that is at least as good. The theorem below challenges this.)

Theorem 1 (Conitzer and Sandholm 2004) *Suppose the centre is trying to maximize social welfare, and neither payments nor randomization is allowed. Then, even with just two agents (one of whom does not even report a type, so dominant strategy implementation and Bayes–Nash implementation coincide), there exists a family of preference aggregation settings such that:*

- *the execution of any optimal incentive-compatible mechanism is $\mathcal{NP}$ -complete for the center, and.*
- *there exists a non-incentive-compatible mechanism which (1) requires the centre to carry out only polynomial computation, and (2) makes finding any beneficial insincere revelation NP-complete for the type-reporting agent. Additionally, if the type-reporting agent manages to find a beneficial insincere revelation, or no beneficial insincere revelation exists, the social welfare of the outcome is identical to the social welfare that would be produced by*

any optimal incentive-compatible mechanism. Finally, if the type-reporting agent does not manage to find a beneficial insincere revelation where one exists, the ***social welfare of the outcome is strictly greater than the social welfare that would be produced by any optimal incentive-compatible mechanism***.

An analogous theorem holds if, instead of counting computational steps, we count calls to a commonly accessible oracle which, when supplied with an agent, that agent's type, and an outcome, returns a utility value for that agent.

Preference (Valuation) Determination Via Computing or Information Acquisition

In many (auction) settings, even determining one's valuation for an item (or a bundle of items) is complex. For example, when bidding for trucking lanes (tasks), this involves solving two $\mathcal{NP}$-complete local planning problems: the vehicle routing problem with the new lanes of the bundle and the problem without them (Sandholm 1993). The difference in the costs of those two local plans is the cost (valuation) of taking on the new lanes.

In these types of settings, the *revelation principle* applies only in a trivial way: the agents report their data and optimization models to the centre, and the centre does the computation for them. It stands to reason that in many applications the centre would not want to take on that burden, in which case such extreme direct mechanisms are not an option. Therefore, I will now focus on mechanisms where the agents report valuations to the centre, as in traditional auctions.

Bidders usually have limited computing and time, so they cannot exactly evaluate all (or even any) bundles – at least not without cost. This leads to a host of interesting issues where computing and incentives are intimately intertwined.

For example, in a one-object auction, should a bidder evaluate the object if there is a cost to doing so? It turns out that the Vickrey auction loses its dominantstrategy property: whether or not the bidder should pay the evaluation cost depends on the other bidders' valuations (Sandholm 2000).

If a bidder has the opportunity to *approximate his valuation to different degrees*, how much computing time should the bidder spend on refining its valuation? If there are multiple items for sale, how much computing time should the bidder allocate on different bundles? A bidder may even allocate some computing time to evaluate other bidders' valuations so as to be able to bid more strategically; this is called *strategic computing*.

To answer these qsts, Larson and Sandholm (2001) developed a deliberation control method called a *performance profile tree* for projecting how an anytime algorithm (that is, an algorithm that has an answer available at any time, but where the quality of the answer improves the more computing time is allocated to the algorithm) will change the valuation if additional computing is allocated toward refining (or improving) it. This deliberation control method applies to any anytime algorithm. Unlike earlier deliberation control methods for anytime algorithms, the performance profile tree is a *fully normative model of bounded rationality*: it takes into account all the information that an agent can use to make its deliberation control decisions. This is necessary in the game-theoretic context; otherwise a strategic agent could take into account some information that the model does not.

Using this deliberation control method, the auction can be modelled as a game where the agents' strategy spaces include computing actions. At every point, each agent can decide on which bundle to allocate its next step of computing as a function of the agent's computing results so far (and in open-cry auction format also the others' bids observed so far). At every point, the agent can also decide to submit bids. One can then solve this for equilibrium: each agent's (deliberation and bidding) strategy is a best-response to the others' strategies. This is called *deliberation equilibrium*.

This notion, and the performance profile tree, apply not only to computational actions but also to information gathering actions for determining valuations. (In contrast, most of the literature on information acquisition in auctions does not take

Computing in Mechanism Design, Table 3 Can strategic computing occur in deliberation equilibrium? The most interesting results are in bold. As a benchmark from classical auction theory, the table also shows whether or not perfectly rational agents, that can determine their valuations instantly without cost, would benefit from considering each others' valuations when deciding how to bid

	Auctionmechanism	Speculation by perfectly rational agents?	Strategic computing	
			Limited computing	**Costly computing**
Single item	First price	Yes	Yes	Yes
	Dutch	Yes	Yes	Yes
	English	No	**No**	**Yes**
	Vickrey	No	**No**	**Yes**
Multiple items	First price	Yes	Yes	Yes
	VCG	No	**Yes**	**Yes**

into account that valuations can be determined to different degrees and that an agent may want to invest effort to determine others' valuations as well – even in privatevalue settings.)

Table 3 shows in which settings strategic computing can and cannot occur in deliberation equilibrium. This depends on the auction mechanism. Interestingly, it also depends on whether the agent has limited computing (for example, owning a desktop computer that the agent can use until the auction's deadline) or costly computing (for example, being able to buy any amount of supercomputer time where each cycle comes at a cost).

The notion of deliberation equilibrium can also be used as the basis for designing new mechanisms, which hopefully work well among agents whose computing is costly or limited. Unfortunately, there is an impossibility (Larson and Sandholm 2005): there exists no mechanism that is *sensitive* (the outcome is affected by each agent's strategy), *preference formation independent* (does not do the computations for the agents; the agents report valuations), *non-misleading* (no agent acts in a way that causes others to believe his true type has zero probability), and *deliberation-proof* (no strategic computing occurs in equilibrium, that is, agents compute only on their own problems). Current work involves designing mechanisms that take part in preference formation in limited ways: for example, agents report their performance profile trees to the centre, which then coordinates the deliberations incrementally as agents report deliberation results. Current research also includes designing mechanisms where strategic computing occurs but its wastefulness is limited.

Preference Elicitation by the Centre

To reduce the agents' preference determination effort, Conen and Sandholm (2001) proposed a framework where the centre (also known as *elicitor*) explicitly elicits preference information from the agents incrementally on an as-needed basis by posing queries to the agents. The centre thereby builds a model of the agents'preferences, and decides what to ask, and from which agent, based on this model. Usually the process can be terminated with the provably correct outcome while requiring only a small portion of the agents' preferences to be determined. Multistage mechanisms can yield up to exponential savings in preference determination and communication effort the agents need to go through compared to single-stage mechanisms (Conitzer and Sandholm 2004).

The explicit preference elicitation framework was originally proposed for CAs (but the approach has since been used for other settings as well, such as voting). For general valuations, an exponential number of bits in the number of items for sale has to be communicated in the worst case

no matter what queries are used (Nisan and Segal 2006). However, experimentally only a small fraction of the preference information needs to be elicited before the provably optimal solution is found. Furthermore, for valuations that have certain types of structure, even the worst-case number of queries needed is small. Research has also been done on the relative power of different query types.

If enough information is elicited to also determine the VCG payments, and these are the payments charged to the bidders, answering the elicitor's queries truthfully is an *ex post* equilibrium (a strengthening of Nash equilibrium that does not rely on priors). (This assumes there is no explicit cost or limit to valuation determination; mechanisms have also been designed for settings where there is an explicit cost (Larson 2006).) This holds even if the agents are allowed to answer queries that the elicitor did not ask (for example, queries that are easy for the agent to answer and which the agent thinks will significantly advance the elicitation process). We thus have a *pull–push mechanism* where both the centre and the agents guide the preference revelation (and thus also the preference determination/ refinement by the agents). For a review, see Sandholm and Boutilier (2006). Ascending (combinatorial) auctions are an earlier special case, and have limited power compared to the general framework (Blumrosen and Nisan 2005).

Preference elicitation can sometimes be computationally complex for the centre. It can be complex to intelligently decide what to ask next, and from whom. It can also be complex to determine whether enough information has been elicited to determine the optimal outcome. Even if the elicitor knows that enough has been elicited, it can be complex to determine the outcome – for example, allocation of items to bidders in some CAs.

Distributed (Centre-Free) Mechanisms

Computer scientists often have a preference for distributed applications that do not have any centralized coordination point (centre). Depending on the application, the reasons for this preference may include avoiding a single vulnerable point of failure, distributing the computing effort (for computational efficiency or because the data is inherently distributed), and enhancing privacy. The preference carries over from traditional computer science applications to different forms of negotiation systems –for example, see Sandholm (1993) for an early distributed automated negotiation system for software agents.

Feigenbaum et al. (2005) have studied lowest-cost inter-domain routing on the Internet, modifying a distributed protocol so that the agents (routing domains) are motivated to report their true costs and the solution is found with minimal message passing. For a review of some other research topics in this space, see Feigenbaum and Shenker (2002).

One can go further by taking into account the fact that agents might not choose to follow the prescribed protocol. They may cheat not only on information-revelation actions, but also on message-passing and computational actions. Despite computation actions not being observable by others, an agent can be motivated to compute as prescribed by tasking at least one other agent with the same computation, and comparing the results (Sandholm et al. 1999). Careful problem partitioning can also be used to achieve the same outcome without redundancy by only requiring agents to perform computing and message passing tasks that are in their own interest (Parkes and Shneidman 2004). Shneidman and Parkes (2004) propose a general proof technique and instantiate it to provide a non-manipulable protocol for inter-domain routing. Monderer and Tennenholtz (1999) develop protocols for one-item auctions executed among agents on a communication network. The protocols motivate the agents to correctly reveal preferences and communicate. For the setting where agents with private utility functions have to agree on variable assignments subject to side constraints (for example, meeting scheduling), Petcu et al. (2006) developed a VCG-based distributed optimization protocol that finds the social welfare maximizing allocation

and each agent is motivated to follow the protocol in terms of all three types of action. The only centralized party needed is a bank that can extract payments from the agents.

Cryptography is a powerful tool for achieving privacy when trying to execute a mechanism in a distributed way without a centre, using private communication channels among the agents. Consider first the setting with passive adversaries, that is, agents that faithfully execute the specified distributed communication protocol, but who try to infer (at least something about) some agents' private information.

- If agents are computationally limited – for example, they are assumed to be unable to factor large numbers – then arbitrary functions can be computed while guaranteeing that each agent maintains his privacy (except, of course, to the extent that the answer of the computation says something about the inputs) (Goldreich et al. 1987). Thus the desire for privacy does not constrain what social choice functions can be implemented.
- In contrast, only very limited social choice functions can be computed privately among computationally unlimited agents. For example, when there are just two alternatives, every monotonic, non-dictatorial social choice function that can be privately computed is constant (Brandt and Sandholm 2005). With special structure in the preferences, this impossibility can sometimes be avoided. For example, with the standard model of quasi-linear utility, first-price auctions can be implemented privately; second-price (Vickrey) auctions with more than two bidders cannot (Brandt and Sandholm 2004).

A more general model is that of active adversaries who can execute the distributed communication protocol unfaithfully in a coordinated way. A more game-theoretic model is that of rational adversaries that are not passive, but not malicious either. For a brief overview of such work, see computer science and game theory.

Comte, Isidore Auguste Marie François Xavier (1798–1857)

Robert B. Ekelund Jr.

Auguste Comte, co-founder of sociology and positivist philosopher, was born at Montpellier in 1798 and died in Paris in 1857. A student at the Ecole Polytechnique until he was dismissed for disobedience and incorrigible behaviour, Comte became the secretary to Henri de Saint-Simon in 1818, a position he held until 1824. Over this period Comte developed the kernel of positivist philosophy and, along with Saint-Simon, modern sociology. The irascible Comte spent the rest of his life – often in the face of frequent poverty and desperate personal circumstances including mental breakdowns and a failed marriage – establishing, altering and working out positivism as a philosophical system of knowledge and as the foundation for the 'science of society'. Comte's *chefs d'oeuvre* included the encyclopedic *Cours de philosophie positive* (1830–42) and his *System of Positive Polity* (1851–4).

Comte's social philosophy encompassed all aspects of life, which he believed to be the harmonious working together of two inseparable elements – an organism and its environment. The 'true' methods of science were empirical (or inductive), and Comte, as did his mentor Saint-Simon, believed that they could be applied, *mutatis mutandis,* to all branches of thought including the social sciences, of which economics was a part. He succinctly described this basis in the *System of Positive Polity*: 'It [the positivist synthesis of all knowledge] rests at every point upon the unchangeable Order of the World. The right understanding of this order is the principal subject of our thoughts; its preponderating influence determines the general course of our feelings; its gradual improvement is the constant object of our actions . . .' (vol. 1, p. 21).

'Gradual improvement' came about in three successive stages of understanding the cause of phenomena. In the 'Law of Three Stages', Comte argued that man's conception of 'order' or the interrelationships of causes and effects, went first through a religious or theological stage, the theological–primitive content of which diminished progressively from fetishism, polytheism and monotheism. The metaphysical or *a priori* stage followed the theological and represented man's attempt to discover 'order' by reason. The final stage in understanding order was the positive stage wherein science, or the knowledge of relationships between disparate phenomena, brought man to a kind of perfection. Within this latter stage, Comte argued that a second great law obtained – that of decreasing generality and increasing complexity of understanding. Here, sciences progressed in a definite ordering, each dependent on the previous one, from mathematics to astronomy to physics to chemistry to biology and, finally, to sociology.

Comte's system, its broadly empirical methodology, and its precept that society was an organism which evolved under constraints that were themselves ultimately altered by social activities and behaviour, had a measurable impact upon classical economics and upon the *form* that

economic analysis would take in the neoclassical period and beyond. J.S. Mill introduced Comte's ideas to England and, for a time at least, was deeply influenced by the French philosopher. Mill's *Logic* (1843) contains copious and favourable references to Comte's inverse-deductive (empirical-historical) method for use in the broader and more important investigation of integrated social studies. In the end, however, Mill reaffirmed the *a priori* 'Ricardian' method for the narrower concerns of political economy. Again, Comte's influence surfaced in Mill's *Principles of Political Economy* (1848) in the form of the famous 'statics and dynamics' distinction and in Mill's admissions that the ultimate aim of social science was a broader conception of the process than political economy had to offer. In his *Principles,* however, Mill reaffirmed the (admittedly provisional) *a priori* deductive method as the essential and proper one for studying political economy. Ultimately, Mill and a number of Comte's followers totally rejected the 'religion of humanity' that Comte later made of his positivist principles (1851–77). Mill was especially aghast at the infringements on individual liberty that Comte's quasi-medieval 'Catholicism without Christianity' envisioned. In his *Autobiography* Mill attacked Comte's planned society as 'the completest system of spiritual and temporal despotism which ever yet emanated from a human brain, unless possibly that of Ignatius Loyola' (1873, p. 149).

In the late classical and early neoclassical period Comte's ideas received some reinforcement at the hands of the British historicists, notably John Kells Ingram. But his impact, especially on methodology and on his belief that political economy should be subordinate to sociology, was successfully nullified by the efforts of John Elliott Cairnes (1870). While admitting that empiricism was a necessary adjunct to economic theory, Cairnes defended an essentially abstract and *a priori* method in political economy. Cairne's ideas on method were replicated by the leading methodologist of the neoclassical and even post-neoclassical periods, John Neville Keynes. The attempt to infuse Comtian and other broader methods into political economy, in other words, reinforced Ricardo's method which became the dominant method of economists in the 20th century.

Concentration Measures

Juan Esteban Carranza

Abstract

Concentration is a characterization of the size distribution and quantity of competing firms within a specific market or industry. The most common concentration measures are the Herfindahl index and the *n*-firm concentration rate. The Herfindahl index is the sum of the squared market shares of all the firms in a market, whereas the *n*-firm concentration rate is the sum of the market shares of the *n* biggest firms. These measures are a significant reflection of the underlying degree of competitiveness, but are sensitive to the adopted market definition, and must be interpreted carefully depending on the specifics of the case.

Keywords

Gini coefficient; Herfindahl index; Lerner index; Market definition; Market structure

JEL Classification

D4

The term *concentration* (also *firm concentration*, *industry concentration* or *market concentration*) refers to aspects of the distribution of firm size within a specific market or industry that have traditionally been used to characterize the degree of competitiveness in the market. Even though the size of firms can be measured using many different variables, such as employment or assets, the sales level is the most commonly used size measure. Accordingly, if very few firms serve a very large portion of the market, it is said that the given market is highly 'concentrated', whereas if no single firm has a large share of sales it is said that the market is not 'concentrated'. Since concentration is an important reflection of the underlying market structure, its measurement is an important characterization of the interaction of firms within a specific market or industry.

The most common concentration measures are the '*n*-firm concentration rate' and the 'Herfindahl index'. Let S_i be the market share of firm i; the '*n*-firm concentration rate' is the sum of the market shares of the n biggest firms within the market:

$$C(n) = \sum_{i=1}^{n} S_i.$$

As indicated, the summation above is taken over the set of n biggest firms in the market. So, for example, the two-firm concentration rate of a given market is the sum of the market shares of the two biggest firms in the market where size is measured according to observed sales. In order to fully characterize the concentration of any given market, though, a number of these rates must be used, since there is no agreed-on value for n. This complicates its use for comparing concentration over time and across sectors, and for its use in statistical analysis.

The Herfindahl index, first devised by Albert Hirschman to measure the concentration of trade across sectors (so that the index is also known as 'Herfindahl–Hirschman index'; see Hirschman 1964, for its history), is the sum of the squared market shares of all firms in the market:

$$H = \sum_{i=1}^{N} S_i^2.$$

The summation in this case is taken over the set of all N firms in the market. This index lies between zero and 1: if there is only one firm in the market, so that the market has the highest possible concentration, the index is 1. If, on the other hand, there are many equally sized firms in the market, the index will be close to zero. By squaring the individual market shares, this index gives relatively greater weight to the market shares of large firms. Conversely, the addition of one small firm to the market dilutes somewhat the market share of larger firms, and has a marginal negative effect on the index, which is consistent with any notion of market concentration. Any value of this index can correspond to multiple

market configurations, being in that sense less illustrative of the actual concentration of a market than a set of *n*-firm concentration rates. On the other hand, this index can be easily correlated with other market characteristics and is therefore very useful for statistical analysis.

Other less commonly used concentration measures include entropy coefficients, the Gini coefficient and measures of the variance of market shares across firms within a market. The entropy coefficient is usually computed using the following formula:

$$E = \sum_{i=1}^{N} S_i log_2 \left(\frac{1}{S_i} \right).$$

This index takes value zero if there is only one firm in the market and grows as market concentration decreases. The interpretation of this coefficient is complicated, because its formula weights both large and small firms less heavily than mid-size firms and grows unboundedly as market concentration decreases. It is therefore less commonly used than the Herfindahl index.

The Gini coefficient is commonly used to characterize the income or wealth inequality within a society. Its drawback as a measure of market concentration is that it is useful only to measure the concentration of firms' sizes within a market, given a number of firms. So according to the Gini coefficient a duopolistic market with two firms of equal size is as concentrated as a market with 100 firms with identical size. The same drawback applies for the use of measures of the variance of firm size – whose definition is simply the sample variance of firm sizes.

All the concentration measures mentioned above are very sensitive to the actual market definition that is used. In markets for differentiated products, for example, products may face a continuum of similar products, and determining which similar products exactly constitute a market is not always easy. Take the specific example of the market faced by US mobile phone services: with just a handful of national providers it is concentrated given the standard concentration measures. These national firms, nevertheless, are also competing with local companies in various segments of the market and even with long-distance phone companies and Internet companies as providers of communication services. The Internet, on the other hand, competes in some instances with cable and satellite companies, radio stations and even newspapers as sources of news and entertainment. What exactly the relevant market faced by mobile phone companies is will depend on the type of issue being addressed. Accordingly, the concentration measures will change depending on the adopted market definition.

On the other hand, even if the market is well defined, computed concentration measures may not reflect at all the real competitive structure of the market. For example, even in markets as highly concentrated as the market for computer processors, the dominant firms have to account for the invisible competition of potential entrants. The same happens in regional markets where outside firms are kept at bay by few local firms with a combination of low prices and high transportation costs. Computed concentration measures for specific markets cannot account for this unobserved competition and may therefore lead to wrong conclusions regarding the underlying behaviour of firms. In these instances, a behavioural measure, such as the Lerner index, which measures the relative size of firms' markups, may be a better indicator of the competitive structure of the market.

There is a body of empirical literature that uses market concentration measures across industries to approximate the underlying differences in industries' competitiveness. They were then used to infer statistically the relationship between market 'structure' and market 'performance'. For example, correlations of R&D expenditure and market concentration were computed to investigate whether firms in concentrated markets were more or less likely to innovate than firms in more competitive markets. The value of such correlations is limited because the observed concentration may be both a cause and an effect of individual firms' behaviour and the relationship is shaped by the specifics of the industry. In order to avoid the ambiguities of such an inter-industry approach, the more recent empirical microeconomic literature has generally focused instead on the understanding of firm behaviour within specific industries, for which the use of concentration measures is less relevant.

Concentration Ratios

William G. Shepherd

These standard indicators of the degree of oligopoly in markets are used in studying market conditions. The ratio is the combined market shares of the 'oligopoly group' of firms which, being few, are closely interdependent. The ratio is usually based on three, four or five firms.

In theory the ratio indicates the market power held by the interdependent group. When the ratio is high, a few firms dominate the market and, with some degree of collusion, can raise prices and perform other conventional monopoly actions. Higher concentration makes effective collusion more probable. If the oligopolists achieve perfect joint maximation of profits, then the market power they exert is as great as if the firms were unified into one dominant firm. Concentration is therefore an indicator of diluted monopoly power.

How diluted it is depends on the degree of firms' cohesion. The fewer the firms, the more impact a departure from collusion will have on the joint outcome. Also, such departures will tend to be discovered more quickly, and therefore be open to more effective punishment by the other oligopolists. Therefore, higher concentration tilts the oligopolists' choices away from maverick price-cutting and toward collusion. Accordingly, high concentration should avoid the disintegration that often afflicts efforts to fix prices.

The distinction between tight oligopoly (a four-firm ratio above 60 per cent) and loose oligopoly (a ratio below 40 per cent) has come to be regarded as particularly important. In tight oligopoly, collusion is likely to crystallize effectively into strong cooperation, as the oligopolists' common interests overwhelm the rewards from cheating. Loose oligopoly, by contrast, is seen as a setting for disintegration, where the many oligopolists with low market shares are jointly unable to avert the endemic price cutting. This reasoning, which is broadly confirmed by the common run of experience in actual markets, suggests that a threshold value of concentration in the 50–60 per cent range should present a clear divide between the effective competition seen in loose oligopoly and the high market power that tight oligopoly may create.

Concentration is usually second in importance to individual market shares, as an element of market structure. Thus, for example, a General Motors may have a market share of 50 per cent, while it and the other three leading firms have a combined concentration ratio of 90 per cent. GM's own price–profit, innovation and other results are likely to be influenced more closely by its own 50 per cent share – giving it a dominant-firm position – than by the fact that it is in a market with high concentration in four firms.

Concentration's effects, such as they are, may be modified by entry conditions. Free and vigorous entry can limit the tight oligopolists' ability to exert market power. This is a controversial area, for there may be few active entrants actually ready to take advantage of free-entry conditions. Also, entry may be slow or marginal, so that it does not strongly affect the core of the market positions held by the leading firms.

Starting in the 1930s, the ratios soon gained pre-eminence in studying the degrees of market power. One was the then-new focus on oligopoly. The other was the new availability of the actual ratios for hundreds of US manufacturing industries for the year 1935. (US and UK ratios appear about every four or five years, as part of the

industrial census. Only manufacturing industries are covered, although ratios on urban US banking markets are prepared by other sources).

Econometric analysis has made extensive use of these ratios, with scores of papers reporting regressions relating concentration to price–cost patterns, growth rates, efficiency, rates of innovation, etc. In fact, concentration ratios reigned as the research focus for analysis of market power and its effects. Indeed, from 1939 to about 1970 the abundant availability of the ratios reinforced the tendency to regard (perhaps over-regard) oligopoly as a central issue. With the growing focus on individual market shares, the role of concentration ratios became less important in the 1970s. Even so, the ratios continue to be an indispensable descriptive statistic, used widely in research into the several elements of structure and their effects.

Before summarizing some of the results, one needs to note that the ratios are subject to a serious technical fault. A correct definition of the market is important, if true concentration within the market is to be measured. The US Bureau of the Census has a detailed system of standard industrial classification (SIC). All sectors are grouped by numbers, ranging from SIC 1 to 100. The manufacturing sector covers 'industry groups' 20 through 39, and so forth. Differing degrees of fineness are given. The five-digit product level is, on balance, about correct in fitting the average scope of true markets. Yet most research has focused on the much broader four-digit 'industries', which now number about 450 in the US.

About half of these four-digit census 'industries' depart seriously from correct market boundaries. The use of raw census ratios has undermined a good deal of the past research on structure and its effects. Commonly, the ratios are too broad, lumping together distinct products and geographic markets (for example, the national four-firm US ratio is 14 per cent for newspapers, but concentration ratios in true local newspaper markets probably average close to 100 per cent). Some cases go the other way, with the official ratios too high (for example, imports are not included in the ratios, and this is important for steel, television sets, shoes, cameras, automobiles and many others).

Adjusting the ratios to fit true market conditions requires care and judgement. Thus the weighted average degree of four-firm concentration in US manufacturing industries has been actually about 60 per cent, rather than the 40 per cent indicated by the raw census ratios.

Properly adjusted to eliminate these biases, a concentration ratio is an excellent descriptive statistic. It conveys the degree of oligopoly 'tightness'. It can show changes in structure pretty accurately. Thus the market power indicated by a ratio of 53 or 63 may be a matter of debate, but a rise in ratio from 53 to 63 for a given industry strongly suggests that there has been a rise in market power.

By 1975, the ratios have provided enormously valuable lessons, in several directions. They were the workhorse statistic in describing the structure of hundreds of industries, in case studies of industries, in antitrust investigations and in other straightforward treatments. They had become a pivotal basis for antitrust policy choices, such as in merger cases, where the degree of concentration was one basis for deciding whether to oppose the merger. During 1960–75 they gave rise to many scores of regression analyses, which tried to relate concentration to the possible effects of market power.

The correlation of concentration with price behaviour drew the largest volume of testing. These estimations were commonly plagued by the use of uncorrected, raw census ratios, which introduced substantial errors. Even so, a broad and significant correlation did emerge, enough to establish a presumption that the theoretical effects of oligopoly market power on pricing activity do occur in practice. The most successful testing involved multivariate models of five to eight independent variables, including filter variables such as capital intensity and growth, and other structure-related variables such as market shares, advertising intensity and capital-requirements barriers to entry.

Another important line of research attempted to explain concentration as the dependent variable. Growth rates were one possible causative variable, while economies of scale were another. Growth emerged as a very weak influence, and scale economies turned out to explain only a limited amount of actual concentration in important national markets. The weakness of these results may, in part, have reflected errors in the concentration ratios themselves.

Finally, concentration's possible effects on innovation, stability and wealth distribution

have been explored. These studies often were forced to adopt quite creative approaches, in light to the data problems. Again, the general patterns have confirmed the main predictions of theory, that high concentration tends to affect results much as high monopoly power does. High concentration was associated, on the whole, with slowed innovation, greater instability of production and the disequalizing of the distribution of wealth.

Yet testing continues on all of these points, and the concentration ratios have tended only to suggest patterns, not resolve them. Studies since 1970 have focused more on individual market shares, showing them to have stronger effects than concentration, just as theory predicts. Though the use of concentration ratios in regression analysis may have peaked, the ratios (adjusted as appropriate) will undoubtedly continue as a main basis for describing the degree of market power in a wide array of markets in the US, UK, Canada, Japan and certain other countries.

Philosopher and economist. Born at Grenoble, the third son of a well-to-do aristocratic family, Condillac took his name from an estate purchased by his father in 1720. As a sickly child with poor eyesight he had little early education and was apparently still unable to read by the age of 12. After his father's death in 1727 he moved to Lyon to live with his oldest brother, continuing his education at its Jesuit college. Through this brother he may have first met Jean Jacques Rousseau, who was tutor to

his nephews in 1740 and became a life-long friend. His second brother, l'Abbé de Mably, took Condillac to Paris in *c*. 1733 to study theology at Saint Sulpice and the Sorbonne. He was ordained in 1740 and for the rest of his life 'ever faithful to the Christian church, would always wear his cassock, always remain l'Abbé' (Lefèvre 1966, p. 11).

For the next 15 years he lived the life of a Paris intellectual, studying the philosophy of Descartes, Malebranche, Leibniz and Spinoza, 'to whose speculative systems he formed a life-long aversion, preferring the English philosophers Locke (who particularly influenced his thinking), Berkeley, Newton and rather belatedly, Bacon' (Knight 1968, pp. 8–9). In this period he published the works which made his philosophical reputation: the *Essay on the Origin of Human Knowledge* (1746), the *Traité des Systèmes* (1749), his most famous philosophical work *Treatise on the Sensations* (1754) described as the 'most rigorous demonstration of the [18th-century] sensationalist psychology' (Knight 1968, p. 12) and his *Traité des Animaux* (1755).

Apart from giving him entry to the Paris salons, where at Mlle de Lespinasse's salon he is reputed to have first met Turgot, another life-long friend (Le Roy 1947, p. ix), his intellectual reputation gained him the position of tutor to Louis XV's grandson, the Duke of Parma. From 1758 to 1767 he resided in Parma. Because of its prime minister's economic development policies, inspired by a mixture of 'mercantilism, physiocracy and the ideas of Gournay', Condillac developed an interest in economic matters, an interest 'indirectly confirmed by his known contacts with the Italian political economists, Beccaria and Gherardo' (Knight 1968, pp. 231–2). In 1768 he returned to Paris, but by 1773 had retired to his estate of Flux near Beaugency, where he died in 1780. During the last decade of his life he published his *Cours d'Etudes* (1775), his work on economics (1776), a text on logic (1780) for use in Polish Palatinate schools, and commenced the unfinished *La Langue des Calculs* (1798). In 1752, he became a member of the Royal Prussian Academy; in 1768 after his return from Parma he was elected to the French Academy. His works have been frequently collected, most recently by Le Roy (1947–51).

The impetus for Condillac's writing *Le Commerce et le Gouvernement* has been ascribed to a desire to assist his friend Turgot in the difficulties he faced in 1775 as finance minister over the grain riots induced by his restoration of the free trade in grain (Le Roy 1947, p. xxv; Knight 1968, p. 232). This fits with the work's unqualified support for free trade in general and the grain trade in particular (1776, esp. pp. 344–5, which seems directly inspired by the Paris events of 1775). Writing the book may also be explained as a return favour for Turgot's assistance in getting Condillac (1775) published (cf. Knight 1968, pp. 13, 232). Despite Condillac's strong support for this major part of Physiocratic policy and his close adherence to other aspects of Physiocracy, his argument that manufacturing was productive brought critical replies from Baudeau and Le Trosne (1777). In this context it may be noted that his work bears little direct Physiocratic influence, the major influence being Cantillon (1755), the only work directly cited apart from Plumard de Dangeul (1754). It is, however, possible to detect some influence from the economics of Turgot, Galiani and Verri on the theory of value, price and competition (cf. Spengler 1968, p. 212).

As published, the work is divided into two parts. The first provides the elements of the science. Its starting point is the foundation of value, which Condillac finds in the usefulness of an object relative to subjective needs making relative scarcity the key variable determining value. Value is distinguished from price because price can only originate in exchange. It is determined by the competition between buyers and sellers guided by their subjective estimation of value. Gains from exchange arise from differences in value; for Condillac, value cannot exchange for equal value. Although Condillac did discuss the costs of acquiring commodities, his emphasis is on exchange, trade and price. Exchange presumes surplus production and a need for consumption. Hence trade inspires and animates production and is essential to increasing wealth. Only simple pictures of production are presented: farm labourers producing prime necessities of food and materials; artisans transforming raw materials into essentials and luxuries; traders who circulate these products at home and abroad. By this circulation trade distributes the annual

product and under competitive conditions settles its true prices. Condillac is more concerned with developing the institutions associated with trade: growth of towns and villages, money, banking, credit, interest and the foreign exchanges, the defence of property by government and hence the need for taxation, and the effects of restraints on trade, including the grain trade. The second part is almost completely devoted to examining effects of specific obstacles to trade ranging from war, tariffs, taxes, excessive government borrowing to luxury spending in the capital city and exclusive trading privileges. Moderate wants combined with complete freedom constitute his recipe for the best form of economic development.

Condillac's economic work received a mixed reception from later economists. J.B. Say (1805, p. xxxv) described it as an attempt 'to found a system of . . . a subject which [the author] did not understand'. Jevons (1871, p. xviii) praised Condillac's 'charming philosophic work [because] in the first few chapters . . . we meet perhaps the earliest distinct statement of the true connections between value and utility. . .'. Macleod (1896 described it as a 'remarkable work . . . utterly neglected but in scientific spirit . . . infinitely superior to Smith'. Since then, it has remained neglected even though as 'a good if somewhat sketchy treatise on economic theory and policy [it was] much above the common run of its contemporaries' (Schumpeter 1954, pp. 175–6).

Condorcet was a French mathematician and philosopher. With many of his fellow *encyclopédistes* he shared the conviction that social sciences are amenable to mathematical rigour. His pioneer work on elections, the *Essai sur l'application de l'analyse a la probabilité des decisions rendues a la pluralité des voix* (1785) is a major step in that direction.

The aim of the *Essai* is to 'inquire by mere reasoning, what degree of confidence the judgement of assemblies deserves, whether large or small, subject to a high or low plurality, split into several different bodies or gathered in one only, composed by men more or less wise' (*Discours préliminaire* to the *Essai*, p. iv).

In modern words, this is the jury problem: to decide whether the accused is guilty or not requires converting the opinions of several experts, with varying competence, into a single judgement. Systematic probabilistic computations for this problem occupy most of the *Essai*, often camouflaging the essential contributions. The opaqueness and technicality of the argument meant that a full recognition of its importance did not occur until more than 150 years later (Black 1958). Since then Condorcet's findings have strongly influenced modern social choice theorists (for example, Arrow, Guilbaud and Black), and still play a central role in many of its recent developments.

The starting point is that majority voting is the unambiguously best voting rule when only two candidates are on stage. This fact, whose modern formulation is known as May's theorem (May 1952) was clear enough to the encyclopedists, too. How, then, can we extend this rule to three candidates or more? The naive, yet widely used, answer is plurality voting (each voter casts a vote for one candidate; the candidate with most votes is elected). Both Condorcet and Borda (his colleague in the Academy of Sciences) raise the same objection against the plurality rule. Suppose, says Condorcet (*Discours préliminaire,* p. lviii) that 60 voters have the opinions shown in Table 1 about three candidates A, B, C.

Condorcet, Marie Jean Antoine Nicolas Caritat, Marquis de (1743–1794), Table 1

	23	19	16	2
Top	A	B	C	C
	C	C	B	A
Bottom	B	A	A	B

In the illustration, candidate A wins by plurality. Yet if we oppose A against *B* only, A loses (25 to 35) and in A against *C,* A loses again (23 to 37). Thus the plurality rule does not convey accurately the opinion of the majority. From these identical premises, Borda proposes his well-known scoring method (each candidate receives 2 points from a voter who ranks him first, 1 point from one who ranks him second, and none from one who ranks him last; hence *C* is elected with score 78), whereas Condorcet opens a quite different route.

Condorcet posits a simple binomial model of voter error: in every binary comparison, each voter has a probability $1/2 < P < 1$ of ordering the candidates correctly. All voters are assumed to be equally able, and there is no correlation between judgements on different pairs. Thus for Condorcet the relevant data is contained in the 'majority tournament' that results from taking all pairwise votes:

$$\text{B beats A, 35 to 25; C beats A, 37 to 23;}$$
$$\text{C beats B, 41 to 19.}$$

Condorcet proposes that the candidates be ranked according to 'the most probable combination of opinions' (*Essai,* p. 125). In modern statistical terminology this is a maximum likelihood criterion (see Young 1986).

In the above example the most probable combination is given by the ranking: CBA since the three statements C over B, C over A, B over A agree with the greatest total number of votes. Condorcet's ranking criterion implies that an

Condorcet, Marie Jean Antoine Nicolas Caritat, Marquis de (1743–1794), Table 2

23	17	2	10	8
A	B	B	C	C
B	C	A	A	B
C	A	C	B	A

alternative (such as C) that obtains a majority over every other alternative must be ranked first. Such an alternative, if one exists, is known as a 'Condorcet winner'.

As Condorcet points out, some configurations of opinions may not possess such a winner, because the majority tournament contains a cycle (a situation known as 'Condorcet's paradox'). He exhibits the example shown in Table 2.

Here A beats B, 33 to 27; B beats C, 42 to 18; C beats A, 35 to 25. According to Condorcet's maximum likelihood criterion, this cycle should be broken at its weakest link (A over B), which yields the ranking B over C over A. Therefore in this case B is declared the winner.

Somewhat later in the *Essai* (pp. 125–6), Condorcet suggests that one may compute the maximum likelihood ranking of n candidates by, first, choosing the $n(n-1)/2$ binary propositions that have the majority in their favour; then, if there are cycles, *successively deleting* those with smallest majorities until a complete ordering of the candidates is obtained. Unfortunately, for $n > 3$ this heuristic algorithm does not necessarily yield the ranking that accords with the greatest number of votes. An axiomatic characterization of Condorcet's rule is given in Young and Levenglick (1978).

Condorcet's idea of reducing individual opinions to all pairwise comparisons between alternatives proved essential to the aggregation of preferences approach initiated by Arrow (1951). The key axiom independence of irrelevant alternatives (IIA) requires that voting on a pair of candidates be enough to determine the collective opinion on this pair: this generalizes majority tournaments by dropping the symmetry across voters and across candidates. In this sense Arrow's impossibility theorem means that the Condorcet paradox is inevitable in any non-dictatorial voting method satisfying IIA.

Many more useful insights can be discovered in the *Essai*. For instance the issue of strategic manipulations, which has played a central role in the theory of elections since the late 1960s, is suggested in places, although it is never systematically analysed. For example, on page clxxix of the *Discours Preliminaire,* Condorcet criticizes Borda's method as more vulnerable to a '*cabale'*. His argument is supported by the modern game theoretical approach: whenever the configurations of individual opinions guarantee existence of a Condorcet winner, it defines a strategy-proof voting rule. This is one of the principal arguments in favour of Condorcet consistent voting rules, namely, rules electing the Condorcet winner whenever it exists (see, for example, Moulin 1983, ch. 4).

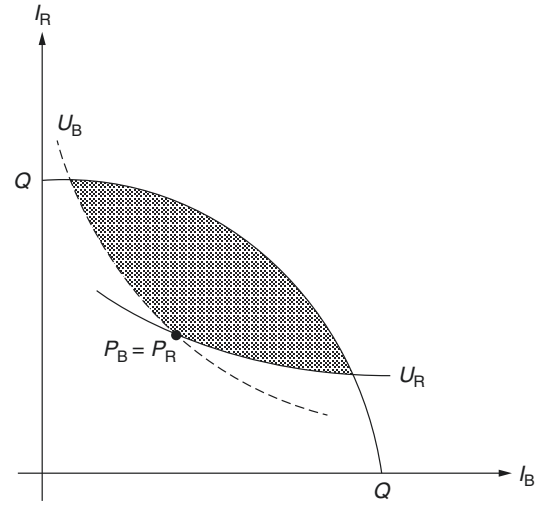
Conflict and Settlement

Jack Hirshleifer

All living beings are competitors for the means of existence. Competition takes the more intense form we call *conflict* when contenders seek to disable or destroy opponents, or even convert them into a supply of resources. Conflict need not always be violent; we speak, for example, of industrial conflicts (strikes and lockouts) and legal conflicts (law suits). But physical struggle is a relevant metaphor for these ordinarily non-violent contests.



Conflict and Settlement, Fig. 1 Statics of conflict – large potential settlement region

The Statics of Conflict

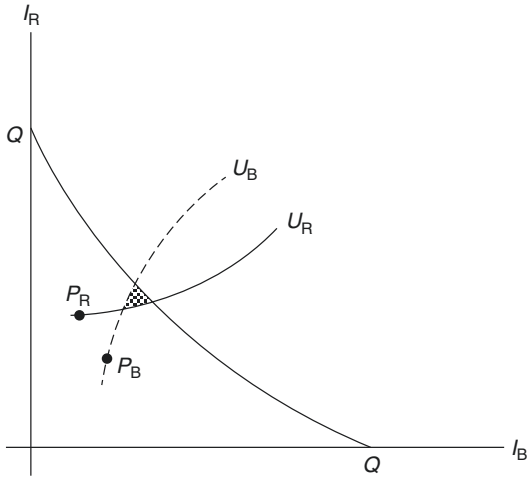
Involved in a rational decision to engage in conflict, economic reasoning suggests, will be the decision-maker's *preferences, opportunities* and *perceptions*. These three elements correspond to traditional issues debated by historians and political scientists about the 'causes of war': Is war mainly due to hatred and ingrained pugnacity (hostile preferences)? Or to the opportunities for material gain at the expense of weaker victims? Or is war mainly due to mistaken perceptions, on one or both sides, of the other's motives or capacities?

Of course it is quite a leap from the choices of individuals to the war-making decisions of collectivities like tribes or states. Group choice-making processes notoriously fail to satisfy the canons of rationality, most fundamentally owing to disparities among the interests of the individual members. Thus the internal decision-making structures of the interacting groups may also be implicated among the causes of war.

Setting aside this last complication, Figs. 1 and 2 are alternative illustrations of how preferences, opportunities, and perceptions might come together in a simple dyadic interaction. In each diagram the curve QQ bounds the 'settlement opportunity set' – what the parties can jointly attain by peaceful agreement or compromise – drawn on axes representing Blue's income I_B and Red's income I_R. The points P_B and P_R, in contrast, indicate the parties' separate *perceptions* of the income distribution resulting from conflict. The families of curves labelled U_B and U_R are the familiar utility indifference contours of the two agents.

Figure 1 shows a relatively benign situation: settlement opportunities are complementary, so there is a considerable mutual gain from avoiding conflict; the respective preferences display benevolence on each side; and the perceptions of returns from conflict are conservative and agreed (P_B and P_R coincide). The 'Potential Settlement Region' PSR (shaded area in the diagram), that is, the set of income distributions such that *both* parties regard themselves as doing better than by fighting, is therefore large – which plausibly implies a high probability of coming to an agreement. Figure 2 shows a less pleasant situation: antithetical opportunities, mutually malevolent preferences, and divergently optimistic estimates of the returns from conflict. The PSR is therefore small, and the prospects for settlement much poorer.

What might be called the *materialistic theory* attributes conflict, ultimately, to competition for resources. Primitive tribes attack one another for land, for hoards of consumables, or for slaves. Similar aims evidently motivated barbarian



Conflict and Settlement, Fig. 2 Statics of conflict – small potential settlement region

invasions of civilized cities and empires in ancient times, and European colonial imperialism in the modern era. Yet, between contending parties there will almost always be some element of complementary interests, an opportunity for mutual gain represented by the potential settlement region PSR. Orthodox economics has always emphasized the scope of mutual benefit, even to the point of losing sight of conflict; certain dissident schools, notably the Marxists, have committed the opposite error. While a detailed analysis cannot be provided here, among the factors underlying the relative material profitability of fighting versus negotiating are wealth differentials, Malthusian pressures, military technology, and the enforceability of agreements.

In contrast with the materialistic approach, *attitudinal theories* of conflict direct attention to the respective preference functions. An issue which has excited considerable interest concerns the relative weights assignable to genetic versus cultural determinants of attitudes. One extreme viewpoint, for example, regards xenophobic wars of family against family, of tribe against tribe, or nation against nation, as biologically 'normal' in the human species. An opposite interpretation pictures man as an innately compliant being, who has to be culturally indoctrinated into bellicosity.

Finally, what might be termed *informational theories* of conflict emphasize differences of perceptions of beliefs. Neoclassical economics tends to minimize the importance of such divergences – partly because they tend to cancel out from a large-numbers point of view, partly because incorrect beliefs are adjusted by experience in the process of establishing an economic equilibrium. But conflict and war are pre-eminently small-numbers, disequilibrium problems. Indeed, conflict may be regarded as in a sense an *educational process*. The school of actual struggle teaches the parties to readjust their perceptions to more realistic levels. Wars end by mutual consent when the potential settlement opportunities are seen as more attractive than continued fighting.

C

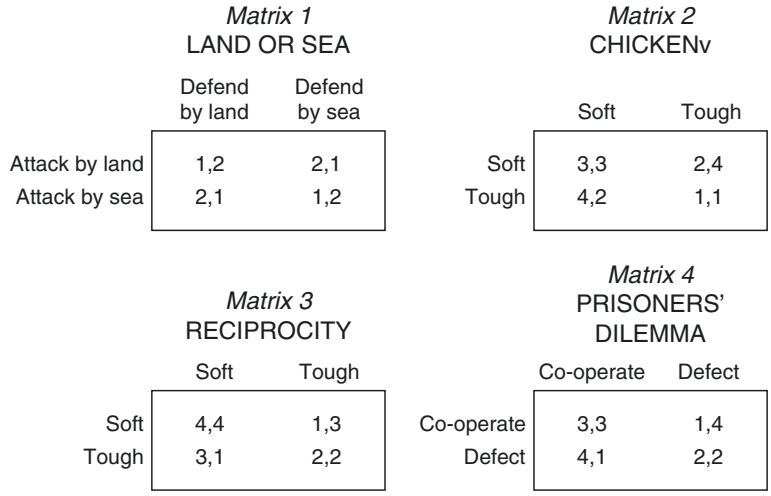
The Dynamics of Conflict

Static and dynamic elements are both importantly involved in conflict or settlement processes. In game theory terms, the *payoff environment*, represented by the familiar normal-form matrix, is the static element. The dynamic element may be called the *protocol of play*; as pictured in the game tree, the protocol specifies the allowable step-by-step moves in the light of the players' information at each stage.

A few very simple payoff environments are shown in Matrices 1–4. The numbers in each cell indicate ordinally ranked payoffs for each player, 1 being the poorest outcome in each case. In Matrix 1, 'Land or Sea', the environment is characterized by completely antithetical (constantsum) payoffs. The other three matrices – 'Chicken', 'Reciprocity' and 'Prisoners' Dilemma' – represent several of the many different possible mixed-motive situations combining an element of opposition of interests with an opportunity for mutual gain.

The simplest protocol to analyse is *one-round sequential play*: first Row selects one of his options, then Column makes his move in the light of Row's choice, and the game ends. In a sequential-play protocol it is always possible to find a 'rational' solution. If Column can be relied to choose his best final move then Row, knowing

Conflict and Settlement, Fig. 3



this, can calculate his best first move accordingly. (This process results in what is called a 'perfect equilibrium'.) In contrast, where the protocol dictates that players in a single-round game choose *simultaneously* – or, equivalently, where each chooses in ignorance of the other's move – solution concepts are harder to justify. The most commonly employed is called the 'Nash equilibrium' (or 'equilibrium point'), a pair of strategies from which neither player would want to diverge unilaterally.

In the 'Land or Sea' payoff environment, under the one-round *sequential-move* protocol, it is the second-mover or defender who has the advantage. If Row moves first, for example, Column can always successfully counter; e.g. if Row attacks by land, Column will defend by land. Hence the (1,2) payoff-pair is the outcome regardless of Row's initial move. In military terms the defence has an intrinsic advantage whenever the attacker must visibly commit his forces to one or another line of attack. And, of course, where the defence has such an advantage neither party is motivated to initiate warfare through aggression. But if 'Land or Sea' is played under the *simultaneous-move* protocol, both parties are groping in the dark and little can be said with confidence. (Here the Nash equilibrium would have each side choosing its move at random, in effect tossing a coin.)

In the payoff environment of 'Chicken' (Matrix 2), while the opportunities remain highly antithetical there is now a mutual interest in avoiding the disastrous (1,1) outcome that comes about when both play Tough. In contrast with 'Land or Sea', in the 'Chicken' payoff environment the advantage lies with the *first-mover*. Specifically, Row should rationally play Tough, knowing that Column then has to respond with Soft. For, Column must accept the bad (payoff of 2) to avoid the worst (payoff of 1). If the protocol dictates simultaneous moves, however, once again the players are groping in the dark. Under the Nash equilibrium concept they choose probabilistically, which implies that the disastrous (1,1) outcome will indeed occur a percentage of the time. There is a suggestive application of this model to industrial conflict. If union (or management) becomes committed to play Soft, it will be at a disadvantage in negotiations – the other side will then surely play Tough. But if both play Tough, there is no hope for peaceful settlement. Hence each side should rationally adopt a 'mixed' strategy, with the consequence that strikes and lockouts will occur in a certain fraction of the dealings.

The 'Reciprocity' payoff environment (Matrix 3) is more rewarding to cooperative behaviour. The idea is that each player would

Conflict and Settlement, Fig. 4

Matrix 5
DETERRENCE WITHOUT COMMITMENT

	Fold	Retaliate
Refrain	2,3	2,3
Attack	3,1	1,2

Matrix 6
DETERRENCE REQUIRING COMMITMENT

	Fold	Retaliate
Refrain	2,3	2,3
Attack	3,2	1,1

answer Soft with Soft – leading to the mutually preferred (4,4) payoffs – but failing this, would respond to Tough with Tough. If the *sequential-move* protocol applies, the first-mover would then always rationally choose Soft, and so the ideal (4,4) payoff-pair should be achieved. But under the *simultaneous-move* protocol, with each party in the dark about the other's move, again the outcome is quite unclear. In fact there are three Nash equilibria: pure-strategy solutions at (4,4) and (2,2), and a mixed-strategy solution as well.

Finally, in the famous 'Prisoners' Dilemma' payoff environment (Matrix 4) the parties are likely to find themselves in the Defect-Defect 'trap' with (2,2) payoffs, even though (3,3) could be achieved were each to play Cooperate. Here the 'trap' takes hold under both sequential-move and simultaneous-move protocols.

The preceding discussion could only be suggestive, limited as it was to 2-player single-round games, within that category to only a few two-strategy symmetrical payoff environments, and finally to the very simplest protocols – excluding, for example, all negotiations and communications between the parties. Space limitations permit comment upon only a few additional points:

Perceptions

Standard game models assume that players know not only their own payoffs but also their opponents'. Unintentional error on this score, or else deliberate deception, may play a crucial role. Suppose two parties in the 'Reciprocity' payoff environment of Matrix 3 find themselves initially playing Tough–Tough with outcome (2,2). Imagine now they are given a chance to shift strategies under a *sequential-move* protocol. As first-mover, Row would be happy to change from Tough to Soft if only he could rely upon Column to respond in kind. But Row may, mistakenly, believe that Column's payoffs are as in 'Chicken', from which he infers that Column would stand pat with Tough. Row would therefore not shift from Tough, hence Column in his turn would not change either. (Some authors have gone so far as to attribute all or almost all of human conflict to such mistaken 'self-fulfilling beliefs' about the hostility of opponents, but of course this pattern is only one of many possibilities.)

Commitment and Deterrence

In some circumstances the second-mover in point of time (Column) may be able to *commit* himself to a given response strategy before Row makes his first move. While Column thereby surrenders freedom of choice, doing so may be advantageous. Consider threats and promises. A *threat* is a commitment to undertake a second-move punishment strategy even where execution thereof is costly. A *promise* similarly involves commitment to a costly reward strategy. Matrices 5 and 6 illustrate how a threat works. Row's choices are Attack or Refrain, while Column's only options are to Retaliate or Fold if Row attacks. Column's problem, of course, is to deter Row's attack. In Matrix 5 Column prefers to Retaliate if attacked, a fact that – given Row's preference – suffices for deterrence. Commitment is not required. (Since Column prefers to Retaliate, there is no need to *commit* himself to do so.) In Matrix 6 the Column player prefers to turn the other cheek; if attacked,

he would rather Fold than Retaliate. Unfortunately, this guarantees he will be attacked! (Note that here it is not excessive hostility, but the reverse, that brings on conflict.) But if Column could *commit* himself to Retaliate, for example by computerizing the associated machinery beyond the possibility of his later reneging, then deterrence succeeds. In short, if a pacific player can reliably *threaten* to do what he does not really want to do, he won't have to do it! (Needless to say, so dangerous an arrangement is not to be casually recommended.)

The Technology of Struggle

Conflict is a kind of 'industry' in which different 'firms' compete by attempting to disable opponents. Just as the economist without being a manager or engineer can apply certain broad principles to the processes of industrial production, so, without claiming to replace the military commander, he can say something about the principles governing how desired results are 'produced' through violence.

Battles typically proceed to a definitive outcome – victory or defeat. *Wars* on the whole tend to be less conclusive, often ending in a compromise settlement. These historical generalizations reflect the working of increasing versus decreasing returns applied to the production of violence:

1. Within a sufficiently small geographical region such as a battlefield, there is a critical range of increasing returns to military strength – a small increment of force can make the difference between victory and defeat.
2. But there are decreasing returns in projecting military power away from one's base area, so that it is difficult to achieve superiority over an enemy's entire national territory. The increasing-returns aspect explains why there is a 'natural monopoly' of military force *within* the nation-state. The diminishing-returns aspect explains why a multiplicity of nation-states have remained militarily viable to this date. (However, there is some reason to believe, the technology of attack through long-range weapons has now so come to prevail over the defence that a single world-state is indeed impending.)

Going into the basis for increasing returns, at any moment the stronger in battle can inflict a more-than-proportionate loss upon his opponent, thus becoming progressively stronger still. Important special cases of this process are modelled via Lanchester's equations. In combat, in the ideal case where all the military units distribute their fire equally over the enemy's line, the process equations are:

$$\mathrm{d}\boldsymbol{B}/\mathrm{d}t = -k_{\mathrm{R}}\mathbf{R}$$
$$\mathrm{d}\boldsymbol{R}/\mathrm{d}t = -k_{\mathrm{B}}\mathbf{B}$$

Here B and R are the given force sizes for Blue and Red, and the per-unit military efficiencies are given by the k_{B} and k_{R} coefficients. It follows that military strengths are equal when:

$$k_{\mathrm{B}}\mathrm{B}^2 = -k_{\mathrm{R}}\mathrm{R}^2$$

But even where military strength varies sensitively than as the square of force size, it remains quite generally the case that in the combat process the strong become stronger and the weak weaker, leading to ultimate annihilation unless flight or surrender intervene. (Of course, a skilful commander finding himself with an adverse force balance will attempt to change the tactical situation – by timely withdrawal, deception, or other manoeuvre.)

One implication of increasing returns may be called the 'last-push principle'. In the course of a conflict each side will typically not be fully aware of the force size and strength that the opponent is ultimately able and willing to put in the field. Hence the incentive to stand fast, even at high cost, lest a potentially won battle be lost. (Foch: 'A battle won is a battle in which one will not confess oneself beaten'.) This valid point unfortunately tends to lead to battlefield carnage

beyond all reasonable prior calculations, as experienced for example at Verdun.

On the other hand, an effective substitute for force size is superior *organization*. An integrated military unit is far more powerful than an equally numerous conglomeration of individual fighters, however brave. Organizational superiority, far more than superiority in weapons, explains why small European expeditionary contingents in early modern times were able to defeat even vast indigenous forces in America, Africa and Asia. Battles are thus often a contest of organizational forms; the army whose command structure first cracks under pressure is the loser.

As for diminishing returns, in the simplest case an equilibrium is achieved at a geographical boundary such that:

$$M_B - s_B x_B = M_R - s_R x_R$$

Here M_B and M_R are military strengths at the respective home bases, S_B and S_R are decay gradients, and x_B and x_R are the respective distances from base. The condition of equality determines the allocation of territory.

The 'social physics' of struggle is of course far more complex than these simplistic initial models suggest. There are more or less distinct offence and defence technologies, first-strike capability is not the same as retaliatory strength, countering insurgency is a different problem from central land battle, etc.

Conflict, Society and Economy

Conflict theory can help explain not only the size and shape of nations, but the outcomes of competition in all aspects of life: contests among social classes, among political factions and ideologies, between management and labour, among contenders for licences and privileges ('rent-seeking'), between plaintiffs and defendants in law suits, among members of cartels like OPEC, between husband and wife and sibling and sibling within the family, and so on. Whenever resources can be seized by aggression, invasion attempts can be expected to occur. Invasive and counter-invasive effort absorb a very substantial fraction of society's resources in every possible social structure, whether egalitarian or hierarchical, liberal or totalitarian, centralized or decentralized. Furthermore, every form of human social organization, whatever else can be said for or against it, must ultimately meet the survival test of internal and external conflict.

Notes on the Literature of Conflict (of Special Relevance for Economists)

Classical military thought from Machiavelli to Clausewitz to Liddell Hart, though rarely analytical in the economist's sense, remains well worth study. An excellent survey is Edward Mead Earle (1941). Modern work in this classical genre understandably concentrates upon the overwhelming fact of nuclear weaponry and the problem of deterrence; the contributions of Herman Kahn (1960, 1962) are notable. There is of course a huge historical literature on conflict and war. An interesting economics-oriented interpretive history of modern warfare is Geoffrey Blainey (1973). William H. McNeill (1982) examines the course of military organization and technology from antiquity to the present, emphasizing the social and economic context. On a smaller scale John Keegan (1976) provides a valuable picture of how men, weapons, and tactics compete with and complement one another on the battlefield. There is also a substantial body of statistical work attempting in a variety of ways to summarize and classify the sources and outcomes of wars; the best known is Lewis F. Richardson (1960b). Mathematical analysis of military activity, that is, quantifiable modelling of the clash of contending forces, is surprisingly sparse. The classic work is Frederick William Lanchester (1916 [1956]).

The modern analysis of conflict, typically combining the theory of games with the rational-decision economics of choice, is represented by three important books by economists: Thomas C. Schelling (1960), Kenneth E. Boulding

(1962), and Gordon Tullock (1974). Works by non-economists that are similar in spirit include Glenn H. Snyder and Paul Diesing (1977) and Bruce Bueno de Mesquita (1981). A tangentially related literature, making use of the rather mechanical psychologistic approach of Richardson (1960a), includes a very readable book by Anatol Rapoport (1960).

Congestion

Richard Arnott and Marvin Kraus

Abstract

'Congestion' is the phenomenon whereby the quality of service provided by a *congestible facility* degrades as its aggregate usage increases, when its capacity is held fixed. Here, the economic theory of congestion is developed in the context of road traffic. The primary questions of interest are how the capacity of a congestible facility and its usage fee should be chosen. This leads naturally to the question of whether the usage fees collected will be sufficient to cover capacity costs at the optimum.

'Congestion' is the phenomenon whereby the quality of service provided by a *congestible facility* degrades as its aggregate usage increases, when its capacity is held fixed. We shall develop the economic theory of congestion in the context of road traffic, but congestion is pervasive: more telephone usage increases the probability of encountering a busy line; higher electricity demand may lead to voltage fluctuations, brownouts and eventually blackouts; more swimmers in a pool make comfortable swimming more difficult; more patients visiting a medical clinic results in longer waits and lower-quality care; in a more crowded classroom, students receive less individual attention, and more time is wasted on administration and discipline; and so on. The economic theory of congestion identifies how the capacity of a congestible facility and its usage fee should be

chosen. Some degree of congestion is typically socially optimal.

The economic theory of congestion has much in common with the theory of clubs and local public goods (Scotchmer 2002). The two literatures examine similar issues, but the economic theory of congestion has a policy perspective, while the theory of clubs and local public goods focuses on decentralized provision.

Formally, we may define congestion as follows. Consider a congestible facility in a steady state, that comprises I congestible elements. (Congestible elements for a sports stadium, for example, include nearby roads, parking facilities, the ticket office, washrooms, concessions, and seating.) Element i is characterized by a flow capacity, k_i, and a stock capacity, K_i, the flow capacity is the maximum throughput per unit time, the stock capacity the maximum number of users at a point in time. Similarly, the level of usage is described in terms of the throughput of congestible element i, n_i, and the number of users at a point in time, N_i. The congestible facility provides J dimensions of quality of service, with the level of dimension j indicated by sj.

Letting k, K,n, N and s denote the corresponding vectors,

$$s = S(k, K, n, N). \tag{1}$$

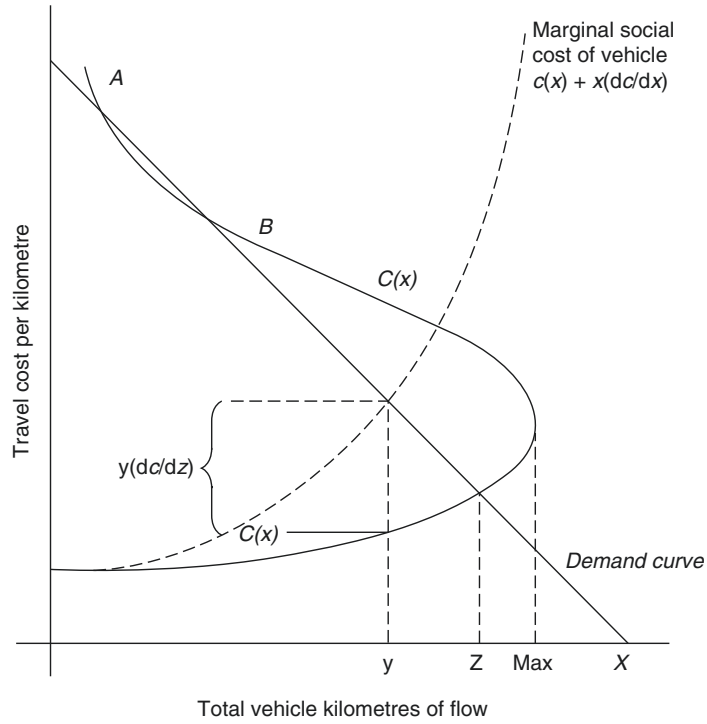
Congestion occurs when there is at least one combination of j and i for which s_j is monotone decreasing in n_i (flow congestion) or N_i (stock congestion), that is, when some dimension of quality of service falls as the throughput or stock of users of some congestible element of capacity increases. This is the static or steady-state definition of congestion. The dynamic definition of congestion adds time subscripts to s, k, K, n and N, and appends equations of motion relating stocks and flows for the various elements of capacity.

For some congestible elements, such as a turnstile, the bottleneck in the Vickrey (1969) bottleneck model of traffic congestion, or a switching circuit, the flow capacity constraint is the more important; for others, such as a telephone line, an elevator, a swimming pool, or seating at a football stadium, the stock capacity constraint is the more important. It should also be noted that a congestible facility can take the form of a network of congestible elements of capacity; a natural distinction is then between link congestion (for example, highway links) and nodal congestion (for example, traffic intersections).

To develop the theory, we consider a particular congestible facility having a single element of capacity and identical users, that is in a steady state: a road of uniform width connecting a single entry point A and a single exit point B, for which an increase in traffic flow increases travel time and an increase in road width reduces it. In this context, the deterioration of quality of service with an increase in usage is the increase in travel time from an increase in traffic flow.

We start with the short-run problem of determining optimal flow and its decentralized attainment, holding road width fixed. Let f denote flow, w road width, $t = t(f, w)$ the travel time function with (functional subscripts denote partial derivatives) $t_f > 0$ and $t_w < 0$ and p the value of time. Then the cost to an individual driver of travelling from A to B, the *user cost,* is $\rho\, t(f, w)$. Total user costs per unit time equal flow times user cost: $\rho f t(f, w)$. The social cost per unit time from increasing flow by one unit, with capacity held fixed, the *short-run marginal social cost,* is $\rho t(f, w) + \rho f t_f(f, w)$. The first term is the user cost of the extra driver; the second, the *congestion externality cost*. A driver imposes a congestion externality by slowing other drivers down; increasing steady-state flow by one car increases each car's travel time by $t_f(f, w)$ and social cost by $p f t_f(f, w)$.

Figure 1 displays short-run equilibrium. p denotes trip price, $D(p)$ the aggregate trip demand function, and $uc(f)$ and $srmsc(f)$ the user cost and short-run marginal social cost as a function of f, holding w fixed. With no toll, a user's trip price equals his user cost, and equilibrium occurs where the demand and user cost functions intersect, with flow f^e. Assuming that the marginal social benefit from a trip equals the corresponding marginal willingness to pay, the optimum occurs where the demand and short-run marginal social cost curves intersect, with flow f^*. Thus, with no toll, equilibrium flow is excessive.



Congestion, Fig. 1 Demand and supply on a congested highway

Efficiency obtains when economic agents face the social costs of their decisions and derive the social benefits from them. In the notoll case, the price of a trip falls short of its marginal social cost since a driver does not pay for slowing down other drivers. Following Pigou (1947), the standard remedy for internalizing the congestion externality is to impose a toll equal to the congestion externality cost, evaluated at the social optimum: τ^* in Fig. 1. This causes the trip price function to shift up from $uc(f)$ to $uc(f) + \tau^*$ and equilibrium flow to fall to the optimal level.

The above argument illustrates the general principle that efficient utilization of a congestible facility requires that the price equal short-run marginal social cost and the toll the congestion externality cost. Different user types - for example, cars and trucks – may impose different congestion externality costs. Efficiency then requires that the toll be differentiated according to user type.

We now turn to the long-run planning problem in which both road width and flow are choice variables. We then consider decentralization of the optimum. Let $B(f)$ denote the social benefit per unit time from flow f, and $C(w)$ the amortized capital cost of road width w. (We ignore the complications that arise when the congestible facility is sufficiently large that its construction alters factor prices.) The social surplus generated by the road (per unit time) equals social benefit minus social cost, and social cost equals total user cost plus amortized capital cost:

$$SS(f,w) = B(f) - \rho ft(f,w) - C(w). \quad (2)$$

It is easily seen from (2) that the road width that maximizes social surplus is that which minimizes social cost. This means that, when the long-run planning problem is solved, production is carried out according to the long-run cost structure, and the short-run marginal cost pricing (which is again) required for optimal flow is equivalent to long-run marginal cost pricing:

$$p = LRMC. \quad (3)$$

Now, recall the basic result of production theory that $LRMC$ is equal to, less than or greater than $LRAC$ (long-run average cost) according to

whether *LRAC* is constant, decreasing or increasing. Combining this with (3), we have the result that, when *LRAC* is constant, $p = LRAC$ holds at a long-run optimum. This is equivalent to equality between the total value of output and the total cost of output. Since total user cost is a component of both, this equality implies equality between toll receipts and amortized capital cost. Thus, *in the case of constant long-run average cost, the revenue raised from the optimal toll exactly covers the capital cost of providing a road of optimal width.* This is known as the 'self-financing' result. It was first derived by Mohring and Harwitz (1962) and subsequently generalized by Strotz (1965) (For a geometric derivation, see Arnott and Kraus 2003).

The self-financing result extends to congestible facilities with multiple elements of capacity, multiple dimensions of quality of service, and multiple user groups. If a congestible facility exhibits constant long-run average costs, provision of the facility can be decentralized via competing 'clubs'; competition will result in each club charging each user a fee for use of its congestible facility equal to the congestion externality cost he imposes, and choosing optimal capacity.

The above theory was developed on the assumption of a steady state. In the extension to treat nonstationary dynamics, which is conceptually straightforward, the distinction between flow externalities and stock externalities becomes sharper.

The theory relates to *first-best* pricing and capacity choice when congestion is the only externality. When usage entails other externalities, such as pollution, firstbest pricing should take these into account. In any policy context, additional practical constraints that rule out attainment of the full first-best allocation need to be considered. These are treated by applying second-best theory (Diamond and Mirrlees 1971). Consider, for example, the pricing problem facing a public transit authority. The underpricing of urban auto travel may call for the underpricing of mass transit (Lévy-Lambert 1968; Marchand 1968); since optimal lump-sum redistribution is infeasible for informational reasons, the authority may choose to sacrifice some efficiency to improve equity by charging lower fares to needy groups (Atkinson and Stiglitz 1980), rationing, or nonlinear pricing (Wilson 1993); administrative costs may preclude fine-tuning the fare according to distance travelled or time of day, leading to variants of Ramsey pricing (Mohring 1970); the authority may face a deficit constraint, requiring it to price above marginal social cost (Boiteux 1956); with distortionary taxation, the social cost of financing an extra dollar of transit authority deficit may significantly exceed one dollar (Vickrey 1959); and the government may choose to deviate from marginal social cost pricing to provide the public transit authority with higher-powered incentives (Laffont and Tirole 1993) or to achieve political objectives. These considerations will also cause second-best capacity to deviate from first-best capacity.

Conglomerates

Alan Hughes

The overall output of a firm may be composed of activity in more than one product market. The growth of individual firms will be composed of changes in the scale of their activities in each of the markets in which they operate and in the numbers of those markets. In any period these changes will consist of horizontal expansion in the market(s) in which they operated at the beginning of the period and entry into new markets; where there is a supplier or buyer relationship with the original market then this expansion will be vertical integration. Expansion which fits neither of these categories is termed diversifying or conglomerate expansion. Growth in any of these directions may be by the purchase of new assets (internal growth), or by the purchase of existing assets through takeover or merger (external growth). Although it is common to refer to non-horizontal and non-vertical expansion as diversified, or conglomerate, the latter term also has a more specific connotation emphasizing particularly diverse external expansion. It has in particular been used to mean a company which has by a deliberate strategy of external growth, often away from declining sectors, developed a highly diversified product range which cannot easily be characterized in terms of a single, or well defined, group of production technologies, a single set of major competitors, or a stable place in a well defined industry group (Steiner 1975; Weston 1980). (And in the US context to have financed that expansion with issues of paper rather than cash, accompanied by accounting techniques for consolidating acquired companies designed to boost earnings per share and make future paper issues even more profitable (Blair 1972; Steiner 1975).)

Although diversified businesses predate World War II (often in the form of financial holding companies in Europe and Japan) conglomerate companies in the above sense are essentially a postwar phenomenon, and have been associated with the widespread adoption of decentralized divisionalized management structures. In particular, in the United States the growth of merger activity in the 1960s was dominated by diversified acquisitions, the most spectacular of which were associated with the emergence of a group of particularly aggressive conglomerates. For instance, between 1961 and 1969 ITT, already a very large multinational telecommunications company, acquired amongst other concerns, the largest US bakery, the largest US hotel chain, and the largest US house builder, the second largest US car rental service and a number of large insurance and finance companies. Gulf and Western over a similar period acquired companies in sugar, tobacco, steel, paper, banking, insurance and motion pictures (Blair 1972).

These are extreme examples of a general longer run tendency for diversification to increase in the post-war period in all the major industrial economies (Berry 1975; Jacquemin and De Jong 1977; Utton 1979). Case studies of corporate growth strategies, and estimates of levels of, and changes in, diversification in the 1960s and 1970s reveal that rapid unrelated product expansion is outweighed by expansion based on a related product, or ‘narrow spectrum’ diversification strategy

(e.g. outside a fairly finely defined (say 3 or 4 digit) primary product group but within a broader (say 2 digit) industry, of which the primary group is a part (Wood 1971; Channon 1973; Rumelt 1974; Berry 1975; Biggadike 1979; Utton 1979; Caves et al. 1980; Spruill 1981). Nevertheless, these studies also suggest an increase in the importance of unrelated product expansion and a situation has now been reached where the largest companies in the major industrial countries have, by the long-term pursuit of such strategies, come to occupy leading positions in many different industries (Shepherd 1970; Blair 1972; Utton 1979) and where the market in corporate takeovers, and divisionalized management structures, permit the easy pursuit of further conglomerate growth by external means (Mueller 1969). This has inevitably raised questions about the relationship between market competition and conglomerate growth, and about the effects of conglomerate merger upon corporate performance.

Estimating the impact of conglomerate activity in an industry upon levels of, and trends in, its concentration are surrounded by empirical problems. These arise from lack of precise data on the market shares of individual firms in different industries, and on the evolution over time of those shares. Similar problems limit attempts to measure the impact of conglomerate entry, either by merger, or new investment. The evidence suggests that conglomerate mergers have had little impact on levels of, or trends in market concentration in the US (Goldberg 1973, 1974) whilst in the UK and the US neither the presence of diversified firms, nor new entry by diversification, seems to lead to increased levels of concentration. If anything the reverse seems to be the case (Berry 1975; Utton 1979). Effects on competitive behaviour rather than market structure are a little better documented. Here the argument is that operating over many markets enhances power in each of them individually (Edwards 1955). Thus it is argued that conglomerate firms may impose reciprocal buying pressures upon suppliers to encourage them to use, as inputs, the products of other divisions of the parent conglomerate; may employ predatory pricing in newly entered markets, cross-subsidized by activities elsewhere; and practice mutual forebearance with accepted spheres of influence agreed with other conglomerates. More difficult to detect may be other effects claimed to arise from reductions in potential competition, where it is argued, for instance, that entry by a large conglomerate may deter other likely entrants, or lead to subsequent anti-competitive behaviour, which could not, or otherwise would not, occur. Where entry is by merger it may also be argued that this is at the expense of new investment in the market, either by incumbents, or the new entrant itself (Markham 1973; Steiner 1976; Scherer 1979). Examples can be found in the US, and in the UK and Europe, of most these practices. There is little to suggest however that these are persistent, typical, or pervasive features of conglomerate behaviour. Where they have been most prominent they appear to have been due at least as much to individual market power as to overall conglomerate strength (Markham 1973; Scherer 1979; Utton 1979).

Corresponding to claims of the anti-competitive losses which may follow from the spread of conglomeration are claims of likely benefits. Here it is claimed that such firms may allocate more resources per unit of sales to research and development, since the chances of utilizing spinoffs and unexpected findings within the organization are higher (Nelson 1959); may experience economies of scope (Panzar and Willig 1981) and may enjoy lower costs of raising capital on the stock market in response to more stable earnings streams, and the reduced risk of bankruptcy that conglomerate spread may bring. There is no consistent evidence to suggest that these effects lead to any superiority in profit performance, either for the individual firm, or for industries in which conglomerate firms play an important role, some studies finding positive, and others negative, effects on profit levels or stability (Rhoades 1973, 1974; Utton 1979; Caves et al. 1980; Kelly 1980). There is, however, some evidence to support the view that diversified firms have higher R&D inputs and patent outputs than specialized firms, although there is an obvious problem of causation involved (Wood 1971; Kennedy and Thirlwall 1972; Scherer 1979). The effects of conglomerate merger have been much

more extensively investigated than the impact of conglomerate firms as such. Those studies for the US which examine periods beyond the stock market conglomerate boom years of the late 1960s show such merging conglomerate companies either doing less well, or at best as well, as other companies (or portfolios of shares) in terms of profitability, profit stability and shareholder returns. This is especially so when profitability measures are used which allow for the loan financing techniques used to build up the most spectacular conglomerate empires in the 1960s merger boom (Mueller 1977). Evidence for other countries is more fragmentary but that for the UK, for instance, suggests that conglomerate mergers perform relatively well in terms of profitability compared to mergers in general, though neither outperform companies relying on internal growth (Meeks 1977; Cosh et al. 1980).

Most of this work may be set in the context of a static neoclassical perspective to trade off monopoly welfare losses against efficiency gains. On this basis it would be hard to mount a significant case for or against conglomerates. To look at the problem in this way is however, to distract attention from what may be regarded as more fundamental questions about the working of the economic system as a whole. There are three interrelated issues here. What are the comparative advantages of organizing economic activity on the basis of interfirm market processes as opposed to intrafirm administrative and organizational processes, what is the impact of the spread of conglomeracy upon the flow of economic resources between alternative prospective uses, and how does diversification and the spread of conglomeracy affect the flow of information upon which a market economy is based.

On one view of the world the growth of divisionalized conglomerate companies may be regarded, in many instances, as a superior resource allocation mechanism to interfirm market transactions. Internal administrative allocative decisions to move resources between the company's individual markets and divisions, it is argued, are based upon more and better information than that available to outsiders in the stock market (Williamson 1975, 1985; Chandler 1962, 1977). From this point of view appropriately organized conglomerates are efficient mini-capital markets, and represent that potent source of new entry by mobile capital, and adjustment away from declining sectors which lies at the heart of the competitive adjustment process (Clifton 1977, and, from a different perspective, Weston 1980). Moreover, the wider the spread of industries covered by any firm, and the wider the threat of takeover of the inefficient, or sleepy, or of entry by new investment, the more forceful this argument becomes. On the other hand conglomerate firms are not all embracing in their industrial coverage, their acquisitions may not be especially driven by industrial logic or production efficiency, and it may be argued that in addition they reduce the efficiency of operation of the capital market itself, given that financial reporting by large firms is notoriously aggregative.

In this sense the defining characteristics of conglomerates are to be found in their internal financial and administrative arrangements, which have in principle freed them from the particular constraints of individual product markets and production technologies. They represent the latest boundary between organization and the market (Coase 1937) and as such fit uneasily into any generally accepted model of the workings of the macro or micro economy as a whole.

Conjectural Equilibria

F. H. Hahn

Abstract

In imperfectly competitive economies, agents must take note of the effects of their decisions on the market environment. Such effects, being uncertain, are the subject of conjecture. Even if conjectures are not derivable from some first principles of rationality, conjectural theories are of interest because they attempt a general equilibrium analysis of non-perfect competition. The conjectural approach takes proper and explicit note of the perceptions by individuals of their market environment; it is possible that what is the case may depend on what agents believe to be the case.

In an economy with very many agents the market environment of any one of these is independent of the market actions he decides upon. More generally one can characterize an economy as *perfectly competitive* if the removal of any one agent from the economy would leave the remaining agents just as well off as they were before his removal. (The economy is said to satisfy a 'no surplus' condition; see Makowski 1980; and Ostroy 1980.) When an economy is not perfectly competitive, an agent in making a decision must take note of its effect on his market environment, for example, the price at which he can sell. This effect may not be known (or known with certainty) and will therefore be the subject of *conjecture*. A conjecture differs from expectations concerning future market environments which may, say, be generated by some stochastic process. It is concerned with responses to the actions of the agent.

In the first instance then the topic of conjectural equilibria is that of an economy which is not perfectly competitive by virtue of satisfying a no surplus condition. But, as we shall see, an economy could fail to satisfy this condition and yet have a perfectly competitive equilibrium.

By an equilibrium in economics we usually mean an economic state which is a rest (critical) point of an (implicit) dynamic system. For instance, it is postulated in the textbooks that, when at going prices the amount agents wish to buy does not equal the amount they wish to sell, prices will change. Strictly this should mean that there would, in such a situation, be an incentive for some agent(s) to change prices. This causes difficulties when the economy is perfectly competitive (Arrow 1959) since it implies that the agent can influence his market environment by his own actions. That is one reason why a fictitious auctioneer has been introduced to account for price changes.

When the economy is not perfectly competitive these difficulties are avoided. A price will be changed if some agent conjectures that such a change would be to his advantage. As a corollary then a conjectural equilibrium must be a state from which it is conjectured by each agent that it would be disadvantageous to depart by actions which are under the individual agent's control. (For a formal definition see below.)

But there are other difficulties. In particular, there is the question of the source of conjectures. If these are taken as given exogenously then there are many states which could be conjectural equilibria for *some* conjectures. It should be noted that a similar objection can be raised in conventional equilibrium analysis. There it is the preferences of agents which are taken as exogenous and there too there are many equilibria which are compatible with some (admissible) preferences. However, while conjectures may turn out to be false and this may occasion a change in conjectures, it is less easy to point to equally simple and convincing endogenous mechanisms of preference change. For that reason one may feel that conjectural equilibrium requires that conjectures are in some sense correct ('rational'). For if they are not they will change in the light of experience. This argument is considered below.

The reason why the idea of conjectural equilibria is of interest is that economies which are not intrinsically perfectly competitive (for example, because of the large number of agents) are of interest and because it allows one to study price formation without an auctioneer.

An Illustration

Consider two agents each of whom can chose an action a_i from a set of action A_i. Let $A = A_1 \times A_2$

with elements $a = (a_1, a_2)$. Then a conjecture c_i is a map from $A \times A_i$ to A_j written as

$$C_i = \theta_i\left(a, a_i^{'}\right).$$

Its interpretation is this: given the actions of the two agents (a), C_i is the action of j conjectured by i to be result from his choice of $a_i^{'}$. (In a more general formulation the conjecture can be a probability distribution but that is not considered here.) We require conjectures to be *consistent*:

$$\theta_i(a, a_i) = a_j \tag{1}$$

This says that if agent i continues in his action a_i then he conjectures that j will do likewise. (This use of the word 'consistent' is *not* that of Bresnahan 1981, and others who use it to mean 'correct'.)

Suppose now that there is a function v from A to R^2, written as $v(a) = [v_1(a), v_2(a)]$, which gives the payoffs to the agents as a function of their joint action a. Consider a^* to be one such joint action. One says that a^* is a *conjectural equilibrium* for the two agents if

$$v^{\mathrm{i}}[a_i, \theta_i(a^*, a_i)] \leq V_i\left[a_i^*, \theta_i(a^*)\right] \text{ all } a_i \in A_i, i = 1, 2 \tag{2}$$

That is, the joint action a^* is a conjectural equilibrium if no agent, given his conjecture, believes that he can improve his position by deviating to a different action.

It is not the case that conjectural equilibrium, as defined, always exists. For instance in the case of a duopoly in a homogeneous product where the action is 'setting the price', v may not be concave and a sensible conjecture may have discontinuities. One thus needs special assumptions to ensure existence or one must face the possibility that agents do not chose actions but probability distributions over actions (mixed strategies); for example, Kreps and Wilson (1982) in their work on sequential equilibrium employ conjectures which are probability distributions.

Supposing that a conjectural equilibrium exists, one may reasonably argue that until conjectures are less arbitrarily imposed on the theory not much has been gained – almost any pair of actions could be a conjectural equilibrium. A first attempt to remedy this is to ask that conjectures be correct (rational). If that is to succeed in any simple fashion it will be necessary to suppose that each agent has a unique best action under this conjecture. This is very limiting and it means that some of the classical duopoly problems cannot be resolved in this way.

Let the status quo again be a^*. Then if θ_1^* and θ_2^* are correct conjectures it must be that

$$v_2\left\{\theta_1^*(a^*, a_2), \theta_1^*\left[(a_1, a_1^*), \theta_2^*(a^*, a_2)\right]\right\} \times > v_1\left\{a_s^{'}, \theta_1^*\left[(a_1^*, a_2), a_1^{'}\right]\right\} \text{ all } a_1^{'} = A_2. \tag{3}$$

$$v_1\left\{\theta_2^*(a^*, a_2), \theta_1^*\left[(a_1^*, a_2), \theta_2^*(a^*, a_2)\right]\right\} > v_1\left\{a_s^{'}, \theta_1^*\left[(a_1^*, a_2), a_1^{'}\right]\right\} \text{ all } a_1^{'} = A_1. \tag{4}$$

A *rational conjectural equilibrium* is then a conjectural equilibrium a* (with conjectures $\theta_1^*(\cdot)$, $\theta_2^*(\cdot)$ which satisfy (3) and (4)). It must be re-emphasized that such an equilibrium may not exist for some A and v (see Gale 1978; Hahn 1978).

However, the idea is simple and, where applicable, coherent. It has however been criticized (in a somewhat intemperate and muddled paper) by Makowski 1983).This criticism appears to have had some appeal to some game theorists who like to think of games in extensive form (which they sometimes like to call dynamic). The criticism is this: when agent 1 deviates from a^* he is interested in the payoffs which he will get given this deviation and agent 2's response. This payoff Makowski thinks of as accruing in the 'period' after agent 1's deviation. But when agent 2 responds in that period he is interested in this payoff in the period following this response. So the agents expect 'the game to end' in different periods (Makowski 1983, p. 8). Moreover, after agent 2 has responded, agent 1, in his turn, will again want to respond, that is, deviate from the deviation he started with. This criticism is then illustrated with an example in which one agent

C

expects the other to return to the status quo *after* he has deviated from it.

All of this, however, is wrong. Firstly, if one wants to give a time interpretation to conjectures and so forth, then actions must be thought of as strategies. That is, the deviating agent deviates in one or more elements of his plan over the whole length of the game (perhaps infinite). Under correct conjectures responses and counter-responses are taken into account in evaluating the benefits of deviation. Hence, and secondly, a deviating agent is in this situation never surprised by the response of the other, which therefore does not lead him to further revise his deviation. On the definition, agent 1 expects the response to his deviation to be $\theta_1(a^*, a_1)$. Suppose this gives a_2 which is correct. Then that agent knows that the new status quo will be $(a_1, a_2) = a$ and if he has calculated benefits correctly he will not wish to deviate again.

However, there is the following to be said in favour of Makowski's criticism. Deviations in strategies may not be observable by the other agent. Therefore in traditional duopoly models with a sequential structure the re-interpretation of actions as strategies may be inappropriate. There is some evidence that in the duopoly literature with conjectures the consequent difficulties have not always been appreciated. It is also the case that too little attention has been paid to the assumption of a unique best response on which the above formulation depends.

An alternative to rational conjectures are *reasonable conjectures* (Hahn 1978). A conjecture is reasonable if acting on any other conjecture would lower profits given the conjectures of other firms. Suppose that $\overline{\theta}$ is the set of all possible consistent conjectures. For any $\theta_i \in \overline{\theta}$, assume that there is a unique optimizing choice of output by firm i of $y_i(\theta_i)$. Then i's conjecture $\theta_i^0 \in \theta$ is reasonable if given jth conjecture θ_j:

$$v_i\left[y_i\left(\theta_i^0\right), y_j\left(\theta_j\right)\right] \geq \hat{v}_i\left[y_i\left(\theta_i^{'}\right), y_j\left(\theta_j\right)\right] \text{ all } \theta_i^{'} \in \theta. \tag{5}$$

But then a *reasonable conjectural equilibrium* is a pair $\left(\theta_1^0, \theta_2^0\right)$ each in θ such that

$$v_i\left[y_i\left(\theta_i^0\right), y_j\left(\theta_j^0\right)\right] \geq \hat{v}_i\left[y_i\left(\theta_i^{'}\right), y_j\left(\theta_j^0\right)\right], \quad i, j = 1, 2, \theta_i^{'} \in \overline{\theta}. \tag{6}$$

This is just a Nash equilibrium where conjectures are interpreted as strategies (Hart 1982).

While this is still quite demanding, it is significantly weaker than (3). If equilibria exist they may be 'bootstrap equilibria', that is, they will depend on beliefs about the actions of others, which beliefs may be incorrect. There is certainly no ground for believing that they will be efficient.

One can go one step further in the direction of plausibility by requiring that conjectures be reasonable only for small, or infinitesimal, deviations from the status quo. After all, large experiments are likely to be costlier than small ones. This will allow a larger class of reasonable conjectures and equilibria.

General Conjectural Equilibrium

It is fair to say that at present general equilibrium theory is in some way complete only for a perfectly competitive economy, that is, one where the returns to an individual agent are just equal to the contribution which he makes (Makowski 1980; Ostroy 1980). In general (although there are exceptions) such an economy exists when it is large (for example, it consists of a non-atomic continuum of agents). But there is now another possibility: an economy can be perfectly competitive if agents conjecture that their market actions will have no effect on the prices at which they can trade.

The following assertion will be clear from what has already been discussed. Let us say that an economy is *intrinsically* perfectly competitive if it satisfies the *no-surplus condition*. Then perfectly competitive conjectures are rational if an economy is intrinsically perfectly competitive. But perfectly competitive conjectures can be reasonable even when the economy is not intrinsically perfectly competitive. That is, conjectures may be such that, if an agent acts on any conjecture other than the perfectly competitive one, his profits will be lower. For instance, this may even be the case for two duopolists with constant marginal costs whose conjectures refer to the price

charged by the rival firm. It will also be clear that if we do not require conjectures to be either reasonable or rational then, in general, conjectures can be found to support a competitive equilibrium in an economy which is not intrinsically perfectly competitive.

In a general equilibrium context it is not clear what it is that firms are supposed to conjecture. In some sense the conjecture must refer to the reaction of the whole economy to the action of the conjecturing agent. In other words, it is not obvious how to define a game which adequately represents the economy. But in what sense?

Consider an economy with n produced goods and m non-produced goods. For simplicity suppose that all firms are single-product firms and that all firms producing the same good are alike, including their conjectures. There are very many households whose reasonable conjectures are always the competitive one. Households receive the profits of firms. Since the action of any one firm can affect the prices at which households can trade it is not at all clear what it is in the households' interest that the firms should maximize (Gabszewicz and Vial 1972). If all households are alike it could be their common utility function, but that seems far removed from the world. I shall arbitrarily assume that firms maximize their profits in terms of one of the non-produced goods, say the first. This is arbitrary but it seems to me equally dubious to suppose that firms always choose in the 'best interests of shareholders', especially when that interest is often difficult and sometimes impossible to define.

Let $p \in R^n$, $w \in R_+^{m-1}$ be the price vectors in terms of good m of produced and non-produced goods respectively (so $w_m \equiv 1$). Let $y_j \in Y_j \subset R^{n+m}$ be the production of firm j where $y_{ij} > 0$ is its output of good j, $y_{ii} < 0$ is an input of good i, produced or non-produced. Let $y = \Sigma y_j$, where $y_j \in Y_j$ all j. Let $z \in R_+^m$ be the endowment of non-produced goods and

$$F = \{y | \, y \geq (0, -z)\}$$

so that F is the set of feasible net production vectors Y. Let θ_{hj} be the share of household h in firm j.

Given any $y \in F$ we think of each household as endowed with a certain strictly positive stock of non-produced goods and $\theta_{hj} Y_j$ of the production of firm j. To avoid unnecessary complications assume θ_{hj} ($j = 1, \ldots, n$). to be such that if z_h is the stock of non-produced goods owned by household h:

$$\text{For all } y \in F : z_h + \sum_j \theta_{hj} y_j \geq 0 \text{ all } h. \qquad (7)$$

Households consume both types of goods. Hence for any $y \in F$ there is now an associated pure exchange economy where each household's endowment is given by (7). Making the usual assumptions there will exist at least one equilibrium $[p(y), w(y)]$. Suppose for the moment that there is only one for each $y \in F$.

Now firm j in this equilibrium observes $[p(y), w(y)]$ and will deviate from y_j (if it deviates at all) if it can thereby increase its conjectured profits. Let

$$\hat{\pi_j}\left[p(y), w(y), y_j^{'}\right]$$

be the conjectural profit function of firm j. Then y^0, $p(y^0)$,$w(y^0)$ is a conjectural equilibrium if for all $j = 1,\ldots, n$:

$$\begin{aligned} &\hat{\pi_j}\left[p(y^0), w(y^0), y_j^0\right] \\ &\times \geq \hat{\pi_j}\left[p(y^0), w(y^0), y_j^{'}\right] \quad \text{all } y_j^{'} \in Y. \end{aligned} \qquad (8)$$

Such a conjectural equilibrium will exist if all $\hat{\pi}_j(\cdot)$ are quasi-concave, an assumption for which there is scant justification (Hahn 1978).

If we demand that conjectures be rational then conjectured and actual profit must coincide for all $y_k^{'}$(the two coincide for $y_k^{'} = y_k^0$ by the requirement that conjectures be consistent). One proceeds as follows. Let $y_k^{'} = y_k^0$. Given the conjectures of the remaining firms find the conjectural equilibrium of the economy $p\{y^*(k), w[y^*(k), y^*(k)]\}$, where $y(k)$ is the vector y with $y_k^{'}$ in the kth place and condition (8) is not imposed for firm k. One then requires that for all $y_k^{'} > 0$

$$\hat{\pi}_k\left[p\left(y^0\right), w\left(y^0\right), y_k'\right] = \pi_k\left\{p[y^*(k)], w[y^*(k)], y_k'\right\} \tag{8a}$$

where $\pi_k(\cdot)$ is actual profit. For rational conjectures this should be true for all k.

It will be seen that rational conjectural equilibrium is very demanding. For a certain class of conjectures it will not even exist (Gale 1978; Hahn 1978). More importantly, the whole procedure breaks down if given a deviation by k, the conjectural equilibrium, is not unique. Lastly, even if by sufficient assumptions one overcomes these difficulties, it is not agreeable to common sense to suppose that firms can correctly calculate general equilibrium responses to their actions, nor is it obvious that they should always be concerned only with equilibrium states.

Reasonable conjectures do not fare much better, although a notable contribution to their study has recently been made by Hart (1982). Hart notices that conjectures of firms induce a supply correspondence (not generally convex) on their part. Here let us suppose that we can in fact speak of supply functions. These can be thought of as strategies in a manner already discussed. A reasonable conjectural equilibrium then satisfies the condition that, given the supply functions of other firms, no deviation by firm k to another supply response can increase its profits. In (8) one then substitutes on the right-hand side for y_j', $\eta_j'[p(y^0), w(y^0)]$, an admissible supply function (see Hart 1982) of j and requires the inequality to hold for all such functions. Of course, one has

$$y_j^0 = \eta_j^0\left[p\left(y^0\right), w\left(y^0\right)\right]$$

for a reasonable conjectural equilibrium.

To show existence of such an equilibrium will require strong assumptions. The technicalities will be found in Hart (1982). However, one of the assumptions which he makes is not only technically useful but economically sensible since it leads firms to face a simpler task in forming conjectures. Hart supposes the economy to consist of a number of islands each of which has many consumers and one firm of each type ($j = 1, \ldots, n$). The islands are small replicas of the whole economy. But households have shares in firms on all islands so that if there are enough islands their share in any firm on their own island is very small. That means that any firm can disregard the effect of a change in its own profits on the demand for the good it produces. To make this work one supposes that produced goods are totally immobile between islands while non-produced goods are totally mobile. By an appropriate assumption on consumers on each island one ensures that they all have the same demand. Lastly, since shares in a firm are held on many different islands the firm, in acting in the shareholder's interest is justified in neglecting the effect of its actions on relative prices on its own island and so is justified in maximizing profits.

From the point of view of conjectural equilibrium the island assumption allows firms (both reasonably and rationally) to ignore effects of their own actions on w – the price vector of non-produced goods. These will be determined by demand and supply over all islands and in this determination any one firm can be regarded as playing a negligible role. This is some gain in realism. But after all allowances have been made it is still true that (*a*) the assumptions required for the existence of reasonable conjectural equilibrium are uncomfortably strong and (*b*) even when that is neglected such an equilibrium seems to have small descriptive power.

Simpler Approaches

Negishi (1960) made the first, justifiably celebrated, attempt to incorporate imperfect competition in general equilibrium analysis. He did this by letting single product firms have consistent inverse demand conjectures (the case he studies most thoroughly makes these linear). Consistency is all he asked for of conjectures but he also needed the uncomfortable postulate that the resulting conjectural profit functions be quasi-concave. Later Hahn (1978), Silvestre (1977) and others added the requirement that, besides being consistent, the conjectured demand functions have, if differentiable, the correct slope at

equilibrium (that is, that the conjecture be *infinitesimally* or 'first order' *rational*). It turns out that this extra requirement does not much restrict conjectures, nor thus the set of equilibria which can be generated by some conjectures. The reason roughly is this: in conjectural equilibrium, when conjectured profit functions are twice differentiable, the partial derivative of the conjectured profit function of firm j with respect to its own output much vanish. Suppose the economy to be in such an equilibrium and consider an infinitesimal output deviation by firm k. To find the equilibrium which ensues, differentiate all equilibrium relations, other than that for firm k, with respect to the output of firm k. Amongst these will be the condition that the marginal profit conjectured of every firm (other than k), be zero. Hence differentiation of that condition will yield second-order terms. But we can choose these arbitrarily since we are requiring only first-order rationality. One can show in fact that these second-order terms can be chosen so as to make the first-order conjectured change in profit of any firm k correspond to the actual change. (Details in Hahn 1977.) Hence first-order rationality imposes few restrictions.

Both Hahn (1978) and Negishi (1979) have also considered kinked conjectures. The idea is this. If an agent can transact at the going price as much as he desires his conjectures are competitive. If he is quantity constrained (for example, if a firm cannot sell an amount determined by equality between marginal cost and price) his conjectures are non-competitive. That is, he considers that a price change is required to relax the quantity constraint. The fixprice methods of Drèze (1975) and others can be interpreted as an extreme form of such conjectures – for instance to relax a constraint on sales, price, it is conjectured, must be reduced to zero.

To such conjectures there have been two objections. Firstly, they assume that an agent's conjectures are not influenced by constraints on others. For instance, a firm which can hire as much labour as it wants at the going wage while workers cannot sell as much as they like does not conjecture that it could have the same amount of labour at a lower wage. To this one can answer that it is not easy for an agent to observe the quantity constraints on others. For instance, unemployment statistics do not tell us whether workers have chosen not to work or whether they are constrained in their sale of labour. None the less, this objection has some force and needs further study with proper attention to the information of agents.

The other objection is that these kinked conjectures are not explained. That is true if explanation turns on what an agent knows or can learn. None the less, the hypothesis seems to be to have psychological verisimilitude. If I can always sell my labour at the going wage there is little occasion for the difficult conjecturing of what would happen if I raised my wage. This is not so if I find that I cannot find employment at the going wage.

In any event these simpler approaches allow one to incorporate traditional monopolistic competition in a general equilibrium framework. Of course, some of the assumptions such as concave conjectured profit functions are strong. On the other hand, one can now allow for a certain amount of increasing returns (Silvestre 1977).

Some Conclusions

The conjectural approach has this merit: it takes proper and explicit note of the perceptions by individuals of their market environment. Economic theory perhaps too often neglects the possibility that what is the case may depend on what agents believe to be the case. Historians and others have long since studied the intimate mutual connection between beliefs and events but economists have not made much headway here. The conjectural approach is perhaps a small beginning. For it deals with the theories agents hold and this must plainly enter into our theory of agents.

In particular one should not pay too much attention to the objection that conjectures may not be derivable from some first principles of rationality. It seems to me quite proper to find their description in history. Nor, as has been argued, will an appeal to learning render conjectures in some sense objectively justifiable. This is clear from the discussion of reasonable

conjectures and from the costs of experimentation. For hundreds of years witches were burned in the light of a reasonable theory which few would now regard as having proper objective correlatives. There is no reason to suppose that it is possible for businesses or governments now to do better than some of the best minds of the past.

From a more immediately relevant standpoint, conjectural theories are of interest because they attempt a general equilibrium analysis of non-perfect competition. It is good to know that in a proper sense perfectly competitive economies can be viewed as limiting Cournot conjectural equilibrium economies (Novshek and Sonnenschein 1978). But this knowledge does not contribute to the study of properly imperfectly competitive economies. Again the study of fixprice equilibria has borne some fruits, but not those which were first sought by Triffin (1940) when he proposed a framework for general equilibrium with monopolistic competition. If it is the case that actual economies are not perfectly competitive nor that they behave 'as if' they were, then the task set by Triffin requires serious attention, and it is likely that conjectural theories will have a role to play.

Recent developments in game theory (for example, Kreps and Wilson 1982) suggest that these two conjectures will have to play a part. Indeed, quite generally in that theory players conjecture that their opponent is 'rational' in an appropriate sense. It is not the case that the conjectural equilibrium approach is an alternative to the game theoretic one.

Conspicuous consumption means the use of consumer goods in such a way as to create a display for the purpose of impressing others rather than for the satisfaction of normal consumer demand. It is consumption intended chiefly as an ostentatious display of wealth. The concept of conspicuous consumption was introduced into economic theory by Thorstein Veblen (1899) in the context of his analysis of the latent functions of 'conspicuous consumption' and 'conspicuous waste' as symbols of upper-class status and as competitive methods of enhancing individual prestige.

Veblen argued that the leisure class is chiefly interested in this type of consumption, but that, to a certain degree, it exists in all classes. The leisure class undoubtedly has much more opportunity for this kind of consumption. The criterion as to whether a particular outlay fell under the heading of conspicuous consumption was whether, aside from acquired tastes and from the canons of usage and conventional decency, its result was a net gain in comfort or in fullness of life.

It is widely though that Veblen introduced the concept of conspicuous consumption into economic literature, but it was known much earlier. Adam Smith (1776, Book I, Ch. 11) wrote about people who like to possess those distinguishing marks of opulence that nobody but themselves can possess. In the eyes of such people the merit of an object that is in any degree either useful or beautiful is greatly enhanced by its scarcity, or by the great amount of labour required to accumulate any considerable quantity of it. This is the labour for which nobody but themselves can afford to pay. Smith concluded that this domain was ruled by fashion. J.-B. Say and McCulloch wrote about this issue in a similar way. But the author who first used the term 'conspicuous consumption' was the Canadian economist John Rae (1796–1872). His explanation of the nature and effects of luxury was based on the meaning of vanity in human life. He understood vanity to be the mere desire for superiority over others without any reference to merit. The aim is to have what others cannot have, whereas the stimulus to productivity in economic life is the passion for effective accumulation: 'Articles of which consumption is conspicuous, are incapable of gratifying this passion' (Rae, 1834).

However, it was Veblen who introduced the concept of conspicuous consumption as a phenomenon important for the understanding of consumption as a whole. He gave Rae no reference at all.

Veblen's historical and socio-economic explanation of this institution gave as a result the so-called 'Veblen effect'. This is the phenomenon whereby as the price of an article falls some consumers construe this as a reduction in the quality of the good or loss of its 'exclusiveness' and cease to buy it.

Constant and Variable Capital

N. Okishio

Definition

In *Das Kapital* Marx defined Constant Capital as that part of capital advanced in the means of production; he defined Variable Capital as the

part of capital advanced in wages (Marx 1867, Vol. I, ch. 6). These definitions come from his concept of Value: he defined the value of commodities as the amount of labour directly and indirectly necessary to produce commodities (Vol. I, ch. 1). In other words, the value of commodities is the sum of C and N, where C is the value of the means of production necessary to produce them and N is the amount of labour used that is directly necessary to produce them. The value of the capital advanced in the means of production is equal to C.

However, the value of the capital advanced in wages is obviously not equal to N, because it is the value of the commodities which labourers can buy with their wages, and has no direct relationship with the amount of labour which they actually expend. Therefore, while the value of the part of capital that is advanced in the means of production is transferred to the value of the products without quantitative change, the value of the capital advanced in wages undergoes quantitative change in the process of transfer to the value of the products. This is the reason why Marx proposed the definitions of constant capital C and variable capital V.

The definition of constant capital and variable capital must not be confused with the definition of fixed capital and liquid capital. Fixed capital is a part of constant capital which is totally used in production process but transfers its value to products only partially. Liquid capital is a part of constant capital which is totally used up and transfers its whole value within one production process. So constant capital is composed of both fixed capital and liquid capital, and on the other hand liquid capital belongs partly to constant capital and partly to variable capital.

Marx introduced the concept 'value-composition of capital', μ, which is defined as the ratio of constant capital C to variable capital V:

$$\mu \equiv \frac{C}{V}. \tag{1}$$

Marx knew well that the value composition of capital reflects not only material characteristics of the process of production but also the social relationship between capitalists and labourers. In fact definition (1) can be rewritten as

$$\mu = \frac{C}{N} \cdot \frac{N}{V} \tag{2}$$

C/N reflects the character of the process of production and N/V reflects the class relationship between capitalists and labourers. C/N is the ratio of the amount of labour necessary to produce the means of production to the amount of labour directly bestowed, which is completely determined by the material condition in the process of production, while N/V is the ratio of the amount of labour which labourers actually expend to the amount of labour that is necessary in order to produce commodities which labourers can purchase with their wages. If labourers are forced to work longer with less wages, this ratio must rise.

Marx proposed to call the value-composition of capital, insofar as it is determined by the material condition of the process of production, 'the organic composition of capital'. More explicitly, 'The value-composition of capital, inasmuch as it is determined by, and reflects, its technical composition, is called the *organic* composition of capital' (*Capital*, Vol. III, ch. 8). However, as shown above, the value composition of capital is not determined by the material condition of the process of production alone. So it is better to introduce the ratio C/N in the place of the organic composition of capital, which is determined only by the material condition in the process of production. In order to avoid confusion, I call this ratio the 'organic composition of production'. This is the ratio of dead labour to living labour, which Marx himself frequently used in *Das Kapital*.

Variable Capital and Source of Profit

In contrast to Smith, Ricardo and others, Marx attached great importance to analysis to find the source of profit. He found that source in surplus labour, which is the excess of labour expended by labourers over the value of commodities which labourers can obtain with their wages (*Capital,*

vol. I, ch. 5). Using the notation introduced above, $N > V$ is the necessary condition for profit to exist. In order to illuminate this fact, he called capital advanced in wages *Variable Capital*. So the validity of this name depends on his analysis of the source of profit. How is it justified?

For simplicity we set up the simplest model which can reflect the fundamental characteristics of a capitalistic economy; these characteristics are the prevalence of commodity production, and the existence of class relationships between labourers and capitalists. There are only two kinds of commodities: the means of production (commodity 1) and consumption goods (commodity 2). In order to produce one unit of the ith commodity an amount of a_i unit of means of production and an amount of labour τ_t are necessary as input. Labourers are forced to work for T hours per day and earn the money wage rate w.

In order for profit to exist in both industries the following inequalities are necessary

$$p_1 > a_1 p_1 + \tau_1 w \tag{3}$$

$$p_2 > a_2 p_2 + \tau_2 w \tag{4}$$

where p_1 and p_2 denote the price of the means of production and consumption goods respectively. As labourers work for T hours a day at money wage w per hour, they can purchase an amount B of consumption goods.

$$B = \frac{wT}{p_2}, \quad B/T = R \tag{5}$$

where R is the real wage rate.

In the first volume of *Das Kapital,* Marx assumed that all commodities are exchanged at prices exactly proportionate to their unit value (equivalent exchange). Unit values of commodities are determined by the following equations

$$t_1 = a_1 t_1 + \tau_1 \tag{6}$$

$$t_2 = a_2 t_1 + \tau_2 \tag{7}$$

which assure unique and positive values, provided $a_1 < 1$ (Dmitriev 1898; May 1949–50; Okishio 1955a, b).

Under the assumption of equivalent exchange, we have

$$p_i = \lambda t_i \tag{8}$$

where λ is a constant which converts the dimension from hours to, say, dollars. Substituting (5) and (8) into (3) and (4) we get

$$t_1 > a_1 t_1 + \tau_1 \frac{B}{T} t_2 \tag{9}$$

$$t_2 > a_2 t_1 + \tau_2 \frac{B}{T} t_2 \tag{10}$$

By equations (6) and (7) and the above inequalities, we have

$$\tau_1 \left(1 - \frac{B}{T} t_2\right) > 0 \tag{11}$$

$$\tau_2 \left(1 - \frac{B}{T} t_2\right) > 0 \tag{12}$$

Consequently we arrive at the conclusion

$$T > B t_2. \tag{13}$$

This inequality implies the existence of surplus value, because surplus value is the excess of working hours T over the amount of labour necessary to produce commodities which labourers can receive with wages B. If the number of workers employed is n, then total expended labour is nT and variable capital measured in terms of value is $Bt_2 n$. So the inequality (13) can be rewritten as

$$N > V \tag{14}$$

This is the reason Marx called capital advanced in wages variable capital.

As shown above, Marx proved the theorem of the source of profit under the assumption of equivalent exchange. Though this is a clear-cut way to show the results, it has induced various critiques. Many critics have said that Marx's theorem would be right if all exchanges were equivalent

exchange, but that in reality exchanges are seldom equivalent so his theorem cannot be valid. In order to refute such a criticism we must prove the theorem without the assumption of equivalent exchange (see Okishio 1955a, 1955b, 1963, 1972; 1978; Morishima 1973). Mathematically, our task is to find necessary and sufficient conditions for inequalities (3), (4) and (5) to have non-negative solutions for p_1, p_2. From (3) we know easily that the condition

$$1 - a_1 > 0 \tag{15}$$

is necessary for p_1 to be positive. This condition ensures that the society will obtain net output. Next, substituting (5) into (3), and from (15) we have

$$\frac{p_1}{p_2} > \frac{\tau_1 B}{T(1 - a_1)}. \tag{16}$$

On the other hand, from (4) and (5) we get

$$\frac{p_1}{p_2} > \frac{T - \tau_2 B}{T a_2}. \tag{17}$$

We can easily get from (16) and (17)

$$\frac{a_2 \tau_1 B}{(1 - a_1)} < T - \tau_2 B. \tag{18}$$

Inequality (18) is rewritten as

$$T > B\left(\frac{a_2 \tau_1}{1 - a_1} + \tau_2\right). \tag{19}$$

By (19), (6) and (7) the above becomes

$$T > B t_2. \tag{20}$$

Thus we can arrive at Marx's result.

For later convenience we show another expression for the existence of surplus value. Dividing (3) and (4) by w, we get

$$\frac{p_1}{w} a_1 \frac{p_1}{w} + \tau_1 \tag{21}$$

$$\frac{p_2}{w} a_2 \frac{p_1}{w} + \tau_2 \tag{22}$$

By comparing (21) and (22), and (6) and (7), we get

$$\frac{p_i}{w} > t_i, \quad (i = 1, 2) \tag{23}$$

Equation (23) implies that if positive profit exists, then the price–wage ratio (the amount of commanded labour) is greater than the amount of value (necessary labour). In the famous controversy with Ricardo, Malthus pointed out this difference between labour commanded and labour embodied. Though he wrongly thought that this difference injured the validity of the labour theory of value, he had come near to the Marxian theory of the source of profit (see Malthus 1820, pp. 61–3, 120).

Condition (23) is rewritten as

$$1/t_i > w/p_i$$

This condition shows that if positive profit exists, then the productivity of labour ($1/t_i$) must be greater than the rate of real wages (w/p_i).

Organic Composition and Production Price

The concept of organic composition of capital plays an important role in Marx's analysis of prices.

The price of production (Ricardo's 'natural price') that gives every industry the equal rate of profit is determined by the following equations:

$$p_1 = (1 + r)(a_1 p_1 + \tau_1 w) \tag{24}$$

$$p_2 = (1 + r)(a_2 p_1 + \tau_2 w) \tag{25}$$

$$w = R p_2 \tag{26}$$

where r is the general (equal) rate of profit.

The first problem is to examine the relationship between

$$\frac{t_1}{t_2} \sim \frac{p_1}{p_2}.$$

If they are equal then we have equivalent exchange, if not we have non-equivalent exchange from the point of view of the labour theory of value. The values of the commodities are determined by (6) and (7). The ratio of the value of production-goods to consumption-goods t_1/t_2 is given as

$$\frac{t_1}{t_2} = \frac{\tau_1\left(\frac{a_1 t_1}{\tau_1} + 1\right)}{\tau_2\left(\frac{a_2 t_1}{\tau_2} + 1\right)} \tag{27}$$

The relative price of production-goods to consumption-goods determined by (24) and (25) is given as

$$\frac{t_1}{t_2} = \frac{\tau_1\left(\frac{a_1 t_1}{\tau_1} + w\right)}{\tau_2\left(\frac{a_2 p_1}{\tau_2} + w\right)}. \tag{28}$$

Comparing (27) with (28), we obtain

$$\frac{t_1}{t_2} - \frac{p_1}{p_2} = \frac{\tau_1}{\tau_2}\left[\frac{\frac{a_1 t_1}{\tau_1} + 1}{\frac{a_2 t_1}{\tau_2} + 1} - \frac{\frac{a_1 t_1}{\tau_1} + w}{\frac{a_2 p_1}{\tau_2} + w}\right]. \tag{29}$$

The expression in brackets on the RHS of (29) is given by

$$[\,] = (t_1 w - p_1)\left(\frac{a_1}{\tau_1} - \frac{a_2}{\tau_2}\right)A, \quad A > 0. \tag{30}$$

If profit is positive, from (23) $t_1 w - p_1$ is negative. So we can conclude

$$\frac{t_1}{t_2} \gtreqless \frac{p_1}{p_2} \Leftrightarrow \frac{a_1}{\tau_1} \lesseqgtr \frac{a_2}{\tau_2}. \tag{31}$$

The RHS of the above means the comparison of the organic composition of production and also the organic composition of capital, because as shown above the organic composition of production is $a_i t_1/\tau_i$ and the organic composition of capital is $a_i t_1/\tau_i\, R t_2$.

The second problem is to examine the influence of the change in real wage rate on the relative prices determined by (24), (25) and (26):

$$d\left(\frac{p_1}{p_2}\right) \Big/ \mathrm{d}R.$$

Denoting the relative price of production-goods to consumption-goods as p, from (24), (25) and (26) we obtain

$$f(p) \equiv a_2 p^2 + (\tau_2 R - a_1)p - \tau_1 R = 0. \tag{32}$$

Differentiating (32) with respect to R, we have

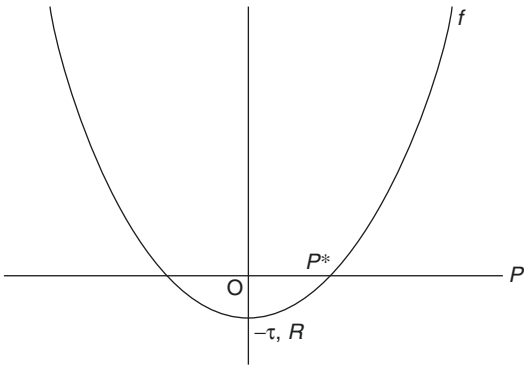
$$\frac{\mathrm{d}p}{\mathrm{d}R} = \frac{\tau_1 - \tau_{2p}}{2a_2 p + \tau_2 R - a_1}. \tag{33}$$

The denominator above is positive, because from (32)

$$\text{denominator} \times p = a_2 p^2 + \tau_1 R > 0.$$

We shall show that the sign of the numerator depends on the comparison between the organic composition of capital in both sectors.

The function $f(p)$ in (32) is drawn in Fig. 1. The meaningful solution of the equation (32) is given at p^*. Substituting t_1/t_2 into $f(p)$, we get



Constant and Variable Capital, Fig. 1

$$f\left(\frac{\tau_1}{\tau_2}\right) = \tau_1(a_2\tau_1 - a_2\tau_2).$$

Therefore if $a_2\tau_1 - a_1\tau_2 > 0$ then $f(\tau_1/\tau_2) > 0$, so considering the graph of $f(p)$ we know that $\tau_1/\tau_2 > p^*$. In the same way we can conclude that if $a_2\tau_1 - a_1\tau_2 \gtreqless 0$, then $\tau_1/\tau_2 \gtreqless p^*$. Consequently, from (3.10) we can conclude

$$d\left(\frac{p_1}{p_2}\right)/\mathrm{d}R \gtreqless 0 \Leftrightarrow \frac{a_1}{\tau_1} \lesseqgtr \frac{a_2}{\tau_2}.$$

This proposition is first established in Ricardo's *Principles* (1821, p. 43).

Organic Composition and the Rate of Profit

The concept of organic composition of capital plays an important role in Marx's analysis of the movement of the rate of profit (Fig. 1).

Marx defined the rate of profit as

$$r = \frac{S}{C+V}. \tag{34}$$

By (1), equation (34) is rewritten as

$$r = \frac{e}{\mu+1}, \quad e = S/V \tag{35}$$

where e is the rate of exploitation.

He asserted that if the organic composition of capital μ increases sufficiently then the rate of profit r must inevitably decrease. This is the famous 'law of the tendency for the rate of profit to fall' (*Capital,* Vol. III, Chap. 13).

Many people have criticized this theorem. They have said that if the rate of exploitation e increases sufficiently, r may increase in spite of the increase of μ. So r does not necessarily decrease, even if μ increases sufficiently (Robinson 1942; Sweezy 1942). Such a critique overlooks the logic of Marx's argument.

Marx stated:

> Since the mass of the employed living labour is continually on the decline as compared to the mass of materialized labour set in motion by it, i.e., to the productively consumed means of production, it follows that the portion of living labour, unpaid and congealed in surplus-value, must also be continually on the decrease compared to the amount of value represented by the invested total capital. Since the ratio of the mass of surplus-value to the value of the invested total capital forms the rate of profit, this rate must constantly fall (*Capital,* Vol. III, Chap. 13, p. 213).

Therefore Marx's true intention is to insist that if the organic composition of production $v = \mathrm{C/N}$ (the ratio of the mass of materialized labour to the mass of living labour) increases sufficiently, the rate of profit must fall.

This can be proved as follows (Okishio 1972). From (34) and (35), and

$$v = C/N \tag{36}$$

we have

$$\begin{aligned} r_{t+1} - r_t &= \frac{S_{t+1}}{C_{t+1}+V_{t+1}} - r_t \\ &= \frac{e_{t+1}}{v_{t+1}(1+e_{t+1})+1} - r_t \\ &= \frac{1}{v_{t+1}(1/e_{t+1}+1)+1/e_{t+1}} - r_t \end{aligned} \tag{37}$$

where suffixes t, $t+1$ denote periods.

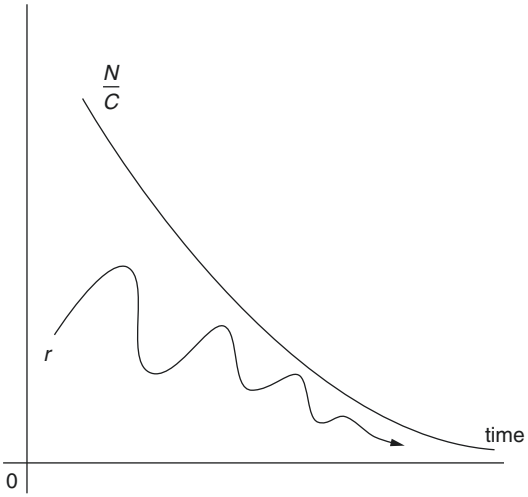
The RHS of (37) is an increasing function of e. If we take the limiting value as e tends to infinity, we have

$$r_{t+1} - t_t < \frac{1}{v_{t+1}} - r_t.$$

Therefore we conclude, if $v_{t+1} > 1/r_t$, then $r_{t+1} - r_t < 0$.

The above reasoning can be restated. The reciprocal of the organic composition of production sets an upper limit to the rate of profit, because

$$r = \frac{S}{C+V} < \frac{S+V}{C} = \frac{N}{C} \tag{38}$$



Constant and Variable Capital, Fig. 2

If this upper limit decreases sufficiently, the rate of profit must eventually decrease, as shown in Fig. 2.

In response to criticisms of this view we must say that as far as we accept Marx's assumption that the inverse of the organic composition (N/C) tends toward zero, Marx's conclusion inevitably follows.

So far we have defined the rate of profit as (34) and C, V, S are all measured in terms of labour value. However, the general rate of profit r must be determined by (24), (25) and (26). Can we derive the same conclusions for such a redefined r?

Eliminating p_1, p_2, w from (24), (25) and (26) we have

$$f(r,R)\equiv(1+r)^2R(a_1\tau_2-a_2\tau)-(1+r)(a_1+\tau_2R)+1=0 \tag{39}$$

Differentiating $f(r, R)$ we have

$$f_r\mathrm{d}r+f_R\mathrm{d}R=0 \tag{40}$$

where

$$f_r=2(1+r)R(a_1\tau_2-a_2\tau_1)-(a_1+\tau_2R)$$
$$f_R=(1+r)^2(a_1\tau_2-a_2\tau)-(1+r)\tau_2$$

Considering (39)

$$(1+r)f_r=(a_1+\tau_2R)(1+r)-2 \tag{41}$$

From (24), (25), (26), we know

$$1-(1+r)a_1>0 \quad 1-(1+r)\tau_2R>0 \tag{42}$$

From (41) $f_r<0$. f_R is rewritten as

$$f_R=(1+r)\{[(1+r)a_1-1]\tau_2-(1+r)a_2\tau_1\}$$

So by (42) $f_R<0$, from which $\mathrm{d}r/\mathrm{d}R<0$. As R goes to zero r tends to its upper limit, which is obtained from (39)

$$r_{\max}=\frac{1-a_1}{a_1}. \tag{43}$$

Since the value of the means of production is determined by (6), we have

$$\frac{1-a_1}{a_1}=\frac{(1-a_1)t_1}{a_1t_1}=\frac{\tau_1}{a_1t_1}=\frac{N_1}{C_1} \tag{44}$$

Thus the upper limit of the general rate of profit is given by the reciprocal of the organic composition of production in the means of production sector. Therefore if the organic composition in that sector rises sufficiently, the general rate of profit must fall.

Organic Composition and Unemployment

The concept of organic composition of capital plays an important role in Marx's analysis of the movement of employment (*Capital,* vol. I, ch. 23).

Marx assumed a rise in labour productivity to accompany the rise in the organic composition of production C/N. If C/N rises then from the definition of organic composition the amount of employment must decrease relative to constant capital.

However, how does the increase in the organic composition influence the absolute level of employment?

Many people thought that even if C/N rises sufficiently, still if constant capital C also increases then the absolute level of employment can also increase, though less than proportionately to constant capital (Oppenheimer 1903). But by reasoning similar to that used for 'the tendency of the rate of profit to fall', we can prove that if organic composition rises sufficiently, then the absolute level of employment must actually decrease.

The organic composition of production in the tth period v_t is defined as

$$v_t = \frac{C_t}{N_t}. \tag{45}$$

The accumulation of constant capital $\Delta C = C_{t+1} - C_t$ is financed from surplus value S.

$$C_{t+1} - C_t < S_t. \tag{46}$$

The surplus value S is a part of the amount of living labour which labourers expend

$$S_t < N_t. \tag{47}$$

By (45), we obtain,

$$\begin{aligned} N_{t+1} - N_t &= \frac{1}{v_{t+1}} C_{t+1} - \frac{1}{v_t} C_t \\ &= \frac{1}{v_{t+1}} (C_{t+1} - C_t) + C_t \left(\frac{1}{v_{t+1}} - \frac{1}{v_t} \right). \end{aligned}$$

From (46) and (47) we get

$$\begin{aligned} N_{t+1} - N_t &< \frac{1}{v_{t+1}} S_t + C_t \left(\frac{1}{v_{t+1}} - \frac{1}{v_t} \right) \\ &< \frac{N_t}{v_{t+1}} + C_t \left(\frac{1}{v_{t+1}} - \frac{1}{v_t} \right) \\ &= \frac{C_t}{v_{t+1} v_t} (1 + v_t - v_{t+1}) 0 \end{aligned}$$

we can say, if $(1 + v_t - v_{t+1}) < 0$ then $N_{t+1} - N_t < 0$. Therefore, if the organic composition of production in the $t + 1$th period, v_{t+1}, increases sufficiently so as to exceed $1 + v_t$, then the amount of employed labourer, N_{t+1} must inevitably become less than N_t, however high the rate of accumulation of capital may be (Okishio 1972). The rate of accumulation of capital $\Delta C/C$ itself is bounded by the reciprocal of the organic composition. From (46) and (47)

$$\frac{\Delta C}{C} < \frac{N}{C} = \frac{1}{v}$$

so that, because it is reasonable to assume that the growth rate of labour supply is non-negative, we can say that if the organic composition rises sufficiently the rate of unemployment inevitably rises. Though Marx did not state this explicitly, we think that this is what he wanted to say.

In analysing Marx's theorem on the movement of the rate of profit and employment, we have accepted his central assumption that the organic composition of production rises sufficiently over time. However, there arises the problem: under what conditions do capitalists choose techniques that have sufficiently high organic compositions of production?

Marx seemed to think that the rise in labour productivity and the rise in the organic composition are two aspects of the same thing. But these two do not always go together. Marx himself knew that if labour productivity in the means of production sector rises very high then even if technical composition rises, still the value composition may remain constant or decrease.

As to the capitalists' introduction of new techniques we have the following propositions:

(1) If the real wage rate remains constant and capitalists introduce new techniques which raise the rate remains of profit (calculated at the current prevailing prices and wage) then the new general rate of profit does not decrease, whatever the organic composition may be.
(2) If the real wage rate rises and capitalists adapt to this situation with the introduction of new techniques, then the new general rate of profit

does is higher than the one which would be expected if such a new technique were not introduced.

For the proofs of these propositions, see ▶ choice of technique and the rate of profit.

Constitutional Economics

James M. Buchanan

The term *Constitutional Economics* (Constitutional Political Economy) was introduced to define and to classify a distinct strand of research inquiry and related policy discourse in the 1970s and beyond. The subject matter is not new or novel, and it may be argued that 'constitutional economics' is more closely related to the work of Adam Smith and the classical economists than its modern 'non-constitutional' counterpart. Both areas of inquiry involve positive analysis that is ultimately aimed at contributing to the discussion of policy questions. The difference lies in the level of or setting for analysis which, in turn, implies communication with different audiences.

Orthodox economic analysis, whether this be interpreted in Marshallian or Walrasian terms, attempts to explain the choices of economic agents, their interactions one with another, and the results of these interactions, within the existing legal-institutional-constitutional structure of the polity. Normative considerations enter through the efficiency criteria of theoretical welfare economics, and policy options are evaluated in terms of these criteria. The policy analyst, building on the analysis, presents his results, whether explicitly or implicitly, to the political decision-makers, who then make some ultimate determination from among the available set. In this role the policy analyst directly, and the theorist indirectly, are necessarily advising governmental decision-makers, whoever these may be.

By both contrast and comparison, constitutional economic analysis attempts to explain the working properties of alternative sets of legal-institutional-constitutional rules that constrain

the choices and activities of economic and political agents, the rules that define the framework within which the ordinary choices of economic and political agents are made. In this sense, constitutional economics involves a 'higher' level of inquiry than orthodox economics; it must incorporate the results of the latter along with many less sophisticated subdisciplines. Normative considerations enter the analysis in a much more complex manner than through the artificially straightforward efficiency criteria. Alternative sets of rules must be evaluated in some sense analogously to ranking of policy options within a specified institutional structure, but the epistemological content of the 'efficiency' criteria becomes more exposed.

The constitutional economist, precisely because the subject matter is the analysis of alternate sets of rules, has nothing to offer by way of policy advice to political agents who act within defined rules. In this sense, constitutional economics is not appropriately included within 'policy science' at all. At another level, however, the whole exercise is aimed at offering guidance to those who participate in the discussion of constitutional change. In other words, constitutional economics offers a potential for normative advice to the member of the continuing constitutional convention, whereas orthodox economics offers a potential for advice to the practising politician. In a real sense, constitutional economics examines the *choice of constraints* as opposed to the *choice within constraints*, and as this terminology suggests, the disciplinary attention of economists has almost exclusively been placed on the second of these two problems.

A preliminary illustration of the distinction may be drawn from the economics of monetary policy. The constitutional economist is not directly concerned with determining whether monetary ease or monetary restrictiveness is required for furthering stabilization objectives in a particular setting. On the other hand, he is directly concerned with evaluating the properties of alternative monetary regime (e.g. rule-directed versus discretionary, fiat versus commodity standards). The ultimate objective of analysis is the choice among the institutions within which political agents act. The predicted behaviour of these agents is incorporated in the analysis of alternative sets of constraints.

Constitutional Economics and Classical Political Economy

As suggested, Constitutional Economics is related to classical political economy and it may be considered to be an important component of a more general revival of the classical emphasis, and particularly as represented in the works of Adam Smith. (The closely related complementary components are discussed briefly in section "The New Political Economy".) One obvious aim of the classical political economists was to offer an explanation and an understanding of how markets operate without detailed political direction. In this respect, orthodox neoclassical economics follows directly in the classical tradition. But the basic classical analysis of the working of markets was only a necessary step toward the more comprehensive purpose of the whole exercise, which was that of demonstrating that, precisely because markets function with tolerable efficiency independently of political direction, a powerful normative argument for constitutional structure exists. That is to say, Adam Smith was engaged directly in comparing alternative institutional structures, alternative sets of constraints within which economic agents make choices. In this comparative analysis, he found it essential to model the working properties of a non-politicized economy, which did not exist in reality, as well as the working properties of a highly politicized mercantilist economy, which could be directly observed.

There is no need here to enter the lists on either side of the 'ideas have consequences' debate. We know that the economy of Great Britain was effectively de-politicized in the late 18th and early 19th centuries, and from the analysis of Smith and his classical fellow travellers there emerged both positive understanding of economic process and philosophical argument for a particular regime. The normative argument for laissez faire was, perhaps inevitably, intermingled with the positive analysis of interaction within a

particular structure of constraints, essentially those that describe the minimal, protective, or night-watchman state. Economics, as a social science, emerged, but in the process attention was diverted from the institutional structure. Even the predicted normative reaction against the overly zealous extension of the laissez faire economics argument was couched in 'market failure' terms, rather than in the Smithian context of institutional comparison. The early socialist critique of market order, both in its Marxist and non-Marxist variants, was almost exclusively negative in that it elaborated putative failures of markets within an unexamined set of legal-political rules while it neglected analysis of the alternative rules that any correction of the alleged failures might require. Only with the debates on socialist calculation in the decades prior to World War II did the issues of comparative structure come to be examined.

It was only in the half-century after these debates that political economy, inclusively defined, returned, in fits and starts, to its classical tradition. Given the legal order of the protective state (the protection of property and the enforcement of contracts), we now know that under some conditions 'markets fail' when evaluated against idealized criteria, whether these be 'efficiency', 'justice', or other abstract norms. We also know that 'politics fails' when evaluated by the same criteria. Any positive analysis that purports to be of use in an ultimate normative judgment must reflect an informed comparison of the working properties of alternative sets of rules or constraints. This analysis is the domain of Constitutional Economics.

Constitutional Economics and Social Philosophy

Classical political economy emerged from moral philosophy, and its propounders considered their efforts to fall naturally within the limits of philosophical discourse. As a modern embodiment, Constitutional Economics is similarly located, regardless of disciplinary fragmentation. How can persons live together in liberty, peace and prosperity? This central question of social philosophy requires continuing contributions from many specialists in inquiry, surely including those of the constitutional economists. By their focus directly on the ultimate selection of a set of constraining rules within which ordinary social interaction takes place, constitutional economists remove themselves at least one stage further from the false position of 'social engineer' than their counterparts in orthodox economics. Precisely because there is no apparently simple evaluative criterion analogous to 'allocative efficiency' at hand, the constitutional economist is less tempted to array alternatives as if an unexamined criterion commands universal assent. The artificial abstraction of 'social utility' is likely to be less appealing to those who concentrate on choices among constraints than to those who examine choices within constraints.

If, however, there is no maximand, how can ultimate normative consequence emerge? In this respect, one contribution lies at the level of positive analysis rather than in a too-hasty leap into normative evaluation. Classical political economy contains the important principle of spontaneous coordination, the great discovery of the 18th century. This principle states that, within the legal umbrella of the minimal state and given certain conditions, the market 'works'. Even if in the principle's modern embellishment we must add 'warts and all', we still have come a long way toward a more comprehensive understanding of the alternatives for social order. To economics the extent that his efforts expand the public understanding of this principle, in application to all institutional settings, the constitutional economist remains under less apparent compulsion to advance his own privately preferred 'solutions' to the ultimate choice among regimes.

The New Political Economy

Care should be taken not to claim too much for Constitutional Economics, especially if a narrow definition is used. As noted earlier, this research programme, by designation, emerged in the 1970s to describe efforts at analysing the effects of

alternative sets of rules, as opposed to analyses of choices made within existing and unexamined structures. In a more comprehensive overview of developments after World War II, Constitutional Economics takes its place among an intersecting set of several research programmes, all of which have roots in classical political economy. Critical emphases differ as among the separate programmes, but each reflects efforts to move beyond the relatively narrow confines of orthodox neoclassical economics.

In continental Europe, the whole set of subdisciplines is included under the rubric 'The New Political Economy'. Within this set we can place (1) Public Choice, from which Constitutional Economics emerged; (2) Economics of Property Rights; (3) Law and Economics or Economic Analysis of Law; (4) Political Economy of Regulation; (5) the New Institutional Economics, and (6) the new Economic History. Defined imperialistically, Constitutional Economics would parallel the inclusive term and embrace all of these programmes, since some attention is drawn in each case to the legal-political constraints within which economic and political agents choose. Differences can be identified, however, and it may be useful to summarize some of these here, even if detailed discussion of the other research programmes cannot be attempted.

Public Choice, in its non-constitutional aspects of inquiry, concentrates attention on analyses of alternative political choice structures and on behaviour within those structures. Its focus is on predictive models of political interactions, and is a preliminary but necessary stage in the more general constitutional inquiry. The economics of property rights, law and economics, and the political economy of regulation remain somewhat closer to orthodox economic theory than Constitutional Economics or Public Choice. The standard efficiency norm remains central to these subdisciplines, both as an explanatory benchmark and as normative ideal. The new institutional economics is directed more toward the interactions within particular institutional forms rather than toward the comprehensive structure of political rules (Furubotn and Richter 1980; Frey 1984). Some elements of the new economic history closely parallel Constitutional Economics, with, of course, an historical rather than a comparative emphasis (North and Thomas 1973).

Presuppositions

Constitutional Economics, along with the related research programmes mentioned above, shares a central methodological presupposition with both its precursor, classical political economy, and its counterpart in modern neoclassical microeconomics. Only individuals choose and act. Collectivities, as such, neither choose nor act and analysis that proceeds as if they do is not within the accepted scientific canon. Social aggregates are considered only as the results of choices made and actions taken by individuals. The emphasis on explaining non-intended aggregative results of interaction has carried through since the early insights of the Scottish moral philosophers. An aggregative result that is observed but which cannot, somehow, be factored down and explained by the choices of individuals stands as a challenge to the scholar rather than as some demonstration of non-individualistic organic unity.

Methodological individualism, as summarized above, is almost universally accepted by economists who work within mainstream, or non-Marxian, traditions. A philosophical complement of this position that assumes a central role in Constitutional Economics is much less widely accepted and is often explicitly rejected. A distinction must be drawn between the methodological individualism that builds on individual choice as the basic unit of analysis and a second presupposition that locates the ultimate sources of value exclusively in individuals.

The first of these presuppositions without the second leaves relatively little scope for the derivation of constitutional structures from individual preferences. There is no conceptual normative bridge between those interests and values that individuals might want to promote and those non-individualistic values that are presumed to serve as ultimate normative criteria. The whole constitutional exercise loses most if not all of its *raison d'être* in such a setting. If the ultimate

values which are to be called upon to inform the choices among institutions are non-individualistic, then there is, at best, only an instrumental argument for using individually expressed preferences in the process of discovering those values.

On the other hand, if the second presupposition concerning the location of the ultimate sources of value is accepted, there is no *other* means of deriving a 'logic of rules' than that of utilizing individually expressed interests. At base, the second presupposition implies democracy in governance, along with the accompanying precept that this structure of decision-making only takes on normative legitimacy with the prefix 'constitutional' appended to it.

Wicksell as Precursor

The single most important precursor to Constitutional Economics in its modern variant is Knut Wicksell, who was individualist in both of the senses discussed above. In his basic work on fiscal theory (*Finanztheoretische Untersuchungen*, 1896), Wicksell called attention to the significance of the rules within which choices are made by political agents, and he recognized that efforts at reform must be directed toward changes in the rules for making decisions rather than toward modifying expected results through influence on the behaviour of the actors.

In order to take these steps, Wicksell needed some criterion by which the possible efficacy of a proposed change in rules could be judged. He introduced the now-familiar unanimity or consensus test, which is carried over into Constitutional Economics and also allows the whole research programme to be related closely to the contractarian tradition in political philosophy. The relationship between the Wicksellian and the Paretian criteria is also worthy of note. If only individual evaluations are to count, and if the only source of information about such evaluations is the revealed choice behaviour of individuals themselves, then no change could be assessed to be 'efficient' until and unless some means could be worked out so as to bring all persons (and groups) into agreement. If no such scheme can be arranged, the observing political economist remains silent. The Wicksellian contribution allowed the modern economist to bring the comparative analysis of rules or institutions within a methodological framework that utilizes and builds on the efficiency criterion, which, when interpreted as indicated, does not require departure from either of the individualistic presuppositions previously discussed.

Homo Economics in Constitutional Choice

Constitutional Economics, as distinct from the complementary research programme on political constitutions that are within the boundaries of law, political science, sociology and other disciplines, goes beyond the logical presuppositions of individualism to incorporate nontautological models of individual utility maximization. *Homo economicus* takes a central role in comparative institutional inquiry. Individuals are assumed to seek their own interests, which are defined so as to retain operational content.

Two quite different arguments can be made in support of this postulate in Constitutional Economics. The first is based simply on methodological consistency. To the extent that individuals are modelled as utility maximizers as they participate in market relationships, there would seem to be no basis for postulating a shift in motivation as they behave within non-market constraints. There is at least a strong presumption that individuals do not undergo character transformation when they shift from roles as buyers or sellers in the market-place to roles as voters, taxpayers, beneficiaries, politicians, or bureaucrats in the political process. A more sophisticated reason for postulating consistency in behaviour lies in the usefulness of the model for the whole exercise of institutional comparison. If the purpose is to compare the effects of alternative sets of constraints, some presumption of behavioural consistency over the alternatives is necessary in order to identify those differences in results that are attributable to the differences in constraints.

A second argument for introducing *homo economicus* in Constitutional Economics is both more complex and more important. It is also the source of confusion because it is necessary to distinguish carefully between the use of *homo economicus* in predictive social science, specifically in positive Public Choice and in neoclassical economics, and in Constitutional Economics. There is an argument for using the construction in the latter, even if there are demonstrated empirical limits on the explanatory power of the model in the former.

The argument is implicit in the work of the classical economists. It was stated as a methodological principle by both David Hume and J.S. Mill:

> In constraining any system of government, and fixing the several checks and controls of the constitution, each man ought to be supposed a knave, and to have no other end, in all his actions, than private interest. (Hume [1741], 1963, pp. 117–18)
>
> The very principle of constitutional government requires it to be assumed that political power will be abused to promote the particular purposes of the holder; not because it is always so, but because such is the natural tendency of things, to guard against which is the special use of free institutions. (Mill [1861], 1977, p. 505)

The ultimate purpose of analysing alternative sets of rules is to inform the choice among these sets. The predicted operating properties of each alternative must be examined, and these properties will reflect the embodied models of individual behaviour within the defined constraints. Behavioural departures from the presumptive models used in deriving the operating properties will, of course, be expected. But the costs of errors may not be symmetrically distributed around the single best predictive model. The predicted differential loss from behavioural departures from a model that involves 'optimistic' motivational assumptions may be much larger than the predicted differential gain if the model is shown to be an accurate predictor. Hence, comparative evaluation of an institution based on an altruistic model of behaviour should take into account the possible non-linearity in the loss function that describes departures from the best estimates. (In legal practice, formal contracts include protections against worst-case behaviour patterns.) In constitutional choice, therefore, there is an argument for incorporating models of individual behaviour that presume more narrowly defined self-interest than any empirical record may warrant (Brennan and Buchanan 1985).

Applications

Applications of Constitutional Economics, as a research programme, have emerged in several settings. First, consider taxation. Post-Marshallian economic theory, either in its partial or general equilibrium model, was often applied to tax incidence. Analysis was directed toward predicting the effects of an exogenously imposed tax on the private economizing behaviour of persons in their varying capacities as demanders and suppliers of goods and services in the market-place. Building on this base of positive analysis, normative welfare economics allows a ranking among alternative equi-revenue tax instruments in terms of the Paretian standard. In both the positive and normative aspects, neoclassical tax theory embodies the presumption that taxes, as such, are exogenous to the choice process.

The major contribution of modern Public Choice, as a subdiscipline in its own right, has been that of endogenizing political decision-making. In its direct emphasis, public choice theory examines the political decision rules that exist with a view toward making some predictions about just what sort of tax institutions or tax instruments will emerge. Constitutional Economics, as an extended research programme that emerges from Public Choice, goes a step further and uses the inputs from both neoclassical economics and public choice theory to analyse how alternative political rules might generate differing tax rules.

The relevant constitutional choice may be that of granting government authority to levy taxes on Tax Base A or Tax Base B. Suppose that under the neoclassical equi-revenue assumption, analysis demonstrates that the taxing of A generates a lower excess burden than the taxing of B. Analysis of the political choice process may

demonstrate, however, that government, if given the authority to tax A, will tend to levy a tax that will generate *more* revenue than would be forthcoming under an authority to tax B. The equi-revenue alternatives may not be effective political alternatives under any plausibly acceptable modelling of the behaviour of political agents. Once this simple point is recognized, the normative significance of the neoclassical ranking of tax instruments is reduced. Discussion shifts necessarily to the level of interaction between political decision structures and fiscal institutions.

A second application of Constitutional Economics is found in the post-Keynesian discussion of budgetary policy. The Keynesian advocacy of the use of governmental budgets to accomplish macroeconomic objectives was based on a neglect of the political decision structure. The proclivity of democratic governments to prefer spending over taxing, and hence to bias budgets toward deficit, is readily explained in elementary public choice theory (Buchanan and Wagner 1977). This essential step in public choice reasoning leads naturally to inquiry into the relationships between the constraints that may be placed on political choice and predicted patterns of budgetary outcomes. Out of this intensely practical, and important, application of Constitutional Economics emerged the intellectual bases for the normative argument that, in the post-Keynesian era when moral constraints on political agents have lost much of their previous effectiveness, formal rules limiting deficit financing may be required to insure responsible fiscal decisions. In the modern setting, such rules would limit spending rates. But it is perhaps worth noting that, in the political environment of Sweden in the 1890s, Wicksell advanced analytically similar proposals for reform in the expectation that, if the suggested reforms should be implemented, public sector outlay would increase.

The analysis of alternative rules for 'the transfer constitution' represents a third application of constitutional economics. With the 1971 publication of John Rawls's *A Theory of Justice*, renewed attention came to be placed on principles of distributive justice. Although explicitly pre-constitutional, Rawls's work has a close relationship with the efforts to derive criteria for political and economic rules of social interaction. Economists, as well as other social scientists and social philosophers, have come increasingly to recognize that the untrammelled interplay of interest-group politics is unlikely to further objectives for distributive justice. Analysis of how this politics operates in the making of fiscal transfers suggests that principled adjustments in the post-tax, post-transfer distribution of values is only likely to be achieved if the institutional rules severely restrict the profitability of investment in attempts to subvert the transfer process.

Further applications include the regulatory constitutions, along with the organization of public enterprises. In its inclusive definition, Constitutional Economics becomes the analytical route through which institutional relevance is reintroduced into a sometimes sterile social science. In its less inclusive definition, Constitutional Economics, along with its related and complementary research programmes, restores 'political' to 'economy', thereby bringing a coherence that was absent during the long hiatus during which 'economics' made putative claims to independent status.

Constitutions, Economic Approach to

Dennis C. Mueller

Abstract

The economic approach to constitutions applies the methodology of economics to the study of constitutions. This entry reviews the normative literature on constitutions, which assumes a two-stage collective decision process, and the positive literature that examines the decisions made by constitutional conventions and their economic consequences.

Keywords

The economic approach to constitutions applies the methodology of economics to the study of constitutions, just as public choice applies this methodology to the full range of topics of political science.

The economic approach to constitutions began with *The Calculus of Consent* by James Buchanan and Gordon Tullock (1962, hereafter B&T). Theirs was largely a *normative* analysis of what ought to go into a constitution. Their main findings and the literature that grew out of their work are reviewed first, after which the *positive* stream of the literature is discussed.

Normative Research on Constitutions

Arguably the most important contribution of *The Calculus* was to view democracy as a two-stage process. In stage one, institutions to make future collective decisions are placed into the constitution. In stage two, collective decisions are made using these rules. The long-run nature of the choices at the first stage creates considerable uncertainty about the consequences of different voting rules. This uncertainty makes unanimous agreement on the rules of the political game likely, even though individuals would disagree in stage two about the outcomes of the game. This unanimity at the constitutional stage provides the normative underpinning for the constitution (B&T, p. 7). Harsanyi (1955) also used uncertainty over future positions to produce unanimity and to provide a normative argument for a Benthamite social welfare function (SWF), as did Rawls (1971) in his ethical theory of a social contract. Mueller (1973) discussed conditions

under which a B&T constitution maximizes a Harsanyian SWF.

Another innovation in *The Calculus* was to introduce the *external costs of collective decisions* (B&T, pp. 63–8). When a collective choice is made without the consent of all members of the community, the decision can make some members worse-off. The votes of those favouring the decision thus impose a negative externality on those opposing it. The smaller the majority required to pass an issue, the more likely it is that an individual is on the losing side. However, the amount of time required to make a collective decision is also likely to increase with the required majority. The optimal majority minimizes the sum of collective decisions' external and decision-making costs.

There is nothing in B&T's costs-minimization-approach that implies that the optimal majority is likely to be a simple majority, and thus their approach does not account for this rule's ubiquitous use. The approach does imply the widespread use of the simple majority rule, if one of the two cost curves – most plausibly decision-making costs – has a sharp discontinuity at 50% (Mueller 2003, pp. 76–8).

Rae (1969) used the two-stage approach to provide a completely different normative justification for the simple majority rule. At the constitutional stage, each individual is uncertain of whether he will favour x or $\sim x$ in future votes on these binary issues. The expected gain if an individual favours x and x wins equals the expected loss if x wins and the individual favours $\sim x$. Rae further assumed that the probability of favouring x equals the probability of favouring $\sim x$. An egoist chooses the voting rule that minimizes the probability that she favours x in the future and $\sim x$ is imposed, or that she favours $\sim x$ and x is imposed. The simple majority is the only rule satisfying this condition. (For additional discussion and references see, Rae and Schickler 1997.)

Mueller (2001) generalized the two-stage approach to show that the optimal majority for binary choices depends on the relative payoffs from the two issues. (Riley 2001, presents a game theoretic analysis of a two-stage constitutional process.) As the loss to those favouring x rises relative to the gain to those favouring $\sim x$, higher required majorities become optimal to implement $\sim x$, with unanimity being optimal when the asymmetry in payoffs is very large. Mueller (1991, 1996, ch. 14) employed this analysis to explain why placing rights to act into a constitution would maximize the expected utilities of those writing it.

C

Positive Research on Constitutions

The positive literature of constitutions falls into two categories: studies of constitutional conventions and of the consequences of constitutions. The second category is obviously very large, and so I provide only the flavour of this type of work.

Charles Beard's work (1913) might well be regarded as the first *economic* analysis of the Philadelphia Convention. Beard stressed the self-interest of the participants, and claimed that the final product reflected the interests of the landowning aristocracy. In an equally cynical analysis, Landes and Posner (1975, p. 893) claimed that the First Amendment was a result of pressure from 'publishers, journalists, pamphleteers, and others who derive pecuniary and nonpecuniary income from publication and advocacy of various sorts'. Case studies of constitutional conventions confirm the importance of the self-interest of the participants in determining the constitution's content. For example, representatives from small parties favour rules that produce proportional representation and low percentage thresholds for taking seats in the parliament. Representatives from large parties favour the reverse. If delegates are selected geographically, the constitution protects geographic interests. (For further discussion and references to the literature, see Elster 1991, and Mueller 1996, ch. 21). Econometric analyses confirm these findings. McGuire and Ohlsfeldt (1986) and McGuire (1988) concluded that the votes of delegates to the Philadelphia convention reflected both their personal interests and those of their constituencies. Eavey and Miller (1989) reached the same conclusion from the voting patterns of those who ratified the Pennsylvania and Maryland constitutions.

A key decision facing any constitutional convention is whether to design institutions that will

produce a two-party system or a multiparty system. In practice, this choice appears to rest upon the number of representatives elected from each electoral district (Taagepera and Shugart 1989; Lijphart 1990; Mueller 1996, chs. 8–10). Recent theoretical and empirical work by Persson and Tabellini (1999, 2000, 2003, 2004a, b) and Persson et al. (2000) demonstrates the economic importance of this choice. They find more rent seeking, more corruption, more redistribution and larger deficits in multiparty systems. Presidential systems lead to smaller governmental sectors because they generally contain stronger checks and balances than parliamentary systems. (For a review and references to other contributions, see Persson and Tabellini 2004a.)

Conclusions

There are two kinds of people in the world: those who believe that constitutions matter and those who do not. The contributors to the literature reviewed here fall into the former category. Their work helps illustrate *why and in what way* constitutions matter, and further illustrates the fruitfulness of undertaking an economic approach to the study of constitutions.

Consumer Durables

John Muellbauer

Applied work on the demand for durable goods has usually analysed two kinds of data. The first is time-series data on purchases, aggregated over consumers and typically with different kinds of durables aggregated into one or two groups. The second is cross-section data on the ownership of different kinds of durables. There has been a corresponding specialization in economic theory with that appropriate to the first type of data neglecting the issues of discreteness of ownership emphasized in the second and instead focusing on the dynamics of investment, expectations and adjustment costs, these being neglected in the theory of discrete choice at the level of individual households. The discussion below is in this tradition. In the first part, the focus is on the dynamics of purchases and in the second on the microeconomics of discrete choice.

A good which is durable yields a flow of services into the future. Whether other issues arise, the analysis of the demand for durables must take into account the distinction between stocks of goods and flows of services and the intertemporal character of the decision to purchase or own a durable good. The simplest coherent model which captures these two essential features was first exposited by Cramer (1957) though somewhat analogous analyses of the demand for investment goods had been in the literature for some time (Fisher 1930).

The assumptions made in this model are the following. Consumers maximize utility through time. They can lend and borrow at the same interest rate. They can instantly buy or sell a durable good at the same price. There are no psychic adjustment costs or habits associated with purchasing or owning a durable good. The service flow from owning a durable is proportional to the stock. Deterioration of the service flow through time is geometric. New vintages of durables are exactly the same as the old, when converted into efficiency units. Durable goods are perfectly divisible and no discreteness issues arise: thus they need not be owned in integer amounts and the question of scrapping never arises though durables can be traded on the second-hand market. Stating the assumptions this baldly when it is plain how counter-factual many of them are serves to anticipate some of the discussion below.

On these 'neoclassical' assumptions, the consumer maximizes

$$u_t = V\left(q_t, S_t, q_{t+1}, S_{t+1}, \ldots, q_T, S_T, A_T\right) \qquad (1)$$

subject to a sequence of period to period budget constraints of the form, for example, at t,

$$A_t = A_{t+1}(1 + r_t) + y_t - q_t - \left(P_t^D / P_t\right)(S_t - (1 - \delta)S_{t-1}) \qquad (2)$$

where q is the flow of non-durable consumption, S is the stock of durables and A is the stock of real financial assets defined as the nominal stock deflated by the price index for non-durable goods. Its presence in (1) reflects the bequest motive. The budget constraint (2) which looks slightly formidable just expresses the fact that the change in financial assets equals financial saving, i.e. income minus expenditure. The change in real financial assets is $A_t - A_{t-1}$ and income is $r_t A_{t-1} + yt$, where r is the real rate of return and y is real non-property income. Note that the real rate of return includes any capital gains or losses so that property income $r_t A_{t-1}$ is an economist's rather than a national income accountant's measure. Expenditure in real terms, i.e. in terms of the flow of non-durable consumption, consists of q_t and money expenditure on durables deflated by the price index for non-durables p_t. Money expenditure on durables is $p_t^D[s_t - (1 - \delta)s_{t-1}]$, where p^D is the price index for durables and where the stock of durables $S_t = q_t^D + (1 - \delta)s_{t-1}$ where q_t^D is the flow of purchases and δ is the rate of deterioration of durables so that $(1 - \delta)S_{t-1}$ is the amount of durables owned at $t - 1$ that survives into period t. The generalization of (1) and (2) when q and S are vectors is easy.

It is conventional in intertemporal consumer theory under point expectations to convert the

period to period budget constraints into the present value form by eliminating financial assets from the sequence of constraints (2) for t, t+1, $t + 2$, ... Life-cycle wealth is defined as the value of initial durables plus financial assets plus human wealth (the present value of current and expected non-property income):

$$W_t \equiv p_t^D/p_t(1-\delta)S_{t-1} + A_{t-1}(1+r_t) + \sum_{j=t}^{T} \rho_j y_j. \tag{3}$$

where the real discount factor ρ_j is defined by

$$\rho_j = \prod_{i=t+1}^{j} (1+r_i)^{-1}, \quad t+1 \leqq j \leqq T$$
$$\rho_j = 1. \tag{4}$$

The budget constraint for the decision variables q_t , S_t , q_{t+1} , S_{t+1} etc. correspondingly is:

$$W_t = \sum_{j=1}^{T} \rho_j q_j + (p_t^D/p_t)S_t + \sum_{j=t+1}^{T} \rho_j (p_t^D/p_j)\left[S_j - (1-\delta)S_{j-1}\right]. \tag{5}$$

The effective relative price associated with S_t can then be written in the 'user cost' form

$$\begin{aligned} \Pi_t &= (p_t^D/p_t) \\ &\times \left\{1 - (1-\delta)\left[1 + \frac{\Delta(p_{t+1}^D/p_{t+1})}{p_{t+1}^D/p_{t+1}}\right]/1 + r_{t+1}\right\} \\ &\times \approx p_t^D/p_t[\delta - \Delta \ln](p_{t+1}^D/p_{t+1}) \\ &+ r_{t+1} \end{aligned} \tag{6}$$

which is the approximation familiar from Jorgenson's (1963) neoclassical theory of investment. Thus (5) becomes

$$W_t = \sum_{j=t}^{T} \rho_j q_j + \sum_{j=t}^{T} \rho_j \Pi_j S_j. \tag{7}$$

Maximizing (1) subject to (7) gives demand functions

$$\begin{aligned} q_t &= g(\rho, \rho\Pi, W_t) \\ S_t &= g^D(\rho, \rho\Pi, W_t). \end{aligned} \tag{8}$$

where ρ , $p\prod$ are the vectors (ρ_j) , $(\rho_j \prod_j)$ which appear in (7). In the above, ρ_j, $\prod_j$, y_j for $j > t$ are, of course, forecasts made at t of the respective real interest rates, relative user costs of durables and real non-property incomes prevailing in the future. In empirical work, as well as choosing tractable restrictions on preferences and so for (8), some assumptions need to be made about how consumers make these forecasts.

Considering the forecasts necessary to construct the relative user cost of durables $\prod_t$ immediately raises a potential problem. In recent experience, the variability in *ex post* $\prod_t$ has been tremendous. In the 1970s in most Western economies, the *ex post* real rate of interest r_{t+1} was frequently negative and, particularly when accompanied by relative price declines in durable goods, it is quite likely that *ex post* the user cost $\prod_t$ was sometimes negative. It is true that there are expectations mechanisms such as the adaptive one which, combined with a low adjustment parameter, might have made the *ex ante* user cost less variable than the *ex post* and perhaps prevented it from becoming negative. However, in practice, even fairly crude extrapolations of past experience would have led to a highly variable series for the relative user cost $\prod_t$, much more so than is plausibly consistent with the relative smooth behaviour of purchases of durables if (8) were the true model. In Muellbauer (1981), I tested a model based on (8) for British quarterly data. The evidence strongly rejects such a model both because of the failure of crossequation restrictions and because of the obvious statistical misspecification of the durables equation.

It seems that one needs a theory which gives rise to much more sluggishness or 'persistence' in purchases of durables. The standard way of building in such persistence is to posit adjustment costs for durables. There has been much work over the years (see Stone and Rowe 1957; Chow 1957; and Nerlove 1957), on the stock adjustment model which is an *ad hoc* way of building in sluggish adjustment. Weissenberger (1984) has estimated a model for quarterly British data on non-durable

and durable demands based on a quadratic utility function with quadratic adjustment costs and rational expectations. Apart from the coefficients on financial assets he finds a reasonable degree of coherence between the two equations and the durables equation fits well and its residuals are well behaved. Muellbauer and Pashardes (1982, revised 1987) build persistence effects into zpreferences in a rather more general way though, in the context of a quadratic utility function, the effect is similar to Weissen-berger's. Since their empirical results on annual British data for a system of nine demand functions, one of which is for durables, are rather satisfactory, it is worth examining the approach.

They assume that the utility function is intertemporally separable in *transformed* quantities z_{ij}:

$$u_t = V\left[v_t(z_{1t},\ldots,z_{nt}),\ldots,v_T(z_{1T},\ldots,z_{nT}),A_T\right]. \quad (9)$$

where

$$\begin{aligned} z_{ij} &= \left(S_{ij} - a_i S_{ij-1}\right)(\delta_i/1-a_i) \\ &= \left[q_{ij} + (1-\delta_i-a_i)S_{ij-1}\right](\delta_i/1-a_i). \end{aligned} \quad (10)$$

and where the stock $S_{ij} = q_{ij} + (1-\delta_i)q_{ij-1} + (1-\delta_t)^2 q_{ij-2} + \cdots$. In a steady state $S_i = q_i/\delta_i$ and so $z_i = q_i$ In the case of a non-durable good (for which $\delta_i = 1$),

$$z_{ij} = \frac{q_{ij} - a_i q_{ij-1}}{1-a_i}.$$

The parameter a_i can be thought of as a 'habit' or 'persistence' parameter when $0 < a_i < 1$. With diminishing marginal utility, the more the consumer consumed of good i last period the greater is his or her marginality utility and so 'need' for the good this period. When $a_i < 0$, it can be interpreted as a shortlived durability parameter since, with $\delta_i = 1$, a purchase last period but not earlier gives utility this period.

It was Spinnewyn (1979, 1981) who first extended the user cost concept of price of a durable good to more general transformed quantities of the type defined in (10) above. As long as these are linear functions of $(q_{ij}, q_{ij-1}, q_{ij-2}, \ldots)$ a user cost price p_{ij}^{υ} can be defined. Then, since the intertemporally separable form of the utility function permits two-stage budgeting (see Gorman, on SEPARABILITY below), there exist demand functions

$$z_{it} = g_i\left(p_t^{\upsilon}, x_t^{\upsilon}\right) \quad (11)$$

Where

$$x_t^{\upsilon} \equiv \sum_{i=1}^{a} p_{it}^{\upsilon} z_{it}.$$

From (10), purchases of good i

$$q_{it} = [a_i - (1-\delta_i)]S_{it-1} + \frac{1-a_i}{\delta_i} z_{it}. \quad (12)$$

This can also be written in the form

$$\begin{aligned} \Delta q_{it} = \frac{1-a_i}{\delta_i}\Delta z_{it} \\ + (1-a_i)(z_{it-1} - q_{it-1}). \end{aligned} \quad (13)$$

This elegantly expresses an extended kind of partial adjustment model termed an 'error correction model' by Hendry. Changes in q respond to changes in z but with a stabilizing feedback to last period's deviation between q and z. The lower is durability, i.e. the higher is δ_i and the higher is a_i, slower is the speed of adjustment. This makes it clear that in the absence of persistence effects, one should expect greater volatility of purchases for durables than for non-durables. In the empirical results reported for annual British data by Muellbauer and Pashardes, there are strong persistence effects both for durables and for non-durables though generally a little larger for durables. Thus the volatility of purchases for durables is higher than for non-durables but much lower than it would be for a zero persistence parameter a_i.

Equation (13) can be estimated in two ways. The one adopted by Muellbauer and Pashardes uses the identity

$$x_t^v \equiv \sum_{i=1}^{n} p_{it} z_{it}.$$

Potentially it suffers from the possible correlation between a disturbance term added to (13) and the z_{it}'s embodied in the budget x_t^v The alternative is to solve the intertemporal optimization problem to give a solution for x_t^v as a function of life-cycle wealth and price and rate of return expectations. Under this alternative some assumptions, as in the study of the life-cycle consumption function, need to be made to model expectations empirically and the results are likely to be sensitive to which assumptions are made.

Models of this type give good results for aggregate time series data, at least relative to formulations that ignore persistence or durability. But one may well wonder about the source of persistence to which the above analysis gives simple expression. In many ways the most plausible explanation is the gap between buying and selling prices of durables due to installation costs, transactions costs or to information asymmetries. According to Akerlof's (1970) 'lemon effect' the potential buyer of a used durable fears that the reason the owner wishes to sell is that the durable is a lemon. Since there may be no way that the seller can convince the buyer that it is not, a car that is only a few weeks old and has suffered no physical deterioration is likely to be saleable only at a price substantially below the showroom price. Thus even if a consumer expects substantial capital gains on a durable, there is little incentive to buy in order to sell at a profit. The most that can then be expected is some advancement of purchases that are likely to have been made soon anyway.

At the individual level, such a gap between buying and selling prices makes corner solutions likely (see Deaton and Muellbauer (1980), pp. 360–64 for a discussion). It is then very difficult to derive tractable econometric models that reflect the theory at all precisely. One might take something like (13) as a starting point and try to build in additional elements such as the asymmetric response that larger restrictions on selling than on buying suggest. For specific durables such as automobiles where most buyers of new cars trade in a used one, the differential of new and used car prices could be added to (13) as an extra, somewhat *ad hoc* explanatory variable.

There are alternative ways of modelling the effects of prices of complementary goods such as the gasoline needed to run a car. One way is just to include this price in the vector of prices p_t^v as long as the form of preferences embodied in $g_i()$ is quite general, e.g. a flexible functional form (Diewert 1971). But imposing rather more structure often yields rewards. If it is car services that appear in the utility function and the cost of these consists both of a user cost or rental equivalent and a running cost that depends on the fuel efficiency of the car, price effects are likely to be modelled more accurately. This kind of approach also suggests vintage effects that could be observable even on aggregate data. In response to the fuel price increases in the 1970s manufacturers eventually brought models to the market which were much more fuel efficient than previous vintages. The effective price differential between new models and the existing stock is likely to be an important element in the replacement decision. As the fuel efficiency gap between the existing stock and new models narrows, *ceteris paribus*, one would expect replacement demand to fall off. Similar vintage effects can arise through other quality improvements in new durables. The only way quality improvements could show up in the simple model leading to (13) is through falls in the quality adjusted price p^D.

Among the advantages of the assumption that new and used durables, when converted into efficiency units, are perfect substitutes is that it simplifies the analysis of the interaction of supply and demand. Total market supply of stock is the sum of the surviving stock $(1 - \delta_i)S_{it-1}$, which is given, plus new supply, which if firms are competitive is a function of current and expected values of p_i^D and costs of production. Aggregate demand for stock given (11) can be written in the form

$$S_{it} = a_i S_{it-1} + \frac{1 - a_i}{\delta_i} g_i\left(p_t^v, x_t^v\right).$$

If prices clear the market, equating supply and demand determines p_{it}^D which is thus endogenous

and ought to be treated as such in econometric work. In practice, however, new and used durables may not be perfect substitutes, new prices may be set by oligopolistic producers and the second-hand market, despite its imperfections, may be more demand responsive in its prices. Nevertheless, the above model is a bench-mark that raises issues which applied economists working on the demand for durables need to face.

The other source of data on the demand for the durables is household surveys. In such cross-sections, the discreteness of ownership must be explicitly recognized. The classic paper by Farrell (1954) was one of the first to analyse the threshold effects which govern ownership. The modern economic treatment in its simplest form can be explained as follows. Let P^D be the rental price of a durable good and the budget constraint be

$$pq + p^D S = x \tag{14}$$

Suppose $S = 1$ if the durable is owned and $S = 0$ if not. Let the single period utility function be

$$u = v(q, S, b, \in)$$

where b is a vector of observable household characteristics and ε summarizes unobservable ones in a scalar. If $S = 0$, we can solve for $q = x/p$ from the budget constraint and if $S = 1$, $q = (x - P^D)/P$. Thus the durable is owned if the utility from owning $v[(x - p^D)/p,\ 1,\ b,\ \in]$ exceeds that from not owning $v[x/p,\ 0,\ b,\ \in]$. These solved out utility functions are termed 'indirect utility functions'. This ownership criterion is still valid if, in fact, durables of this type vary in size, performance, luxuriousness or other characteristics that can be summarized in a quality index. $S = 1$ then refers to the minimum quality available while $S > 1$ for higher qualities. Maximizing (15) subject to (14) then gives conventional demand functions, given $S \geqq 1$, $q = g(x, p, p^D; b,\ \in)$, $S = g^D(x, p, p^D; b,\ \in)$ and the durable is owned if

$$g^D\left(x, p, p^D; b, \in\right) \geq 1. \tag{16}$$

Here p^D is a quality corrected price index, which in a single cross-section, like p, is usually assumed to be the same for all consumers. Equation (16) suggests the use of Probit or Logit analysis to examine ownership variations on micro-data (see McFadden 1973, McFadden 1981). Given information on rental expenditure defined as $p^D S = p^D g^D(x, p, p^D; b,\ \in)$ if $g^D(\ ) \geq 1$, Tobit analysis is the appropriate technique (see Tobin 1958).

Equation (16) also has implications for 'quasi'-Engel curves which link ownership in an income bracket to the income level. Suppose that (16) holds if $\in < \theta(x, p, p^D, b)$. Then the proportion of households with budget x and characteristics b owning the durable is

$$\int_{-\infty}^{\theta} f(x, b, \in)\mathrm{d}\in \Big/ \int_{-\infty}^{\infty} f(x, b, \in)\mathrm{d}\in \tag{17}$$

where $f(\ )$ is the joint probability density of x, b and ε. Provided the budget x can be plausibly linked to observable income, this provides a justification for the 'quasi'-Engel curves estimated, for example, by Aitchison and Brown (1957), Cramer (1962), Pyatt (1964), and Bonüs (1973). These studies have not always, however, given as much attention to the household characteristics b as they might have done. If b and ε were independently distributed of x and θ monotonic in x, then there must be a sigmoid relationship between the level of x and the proportion owning the durable given the sigmoid shape of the cumulative distribution function for x. In practice, though there is quite a high correlation between such household characteristics as size and income, empirical 'quasi'-Engel curves are usually sigmoid in shape. In aggregate, as average income rises over time there is also a sigmoid relationship between the average income level and the aggregate proportion owning a durable. As Deaton and Muellbauer (1980, pp. 370–1) note, this sigmoid shape could be partly due to the sigmoid shape of the cumulative distribution function of income and partly due to other causes of diffusion such as epidemic models of the spread of a disease which may be appropriate when new goods such as television are introduced.

For simplicity the discussion above has taken the case of a single type of durable. But as

McFadden (1981) and Dubin and McFadden (1984) demonstrate, the generalization to a portfolio of different kinds of durables still results in tractable models which can be estimated by maximum likelihood techniques. All these models of ownership, however, need to be given a long-run interpretation which abstracts from transactions costs and imperfections in second-hand markets. The latter may cause specific households to have ownership patterns that differ from those they would have in a steady state. In cross-sections, information on past decisions and past income is usually missing, so that the kind of dynamic elements discussed in the earlier part of this entry cannot be analysed empirically.

Consumer Expenditure

Angus Deaton

Abstract

Consumers' expenditure is a central concern of economics, both in microeconomic terms (the relationship between prices, expenditure and welfare) and in macroeconomic terms (the relationship between expenditure and income).

This article examines the interplay between theory and evidence in the study of consumers' expenditure and its composition. Although models have been developed from the theory of consumption that illuminate much of the available data, many standard presumptions of economics lack substantial bodies of evidence such as central theories in the natural sciences enjoy.

The study of consumers' expenditure, both in total and in composition, has always been of major concern to economists. Neoclassical economics sees the delivery of individual consumption as the main object of the economic system, so that the efficiency with which the economy achieves this goal is the criterion by which alternative systems, institutions and policies are to be judged. Within a capitalist economy, such considerations lead to an examination of the relationship between *prices* and consumption behaviour, and theoretical development and empirical analysis have been a major continuous activity since the middle of the last century. Even older is the tradition of using individual household budgets to dramatize poverty, and the relationship between household incomes and household expenditure patterns has occupied social reformers, statisticians and econometricians since at least the 18th century. In more modern times, it has been recognized that the study of public finance and of taxation depends on a knowledge of how price changes affect the welfare and behaviour of individuals, and the recent development of optimal tax theory and of tax reform analysis has placed additional demands on our understanding of the links between prices, expenditures and welfare.

In the last fifty years, aggregate consumption has become as much of an object of attention as has its composition, and in spite of a common theoretical structure, there has been a considerable division of labour between macro economists, interested in aggregate consumption and saving, and micro economists whose main concern has been with composition, and with the study of the effects of relative prices on demand. The interest of macroeconomics reflects both long-term and short-term interests. What is not consumed is saved, saving is thrift and the basis for capital formation, so that the determinants of saving are the determinants of future growth and prosperity. More immediately, aggregate consumption accounts for a large share of national income, typically more than three-quarters, so that fluctuations in behaviour or 'consumption shocks' have important consequences for output, employment, and the business cycle. Since Keynes's *General Theory,* the consumption function, the relationship between consumption and income, has played a central role in the study of the macroeconomy. Since the 1930s, there has been a continuous flow of theoretical and empirical developments in consumption function research,

and some of the outstanding scientific achievements in economics have been in this field.

In this essay, the major themes will be the interplay between theory and evidence in the study of consumers' expenditure and its composition. If economists have any serious claim to being scientists, it should be clearly visible here. The best minds in the profession have worked on the theory of consumption and on its empirical implementation, and there have always been more data available than could possibly be examined. I hope to show that there have been some stunning successes, where elegant models have yielded far from obvious predictions that have been well vindicated by the evidence. But there is much that remains to be done, and much that needs to be put right. Many of the standard presumptions of economics remain just that, assumptions unsupported by evidence, and while modern price theory is logically consistent and theoretically well developed, it is far from having that solid body of empirical support and proven usefulness that characterizes similar central theories in the natural sciences.

A Simple Theoretical Framework

Almost all discussions of consumer behaviour begin with a theory of *individual* behaviour. I follow neoclassical tradition by supposing that such behaviour can be described by the maximization of a utility function subject to suitable constraints. The axioms that justify utility maximization are mild, see any microeconomic text such as Varian (1978/1984) or Deaton and Muellbauer (1980b), so that utility maximization should be seen as no more than a convenient framework that rules out the grossest kind of behavioural inconsistencies. The assumptions that have real force are those that detail the constraints facing individuals or else put specific structure on utility functions. Perhaps the most general specification of preferences that could be considered is one that is written

$$u_t = E_t\{f(q_1, q_2, \ldots, q_t, \ldots, q_T)\} \qquad (1)$$

where u_t is utility at time t, E_t is the expectation operator for expectations formed at time t, q_1 to q_T are vectors of consumption in periods 1 to T, and $f(\cdot)$ is a quasi-concave function that is non-decreasing in each of its arguments. Several things about this formulation are worth brief discussion. The function $f(\cdot)$ yields the utility that would be obtained from the consumption vector under certainty, and it represents the utility from a *life-time* of consumption; the indices 1 to T therefore represent *age* with 1 the date of birth and T that of death. The expectation operator is required because choice is made subject to uncertainty, not about the choices themselves, which are under the consumer's control, but about the consequences of current choices for future opportunities. It is not possible to travel backward through time, so that choices once made cannot be undone, and yet the cost of current consumption in terms of future consumption foregone is uncertain, as is the amount of resources that may become available at future dates. The consumer must therefore travel through life, filling in the slots in (1) from left to right as best as he or she can, and at time (or age) t, everything to the left will be fixed and unchangeable, whether now seen to be optimal or not, while everything ahead of t is subject to the random buffeting of unexpected changes in interest rates, prices, and incomes. The solution to this sort of maximization problem has been elegantly characterized by Epstein (1975); here I shall work with something that is more restrictive but more useful and note in section "Recent Econometric Experience" below some phenomena that are better handled by the more general model.

Intertemporal utility functions are frequently assumed to be *intertemporally additive*, so that the preference rankings between consumption bundles in any two periods or ages are taken to be independent of consumption levels in any third period. If so, the utility function (1) takes the more mathematically convenient form

$$u_t = E_t \sum_{r=1}^{T} v_r(q_r). \qquad (2)$$

Note that by writing utility in the form (2), since the expectation operator is additive over states of the world preferences are in effect assumed to be

simultaneously additive over both states and periods, an assumption that can be formally defended, see Gorman (1982) and Browning et al. (1985). It has the consequence that risk aversion and intertemporal substitutability become two aspects of the same phenomenon. Individuals that dislike risk, and will pay to avoid it, will also attempt to smooth their consumption over time and will require large incentives to alter their preferred consumption and saving profiles. Note also that the additive structure of (2) means that, unlike the case of (1), previous decisions are irrelevant for current ones. For decision-making at time t, bygones are bygones, and conditional on asset and income positions, future choices are unaffected by what has happened in the past. There can therefore be no attempt to make up for lost opportunities, nor can such phenomena as habit formation be easily modelled.

Because utility in (2) is intertemporally separable, maximization of life-time utility implies that, within each period, the period subutility function $v_t(\cdot)$ must be maximized subject to whatever total it is optimal to spend in that period. The period by period allocation of consumption expenditure to individual commodities need not, therefore, be planned in advance, but can be left to be determined when that period or age is reached, and period t allocation will follow according to the rule

$$\text{maximize } v_t(q_t) \text{ subject to } p_t \cdot q_t = x_t, \qquad (3)$$

where p_t is the price vector corresponding to q_t and x_t is the total amount to be spent in t. Problem (3) is one of standard (static) utility maximization, though note that x_t is not given to the consumer, but is determined by the wider intertemporal choice problem. Nevertheless, not the least advantage of the intertemporally additive formulation is its implication that the composition of expenditure follows the standard utility maximization rule. It allows separate attention to be given to demand analysis on the one hand, i.e. to the problem (3), and to the consumption function on the other hand, this being understood to be the intertemporal allocation of resources, i.e. the determination of x_t.

Write the maximized value of utility from the period t problem as $\psi_t(x_t, p_t)$, where $\psi(\cdot)$ is a standard indirect utility function. The original intertemporal utility function then takes the form

$$u_t = E_t \sum_{r=0}^{T-t} \psi_r(x_{t+r}, p_{t+r}). \qquad (4)$$

The constraints under which this function is maximized are most conveniently analysed through the conditions governing the evolution of wealth from period to period. If A_t is the (ex-dividend) value of assets at the start of period t, N_{it} is the nominal holdings of asset i with price P_{it}, d_{it} is the dividend on i paid immediately before the beginning of t, and y_t is income in period t, then

$$A_{t+1} = \sum_i N_{it}(P_{it+1} + d_{it+1}) \qquad (5)$$

$$\sum_i N_{it} P_{it} = A_t + y_t - x_t. \qquad (6)$$

Conditions (5) and (6) determine how wealth evolves from period to period, and the picture is completed by requiring that the consumer's terminal assets be positive, i.e.

$$A_{T+1} \geq 0 \qquad (7)$$

To solve this problem, the technique of backward recursion is used. This rests on the observation that it is impossible to know what to do in period t without taking into account the problem in period $(t + 1)$, nor that in $(t + 1)$ without thinking about $(t + 2)$, and so on. However, in period T there is no future, so that looking ahead from date t, we can write subutility in period T in terms of that period's price and inherited assets, and we write this as v_T, i.e.

$$v_T = v_T(A_T) = \psi_T(A_T + y_T, p_t). \qquad (8)$$

Given this, the consumer can look ahead from period t to period $(T - 1)$ and foresee that the problem then will be to choose the composition of assets N so as to maximize v_{T-1}, where

$$v_{t-1}(A_{T-1}) = \max_{N} \left[\!\left[\psi_{T-1}(A_{T-1} + y_{T-1} - N \cdot P_{T-1},\ p_{T-1}) + E_{T-1}\{v_T[N \cdot (P_T + d_T)]\} \right]\!\right]. \tag{9}$$

At the next stage, assets in $(T-2)$ will be allocated so as to trade off the benefits of consumption in $(T-2)$ versus the benefits of A_{T-1} in v_{T-1} in (9) above and again yielding a maximized value v_{T-2}. As we follow this back through time, the consumer finally reaches the current period t, where he or she faces an only slightly complicated version of the usual 'today tomorrow' trade-off; the asset vector N must be chosen to solve the problem,

$$u_t = \max_{N} \psi_t(A_t + y_t - N \cdot P_t, p_t) + E_t\{v_{t+1}[N \cdot (P_{t+1} + d_{t+1})]\}. \tag{10}$$

From this sequence of problems, several important results readily follow. First, consider the derivatives of each of the functions $v_r(A_r)$ which represent the marginal value of an extra unit of currency for the remaining segment of life time utility from r through to T. By the envelope theorem (see for example Dixit (1976) for a good exposition), it is legitimate to differentiate through the maximization problem, from which

$$v_r'(A_r) = \partial\psi_r/\partial x_r = \lambda_r, \text{say}, \tag{11}$$

so that λ_r is the marginal utility of money in period r. Secondly, the maximization of (10) with respect to portfolio choice gives the relationship, for each asset i,

$$P_{it}\partial\psi_t/\partial x_t = E_t\{(P_{it+1} + d_{it+1})\partial\psi_{t+1}/\partial x_{t+1}\} \tag{12}$$

which, defining the asset *return* R_{it+1} as $(P_{it+1} + d_{it+1})/P_{it}$, and using (11) can be rewritten in the simple form

$$\lambda_t = E_t(\lambda_{t+1}R_{it+1}). \tag{13}$$

This equation, in current parlance often referred to as the 'Euler equation', can be used to derive many of the implications of the theory of consumption. Note first that it is little more than the standard result that the marginal rate of substitution between today's and tomorrow's consumption should be equal to the relative price. However, the equation is set in a multiperiod framework, not a two-period one, and it explicitly recognizes the uncertainty in both asset returns and in the value of money in subsequent periods. The equation also holds for all i, i.e. for all assets, so that the result also has implications for asset pricing as well as for consumption and saving, and for this reason the model is often referred to as the consumption-asset pricing model. I shall return to these implications below.

The theory as presented above is the modern equivalent of the life-cycle theory of consumption that dates back to Irving Fisher (1930) and Frank Ramsey (1928), and that had its modern genesis in the papers by Modigliani and Brumberg (1954) and (1954, published 1979). Modigliani and Brumberg's treatment differs from the above only in not explicitly modelling uncertainty, and by including only a single asset. The modern version appears first in Breeden (1979) and in Hall (1978), see also Grossman and Shiller (1981).

Predictions and Evidence

One of the most important implications of the theory above, and of Eq. (13) in particular, is that the evolution of consumption over the life-cycle is independent of the pattern of income over the life-cycle. The asset evolution Eqs. (5) and (6) allow consumers to borrow and lend at will, so that the only ultimate constraint on their consumption is one of life-time solvency. In consequence, consumption patterns are free to follow tastes, the evolution of family structure, or the different needs that come with ageing, provided that in the end total life-time expenditure lies within (total) life-time resources, whether from inherited wealth or from labour income. It is often assumed that tastes are such that consumers prefer to have a relatively smooth consumption stream, and this can be illustrated from a special case of Eq. (13). Assume that the within-period utility function is

homothetic so that $\psi(x, p)$ is $\varphi(x/a(p))$ for some linearly homogeneous function $a(\cdot)$, and that $\varphi(\cdot)$ has the isoelastic from with elasticity $(1 - \sigma)$. Life-time utility takes the form

$$u_t = \sum_{r=0}^{T-t} (1+\delta)^{-r} \left[x_{t+r}/a\left(p_{t+r}\right)\right]^{1-\sigma} \qquad (14)$$

where δ is the rate of pure time preference, and $\sigma \geq 0$ is the coefficient of relative risk aversion and the reciprocal of the intertemporal elasticity of substitution. Equation (14) can be used to evaluate (13), and gives immediately

$$E[\{(1 + r_{t+1})/(1+\delta)\}\{c_t/c_{t+1}\}^{\sigma}] = 1 \qquad (15)$$

where r_{t+1} is the real after tax rate of interest from t to $t + 1$ on any asset, and c_t is real consumption, $x_t/a\,(p_t)$. Equation (15) shows that, if expectations are fulfilled, consumption will grow over the life-cycle if the real rate of interest is greater than the rate of pure time preference, and vice versa, while with $r_t = \delta$, consumption is constant with age. These results are of course an artefact of the specific assumptions about utility, and for any real household consumption can be expected to vary predictably with age according to patterns of family formation, growth, and ageing; Modigliani and Ando (1957) have suggested that consumption per 'equivalent adult' might be constant over the life-cycle. But whatever the shape of preferences, there need be no relationship between the profiles of consumption and of income; income can be saved until it is needed, or borrowed against if it is not yet available.

Independent of the life-time *pattern* of consumption is its level, which under the life-cycle model is determined by the level of total life-time resources, so that individuals with the same tastes but with higher incomes or higher inherited assets will have higher levels of consumption throughout their lives. If the future were entirely predictable, the consumption plan at any point in time could be decided with reference to the level of total wealth, this being the value of financial assets and the discounted present value of current and future incomes. In this sense, the life-cycle model is a permanent income theory of consumption, where permanent income is the annuity value of lifetime wealth, though the lifetime interpretation is only one of the many that are offered in Friedman's (1957) original statement. Whether life-cycle or not, linking consumption to *future* incomes has important consequences. First, consumption will respond only to 'surprises' or 'shocks' in income; changes in income that have been foreseen are already discounted in previous behaviour and should not induce any changes in plans. Of course, this does *not* mean that consumption will not change along with changes in income; a change may have been planned in any case, and some proportion of any actual change may well have been unforeseen. However, if a substantial fraction of the regular changes in income over the business cycle are foreseen by consumers, or if unanticipated fluctuations in income are regarded as only temporary with limited consequences for total life time resources, then consumption will not respond very much to cyclical fluctuations in income. Aggregate consumption is indeed much smoother than is aggregate income, and this has been traditionally accepted as an important piece of confirmatory evidence. I shall take up the matter again below when I deal with the recent econometric evidence.

The distinction between measured income and permanent income is also important for the interpretation of cross-sectional evidence. Since measured income can be regarded as an error-ridden proxy for permanent income, the regression of consumption on measured income will be biased downward (rotated clockwise) compared with the true regression of consumption on permanent income. Crosssectional regressions, or time-series regressions of simple Keynesian consumption functions will therefore tend to understate the long-run marginal propensity to consume. Well before the work on life-cycle models, Kuznets (1946) showed that the long-run saving ratio in the United States had been roughly constant in spite of repeated cross-sectional analyses showing that the saving ratio rose with income, and the life-cycle theory could also readily account for these findings. It is interesting to note that the constancy of the saving ratio is far from being well

C

established as an empirical fact; the evidence for other countries with long-run data is very mixed, and even the United States saving ratio is clearly influenced in the long-run by technical change, migration patterns, and demographic shifts, see Kuznets (1962) and Deaton (1975). Life-cycle and permanent income theories also predict that households with atypically high income will tend to save a great deal of it, a prediction which explained the apparently anomalous finding that black households tend to save more than white households at the same level of measured income; since blacks typically have lower household income than whites, those with the same measured income can be expected to have a higher transitory component.

The Modigliani and Brumberg life-cycle story was also important because it offered a story of capital accumulation in society as a whole that relied on the way in which people made preparation for their own futures, particularly for their future retirement. In a stationary life-cycle economy, in which there is neither economic nor population growth, aggregate saving is zero, and the old, as they dissave, pass on the ownership of the capital stock to the next generation who are, in turn, saving for their own retirement. With either population or income growth, the aggregate scale of saving by the young would be greater than that of dissaving by the old, so that, to a first approximation, the aggregate saving ratio, while in the long run independent of the *level* of national income, would depend on the sum of its population and per capita real income growth rates. Modigliani (1986), in his Nobel address, has given an account of how very simple stylized models of saving and refinement yield quite accurate predictions of the saving ratio and of the ratio of wealth to national income, and the predictions about the growth effects have been repeatedly borne out in international comparisons of saving rates, see Modigliani (1970), Houthakker (1961, 1965), Leff (1969) and Surrey (1974). Perhaps the only problem with these interpretations is that there is little evidence that the old actually dissave, except by running down state social security or pension schemes; see for example Mirer (1979). Partly, this may be a rational response to uncertainty about the date of death and about possible medical expenses near the end of life (Davies 1980), partly there may be statistical problems of measurement (Shorrocks 1975), and partly consumers may wish to leave bequests. However, most countries' tax systems penalize donors who do not pass on assets prior to death, so the reason for the size of actual bequests remains something of a mystery. Bernheim et al. (1985) have gone so far as to suggest that parents retain their wealth until death in order to control their heirs and to solicit attention from them. They claim empirical support for a positive relationship between visits by children to their parents and parents' bequeathable assets; visits are apparently especially frequent to rich sick parents, but not at all frequent to poor sick parents. Related to the dispute about the reason for bequests is a parallel dispute on their importance in the transmission of the capital stock, see the original contribution by Kotlikoff and Summers (1981) and Modigliani's reply, summarized in his (1986) Nobel lecture.

The life-cycle and permanent income models also provided the econometric specifications for a generation of macroeconometric models. Ando and Modigliani (1963) suggested a simple form for the aggregate consumption function in which real aggregate consumption was a linear function of expected real labour income, *YL,* and of the real value of financial assets, i.e.

$$c_t = \alpha E_t(YL) + \delta W_t. \tag{16}$$

In practical econometric work, the expectation was typically replaced by a linear function of current and past values of labour income, a procedure that can be formally justified by modelling labour income as a linear ARIMA process, a topic to which I shall return below. Wealth or a subset of wealth was included as data allowed, although sometimes the return to wealth was included with labour income which could then be replaced by total income, so that, with smoothing, (16) becomes a permanent (total) income model of consumption. A favourite variant, suggested in Friedman (1957), was to model permanent income as an infinite moving average of current income with geometrically declining weights,

$$y_t^p = (1-\lambda)\sum_{r=0}^{\infty}\lambda^r y_{t-r}, \tag{17}$$

so that if current consumption is proportional to permanent income, substitution yields

$$c_t = kc_{t-1} + k(1-\lambda)y_t, \tag{18}$$

a formulation that is also easy to defend if consumers 'partially adjust' to changes in current income. Models like (18), possibly with additional lags, and with the occasional appearance of more or less 'exotic' regressors, such as wealth, interest rates, inflation rates, money supply, as well as various dummy variables for 'problem' observations, were the standard fare of macroeconometric models in their heyday, from the early sixties for about a decade and a half. They fit the data well, they accounted for the smoothness of consumption relative to income, and they accorded at least roughly with the general features of the life-cycle and permanent income formulations which provided them with pedigree and general theoretical legitimacy. Dozens of papers could be cited within this tradition; those by Stone (1964, 1966), Evans (1967), and Davidson et al. (1978) will perhaps stand as good examples.

Recent Econometric Experience

In the mid-1970s, the general state of complacency of macroeconomic modelling was rapidly eroded, largely by the apparent inability of the standard models to explain, let alone to predict, the coexistence of unemployment and inflation. The relationship between consumption and income did not escape some of the blame, although the main focus of attack was elsewhere. Standard consumption functions, which had worked well into the early seventies, seriously under-predicted aggregate saving during the period of (at least relatively) rapid inflation that characterized most Western economies in the middle of the decade. The implementation of the theory of the consumption function was also singled out for discussion in Lucas's famous (1976) essay that became known as the Lucas 'critique'. As Lucas forcefully argued, if consumption is determined by the discounted present value of *expected* future incomes, the response of consumption to a change in income is not well-defined until we know how expectations of income are formed. Each observed realization will cause a re-evaluation of future prospects in accordance with formulae that depend on the nature of the stochastic process governing income. If the nature of the stochastic process is changed, for example by a fundamental change in the tax code, then the way in which information is processed will change, and new information about incomes will have different implications for future expectations and for future consumption. This insight is of great importance, although its implications for econometric modelling were initially taken much too negatively; if the rules keep changing, econometric models will be inherently unstable (as evidenced by their performance in the mid-seventies) and we should give up trying to find stable relationships. Instead, as events have shown, the introduction of rational expectations has given a whole new lease of life to the study of consumption, with developments as positive as anything that has happened since the life-cycle and permanent income models were the 'new' theories in the mid-fifties. Lucas's critique suggested at least two lines for research. First, could the failure of consumption functions, or indeed of macroeconometric models in general, really be traced to a change in the way expectations were formed? If so, it ought to be possible to detect changes in the stochastic process generating real income. Second, and more generally, if expectations are important, there ought to be high returns to the simultaneous modelling of consumption and income, so that knowledge of the structure of the latter can be used either to estimate the consumption function or to test for the validity of the expectations mechanism. My own reading of the evidence is that the Lucas critique is *not* capable of explaining the failure of the empirical consumption function, but that the under-prediction of saving resulted from ignorance of the fact that saving appears to respond positively to inflation, or at least to unanticipated inflation.

C

There is overwhelming evidence from a large number of countries, see in particular Koskela and Viren (1982a, b), that saving increased with inflation in the 1970s, even when we allow for real income and its various lags. Such a finding is also consistent with the life-cycle theory since unanticipated inflation imparts a negative shock to real assets, so that risk-averse, low inter-temporal elasticity consumers will save to replace the lost assets so as to avoid the chance of low consumption later. It is also possible to explain the relationship through the confusion between relative and absolute price changes that is engendered by unanticipated inflation in an environment in which goods are bought sequentially, see Deaton (1977), but it would be hard to devise a test that would separate this from the life-cycle explanation. But if inflation was indeed the cause of the failure of the empirical consumption functions, then it is a standard enough story. An important variable was omitted from the analysis, it had not been very variable in the past so that its omission was hard to detect, and economists had not been imaginative enough to perceive its importance in advance. The Lucas critique is only one of the many problems that can beset an econometric equation, and it does not seem to have been the fatal one in this case.

The second research direction, the joint examination of income and consumption, has proved more productive. The first important step was taken by Hall (1978), who pointed out that Eq. (15) implies that, as an approximation consumption should follow a random walk with drift. To see why, assume that the real interest rate r is constant and known, and write (15) in the form

$$c_{t+1}^{-\sigma} = \{(1+\delta)/(1+r)\}c_t^{-\sigma} + \varepsilon_{t+1} \qquad (19)$$

where the expectation at t of ε_{t+1} is zero. Equation (19) is exact, but a convenient expression can be reached by factoring c_t out of the right hand side, taking logarithms, and approximating. This gives

$$\ln c_{t+1} = \ln c_t + g + v_{t+1} \qquad (20)$$

where g is positive or negative as r is greater than or less than δ, and the 'innovation' v_{t+1}, like ε_{t+}, has expectation zero at time t. Equation (20) shows that, in the absence of 'news', consumption will grow or decline at a steady rate g, so that nothing that is known by the consumer at time t or earlier should have any value for predicting the deviation of the rate of change of consumption from its constant mean. The result is often referred to as the 'random walk' property of consumption, though the theory does not predict that v_{t+1} has constant variance, so that, strictly speaking, the stochastic process is not a random walk.

For someone used to thinking about the consumption function as the relationship between consumption and income, Eq. (2) is notable for the apparent absence of any reference to income. But of course income can appear through the stochastic term v_{t+1} if current income contains new information about its own value or about future values of income, and this will generally be the case. The random walk model does not predict that consumption should not respond to current income. It does however predict that, conditional on lagged consumption, past income or changes in income should not be correlated with the current change in consumption, and a considerable amount of effort has recently gone into testing this proposition. In Hall's (1978) original paper, to the surprise of the author and of much of the profession, the model worked well for an aggregate of United States consumption of nondurables and services. The level of consumption certainly depends on its own lagged value, but the addition of one or more lagged values of income or of further lagged values of consumption did not significantly add to the explanatory power of the model. Hall examined the role of the number of other lagged variables and discovered that lagged stockmarket prices had predictive power for the change in consumption, so that he concluded by formally rejecting the model. However, the overwhelming impression was favourable, at least relative to expectations.

Hall's test procedures are attractive because they do not depend on the properties of the income process, and focus only on consumption and its lags. But robustness comes at the price of power, and later work has devoted considerable attention to the joint properties of consumption and real

income. Perhaps the natural route to modelling is to find a representation of real income as a stochastic process, typically as some sort of ARIMA. Once this is known, changes in income can be decomposed into anticipated and unanticipated components using the standard forecasting formulae from statistical time series analysis, so that it becomes possible to test whether consumption responds to one but not to the other. The random walk model seemed not to survive these tests so well. Papers by Flavin (1981) and by Hayashi (1982) showed that, for United States data, consumption is sensitive to *anticipated* changes in income, something that should not be the case in a thoroughgoing life-cycle model in which consumers are efficiently looking into the future. The phenomenon became known as the 'excess sensitivity' result, and was typically ascribed to the existence of a substantial number of consumers who wish to borrow against future income but are unable to do so. Such liquidity constrained consumers can be expected to consume all their available income, so that their consumption will increase one for one with all income changes, whether anticipated or not.

However, it is not clear that the excess sensitivity finding is itself robust. First, it is becoming increasingly recognized that the problems of econometric testing in the time-series models are more severe than had been generally supposed. The time series of both consumption and income are non-stationary, and it sometimes seems as if hypothesis testing in models involving non-stationary variables is like building on shifting sands; see Mankiw and Shapiro (1985, 1986) and Durlauf and Phillips (1986) for some of the problems. Second, there are a large number of variables other than income which can affect consumption, so that, according to (20), surprises in wealth and in inflation should affect consumption, as should the level of real interest rates. Adding even a few of these variables reduces degrees of freedom and diminishes the probability of being able to reject the basic model. Both Bean (1985) and Blinder and Deaton (1985) find that time-series models of consumption with several variables are more easily reconciled with the theory than are the simple two variable models. Not all of this should be ascribed to lack of degrees of freedom; for example Blinder and Deaton consistently find that unanticipated changes in wealth affect consumption and that anticipated changes do not. Third, even in a bivariate income-consumption model, Campbell (1987) has found that the model is largely consistent with the time-series evidence. Campbell recognizes the possibility of time-series feedback from lagged consumption to income, and models saving and the change in income as a bivariate vector-autoregressive system in which each series is regressed on lagged values of both. The structure of this representation then turns out to be very close to what it would have to be if the life-cycle rational expectations model were correct. The conflict between Campbell's results and the excess sensitivity findings are presumably accounted for by the feedback from saving to changes in labour income, since his model is otherwise compatible with the earlier ones.

Similarly mixed findings are also being uncovered from longitudinal panels that follow individual households over time. In contrast to the situation with labour supply, there are few panel data in the United States that cover household consumption, and most work has used the data on expenditure on food that is contained in the Michigan Panel Study of Income Dynamics (PSID). In an elegant paper, Hall and Mishkin (1982) found results that were in accord with the excess sensitivity results; there is a strong negative correlation in their data between changes in consumption and changes in lagged income that is inconsistent with the view that only surprises in income should matter. However, since in their data changes in income are negatively correlated over time, a negative correlation between the lagged income change and the change in consumption can be interpreted as a positive correlation between consumption changes and changes in actual income, as predicted by the model of liquidity constraints. Hall and Mishkin conclude that these results would be consistent with a model in which about one fifth of consumers were unable to borrow as much as they wished. Once again, these results were supported by other similar evidence, see in particular Zeldes (1985) and

Bernanke (1984), also using the PSID, Runkle (1983), using data from the Denver Income Maintenance Experiment, and Hayashi (1985a) using panel data from Japan. However, one potential problem with the use of panels is the importance of errors of measurement in such data. There is a considerable body of evidence that PSID income changes are subject to very substantial reporting errors, see in particular Altonji (1986), Duncan and Hill (1985), and Abowd and Card (1985). Altonji and Siow (1985) have recently estimated a model similar to Hall and Mishkin's using the PSID but with allowance for measurement error, and they find little conflict with the view that consumption responds only to news. However, it is unclear, at least to this reader, whether the acceptance of the model represents low power once errors of measurement are allowed for, or whether such errors really offer a plausible explanation for Hall and Mishkin's findings.

A more formal line of research has attempted to estimate the Euler condition (15) directly, thus avoiding the approximations made by Hall and by others. Rewrite (15) once more, this time as

$$(1 + r_{t+1})(c_{t+1})^{-\sigma} - (1 + \delta)(c_t)^{-\sigma} = \varepsilon_{t+1} \quad (21)$$

where, as before ε_{t+1} is orthogonal to any variable known in period t or earlier. Hansen and Singleton (1982) proposed that the parameters in (21) be estimated by a generalized methods of moments scheme. Suppose that we have two variables or instruments z_{1t} and z_{2t}, each known at time t, so that we have $E_t(z_{it}\ \varepsilon_{t+1}) = 0$ for $i = 1, 2$. We can then estimate the two unknown parameters, σ and Δ, by equating sample and theoretical moments, and solving the two equations, $i = 1, 2$

$$T^{-1}\sum_{t=0}^{T-1}[z_{it}\{(1 + r_{t+1})(c_{t+1})^{-\sigma} - (1 + \delta)(c_t)^{-\sigma}\}] = 0. \quad (22)$$

If, as is typically the case, we have more than two z-variables, then it will not generally be possible to choose the two parameters so that (22) is exactly zero. Instead, the vector can be made as small as possible, or more specifically, the parameters can be estimated by minimizing a quadratic form that can be thought of as a weighted sum of squares of the left-hand side of (22); see Hansen and Singleton for details. If the model were true, this minimized value ought to be small, so that with more instruments than parameters, the generalized method of moments procedure yields a test-statistic that is diagnostic for model adequacy.

Test procedures based directly on the Euler conditions have several notable advantages. As was the case for Hall's procedures, few assumptions have to be made about the structure of the income process, and the model satisfies the best professional standards of seeking a direct confrontation between theory and data with as few approximations and supplementary assumptions as possible. The model can also be readily extended to test the implications of the consumption asset pricing model by repeating the tests using the returns on a range of alternative assets, see (13) above. Hansen and Singleton's study, as well as several others, find that the test statistics are much too large to be consistent with the theory and so reject the intertemporal model implied by the Euler conditions. Given the apparent superiority of the tests, these results have been accorded a great deal of weight in the literature. However, while I believe that Hansen and Singleton's work represents a very important methodological advance, I think that there are good reasons for not treating their results as a definitive rejection of life-cycle theory. The high level of technique that is embodied in deriving the Euler equation, not to mention the complexity of generalized methods of moments estimation, should not blind us to the very simple, even simple-minded, economic story that underlies these models. Fundamentally, the Euler equation says that the marginal rate of substitution between today's and tomorrow's consumption should be equal to the rate of return on assets between today and tomorrow, so that estimation of the Euler equation, unlike the Hall or excess-sensitivity tests, focuses very directly on the relationship between real interest rates and changes in real consumption, and the model will not fit the data if there is no close association between the two. And it only takes a very cursory

inspection of United States time-series data to see that there is no such association. Real consumption grew in all but one year between 1954 and 1984, while real after-tax interest rates were as often negative as positive, so that consistency with the theory would require that the pure rate of time preference be negative. Nor is there any association between the rate of growth of consumption and the level of real after-tax interest rates, see Deaton (1986b) for some data. But this in no way reflects badly on the life-cycle theory. As was made perfectly clear in the original Modigliani and Brumberg papers, and it is the *essence* of the life-cycle model, aggregate consumption cannot be expected to behave like individual consumption. Imagine a stationary economy with neither population nor real income growth, in which there is an excess of real interest rates over the rate of pure time preference, and in which all consumers have identical additive lifetime preferences with isoelastic subutility functions. In such an economy, each individual has a consumption path that is growing over time, but aggregate consumption is constant, a result that is achieved by old people dying and being replaced by young people who have much lower consumption levels relative to their incomes. Unless we believe that there is some automatic and immediate relationship between real interest rates, time preference and growth, as would obtain for example along a 'golden age' growth path, or unless we believe that consumers have infinite lives, then there is no reason at all to suppose that aggregate consumption should look at all like the life-cycle path of a representative consumer. Representative agent models are frequently useful, and it is not very constructive to dismiss macroeconomics because it requires implausible aggregation assumptions. However, the life-cycle model provides a well-worked-out account of individual and aggregate saving, an account that is consistent with a good deal of other evidence and theory, and it *does not* predict that aggregate consumption should be consistent with the intertemporal optimization conditions for a single individual. The general question of the effects of interest rates on consumption is something that has remained in dispute for a long time, and in spite of repeated attempts to isolate the effect, careful studies have tended to be unable to do so, or at least to find effects that are at all robust, or that can be replicated on even slightly different data sets or data periods. Economic theories or policy prescriptions that rely on intertemporal substitution of consumption in response to changes in real interest rates are not well-buttressed by any solid body of empirical evidence.

Another useful approach to testing the life-cycle model is to consider the stylized facts of the income and consumption processes, and to see whether consumption behaves in the way that is to be expected given the stochastic process of income. Most people who have studied the time series for quarterly real disposable income in the United States agree that, like GDP, the series can be parsimoniously described by a model that is linear in its first two lags, i.e. an autoregression of the form

$$y_t = \alpha_1 + \alpha_2 y_{t-1} + \alpha_3 y_{t-2} + u_t \qquad (23)$$

where u_t is the income innovation, that part of current income that cannot be anticipated from previous observation of the series. Of course, real income is not a stationary series, but has a strong upward trend, and there is considerable disagreement about the nature of this trend, what is the economic story behind it, and how it should be modelled. One possibility is that real income contains a *deterministic* time trend, so that there is some sort of equilibrium growth path that cannot be altered by shocks to the economy. Shocks certainly exist, but they cause only short term temporary deviations from the path and have little or no long-term temporary deviations from the path and have little or no long-term significance. In this view, Eq. (23) applies to the *deviations* of income from trend, not to income itself; equivalently, (23) can be modified by including a linear or quadratic time trend. The alternative view is that there is no deterministic trend, but that the rate of change of income is a stationary stochastic series with constant mean. In practice, this can look very like the previous model, but there is the vital conceptual difference that in the second, non-deterministic model, there is nothing that will

ever bring income back to any deterministic path. In consequence, shocks to current income have permanent and long-lasting effects. The version of (23) that corresponds to this view can be written.

$$\{(y_t - y_{t-1}) - \gamma\} = \rho\{(y_{t-1} - y_{t-2}) - \gamma\} + u_t \tag{24}$$

which can readily be seen to be a special case of (23), though note that it is the case where the time series possesses a unit root, or is stationary in first differences. For (24) to be a valid specialization of (23), the quadratic equation with the α's of (23) as coefficients must have a unit root, hence the term. Equation (24) appears to fit the data well and the parameter ρ turns out to be around 0.4, so that (24) says that if the increase in real income in one quarter is greater than its long term mean, then the next quarter's increase is also likely to be above the mean, though by less. While the long-term mean of the rate of change of income is constant and equal to γ, good fortune (positive u's) and bad fortune (negative u's) never have to be paid for (or made up), since shocks are immediately consolidated into the income level, and growth goes on in the same way as before, but from the new base. As Campbell and Mankiw (1986) have emphasized, the unit root model exhibits shock *persistence,* while the deterministic trend model does not; they suggest that shock persistence is what we should expect if supply shocks predominate over demand shocks, with the reverse in standard Keynesian models where shocks are typically attributed to fluctuations in aggregate demand.

It turns out that it is almost impossible to tell these two processes apart on United States time-series data. Processes with unit roots are inherently difficult to tell apart from processes that are stationary around deterministic trends, and the tests that are available, Dickey and Fuller (1981), Phillips and Perron (1986), certainly cannot reject the hypothesis that (24) is a valid specialization of (23). Nor would the tests convince a believer in the deterministic model that income does not have a deterministic trend, even though it will readily be recognized that the deviations from trend are themselves close to non-stationarity. Since both process are special cases of (23) with the inclusion of a trend, and since each assumes parameter values that are very close to one another, one might think (and hope) that the two models would have very similar implications. But it is easy to see this is not true. If permanent income is taken as the annuity value of discounted future incomes, then (24) implies that any innovation u_t to current income, because it will persist forever, and because it can be expected to be followed by another infinitely persistent innovation of the same sign, will change permanent income by more than the amount of the innovation. Equation (25) below gives the formula for the change in permanent income, if the real interest rate is r, and if real income follows (24), see Flavin (1981) or Deaton (1986b),

$$\Delta y_t^p = \frac{(1+r)^2}{r+1-\rho} u_t \tag{25}$$

so that the change in permanent income is between one and a half and twice as large as the innovation in current income. By contrast, fitting the deterministic model yields a much smaller effect, with the change in permanent income about one fifth of the shock in measured income. Since consumption should change by about the same amount as does permanent income, the life-cycle model, together with the unit root formulation, yields the uncomfortable prediction that consumption should be *more* variable than income over the business-cycle, not less. If the unit root model is correct, then the life-cycle and permanent income models can be rejected because they predict what they were designed to predict, that consumption is smooth relative to real income! The deterministic model gives no such problems, but as yet we have no way of being sure that it is correct, unless, of course we assume from the start that the life-cycle story is true.

There is insufficient space in this essay to follow these issues further, or to discuss in detail the evidence for and against the two formulations of the stochastic process governing real income; the interested reader can refer to Deaton (1986b) and

to the evidence on persistence in GDP presented by Campbell and Mankiw (1986) and by Cochrane (1986). There are a number of possible solutions to these puzzles, and a great deal of empirical work remains to be done, though I suspect that the time-series data on income are insufficiently long to allow the isolation of the very long-run properties on which the permanent income theory rests, see in particular the interesting paper by Watson (1986).

Variations on the Basic Theme

There exist many interesting developments of the basic life-cycle model, and I have space to discuss only a few. I have already mentioned the role of liquidity constraints, and many people would take it as transparent that many consumers do not have access to unlimited credit, or else face borrowing rates that are higher than the rates at which they can lend. Of course, many consumers may be able to smooth their consumption without recourse to borrowing, and the borrowing needs of many others may be met by the typically rather good markets in home mortgages. For consumers who nevertheless wish to borrow but cannot, their spending will be closely tied to their actual income. For some of the theoretical and empirical literature on this point see Flemming (1973), Dolde and Tobin (1971), and Hayashi (1985b). The theoretical consequences of uncertainty about the date of death have been worked out by Yaari (1965), and as argued above, play a possibly important part in the explanation of the saving behaviour of the elderly.

Another line of research is the possible relaxation of the assumption that preferences are intertemporally additive. Allowing all periods (or ages) to interact with all other periods in an unrestricted way, as in Eq. (1), would be much too general to be useful, and the search has been for simple models that break the restriction in a natural and straightforward way. One useful analogy is with the theory of durable good purchases, where utility depends on the *stock* of assets possessed, the stock in turn being the integral of past purchases less depreciation. Purchases in one period therefore have consequences for utility in subsequent periods, something that will be taken into account by a forward looking consumer. In the case of durable goods, the assumption of perfect capital markets effectively converts durable into non-durable goods, with the price of a unit of stock for one period being the implicit rental or user cost, the latter being defined as the sum of interest cost, depreciation, and expected capital loss, see for example Diewert (1974) or Deaton and Muellbauer (1980b, ch. 13).

However, various authors, Houthakker and Taylor (1970) perhaps being the first, have extended the durable model to encompass 'psychic' stocks which, like physical stocks, are augmented by purchases and diminished by depreciation, but unlike physical stocks, can either increase or decrease utility. The latter case covers habit formation; consumption of an addictive good generates pleasure now, but engenders a hungry habit that is pleasureless but costly in the future. The model has been given an elegant formulation in two papers by Spinnewyn (1979a, b). As an example, see also Muellbauer (1985), take the utility function

$$u_t = \sum_{k=0}^{T-t} (1+\delta)^{-k} v(c_{t+k} - \alpha c_{t+k-1}) \qquad (26)$$

where α is a measure of habit formation. Spinnewyn maximizes this function with respect not to c_t, but with respect to the 'net' quantities $z_t = c_t - \alpha c_{t-1}$, and shows how to rewrite the budget constraint so as to define corresponding prices of the z's that reflect not only market prices of the goods, but also the costs of consumption now in terms of pleasure foregone later. Under certainty, and looking ahead from time t, the full shadow price of an additional unit of consumption now is

$$p_z = \sum_{k=0}^{T-t} [\alpha/(1+r)]^k p_{t+k} \qquad (27)$$

because the habits that are built up now have to be paid for later. Note that this sort of formulation also predicts that it is $c_t - \alpha c_{t-1}$ not c_t, that is

proportional to permanent income, so that consumption itself will adjust only sluggishly to changes in permanent income with habits causing a drag. Other formulations of non-separable preferences can be found in the papers by Kydland and Prescott (1982), and by Eichenbaum et al. (1984), both of which are concerned to reconcile fluctuations in the aggregate economy with the behaviour of a single representative agent.

Many of the models discussed so far assume that the consumption function actually exists, hence taking for granted the essentially keynesian assumption that income is given to the consumer, and is not chosen together with consumption. A considerable body of work has grown up in the last ten years that is concerned with the simultaneous choice of labour supply and consumption in a life-cycle setting. Heckman (1971) and Ghez and Becker (1975) are among the pioneers of this approach. Unlike the price of goods, the price of leisure tends to show a systematic pattern over the life-cycle, so that, if consumers are free to choose their hours, and if they can freely borrow and lend so as to transfer resources between periods, it will pay them to work hardest during those periods in their life-cycles when the rewards for doing so are highest, and to take their life-time leisure when wage rates are low and leisure is cheap. There is superficial evidence in favour of this story, and Ghez and Becker, followed by Smith (1977) and Browning et al. (1985), all find that workers tend to work longest hours in middle age when wage rates are high and the lowest number of hours at the beginning and end of the economically active life, when wage rates are relatively low. Consumption also tends to peak in the middle age, and this can be brought into the story by assuming that consumption and leisure are complements, so that the lack of leisure in middle age is partially compensated by high levels of expenditure. This elegant fable has also been made much of in equilibrium theories of the business cycle, which accounts 'unemployment' as a voluntary vacation taken when the real wage is low and leisure is on sale, see in particular Lucas and Rapping (1969) and Lucas (1981).

There now exists a growing volume of literature that shows just how much violence to the facts is done by this story. All the evidence quoted above looks across different individuals at different points in their life-cycles, while the theory says that the same individual will change his or her hours of work along with changes in the real wage over the life-cycle. Time-series and panel data from the United States and time-series of cross-sections from the United Kingdom suggest that this is simply not the case, see for example Mankiw et al. (1985), Ashenfelter and Ham (1979), Ashenfelter (1984), and Browning et al. (1985). Even MaCurdy's (1981) more postive study provides only very weak evidence, see in particular Altonji (1986). The joint consumption and labour supply story fares even less well than the labour supply model alone, and there is clear evidence that the way in which consumption and hours fluctuate over the cycle (sometimes together and sometimes in opposite directions) is not consistent with the way in which they move together over the life-cycle. The attempt to provide a unified theory of business and life-cycles has been an interesting and important one, but it cannot be said to have been successful.

I have been somewhat cavalier in my treatment of aggregation issues, choosing to emphasize them when I believe them to be important, for example in the fitting of Euler conditions, and ignoring them when it has been convenient to do so. Attempts to do better than this have not been notably successful. Formal conditions that allow aggregation in consumption function models are typically too restrictive to be useful, so that, in theory, changes in the distribution of income should have detectable effects on aggregate consumption. However, attempts such as that by Blinder (1975) to link the distribution of income to consumption have not been notably successful, perhaps because the income distribution is not variable, or because it changes smoothly enough over time to preserve a stable relationship between average income and average consumption. There is also an issue of aggregation over goods in order to define real consumption at all, even at the level of the individual agent. In the derivation in section "A Simple Theoretical Framework" above, I made the convenient assumption that within-period preferences were homothetic, so that an

index number of real consumption could be formed. But homotheticity, although very convenient for studying the consumption function, is very inconvenient for studying the allocation of expenditure among goods since it implies that the within-period total expenditure elasticities of each good are all equal to unity. Fortunately, there are aggregation results of Gorman's (1959), see also Deaton and Muellbauer (1980b, ch. 5) for an exposition that allows us to have the best of both worlds, at least if we remain with intertemporally additive preferences. If the single-period indirect utility function $\psi(x, p)$ takes the form known as the 'generalized Gorman polar form'

$$\psi(x,p) = F[x/a(p)] + b(p) \tag{28}$$

where $a(p)$ and $b(p)$ are linearly homogeneous functions of prices and $F(\cdot)$ is monotone increasing, then the real expenditure index $x/a(p)$ can serve as an indicator of real consumption just as in the homothetic case. This happens because when the consumer chooses the allocation of life-time expenditure over periods so as to maximize the intertemporal sum of terms like (28), the $b(p)$ terms are irrelevant. However, the intra-period demand functions that correspond to (28) do not display unitary elasticities unless the $b(p)$ is identically equal to zero, and quite general functional forms are permitted. There is therefore no real conflict between the analysis of the consumption function on the one hand, and the analysis of demand on the other. It is to the latter that I now turn.

Theoretical and Empirical Demand Functions

Demand functions are the relationships between the purchase of individual goods, income or total expenditure, prices, and a variety of other factors depending on the context. Economists have attempted to make empirical links between demand and price since Gregory King's famous demand curve for wheat, see Davenant (1699), and since the middle of the 19th century, there has been a great development in the theory of consumer behaviour. Much practical work continues in the tradition of King, paying little attention to formal theory, concerning itself instead with finding empirical regularities. For a firm studying the demand for its product, or for anyone interested in establishing a single price elasticity, this probably remains the best approach; the major developments in econometric technique and empirical formulation have not been much concerned with, or relevant to, these very practical questions. The pragmatic approach (the term comes from Goldberger's famous but unpublished (1967) study), probably reached its peak with the publication of Richard Stone's great monograph, (Stone 1954a), and much is still to be learned by a careful study of Stone's procedures for measuring income and price elasticities. However, in this essay, I shall follow the literature, and follow its more methodological approach.

The theory outlined in section "A Simple Theoretical Framework" above suggests that the demand functions of an individual consumer can be derived by maximizing a utility function $v(q)$ subject to a budget constraint $p \cdot q = x$, where x is total expenditure. In the analysis here, x is chosen at some previous level of decision making, but traditionally it is treated as if it were a datum by the consumer, the utility maximization yields a vector q that is some function $g(x, p)$, say, of total expenditure and prices. These demand functions cannot simply be any functions, but must have certain properties as a result of their origins in utility maximization. Obviously, the total value of the demands should be equal to total outlay x, the 'adding-up' property, and it must be true that proportional changes in x and in p do not have any effect on quantities demanded, the 'homogeneity' or 'absence of money illusion' property. Somewhat less obvious are the famous symmetry and negativity properties. These apply to the Slutsky (1915) matrix, S, the typical element of which is defined as

$$s_{ij} = \partial q_i/\partial p_j + q_i \partial q_j/\partial x. \tag{29}$$

As any intermediate text shows, see for example Deaton and Muellbauer (1980b, ch. 2), the Slutsky matrix must be symmetric and negative

semi-definite. The symmetry property is not readily turned into simple intuition; negativity implies that the diagonal elements of the matrix are non-positive, a proposition often referred to as 'the law of demand'. The four properties, adding-up, homogeneity, symmetry and negativity, essentially exhaust the implications of utility maximization, so that any empirical demand functions that satisfy them can be regarded as having been generated by utility maximization, or by rational choice, with 'rational' defined, following Gorman (1981), as 'having smooth strictly quasi-concave preferences, and being greedy'.

Stone (1954b) was the first to attempt to use this theory directly to confront the data. He started from a (general) linear expenditure system of the form

$$p_i q_i = \sum_j a_{ij} p_j + b_i x \tag{30}$$

where a_{ij} and b_i are unknown parameters. Stone showed that, in general, the system (30) does not satisfy the four requirements, but will do so if, and only if, the parameters are restricted so that the model can be written in the form

$$p_i q_i = p_i \gamma_i + \beta_i (x - p \cdot \gamma) \tag{31}$$

with the β-parameters summing to unity. In this form the model is known as the linear expenditure system. As Samuelson (1947–8) and Geary (1949–50) had earlier shown, the utility function corresponding to (31) has the form

$$u = \sum_i \sum \beta_i \ln(q_i - \gamma_i), \tag{32}$$

sometimes referred to (somewhat inappropriately) as the Stone–Geary utility function. It can be thought of as a sum of Bernoulli utility functions of the quantity of each good above the minimal γ's.

Stone's achievement lay not in deriving the demand functions, but in thinking to estimate them. The demand functions (30), even if fitted to the data by least-squares, require non-linear optimization, and Stone invented a simple and not very efficient scheme, but one that allowed him to obtain parameter estimates and a good fit to interwar British data for a six commodity disaggregation of expenditures. This was a major breakthrough, not only in demand analysis, but also in applied econometrics in general. Indeed, much of demand analysis for a decade or so after Stone's paper consisted of applying better algorithms and faster computers to the fitting of Stone's model to different data sets.

The linear expenditure system offers a demand model for a system of, say n goods, and requires only $2n - 1$ parameters, a degree of parsimony that was very important in allowing the model to be estimated on very short time-series data. However, such economy brings its own price, and the linear expenditure system is very restrictive in the sort of behaviour that it can allow. In particular, and pathological cases apart, the model cannot allow inferior goods (goods the demand for which falls as total outlay increases), nor can it allow goods to be complements rather than substitutes. (As defined by Hicks (1939) goods i and j are complements if the (i, j)th term in the Slutsky matrix is negative, so that the utility compensated cross-price response of i to an increase in the price of j is positive.) Normal (non–inferior) goods that are substitutes for one another may be the most important case, but they do not encompass everything that we might want to study. The linear expenditure system also implies that the marginal propensity to consume each good is the same no matter what is the total to be spent, and many cross-section studies of household budgets have suggested that this is not in fact the case.

Unfortunately, it is quite difficult to write down utility functions that will lead to more general demand functions than those of the linear expenditure system, nor is there any obvious way of generalizing Stone's procedure of writing down functions and making them consistent with the theory. Progress was only really made once applied demand analysis started using 'dual' formulations of preferences to specify demands. In the demand context, duality refers to a switch of variables, from quantities to prices, so that utility becomes a function, not directly of quantities consumed, but indirectly of prices and total expenditure. This indirect utility formulation is given by

the function $\psi(x, p)$, already used above, and this is simply the maximum attainable utility from total outlay x at prices p. Since $\psi(x, p) = u$, and the function is monotone increasing in x, it can be inverted to give $x = c(u, p)$, known as the 'cost function', since it gives the minimum necessary cost that is required to reach the utility level u. By a theorem usually attributed to Shephard (1953) and to Uzawa (1964), these two functions contain a complete representation of preferences; provided preferences are convex, and provided the functions satisfy homogeneity and convexity (or concavity) conditions, preferences can be reconstructed from knowledge of either of the two functions. It is also very easy to move from either cost or indirect utility functions to the demand functions. For the indirect utility function, we have Roy's identity (Roy 1943).

$$q = -\nabla_p \psi(x,p)/\psi_x(x,p) \equiv g(x,p) \qquad (33)$$

which immediately yields demand functions from preferences in a form that are suitable for estimation, while for the cost function, we have Shepard's Lemma (1953),

$$q = \nabla_p c(u,p) = \nabla_p c[\psi(x,p),p] \equiv g(x,p) \quad (34)$$

where, as in (33), the operator ∇ denotes a vector of partial derivatives.

Demand analysis now had a high road to specification. Think of some quasi-convex decreasing function of the ratios of price to total outlay and call it an indirect utility function, or think of some function of utility and prices that is increasing in its arguments and linearly homogeneous and concave in prices and call it a cost function. Either way, and with only simple differentiation, new (and sometimes) interesting demand functions will be generated. Alternatively, and even more importantly, it is possible to use theory to aid and check out empirical knowledge. If it is known that the marginal propensity to spend on food is a declining function of total expenditure, or if it is thought likely that some goods do not depend very directly on the prices of other goods, it is relatively straightforward to find out what preferences (if any) will yield the result. It becomes possible, not just to generate demand functions serendipitously, but to generate good and useful ones deliberately.

There are many examples that could be cited from the literature. One of the most widely used in the *translog* model which was first proposed in 1970 by Jorgenson and Lau, see Christensen et al. (1973) for a convenient reference. To derive the translog, write the indirect utility function in terms of the ratios of prices to outlay, $r = p/x$, and approximate the indirect utility function as a second order polynomial in the logarithms of r. Application of Roy's identity yields demand functions in which the budget share of each good is the ratio of two functions, each of which is linear in the logarithms of the price to outlay ratios. Estimation of these rational functions, like estimation of the linear expenditure system, requires the use of non-linear maximization techniques. A related model, the 'almost ideal demand system' (AIDS) has been proposed by Deaton and Muellbauer (1980a), and I use this to illustrate some of the issues that arise with the current generation of demand models. The AIDS is specified by the logarithm of its cost function which takes the form

$$\ln c(u,p) = \alpha_0 + \sum_k \alpha_k \ln p_k + 0.5 \sum_k \times \sum_m \gamma_{km} \ln p_k \ln p_m + u \exp\left\{\sum_k \beta_k \ln p_k\right\}, \qquad (35)$$

so that, applying Shephard's lemma and rearranging, we have demand functions

$$p_i q_i / x \equiv w_i = \alpha_i + \beta_i \ln(x/P) + \sum_j \gamma_{ij} \ln p_j \qquad (36)$$

where P is a linearly homogeneous price index, the form of which can readily be inferred from (35). The parameters of the model must satisfy certain restrictions if (35) is to be a proper (log) cost function, and (36) a proper system of demand functions. The matrix of γ-parameters can be

taken to be symmetric in (35), but must be so in (36), and its rows and columns must add to zero for the homogeneity and adding-up properties to be satisfied. The β-parameters can be positive or negative, with positive values indicating luxury goods, and negative values necessities. The main advantage of the AIDS model in time-series applications is that the price index P can typically be approximated by some known price index selected before estimation, so that the demand system is linear in its parameters. In consequence, it can be estimated by ordinary least squares on an equation by equation basis, at least if the symmetry of the γ-matrix is ignored. The homogeneity restrictions can be tested equation by equation using a t- or F-test, and while imposing or testing symmetry requires an iterative procedure, estimation can be done by straightforward iterated restricted generalized least-squares, see Barten (1979) or Deaton (1974a) for further discussion.

The results of estimating the AIDS model are sufficiently similar to those from other models and other studies, see e.g. Barten (1969), Deaton (1974a), Christensen et al. (1973), and many others, that perhaps they can be taken as representative. What typically seems to happen is that the homogeneity restrictions appear *not* to be satisfied, so that in the application of AIDS to British data, Deaton and Muellbauer found, for example, that the F-test for transport had a value of 172 compared with the 5 per cent critical value of 4.8. Results on symmetry from AIDS and other systems are more mixed, and it now seems clear that testing symmetry is not usually possible given the amount of data typically available in time series, or put more positively, that there is no convincing evidence against symmetry. The difficulty is that symmetry involves a set of restrictions *across* different equations, so that unlike homogeneity, which involves tests *within* each equation, exact, small sample tests are not available. Researchers have therefore fallen back on asymptotically valid tests, and it turns out that these work very badly for the usual sort of samples, especially when there are more than a very small number of goods in the demand system. The papers by Laitinen (1978) and Meisner (1979) first established the problem, see also Evans and Savin (1982) and Bera et al. (1981) for further evidence.

The AIDS model, like the translog and several others, e.g. Diewert's (1973) 'generalized Leontief' system, fall into the class of 'flexible functional forms'. This criterion of flexibility, first proposed by Diewert (1971), is an important guarantee that the model is sufficiently richly parametrized so as to allow estimation of what are thought to be the main parameters of interest, typically the total expenditure elasticities, and the matrix of own and cross-price elasticities. A 'second order' flexible functional form is one that has sufficient parameters, so configured, that it is possible to set the value of the function, and of its first and second partial derivatives to any arbitrary set of (theoretically permissible) values. By applying Roy's identity or Shephard's lemma, it is clear that a cost or indirect utility function that is a second order flexible functional form will yield demand functions that are first-order flexible, so that it is possible for estimation to yield any set of price and expenditure elasticities that are consistent with utility theory. For empirical work, such a guarantee is important, because it ensures that the elasticities are being measured, not assumed. Contrast, for example, the linear expenditure system (31) with the AIDS model (36). Both could be fitted to the same set of data, and the parameter estimates of each could be used to generate a complete set of expenditure and price elasticities. But the linear expenditure system is *not* a flexible functional form, and so its estimated elasticities are not independent of one another, as is apparent from the fact that there are $2n - 1$ parameters compared with the total number of potentially independent elasticities, which is $(n - 1)(1 + n/2)$. (There are $n - 1$ independent demand equations, each of which has an expenditure elasticity, and n price elasticities; however, one price elasticity per equation is lost to homogeneity, and symmetry imposes a further $(n - 1)(n - 2)/2$ constraints.) The linear expenditure system does not therefore *measure* all the price and income elasticities, but determines them by a mixture of measurement and assumption, the main assumption being that of additive preferences, see Deaton (1974b) for further details. The AIDS, by contrast, has exactly

the right number of parameters to allow for intercepts and a full set of elasticities, so that when it (or the translog, or the generalized Leontief) is estimated, so is the full set of elasticities.

Being able to do this is a great step forward in methodology, but just as the linear expenditure system probably asks too little of modern data, (although not of the data available to Stone and the early pioneers of the systems approach), the second-order flexible functional forms probably ask too much, or equivalently, put too little structure on the problem. The consequences show up in large standard errors, a high frequency of apparently chance correlations, and a lack of robustness to functional form changes within the class of flexible functional forms, in other words, in all the standard symptoms of over-parametrization. These problems are particularly acute for the measurement of *price* elasticities, because in most time-series data, commodity prices tend to move together with relatively little variation in relative prices. And although the focus of most research on demand analysis over the last thirty years has been on the estimation and testing of price responses, there is certainly no consensus on what numbers, if any, are correct. Estimates obtained from the linear expenditure system are not credible because they are forced to satisfy an implausibly restrictive structure, while those from flexible functional forms are not credible because the data are not informative enough to supplement the lack of prior structure. Some intermediate forms are clearly required.

One of the attractions of flexible functional forms is their ability to approximate quite general forms for preferences. However, the models so far considered offer only approximations, and there is no guarantee that they have satisfactory *global* properties. Partly this is the standard problem that a fitted model will be forced to give a reasonable account of the data over the sample used for estimation, but may predict very badly elsewhere. But there are other deeper issues. Taking the AIDS as an example, estimation of (36) subject to symmetry and homogeneity will produce a system of estimated demand functions that will satisfy adding-up, homogeneity and symmetry for *all* values of x and p. However, there are two other important properties that are not assured. First, there is no guarantee that the predicted budget shares will necessarily lie between zero and one, so that there may be regions of price space in which the estimated model yields nonsensical predictions. Second, there is no way that the AIDS can be guaranteed to have a negative semi-definite Slutsky matrix for all prices, at least not without restricting parameters to the point where the model ceases to be a flexible functional form. The parameters could be chosen so as to satisfy negativity for some particular combination of prices and outlay, but there will be no guarantee that the law of demand will be satisfied elsewhere. In the translog model, it is possible to impose a restriction that guarantees negativity everywhere, but the model with the restriction has the property that all estimated own price elasticities must be less than minus one, independently of whether this is in fact true, and it almost certainly is not, see Diewert and Wales (1987). A demand system is described as 'regular' if it has a negative definite Slutsky matrix and predicts positive demands, and several empirical studies, see e.g. Wales (1977) for one of the first, found that estimated flexible functional forms were not regular over disturbingly large regions of even the parameter space used to estimate them. Caves and Christensen (1980), and later Barnett and Lee (1985) and Barnett et al. (1985), investigated the same problem theoretically by taking a known utility function, choosing the parameters of flexible functional forms to match its level and derivatives at a point, and then mapping out the regions of price space in which the systems remained regular. The results at least for the translog and the generalized Leontief model, were not good.

These regularity issues may seem of limited importance in practice, but this is far from being the case. One of the major reasons for being interested in complete empirical demand systems is to be able to examine the consequences of price changes, particularly of price changes that follow changes in government policy. The United States relies relatively little on indirect taxation as a source of public finance, but such is not the case in most of Europe, and the vast majority of developing countries maintain complex systems of

price wedges, particularly for foods and for agricultural production. The effects of such systems cannot be predicted without good information on how demands respond to price changes, nor can reforms be intelligently discussed. However, estimated demand systems that are not regular are not a great deal of help. All of the theory of welfare economics, of consumer surplus, of optimal taxation and of tax reform, *assumes* that demand behaviour is generated by utility maximization at the individual level, and implementation without regularity risks internal contradiction. For example, if compensated demand functions slope *upwards,* the government can generate a deadweight gain by imposing a distortionary tax. Of course, it may not be the empirical work that is wrong, but the theory that we used to try to model behaviour. If so, the estimated demand functions are still not useful, since we now have no idea what to do with them. But I doubt that evidence goes so far; it is not that behaviour itself is irregular, but that we have not yet found a good modelling strategy that contains a reasonable amount of prior information to supplement the paucity of data, and at the same time can deliver global regularity if it is warranted by the evidence.

A number of interesting experiments are currently under way that involve new modelling techniques. One possibility is that the Taylor series expansions that motivate most flexible functional forms are themselves inadequate to the task. In particular, Taylor approximations lose their ability to approximate if they are also asked to possess other properties of the functions that they are approximating. For example, we might want to test whether or not preferences are additively separable, as in the linear expenditure system. One strategy would be to write down some second-order approximation to preferences, estimate the resulting demand model, and then test whether or not the conditions imposed on the demands by additivity are satisfied. But this will not work in general, because there may be no additive system of demand equations that has the precise functional form demanded by the approximation. The same phenomenon is well illustrated by Stone's derivation of the linear expenditure system itself. The original general linear expenditure Eq. (29) can clearly be justified as a Taylor approximation to any set of homogeneous demand functions, and yet the imposition of only *symmetry* generates the demand system (30) which comes from the *additive* utility function (31). Additivity is not imposed, but linear expenditure systems are only symmetric if they are additive. Similarly many flexible function forms are only globally regular if they are homothetic, see for example, Blackorby et al. (1977). Several recent studies have proposed alternative ways of making functional approximations. Gallant (1982) has proposed using Fourier series approximations while Barnett (1983) has suggested that Laurent series can be used to generate demand models with good properties. Gallant's models are even more heavily parametrized than standard flexible functional forms, and there must be some question as to the suitability of trigonometrical functions for demand functions. Barnett's 'miniflex Laurent' model does not use the full flexibility of the Laurent series, but appears to have quite good approximation and regularity properties in practice, see Barnett and Lee (1985) and Barnett et al. (1985); even so, its estimation is complex, and many of the parameters have to be estimated subject to inequality constraints.

A second line of current research has abandoned the standard approach of econometric analysis, taking instead a completely non-parametric approach. Since many of the difficulties discussed above arise from choice of functional form, it is useful to ask how far it is possible to go without assuming any functional form at all. We know from standard revealed preference theory that two observed vectors of prices and quantities can be inconsistent with utility maximization; if bundle one is chosen when bundle two is available, so that bundle one is revealed preferred to bundle two, then no subsequent choice should reveal bundle two to be preferred to bundle one. Before embarking on the exercise of fitting some specific utility function to any finite collection of price and quantity pairs, one might then ask whether the collection is conceivably consistent with any set of preferences. If it is, then contradictions between an estimated system and the theory must be a matter of inappropriate functional form. The

conditions for utility consistency of a finite set of data were originally derived by Afriat (1967), who proposed a condition called cyclical consistency. Much later Varian (1982) not only provided an accessible and clear account of Afriat's results, but also recast the cyclical consistency condition into a 'generalized axiom of revealed preference (GARP)' that runs as follows. A bundle q^i is strictly directly revealed preferred to a bundle q if $p^i q^i > p^i q$, while q^i is revealed preferred to q, if there exists a sequence, $j, k, \ldots, m$ such that $p^i q^i \geq p^i q^j$, $p^j q^j \geq p^j q^k, \ldots, p^m q^m \geq p^m q$, so that q^i is directly or indirectly (weakly) revealed preferred to q. GARP is satisfied if for all q^i revealed preferred to q^j, it is not true that q^j is strictly directly revealed preferred to q^i, and given GARP the data can be rationalized by a continuous, strictly concave, and non-satiated utility function. Differentiability can also be ensured by a sight strengthening of GARP, see Chiappori and Rochet (1987). GARP is readily tested for any given set of data by checking the pairwise inequalities and using a simple algorithm provided by Varian to map out the patterns of indirect revealed preference. Repeated applications of the method to time-series data have nearly always confirmed the consistency of the data with the theory. In retrospect, it is clear that violations of GARP cannot occur unless some budget lines intersect, so that if, over time, economic growth has resulted in the aggregate budget line moving steadily outward with little change in slopes, GARP is bound to be satisfied. (However, post-war United States data budget planes do occasionally intersect, and Bronars (1987) has recently shown that hypothetical demands generated by selecting random points on the actual budget lines would more often than not fail GARP.)

The contradictions between the parametric and non-parametric approaches can perhaps be resolved by thinking of the latter as a modelling technique that uses a very large number of parameters, so that the failure of the parametric models to fit theory to data can be thought of as failure to parametrize the models sufficiently richly. But I have already argued that these models already have too many parameters, and adding more would only exacerbate the already serious problems of measurement. For many purposes, the theory is only useful if it is capable of delivering a description of the data that is reasonably parsimonious. There is also something rather simple minded about non-parametric techniques that tends to be disguised by the sophisticated and elegant expositions that have been given them by Varian and others. Consider a very simple theory that says variable x should move directly with variable y as, for example, in the Euler Eq. (15) above which says that, under certainty consumption should grow from period t to $t+1$ if and only if the real interest rate from t to $t+1$ is greater than some fixed constant. A non-parametric test on a finite set of data would accept the theory if, in fact, x, and y always did move together, and reject it if x and y ever moved in opposite directions. That such testing procedures are widely employed in the press and by the uninformed public is no reason for treating them seriously in economics.

I have so far discussed the formulation and estimation of demand functions, meaning the relationships between quantities, outlay, and prices, and this has been the topic of most applied demand analysis over the last thirty years. However, there is an older tradition of demand analysis, in which the object of attention is household budget data, and this literature has recently been enjoying something of a revival. Since household budget data typically come from a cross-section of households over a short period of time, usually within a single year, prices are treated as common to all sample points, so that the focus of attention becomes the relationship between demand and outlay and the influence of household composition on the pattern of household expenditures. The oldest, and perhaps only law of economics, Engel's Law that the share of food in the budget declines as total outlay increases, comes from Engel's (1857, published 1895) study of Belgian working-class families, and early empirical studies of demand were almost inevitably based on household surveys (see Stigler (1954) for a masterly review). The modern study of Engel curves, the relationships between expenditure and total outlay, begins (and almost ended) with Prais and Houthakker (1955). Prais and Houthakker studied

the shapes of Engel curves, the relationship between demand and households, particularly in relation to the choice of quality, a topic that has subsequently been unjustly neglected. The functional forms for Engel curves that Prais and Houthakker examined became the staple menu for most subsequent studies, even though only one of their forms, the linear Engel curve, is capable of satisfying adding-up, and the linear form typically performs very badly on the data. Since 1955 a number of other Engel curves have been proposed, notably the lognormal Engel curve of Aitchison and Brown (1957), and Leser's (1963) revival of the form suggested much earlier by Holbrook Working (1943). Working's form, which apparently escaped the attention of Prais and Houthakker, makes the budget share of each commodity a linear function of the logarithm of total outlay. The formulation is particularly useful, for not only is it capable of accounting for most of the curvature that is discovered in empirical Engel curves, but it is also consistent with utility theory, and corresponds to the case where the welfare elasticity of the cost of living is independent of income. Gorman (1981) has provided a general characterization theorem for Engel curves of the form

$$p_i q_i = \sum_k a_{ik}(p)\xi_k(x) \tag{37}$$

and has shown that the $\xi_k(\cdot)$ functions can be powers of x (polynomial Engel curves), or x multiplied by powers of log x (Engel curves relating budget shares to powers of the logarithm of outlay), or have trigonometric forms. This last form includes Fourier representations of Engel curves, while the first two allow Taylor or Laurent expansions for the expenditure/outlay and for the share/log-outlay forms. The Working–Engel curve is the first member of Gorman's 'share to log' class, and the theorem tells us that we may add quadratic or higher order terms to improve the fit. However, Gorman's paper contains a remarkable result; the matrix of the a-coefficients in (37) has rank at most equal to three. In consequence, the share to log and log-squared Engel curves are as general as any, as are the Engel curves of the quadratic expenditure system, see Howe et al. (1979). Given Gorman's results, and the empirical success of the Working form, it and its quadratic generalization deserve wide use in the analysis of budget studies. There is also accumulating evidence that such forms are indeed necessary. Thomas (1986), in a wide-ranging examination of household survey data from developing countries, has shown that Engel's Law itself does not appear to hold among the very poor, so that, in many cases, the share of the budget devoted to food at first rises with total outlay before falling in conformity with the Law.

Prais and Houthakker also proposed a much-used formulation for the effects of household composition on behaviour. It can be written

$$p_i q_i / m_i(a) = f_i\{x/m_0(a)\} \tag{38}$$

where a is a vector of household demographic characteristics (perhaps a list of numbers of people in each age and sex category) and m_i and m_0 are scalar valued functions known as the 'specific' and 'general scales' respectively. In this literature, scales are devices that convert family structure into numbers of equivalent adults, so that a family of two adults and two children might be two equivalent adults for theatre entertainment, three equivalent adults for food, and six equivalent adults for milk. The general scale is supposed to reflect the overall number of equivalent adults, so that the Prais and Houthakker model is a simple generalization of the idea that *per capita* demand should be a function of *per capita* outlay. Barten (1964), in a very important paper, took up the Prais–Houthakker idea of specific scales, but assumed that the arguments of the household utility function were the household consumption levels each deflated by the corresponding specific scale. The consequences of Barten's formulation are similar to those of Prais and Houthakker, but embody the additional insight that changes in family composition affect the effective shadow prices of goods, so that demographic changes will exercise, not only income, but also substitution effects on the pattern of demand. The story is often summarized by the phrase, 'if you have a wife and child, a penny bun costs three-pence',

quoted in Gorman (1976), but the really far-reaching substitution effects of children are probably on time use and labour supply, particularly of women.

Since household surveys typically contain large samples of households, there is less need for theory to save degrees of freedom, and it is possible to estimate quite general functional forms that link expenditures to household composition patterns and then to interpret the results in terms of the various models. In addition, neither the Prais–Houthakker nor the Barten model seem to yield easily implemented functional forms, e.g. linear ones, nor is it clear that either model is even identified on a single cross-sectional household survey in which all prices are constant, see for example Muellbauer (1980) and Deaton (1986a). However, some empirical results for the two models can be found in Muellbauer (1977, 1980) and in Pollak and Wales (1980, 1981) who also examine Gorman's (1976) extension of Barten's model in which additional people are supposed to bring with them fixed needs for particular commodities. The fixed needs model is close to the formulation proposed by Rothbarth (1943) for measuring the costs of children. Rothbarth pointed out that there are certain commodities, adult goods, that are not consumed by children, so that when children are added to a household, the only effects on the household's consumption of adult goods will be the income effects that reflect the fact that, with unchanged total resources, the household is now poorer. Deaton et al. (1985) have recently attempted to test Rothbarth's contention, and in their Spanish data it seems possible to identify a sensible group of adult goods, the expenditure on each of which changes with additional children in the same way as they change in response to changes in outlay.

Studies of the effects of family composition on household expenditure patterns have frequently been concerned, not only with estimating demands, but also with attempts to measure the 'cost' of children. It would take me too far afield to do justice to this topic here. Readers interested in this controversial area should perhaps start with Rothbarth (1943), who in a few pages makes a very simple and quite convincing case, and look also at Nicholson (1976). Pollak and Wales (1979) weigh in on the opposite side, and claim that it is impossible to measure child costs from expenditure data. My own position is argued in Deaton and Muellbauer (1986); there are certainly grave problems to be overcome in moving from the analysis of household survey data to the measurement of the costs of children, and it is clear that identifying assumptions must be made that are more severe and more controversial than those required, for example, to go from demand functions to consumer surplus. But that does not mean that it is not possible for such assumptions to be proposed and to be sensibly discussed.

Consumer Expenditure (New Developments and the State of Research)

Orazio P. Attanasio and Guglielmo Weber

Abstract

We provide an overview of recent developments in the life-cycle permanent income model under uncertainty, starting from the certainty equivalence case, and considering precautionary saving, the workings of insurance and credit markets, and non-standard preference structures.

The state of research on consumer expenditure up to the mid-1980s is described in consumer expenditure. Here, we provide an overview of recent developments on the intertemporal model of consumer behaviour under uncertainty. We organize our discussion around what has been the workhorse model for the analysis of dynamic consumption behaviour – the life-cycle permanent income model. Although our discussion of the intertemporal model is self-contained, it is not meant to be an exhaustive survey of this large literature. We do not cover demand analysis, despite the many exciting developments that have occurred in recent years.

The permanent income life-cycle (PILC) model, introduced during the 1950s by Modigliani and Brumberg (1954) and Friedman (1957), still plays an important role in the consumption literature. The PILC model can be loosely defined as a framework where individuals maximize utility over time given a set of intertemporal trading opportunities. Consumption at different points in time is treated as different commodities, so that, given intertemporal trading opportunities, consumption in a given period depends on total (life-cycle) resources and (intertemporal) prices. Optimal consumption choices are such that the ratio of (expected) marginal utilities of consumption at different times equals the ratio of intertemporal prices. Therefore, the relationship between consumption and total resources is likely to depend on preferences (and in particular on the elasticity of intertemporal substitution and the rate at which the future is discounted) and on interest rates (as they represent intertemporal prices). If we allow for uncertainty, as we discuss below, risk will also enter as a potentially important determinant of consumption.

This model can generate implications and insights for many important questions not only in macroeconomics but also in public finance, and has therefore attracted much attention, both theoretically and empirically. Recent research has stressed the need to look at preferences on the one hand and markets on the other, as the policy implications are the result of both.

The Permanent Income Life-Cycle Model

In its simplest incarnation the PILC model considers a finite horizon, no uncertainty and very simple preferences. In such a situation, it is simple to translate the basic intuition of the model, to which we referred above, into a closed form solution for consumption that depends not just on current income but on the total amount of resources available to an individual and intertemporal prices. The problem of this specification, of course, is its lack of realism. Not only do consumers in reality face much more complicated intertemporal environments, but it is likely that these complications have a first-order effect on consumption choices. Therefore, the simplest version of the model is a useful way to convey the main ideas behind PILC, but it needs to be complicated considerably to be of use for policy analysis.

The introduction of uncertainty in the model, which makes it much more realistic, complicates the problem enormously. The first formalizations of the life-cycle model under uncertainty date back to the 1970s (Bewley 1977). Typically, one assumes that consumers maximize expected life-cycle utility choosing consumption and, in more general settings, leisure and financial asset holdings. Consumers are assumed to know the stochastic nature of their environment. Even with many simplifications on the nature of preferences, the model does not yield closed form solutions for consumption, except in the most special cases.

MaCurdy (1981, see also 1999) uses dynamic optimization techniques to derive necessary conditions for the optimal solution of the intertemporal optimization problem faced by consumers. The attractiveness of this approach lies in the fact that it cuts through the necessity of solving the model completely, which is a very hard task indeed, to focus on some useful implications of the model. In particular, these contributions focus on the basic first order condition, the so-called Euler equation, that equates the ratio of marginal utilities to intertemporal prices.

The first macro paper to take this approach is Hall (1978): under strong assumptions on preferences and returns, (non-durable) consumption is a random walk, that is:

$$E(C_{t+1}|I_t) = C_t \quad (1)$$

where I_t denotes information available at time t. This remarkable proposition requires that utility be quadratic in consumption (and additively separable over time, states of nature and in its other arguments, notably male and female leisure and durable goods). It also requires that there is at least one financial asset with fixed real return, and that this equals the time-preference parameter. If consumers have rational expectations, then:

$$C_{t+1} = C_t + \varepsilon_{t+1}E(\varepsilon_{t+1}|Z_t) = 0 \quad (2)$$

for all variables Z known at time t. A notable feature of Hall's model is that the Euler equation for consumption aggregates perfectly, because it involves linear transformations of the data. Hall used the Euler equation to test for the prediction implied by (2): no variable known to the consumer at time t should help predict the change in consumption between t and $(t + 1)$.

Hall's paper was the first of many contributions that exploited the Euler equation and the fact that such an approach does not require the complete specification of the environment in which the consumer lives, or even the complete budget constraint. Moreover, the approach is robust to the presence of various imperfections in some intertemporal markets. And while the specification with quadratic utility yields a linear equation for consumption, alternative specifications, with more plausible preferences, are easily introduced. For instance, in the case of power utility, an expression similar to (2) can be obtained for the log of consumption.

The price that one pays in using the Euler equations approach, which we discuss below, is that one does not obtain a closed form solution for consumption.

An approach that goes beyond the consideration of the Euler equations is taken up in an important paper by Flavin (1981).

Flavin (1981) adopts the same theoretical framework as Hall (1978), and assumes that no other asset is available to the consumer (as in Bewley 1977). However, Flavin develops a solution for consumption. To do so, she has to specify completely the stochastic environment in which the consumer lives and use particularly simple preferences. In particular, Flavin (1981) assumes that the only stochastic variable is labour income, that preferences are quadratic and that the consumer can save or borrow in a single asset with a fixed rate of interest. Under these conditions, Flavin shows that consumption is set equal to permanent income, and this is in turn defined as the present value of current and expected future incomes:

$$C_t = \frac{r}{1+r}A_t + \frac{r}{1+r}\sum_{k=0}^{\infty} E\left(y_{t+k}|I_t\right) \quad (3)$$

where A denotes financial wealth and y is labour income. In this model, the first difference in consumption equals the present value of income revisions, due to the accrual of new information between periods t and $(t + 1)$:

$$\Delta C_t = \frac{r}{1+r}\sum_{k=0}^{\infty}\frac{1}{(1+r)^k}\left[E\left(y_{t+k}|I_t\right) - E\left(y_{y+k}|I_{t-1}\right)\right]. \quad (4)$$

Equation (3) makes clear the main implications of the model: consumption depends on the present discounted value of future expected income. The interest rate plays the important role of converting future resources to present ones and therefore constitutes an important determinant of consumption. Flavin (1981) noticed that Eq. (3) imposes cross-equation restrictions on the joint time series process for income and consumption. A similar approach had been followed by Sargent (1978) and, subsequently, by Campbell (1987) who noticed that an implication of (4) is that saving predicts future changes in income, the so-called 'saving for a rainy day' motive.

One of the main implications of the PILC model, particularly evident in Eq. (3), is that, in appraising the effects of a given policy, for instance a tax reform that affects disposable income, a distinction must be drawn between permanent and temporary changes (Blinder and Deaton 1985; Poterba 1988).

Another feature of Flavin's model is that the closed form solution for consumption is the same under certainty and uncertainty, as long as expected values of future incomes are taken. This is a direct consequence of the assumption of quadratic utility that makes the marginal utility linear in consumption. For this reason, it is often referred to as the certainty equivalent model.

Extensions of the Simple Certainty Equivalent Model

The certainty equivalent model is appealing for its simplicity, but its implications are typically rejected by the data: Hall and Mishkin (1982) were particularly influential in suggesting that some of the model implications were rejected in micro data. At the same time, the model with quadratic preferences was perceived to be too restrictive in its treatment of financial decisions: quadratic preferences imply increasing absolute risk aversion in consumption (or wealth), something that is unappealing on theoretical grounds and strongly counterfactual (riskier portfolios are normally held by wealthier households). Quadratic preferences also imply that the willingness to substitute over time is a decreasing function of consumption: poor consumers should react much more to interest rate changes than rich consumers, after allowance has been made for the wealth/income effect.

The alternative adopted in much of the literature has been to assume power utility and to allow for the existence of a number of risky financial assets. Once one deviates from quadratic utility, however, and/or allows for stochastic interest rates, one loses the ability to obtain a closed form solution for consumption. Many of the studies that made this choice, therefore, focused on the study of the Euler equations derived from the maximization problem faced by the consumer. The basic first-order conditions used in this literature are two:

$$U_{ct} = \lambda t, \tag{5}$$

$$\lambda_t = E\left(\lambda_{t+1}\frac{1+r^k_{t+1}}{1+\delta}\,|\,I_t\right). \tag{6}$$

Equation (5) says that, at each point in time, the marginal utility of consumption equals the Lagrange multiplier associated with the budget constraint relevant for that period, which is sometimes referred to as the marginal utility of wealth. The second condition, Eq. (6), that is derived from intertemporal optimality, dictates the evolution of the marginal utility of wealth (δ is a subjective discount rate). An equation of this type has to hold for each asset k for which the consumer is not at a corner. This is because the consumer is exploiting that particular intertemporal margin.

The attractiveness of Euler equations is that one can be completely agnostic about the stochastic environment faced by the consumer, about the time horizon, about the presence of imperfections in financial markets (as long as there is at least one asset that the consumer can freely trade), about the presence of transaction costs in some component of consumption or labour supply. All relevant information is summarized in the level of the marginal utility of wealth. The approach is conceptually similar to the use of an (unobservable) fixed effect in econometrics. By taking first differences, one eliminates the unobservable marginal utility of wealth and is left only with the innovations to Eq. (6).

Early papers along these lines were Hansen and Singleton (1982, 1983), who used power utility (also known as isoelastic, isocurvature or CRRA) as it has more appealing theoretical properties (relative risk aversion is constant in wealth or consumption, the elasticity of intertemporal substitution is also a constant). If we substitute Eq. (5) into (6) and using the properties of the CRRA utility function, the Euler equations for consumption corresponding to each asset (k) will be:

$$E\left\{\left(\frac{C_{t+1}}{C_t}\right)^{-\gamma}\frac{1+r^k_{t+1}}{1+\delta}\right\} = 1 \tag{7}$$

where γ is a curvature parameter (equal to the relative risk aversion parameter and to the reciprocal of the elasticity of intertemporal substitution) and δ, the subjective discount rate, measures impatience.

An equation such as (7) can be log-linearized to obtain (see Hansen and Singleton 1983):

$$\Delta \log C_{t+1} = k + \frac{1}{\gamma} \log\left(1 + r^{k}_{t+1}\right) + \varepsilon_{t+1}. \quad (8)$$

Although consumption appears on the left-hand side of Eq. (8), this equation is not a consumption function, but an equilibrium condition. It cannot explain or predict consumption levels: consumption is crucially determined by the residual term ε_{t+1} and there is nothing that tells us what determines such a term or how this term changes with news about income, interest rates or any other relevant variable.

The Euler equation for a single asset can identify the elasticity of intertemporal substitution, a key parameter for the evaluation of the welfare costs of interest taxation (Boskin 1978; Summers 1981) and for the analysis of real business cycles (King and Plosser 1984). The joint estimation of several Euler equations can help identify the pure discount rate parameter (governing patience), but also shed light on risk aversion, given that different assets typically have different risk characteristics.

The derivation of a closed form solution for consumption when certainty equivalence does not hold was first successfully tackled by Caballero (1990, 1991). Caballero (1991) took the Flavin model with known finite life, and constant absolute risk aversion (CARA) preferences, and showed that, when the optimal consumption age profile is flat with no uncertainty, it is increasing with income uncertainty. This change in the slope of the consumption profile was described as precautionary saving, because early in life consumers save more if labour income is more uncertain. Later work by Gollier (1995) and Carroll and Kimball (1996) established that a similar result holds whenever the third derivative of the utility function is positive, a feature of preferences labelled prudence. Both CARA and power utility exhibit prudence. The presence and size of precautionary savings is a matter of great relevance for public policy, in so far as public insurance schemes covering such risks as unemployment, health and longevity should reduce the need for consumers to accumulate assets.

The great merit of the model with prudence is that it highlights the need to save for rainy days even if sunny days are equally likely. An increased variance in the shocks to income reduces consumption even if expected income does not change. In the case of discrete variables, such as unemployment or illness, changes in first and second moments occur simultaneously, but this is not the case for continuous variables. The ability to distinguish between first and second moment effects is of crucial importance in the analysis of public policy, because of its social insurance characteristics.

The solution of the Bewley model with more general utility functions has to be computed numerically or rely on approximations. Several studies in the early 1990s took up the challenge of characterizing such solutions. Deaton (1991) studied a model with power utility and infinite life. Deaton considered the existence of liquidity or no-borrowing constraints, and showed that impatient consumers would hold limited assets to insure against low income draws. Carroll (1992) instead covered the case of finite lives, and showed that, if consumers are sufficiently impatient and their labour income is subject to both permanent and temporary shocks, they set consumption close to income. The model with impatient consumers under labour income uncertainty has been labelled ‘the buffer stock model’, because saving is kept to the lowest level compatible with the need to buffer negative income shocks. Later work by Attanasio et al. (1999) and Gourinchas and Parker (2002) clarifies the role played by age-related changes in demographics and the hump-shape age profile of labour income in generating income tracking for relatively young consumers (micro data show that financial asset accumulation starts around age 40). Hubbard et al. (1994, 1995) show instead how precautionary motives interact with the insurance properties of Social Security in the United States.

Many of the papers cited in the preceding paragraph consider relatively simple versions of the life-cycle model. In particular, a single non-durable commodity is assumed and preferences are assumed to be additively separable

with leisure and over time. While this greatly simplifies the solution, the construction of a more realistic and complex model has become an important area of research. This development follows from the recognition that, for many purposes, and in particular for policy analysis, a model that delivers consumption as a function of exogenous variable is a very useful tool indeed.

This area of research has to deal with two important issues. First of all, the model can become very quickly, from a numerical point of view, very difficult to solve. The large number of state variables that characterize the solution of reasonably realistic models and the consideration of discrete choices and non-convexities linked to transaction costs can push the numerical capabilities of even very powerful computers. Second and even more importantly, if one wants to obtain solutions for consumption in a dynamic context, one has to characterize completely the stochastic environment in which the consumer lives. This contrast sharply with the Euler equation approach that allowed the researcher to be agnostic about most aspects of the environment and, under certain conditions, avoid solving difficult problems, such as labour supply, housing and other durable choices and so on. The Euler equation would hold regardless of the presence of non-convexities and other type of difficulties connected with these choices. These, instead have to be fully specified if one wants to work with a model that delivers a solution for consumption. These two difficulties constitute limits for the research in this area that, in all likelihood will not be overcome in the near future.

The Empirical Evidence on the PILC Model

Since its introduction in the 1950s, there is no consensus about the empirical relevance of the PILC model. While the model it is one of the main tools in modern macroeconomics and public finance, its empirical performance is mixed. In this section, we discuss two branches of the literature.

The life-cycle model with various sources of uncertainty and generic preferences generates decision rules and behaviour of great complexity. Consumption and saving choices depend in an unknown fashion on every single aspect of the stochastic environment faced by the consumer, for instance on the entire distribution of future wages and earnings opportunities, on pension arrangements, on the asset markets the consumer can access, on mortality risks and so on and so forth. The Euler equation approach allows researchers to deal in a rigorous fashion with extremely rich models and yet derive relatively simple implications to test some aspects of the model and, with the help of additional assumptions, to identify some of the structural parameters that inform individual behaviour. We now understand that Euler equations can be used to determine what type of preferences fits the available data and can therefore provide one of the building blocks (preferences) in the study of the questions above. We also know that the presence of liquidity constraints does not necessarily produce violations of Euler equations because, even when liquidity constraints are present, they might be rarely binding.

The Euler equation is robust to a number of market imperfections, but is silent about how consumption or its growth reacts to specific news about shocks, changes in interest rates, taxation and so on. It is therefore useless for specific policy analysis. In other words, while the parameters of an Euler equation can be estimated in a wide set of circumstances, and one can use the equation to test the specification of the model, none of these results will provide an answer to questions like what is the effect of a change in taxation or interest rates on the level of consumption and saving?

This important shortcoming of the Euler equation approach explains why such an approach, which has informed and dominated the large empirical literature on the validity of the life-cycle permanent income model is virtually absent in the public economics literature on, say, the effect of pension reforms on saving or on the effect of changes in the taxation of interest on saving. And yet the conceptual framework that is

behind the study of these issues is the same as that used to study consumption behaviour.

Policy analysis requires instead the availability of a consumption function, that is, a relation that explains consumption as a function of those variables that the consumer can take as exogenous at any given moment. Only in the simplest versions of the life-cycle model is it possible to derive an analytical expression for the consumption function. In general, given a set of assumptions on preference parameters and market and non-market opportunities, one has to rely on numerical solutions and/or approximations.

A less ambitious but potentially profitable approach that does not require numerical methods or incredibly rich data-sets is the estimation of reduced form equations, whose specification is informed by the life-cycle model. These are particularly useful in situations in which one analyses large (and possibly exogenous) changes to some of the likely determinants of consumption or saving. Such studies can address substantive issues and even test some aspects of the life-cycle model. Examples of studies of this kind include the reaction of consumption (and saving) to changes in pension entitlements (Attanasio and Brugiavini 2003; Attanasio and Rohwedder 2003; Miniaci and Weber 1999), to swings in the value of important wealth components (such as housing, Attanasio and Weber 1994) and to changes in specific taxes (Parker 1999; Souleles 1999; Shapiro and Slemrod 2003).

Below we review the empirical evidence on the PILC model, organizing it in two subsections. First we start with the empirical evidence derived from Euler equations. We then move on to evidence that considers the *levels* of consumptions, rather than its changes.

Evidence from Euler Equations

Two important empirical issues can be addressed with the study of Euler equations:

- What is the empirical relevance of the model? Is there a sensible specification of preferences that fits the observed data?
- What is the magnitude of the relevant preference parameters?

Tests of the Model

As mentioned above, a prediction of the model is that changes in consumption cannot be predicted by expected changes in income or any other variable known to the consumer at time $t-1$. This is the essence of the Hall (1978) test and of many others. Evidence that consumption can be predicted by lagged variables has been interpreted as indicative of liquidity constraints, myopic behaviour, misspecification of preferences and so on. The relationship between consumption and income has received considerable attention. The first to observe that the life-cycle model predicts no relation between the life-cycle profile of income and consumption was Thurow (1969). Thurow argued that the fact that consumption tracked income over the life-cycle was a rejection of the main implications of the PILC model. To this argument, essentially identical to many others proposed subsequently, Heckman (1974) replied that non-separability between consumption and leisure could explain such a relationship.

Despite this early exchange, after Hall (1978) a large fraction of the literature based on consumption Euler equations focused on the relationship between predictable changes in income and expected consumption growth. Hall and Mishkin (1982), as well as Campbell and Mankiw (1990, 1991) all report violations of this prediction, and label this finding 'excess sensitivity'. Excess sensitivity can be explained by the presence of liquidity constrained consumers, or of rule-of-thumb consumers, that is, consumers who let their expenditure track their income as a way to avoiding the complexities of choosing the optimal consumption path. However, consistently with Heckman's (1974) argument, excess sensitivity can be reconciled with the intertemporal optimization model if more general, and sensible, utility functions are used. In particular, if one assumes that leisure affects utility in a non-additive way, consumption changes respond to predictable labour income changes, whether or not leisure is a freely chosen variable. Finally, and importantly, the aggregation

issue proves to be important. Attanasio and Weber (1993) show that results obtained with improperly aggregated micro data are consistent with results obtained with aggregate data and indicate rejections of the model that instead disappear with properly aggregated data and rich enough preference structures.

To summarize the discussion so far, it seems that while simple tests of the life-cycle model seem to reject the implications from the model and in particular those derived from Euler equations, it is possible to find specification of preferences that do a good job at fitting the available data, especially for households that are headed by prime-aged individuals. Aspects that are crucial for fitting the data are the use of household level data, allowing for changes in consumption needs induced by changes in family composition and the use of preferences specifications that allow for the marginal utility of consumption to depend on labour supply.

Estimation of Preference Parameters

Recent research on consumption and saving has singled out three preference parameters for attention: the elasticity of intertemporal substitution, the relative risk aversion parameter and the subjective discount rate. The size of these parameters has important implications in many applications of the model, ranging from macroeconomics to public finance to financial economics.

Perhaps surprisingly, not much evidence has been accumulated on the discount factor from the estimation of Euler equations. This can be explained by the fact that in log-linearized versions of the Euler equation, the parameter is not identified, while non-linear versions of the model are ridden by a number of econometric problems, particularly in relatively small samples of the type used in Euler equation estimation (see Attanasio and Low 2004).

As for the distinction between the elasticity of intertemporal substitution (EIS) and the coefficient of risk aversion, it is absent in the most popular specifications used in the literature: a model where consumers maximize expected utility and preferences are iso-elastic and additively separable over time. In such a situation, the EIS is the reciprocal of the coefficient of relative risk aversion. Not many empirical papers have worked with preferences that allow for these two parameters to be disjoint.

An influential paper by Hall (1988) claimed that this parameter is close to zero. This finding has been challenged on various grounds. Attanasio and Weber (1993, 1995) point out that aggregation bias could be responsible for such a low estimate: they estimated a much higher elasticity (around 0.8) using UK and US cohort data (that is, data from repeated cross-sections, consistently aggregated over individuals born in the same years).

In the macro literature little attention has been paid to the possibility that the EIS may differ across consumers, particularly as a function of their consumption. A simple way to capture the notion that poor consumers may be less able to smooth consumption across periods and states of nature is to assume that the utility function does not depend on total (non-durable) consumption, but rather on the difference between consumption and needs. Thus we could retain the analytical attraction of power utility, but have $(C - C^*)$ as its argument, where C^* is an absolute minimum that the consumer must reach in each and every period. This functional form is known as Stone–Geary utility in demand analysis, and is the simplest way to introduce non-homotheticity in a demand system. One could interpret 'external habits' (Abel 1990; Campbell and Cochrane 1999) as a special way to parameterize C^* (by making it a fraction of past consumption of other consumers). Attanasio and Browning (1995), Blundell et al. (1994) and Atkenson and Ogaki (1996) are among the few examples of papers that explicitly allow for wealth-dependent EIS.

Demographics might also affect preferences, and might explain consumption changes and the shape of the consumption age profile, as argued by Attanasio et al. (1999) as well as Browning and Ejrnaes (2002).

Evidence from the Levels of Consumption

As stressed above, the Euler equation imposes some restrictions on the dynamics of consumption

but, on its own, does not determine the level of consumption. If one neglects numerical complications, a solution for consumption can be obtained by considering jointly the Euler equation and the sequence of budget constraints faced by the consumer as well as his or her initial wealth and a terminal condition. As noted by Sargent (1978), Flavin (1981) and later by Campbell (1987), the Euler equation and the intertemporal budget constraint imply a number of cross-equation restrictions for the joint time series processes of consumption and income. When one is able to obtain a closed form solution for consumption, as is the case with quadratic utility, these restrictions can be easily expressed in terms of a linear time series model, and tested.

Some of these restrictions are also implied by the Euler equation, while others are not. In particular, the restrictions on the contemporaneous correlation between income and consumption are not implied: as we stressed above, the Euler equation is silent about how news about income is translated into news about consumption.

Campbell and Deaton (1989) and West (1988) proposed a test that links the innovation to permanent income to consumption and presented evidence that aggregate consumption seems to be 'excessively smooth' in that it does not react enough to news about income. Campbell and Deaton make a connection between excess sensitivity and excess smoothness. Within the certainty equivalent model, they jointly model the consumption and income processes as a vector autoregression, assuming that income has a unit root plus some persistence. In this context, consumption changes reflect the permanent income innovation more than one-to-one: not only is the income shock permanent, but it also predicts future, smaller shocks of the same sign. This implies that over the business cycle consumption should be more volatile than income. But in actual aggregate data consumption is smoother than income: this is labelled 'excess smoothness', and is shown to be exactly equivalent to excess sensitivity.

Clearly the implications of a given set of intertemporal preferences for policy relevant questions depend crucially on the markets individuals have access to, on their imperfections and on the nature of the equilibrium they give rise to. The implications of complete markets would be very different from those one would derive if liquidity constraints or other markets imperfections were prevalent.

C

Insurance and Credit Markets

So far we have taken the assets the consumer can use to move resources over time as given and, in the simplest versions of the model, we have made very strong assumptions on this crucial aspect. For instance, we have assumed that consumers can borrow and lend at a fixed interest rate. The reality is, obviously, much more complex and, from a theoretical point of view, very many different environments have been studied. In particular, the possibilities open to a consumer depend on the market arrangements available. Below we discuss several of these market arrangements and briefly mention their implications for the determination of consumption.

Perfect Insurance Markets

If markets are complete and consumers can trade a full set of contingent claims without cost, individual risk will be completely diversified. In such a situation, a number of results deliver very useful predictions. In particular, it can be shown that a competitive equilibrium is symmetric and it is therefore possible to characterize the properties of competitive equilibria by considering the problem of a fictitious social planner, which, given a set of Pareto weights, maximizes social welfare. A strong implication of perfect markets is that the marginal utility of different consumers will move proportionally over time. The implication is very intuitive: the social planner faces a unique resource constraint, and marginal utility of all individuals, multiplied by the appropriate (and arbitrary) Pareto weight, will be equal to the multiplier associated to this unique constraint. As a consequence, marginal utility will move proportionally. If utility is isoelastic, consumption moves proportionally. These implications, stressed by Townsend (1994), have been tested in several

papers (Cochrane 1991; Attanasio and Davis 1996; Hayashi et al. 1996).

Many Assets

When there are many assets, one can derive an Euler equation such as (7) for each of the assets for which the consumer is not at a corner. The Euler equations for consumption with different assets naturally ties up with asset pricing equations. This approach to asset pricing was developed by Breeden (1979) and Lucas (1978), and extended to the case of non-additive separability of consumption and leisure in an incomplete markets setting by Bodie et al. (1992). The model we sketched above is quite restrictive: the relative risk aversion parameter is inversely related to the elasticity of intertemporal substitution: Epstein and Zin (1989) show how this restriction can be relaxed in a more general model with power utility where the timing of uncertainty resolution matters (see also Epstein and Zin 1991; Attanasio and Weber 1989).

Interestingly, an Euler equation for an asset holds even if there are important imperfections in some other assets. As long as the consumer is exploiting a given margin to move resources over time, an equation such as 7 will apply. If the interest rate for a given asset changes with the level of the asset, then the Euler Eq. (7) will have to be augmented with a term reflecting this effect (Pissarides 1978).

Liquidity Constraints

The Euler equation will be violated when the consumer is able, for some reason, to borrow against future income. In such a situation, Eq. (7) will hold as an inequality and the marginal utility of current consumption will be higher than the present discounted value of future consumption. Consumers who are liquidity constrained will be very sensitive to changes in current income. This case has received a considerable amount of attention in the literature. Many of the tests of violation of the Euler equation, such as Zeldes (1989), have focused on the so-called 'excess sensitivity' of consumption changes to predictable changes in income. It should be mentioned that, in a model with finite lives and a non-zero probability that income would be zero in each time period, standard regularity conditions on the utility function imply that a consumer will never want to borrow. If income is bounded away from zero, then the maximum the consumer will want to borrow is the present discounted value of the minimum value of income repeated in the future. This type of constraint has been sometimes referred to as a 'natural' liquidity constraint. Notice that such a constraint does not imply a violation of the Euler equation. If the restriction to borrowing is tighter, the Euler equation will instead be occasionally violated. And, even in periods in which it is not violated, the level of consumption will be affected by the possibility that the constraint will be binding in the future. As Hayashi (1987) explains, the presence of an operative, albeit not binding, liquidity constraint is equivalent to a shortening of the planning horizon or an increase in the discount rate. Evidence can be obtained by noting that consumers who are liquidity constrained will not be sensitive to changes in the level of the interest rate. As they will be at a kink of an intertemporal budget constraint, the demand for loans will be inelastic to changes in the slope of such an intertemporal budget constraint: the interest rate.

Endogenous Liquidity Constraint

In recent years, several studies have tried to model the shortcomings of credit and insurance markets by allowing for specific imperfections and frictions explicitly. The two main causes of imperfections that have been considered are: (*a*) private and asymmetric information and (b) the inability to perfectly enforce contracts. Models of this type can be seen as ways to endogenize specific market structures (such as one where consumers have access to a single asset in which they cannot borrow). In an influential paper, for instance, Cole and Kocherlakota (2001) show that an economy where individuals have a single bond in which they can borrow can be derived as a constrained equilibrium outcome where individuals have private information both on their income and on their savings.

Further Extensions and Alternative Models

While the evidence on the relevance of the life-cycle model is still inconclusive, a number of empirical puzzles have directed attention to more complex preference structures. In particular, the equity premium puzzle and the evolution of aggregate saving rates in high-growth economies (South East Asia) has led macroeconomists to incorporate habits into the model. However, there is still little formal evidence on the empirical relevance of habits in micro data. The widely documented retirement consumption puzzle (that is, a sudden drop of consumption at retirement) as well as a number of more or less anecdotal pieces of evidence on the inadequacy of saving for retirement and other forms of 'irrational' behaviour, have been interpreted as potentially supportive of time-inconsistent preferences. The most elegant way to introduce time-inconsistent preferences is provided by the hyperbolic discounting assumption (Laibson 1997).

Habits

Habits cause consumers to adjust slowly to shocks to permanent income, thus potentially explaining the excess smoothness of aggregate consumption, but also increase the utility loss associated with consumption drops, and may therefore help explain the equity premium puzzle.

Habits can take various forms: today's marginal utility may depend on the consumer's own past consumption level (internal habits) or the past consumption level of other consumers (external habits). This latter model seems to work better on aggregate data (Campbell and Cochrane 1999), even though a recent survey by Chen and Ludvigson (2004) challenges this conclusion.

Empirical macro-evidence on the presence of habits is mixed, and this may be due to the very nature of aggregate consumption data, as stressed in Dynan (2000). The serial correlation of aggregate consumption growth is affected by time aggregation (Heaton 1993), by aggregation over consumers, and by data construction methods (particularly for the services from durable goods). For this reason micro data seem preferable.

The simplest way to introduce habits (or durability) of consumption is to write the utility function as follows:

$$\Sigma_t u(x_t - \gamma' x_{t-1}; z_t) \tag{9}$$

where x is a vector of goods or services and z is any other variable that affects marginal utility (demographics, leisure, other goods that are not explicitly modelled). The γ parameters are positive for goods that provide services across periods (durability), negative for goods that are addictive (habit formation) or zero for goods that are fully non-durable, non-habit forming (Hayashi 1985).

The Euler equations corresponding to (9) involves x at four different periods of time, and their estimation typically requires panel data. High-quality consumption panel data are rare, and this has limited the scope for empirical analysis. Meghir and Weber (1996) have used Consumer Expenditure Survey (CEX) quarterly data on food, transport and services (and a more flexible specification of intertemporal non-separabilities than is implied by Eq. 9), and found no evidence of either durability or habits once leisure, stock of durables and cars as well as other conditioning variables are taken into consideration.

Similarly negative evidence on habits has been reported by Dynan (2000), using Panel Study of Income Dynamics (PSID) annual food at home data. Carrasco et al. (2005) use Spanish panel data and find some evidence for habits.

The few studies that have used micro data on non-durable consumption items to investigate the issue find little or no evidence of habits, at least once preferences capture the presence of non-separabilities between goods and leisure.

Durable Goods

The presence of durable goods has received less attention in the micro-based literature than in the macro-literature, which has stressed the importance of their high volatility to explain business cycle fluctuations (Mankiw 1982; Chah et al. 1995).

The simplest way to introduce durable goods into the analysis is to let the stock of durables affect utility (on the assumption that services are proportional to the stock), and to posit a relation between current stock, S_t, previous stock, S_{t-1}, and current purchases q_t (or maintenance and repairs) in physical terms like:

$$S_t = (1 - \rho)S_{t-1} + q_t \tag{10}$$

where ρ is a constant depreciation rate. This leads to the standard first-order condition for the durable good, according to which the relevant price is the user cost.

Typically, durable goods are costly to adjust, because of transaction costs (resale markets are dominated by information problems, known as the 'lemon' problem, and search costs are non-negligible). Sometimes these costs are modelled as a convex, differentiable function (Bernanke 1985), but the recent literature has stressed the need to take into account their non-differentiable nature (Grossman and Laroque 1990; Eberly 1994; Attanasio 2000; Bertola et al. 2005). This generates infrequent adjustment: consumers do not adjust continuously in response to depreciation, or income and price shocks, but wait until the actual stock hits either a lower limit, s, or an upper limit, S, and then adjust it to a target level. An interesting feature of this literature is that aggregate behaviour reflects changes in both the number of consumers that adjust and in the target level.

Durable goods might also play an insurance role, because they can be used to sustain consumption when times are bad. Postponing the purchase of food, or clothing, is certainly harder than failing to replace an old refrigerator or car, and housing maintenance can be put off for very long periods before structural damage occurs (Browning and Crossley 2000). Durable goods also play a more specific insurance role, against changes in the price of the corresponding services. This is particularly relevant in the case of housing, where owning your home may be the best way to hedge the risk of future increases in the market price of housing services (Sinai and Souleles 2005). Durable goods can also play a liquidity role, if they can be used as collateral to obtain a loan that pays for current consumption (Alessie et al. 1997). A typical example could be the ability to remortgage a house, or to borrow 100 per cent of the value of a newly purchased car.

Even if one is not interested in modelling durable goods, the existence of a stock of durables should not be neglected when estimating preference parameters if utility is not additive in non-durable goods and durable services. Significant effects of durable goods (cars) on the Euler equation for non-durables have been found in UK data (Alessie et al. 1997), and US data (Padula 1999).

Quasi-Hyperbolic Discounting

The widely documented consumption puzzle (that is the sudden drop of consumption at retirement, see Hamermesh 1984; Banks et al. 1998; and Bernheim et al. 2001), as well as a number of more or less anecdotal pieces of evidence on the inadequacy of saving for retirement and other forms of 'irrational' behaviour, have been interpreted as potentially supportive of time-inconsistent preferences. The most elegant way to introduce time-inconsistent preferences is provided by the quasi-hyperbolic discounting assumption (Laibson 1997). Consumers maximize the expected value of the following life-time utility index:

$$u(c_t) + \beta \sum_{\tau=1}^{T-t} \delta^t u(c_{t+\tau}) \tag{11}$$

This implies that a different, lower discount factor is used to choose between this period and the next (the product of β and δ) and between any two other periods (δ). This generates time-inconsistent plans, with too little saving for retirement. For this reason, consumers may choose to enter long-term commitment plans, such as 401(k) s in the United States.

The quasi-hyperbolic discounting model lends itself to estimation and testing, but requires solving for the consumption function numerically. Even though an Euler equation for this model has been derived, its empirical use is limited, because it involves the marginal propensity to consume out of wealth (Harris and Laibson

2001). It also suffers from some potential difficulties related to the definition of the time period, which crucially affects the properties of the solution, the length of which is arbitrarily set by the researcher.

A more tractable specification of preferences that may be used to model quasi-rational impatience has been put forward by Gul and Pesendorfer (2001, 2004), who stress the importance of self-control problems leading to the postponement of saving.

Where Do we Stand?

Since the 1970s we have learned much about the empirical implications of the life-cycle model and about the details of the model that need to be modified to fit the available evidence. Much work, however, remains to be done. In particular, there is scope to develop more complex numerical models that incorporate several realistic features. The areas of labour supply and housing are, in our opinion, particularly important. We also need to develop our understanding of the empirical implications of alternative models, such as hyperbolic discounting and check the extent to which they are empirically distinguishable from more standard models with complex preferences. Finally, it is important to stress the need for more and better data. One of the lessons learned from the development of new surveys that have been used to measure household wealth is that with enough ingenuity and creativity one can measure several of the variables that are relevant for our understanding of consumption and saving behaviour.

Our analysis of consumption and saving requires that more comprehensive measures of consumption are included in existing surveys, and that we learn to make systematic use of records on expectations, perceived uncertainty and so on.

Consumer Surplus

Daniel T. Slesnick

Abstract

Over the years, consumer surplus has been used to measure the welfare effects of price and income changes. Despite its widespread use, it provides a measure of well-being that is ordinally equivalent to the change in utility only under conditions that are inconsistent with long-standing empirical evidence. Hicksian surplus measures, such as the equivalent or compensating variations, provide exact indicators of the change in utility without such restrictions. Beginning in the early 1980s, empirical methods have been developed to estimate the equivalent variation that has the same data requirements as consumer surplus.

How does the market power exercised by firms influence consumer welfare? What is the effect of excise taxes on households with different levels of income? Does governmental regulation increase the welfare of consumers? Topical issues such as these indicate that the measurement of welfare is a fundamental element of public policy analysis. Indeed, a full consideration of taxes, subsidies, transfer programmes, health care reform, regulation, environmental policy, the social security system, and educational reform must ultimately address the question of how these policies affect individual well-being.

While centrally important to many problems of economic analysis, confusion persists concerning the relationship between commonly used indicators of welfare and well-established theoretical formulations. For more than 150 years, consumer surplus has been used to measure the welfare effects of changes in prices and incomes. Its popularity can be ascribed to its intuitive appeal, the ease with which it is implemented, and its modest data requirements. Although it is generally accepted that Dupuit (1844) was the originator of the concept of consumer surplus, it is largely attributed to Marshall (1890). (Chipman and Moore (1976), provide a brief survey of the history of the debate related to consumer surplus.) We begin with the following notation:

$\mathbf{p} = (p_1, p_2, \ldots, p_n)$ – a vector of commodity prices.
Y_k – the income of individual k.
A_k – a vector of demographic characteristics of individual k.
$x_{ik} = x_i(\mathbf{p}, Y_k, \mathbf{A_k})$ is the demand for good i by individual k.

Suppose we are interested in the welfare impact of a change in the price of a single commodity from p_1^0 to p_1^1. The change in consumer surplus is given by:

$$\Delta CS_k = -\int_{p_1^0}^{p_1^1} x_1(t, p_2, \ldots p_n, Y_k, \mathbf{A_k})dt. \quad (1)$$

If ΔCS_k is positive (negative), the price change is judged to have increased (decreased) the welfare of individual k. Is it ordinally equivalent to the change in utility? A necessary condition is that the demand function is generated by a rational consumer who maximizes utility subject to a budget constraint. Unless consumers have optimized and are at the boundaries of their budget sets, it is impossible to assess the welfare effects of changes in prices and incomes. (That is, demands must be 'integrable' and consistent with a well-behaved utility function. Hurwicz and Uzawa (1971),

provide a formal statement of the integrability conditions.)

If demands are consistent with rational consumer behaviour, an indirect utility function $V(\mathbf{p}, Y_k, \mathbf{A_k})$ represents the maximum utility attained at prices $\mathbf{p}$ and income Y_k, and Roy's Identity provides the link between demands and utility:

$$x_1(\mathbf{p}, Y_k, \mathbf{A_k}) = -\frac{\partial V(\mathbf{p}, Y_k, \mathbf{A_k})/\partial p_1}{\partial V(\mathbf{p}, Y_k, \mathbf{A_k})/\partial Y_k}. \quad (2)$$

If the marginal utility of income is constant, substitution of (2) into (1) yields an explicit expression for the change in consumer surplus that is ordinally equivalent to the change in utility:

$$\Delta CS_k = \frac{V(\mathbf{p}^1, Y_k, \mathbf{A_k}) - V(\mathbf{p}^0, Y_k, \mathbf{A_k})}{\partial V/\partial Y_k}.$$

While constancy of the marginal utility of income is restrictive, Chipman and Moore (1976, 1980) have shown that application of consumer surplus is more problematical if there are changes in more than one price. In such circumstances, the change in consumer surplus must be evaluated using a line integral defined over the path of price changes from $\mathbf{p^0}$ to $\mathbf{p}^1$:

$$\Delta CS_k = \int_{p^0}^{p^1} \sum_i \mathrm{X}_i(\mathbf{p}, Y_k, \mathbf{A_k}) \mathbf{dp_i}. \quad (3)$$

Price paths are not observed so it is essential that (3) be path independent. This holds if the uncompensated price effects are symmetric (see, for example, Angus Taylor and Robert Mann 1972, pp. 500–4):

$$\frac{\partial x_i}{\partial p_j} = \frac{\partial x_j}{\partial p_i} \text{ for } all\ i \neq j.$$

This form of symmetry requires preferences to be homothetic, which is a restriction that is inconsistent with well-established empirical regularities.

In the most general circumstance of changes in prices and income, consumer surplus is defined as:

$$\Delta CS_k = -\int_Z \sum x_{\mathrm{i}}(\mathbf{p}, Y_k, \mathbf{A_k}) \mathrm{d}p_i + \left(Y_k^1 - Y_k^0\right), \quad (4)$$

where $\mathbf{Z}$ is a path between $\left(\mathbf{p}^0, Y_k^0\right)$ and $\left(\mathbf{p}^1, Y_k^1\right)$. Chipman and Moore (1976) have demonstrated that here are no circumstances under which (4) is path independent and ordinally equivalent to the change in utility of a rational consumer.

Hicksian Surplus Measures

Given the problems with consumer surplus, how should the welfare effects of price and income changes be measured? Hicks (1942) developed an approach that is exactly analogous to (4) once we substitute compensated for uncompensated demand functions:

$$\Delta HS_k = -\int_z \sum x_i^c(\mathbf{p}, V, \mathbf{A_k}) \mathrm{d}p_i + \left(Y_k^1 - Y_k^0\right) \quad (5)$$

where $x_i^c(\mathbf{p}, V, \mathbf{A_k})$ is the compensated demand for the ith good evaluated at utility level V. Compensated price effects are symmetric, so the line integral in (5) is path independent and the surplus measure is single-valued.

For simple binary comparisons of policies, the utility level at which ΔHS_k is evaluated is often treated as a matter of little consequence. If it is calculated at the utility attained at prices $\mathbf{p}^1$ and income Y_k^1 (denoted V^1), a generalized version of the equivalent variation is obtained:

$$\begin{aligned} EV_k &= E\left(\mathbf{p}^0, V^1, \mathbf{A_k}\right) \\ &\quad - E\left(\mathbf{p}^1, V^1, \mathbf{A_k}\right) + \left(Y_k^1 - Y_k^0\right) \\ &= E\left(\mathbf{p}^0, V^1, \mathbf{A_k}\right) - E\left(\mathbf{p}^0, V^0, \mathbf{A_k}\right) \end{aligned} \quad (6)$$

where $E(\mathbf{p}, V, \mathbf{A_k})$ is the expenditure function, defined as the minimum income needed for individual k to attain utility V at prices $\mathbf{p}$. Not only is the generalized equivalent variation single-valued, but it is ordinally equivalent to the change

in utility. That is, EV_k is positive if and only if $V^1 > V^0$.

The utility level at which (5) is evaluated is important for multiple comparisons of price and income changes. The generalized equivalent variation will give an ordering of outcomes that is identical to that based on utility levels. If (5) is evaluated at $V^0 = V(\mathbf{p}^0, Y_k^0, \mathbf{A_k})$, we obtain the generalized compensating variation:

$$\begin{aligned} CV_k &= E(\mathbf{p}^0, V^0, \mathbf{A_k}) - E(\mathbf{p}^1, V^0, \mathbf{A_k}) + (Y_k^1 - Y_k^0) \\ &= E(\mathbf{p}^1, V^1, \mathbf{A_k}) - E(\mathbf{p}^1, V^0, \mathbf{A_k}). \end{aligned} \tag{7}$$

Because the utility levels are 'cardinalized' using different prices for each set of binary comparisons, the ordering of multiple outcomes based on (7) need not match the ordering based on utility levels. Chipman and Moore (1980) have shown that consistent rankings of outcomes require restrictions on preferences that are the same as for consumer surplus.

While the simple static formulation of consumer surplus is the most frequent application, the conceptual framework can be extended to analyse the effects of changes in utility in more general settings. For example, intertemporal welfare effects are often represented as the discounted sum of the within-period equivalent or compensating variations.

Keen (1990) has shown that this will differ from the lifetime equivalent variation to the extent that individuals are able to substitute intertemporally. As an alternative approach, he defines V_L to be the maximum level of lifetime utility of an individual who lives T periods when the profiles of prices and interest rates are $\{\mathbf{p_t}\}$ and $\{r_t\}$ respectively. If the (optimal) time path of utility corresponding to V_L at these prices and interest rates is $\{V_{kt}\}$, the lifetime expenditure function can be represented as:

$$\Omega_L(\{\mathbf{p_t}\}, \{r_t\}, V_L) = \sum_t g_t \; E(\mathbf{p_t}, V_{kt}, \mathbf{A_{kt}}),$$

where $g_t = \Pi_{s=0}^{t}(1 + r_s)^{-1}$.

As in the static framework, the lifetime expenditure function can be used to represent an exact measure of the change in lifetime welfare. Define V_L^1 to be the maximum level of lifetime welfare when the profile of prices and interest rates are $\{\mathbf{p_t^1}\}$ and $\{r_t^1\}$ and denote the corresponding time path of utility as $\{V_{kt}^1\}$. The reference prices and interest rates, $\{\mathbf{p_t^0}\}$ and $\{r_t^0\}$, yield a lifetime utility level of V_L^0 and within-period utilities $\{V_{kt}^0\}$. Keen's exact measure of the change in lifetime welfare, evaluated at the reference prices, is exactly analogous to the generalized equivalent variation:

$$\begin{aligned} \Delta W_L = \Omega_L(\{\mathbf{p_t^0}\}, \{\mathrm{r}_t^0\}, V_L^1) \\ - \Omega_L(\{\mathbf{p_t^0}\}, \{r_t^0\}, V_L^0). \end{aligned}$$

The concepts of the equivalent and compensating variation can also be extended to cases in which the choices made by consumers are discrete rather than continuous. Dagsvik and Karlstrom (2005) describe the compensating variation in the context of a random utility model defined as:

$$U_{jk} = V(\mathbf{p_j}, \mathrm{Y}_k, \mathbf{A_k}) + \varepsilon_{\mathrm{jk}}(\mathrm{j} = 1, 2, \ldots, \mathrm{J}),$$

where U_{jk} is the utility of individual k in alternative j, $V(.)$ is a deterministic indirect utility function, and ε_{jk} are random variables. There are a total of J choices available to the consumer and, for simplicity, it is assumed that only prices vary across alternatives.

Consider the welfare effect of a change in the set of prices and income facing individual k from $(\mathbf{p}_1^0, \mathbf{p}_2^0, \ldots, \mathbf{p}_\mathbf{J}^0, Y_k^0)$ to $(\mathbf{p}_1^1, \mathbf{p}_2^1, \ldots, \mathrm{p}_\mathbf{J}^1, Y_k^1)$. If the consumer chooses the alternative that maximizes U_{jk}, the compensating variation is defined implicitly as that value CV_k that satisfies the following equality:

$$\begin{aligned} &\max_j V(\mathbf{p_j^0}, Y_\mathrm{k}^0, \mathbf{A_k}) + \varepsilon_{jk} \\ &\quad = \max_j V(\mathbf{p_j^1}, Y_k^1 - CV_k, \mathbf{A_k}) + \varepsilon_{jk}. \end{aligned}$$

Although conceptually analogous to the equivalent and compensating variation described previously, CV_k is now random and cannot, in general, be represented in closed form.

From Demand Functions to Welfare Measurement

While it was understood that the equivalent variation resolved the conceptual problem of welfare measurement, it had little influence on applied welfare economics because compensated demand functions were presumed to be unobservable. Willig (1976) made the first attempt to bridge the gap between theory and application by showing that, for a single price change, consumer surplus can provide an approximation to the equivalent or compensating variation. However, with multiple price and income changes, consumer surplus is not single-valued and is of no use in approximating changes in economic welfare (McKenzie 1979).

Shortly after the publication of Willig's paper, however, empirical procedures were developed to estimate the equivalent or compensating variation. Each method begins with the specification of a demand function and, under the assumption of integrability, is used to recover the utility or expenditure functions. The complexity of this procedure diminishes if demand functions are linear, and consideration is restricted to changes in the price of a single good.

Hausman (1981) provided an analytic solution to this problem for a demand function given by:

$$x_1 = \gamma_p p_1 + \gamma_Y Y_k + \gamma_{\mathbf{A}} \mathbf{A_k},$$

where γ_p, γ_Y, and $\gamma_{\mathbf{A}}$ are unknown parameters to be estimated econometrically. Roy's Identity provides a partial differential equation that can be solved to obtain an expenditure function of the form:

$$E(p_1, V, \mathbf{A_k}) = \mathrm{V}e^{\gamma_Y p_1} - (1/\gamma_Y)\left[\gamma_p p_1 + \left(\gamma_p/\gamma_Y\right) + \gamma_{\mathbf{A}} \mathbf{A_k}\right]. \quad (8)$$

The expenditure function allows the equivalent variation to be computed exactly as in (6) and Willig-type approximations are unnecessary. Hausman's method has the same data requirements as consumer surplus, and only linear regression methods are needed to estimate the unknown parameters.

Closed form solutions to the partial differential equation implied by Roy's Identity can be obtained for only a limited class of demand functions. An alternative approach is to begin with an assumed form of the indirect utility function and use Roy's Identity to obtain a system of demand equations. Since the form of the utility function is assumed from the outset, it is unnecessary to solve a complex system of partial differential equations.

Muellbauer (1974) provided an early example of this approach. He assumed that demands were consistent with a Stone-Geary utility function given by:

$$V(\mathbf{p}, Y_k) = \frac{(Y_k - \sum p_i \delta_i)}{\Pi p_i^{\alpha_i}} \quad (9)$$

where $\delta = (\delta_1, \delta_2, \ldots, \delta_n)$ and $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_n)$ are unknown parameters. The corresponding expenditure function is:

$$E(\mathbf{p}, V) = \sum p_i \delta_i + V\left(\Pi p_i^{\alpha_i}\right).$$

The unknown parameters can be estimated by fitting the linear expenditure system to household budget data:

$$p_i x_i = p_i \delta_i + \alpha_i \left(Y_k - \sum p_i \delta_i\right) (i = 1, 2, \ldots, n). \quad (10)$$

Given estimates of $\boldsymbol{\alpha}$ and $\boldsymbol{\delta}$, the expenditure function can be used to compute the equivalent or compensating variation as in (6) and (7).

While this is more general than Hausman's approach, it has its own disadvantages. For an assumed form of the utility function, the functional forms of the demands are the same for every good, which may hinder the ability of the model to fit the data. Is it possible to start with an arbitrary demand system (rather than a utility function) and measure the welfare effects of multiple price changes? Two elegant procedures were proposed that required more complicated calculations to recover the expenditure function, but did not impose restrictions on the form of the demand

functions other than the standard integrability conditions.

The first method is based on an approximation to McKenzie's (1957) indirect money metric utility function defined as:

$$\mu\left(\mathbf{p}, Y_k, \mathbf{A_k}; \mathbf{p}^0\right) = E\left(\mathbf{p}^0, V(\mathbf{p}, Y_k, \mathbf{A_k}), \mathbf{A_k}\right).$$

McKenzie and Pearce (1976) showed that $\Delta\mu$ can be approximated by a Taylor's series expansion about the initial equilibrium:

$$\begin{aligned}\Delta\mu = &\frac{\partial\mu}{\partial\mathbf{p}'}\Delta\mathbf{p}(1/2) + \Delta\mathbf{p}'\frac{\partial^2\mu}{\partial p\partial p'}\Delta\mathbf{p} \\ &+ \left(\frac{\partial\mu}{\partial Y} + \frac{\partial^2\mu}{\partial\mathbf{p}\partial Y'}\Delta\mathbf{p} + 1/2\frac{\partial^2\mu}{\partial Y^2}\Delta Y\right)\Delta Y \\ &+ R\end{aligned} \tag{11}$$

where R represents higher order terms in the series.

The expression in (11) can be represented as a function of uncompensated demand functions when μ is evaluated at the reference prices (this follows from Roy's Identity and from the fact that at these prices the marginal utility of income is equal to one and all higher income derivatives are zero – see McKenzie and Pearce 1976, for details):

$$\begin{aligned}\Delta\mu = &-\mathbf{X}'\Delta\mathbf{p} \\ &- (1/2)\Delta\mathbf{p}'\left(\frac{\partial\mathbf{X}}{\partial\mathrm{p}} - \mathbf{X}\frac{\partial\mathbf{X}}{\partial\mathbf{Y}'}\right)\Delta\mathbf{p} \\ &+ \left(1 - \frac{\partial\mathbf{X}}{\partial\mathbf{Y}'}\Delta\mathbf{p}\right)\Delta Y + R.\end{aligned} \tag{12}$$

Given knowledge of the demand functions and the magnitudes of the price and income effects, one has all of the information necessary to get as accurate an estimate of the change in utility as desired.

Vartia (1983) developed an algorithm that recovers the expenditure function numerically to any desired level of accuracy. Let $\mathbf{p}(t)$ and $Y_k(t)$ be the paths of price and income changes for $0 \leq t \leq 1$. As prices and income change, the movements of demands along an indifference curve can be represented implicitly by the differential equation:

$$\frac{dY_k(t)}{dt} = \sum_{i=1}^{n} x_i(\mathbf{p}(t), Y_k(t), \mathbf{A_k})\frac{dp_i(t)}{dt}.$$

Integrating over t yields an expression that can, in principle, be solved to obtain $E(\mathbf{p}(t), V^0, \mathbf{A_k})$ which is the centrepiece of the welfare calculations:

$$\begin{aligned}&E\left(\mathbf{p}(t), V^0, \mathbf{A_k}\right) - E\left(\mathbf{p}^0, V^0, \mathbf{A_k}\right) \\ &\quad = \sum_{i=1}^{n}\int_0^t x_i\left(\mathbf{p}(t), E\left(\mathbf{p}(t), V^0, \mathbf{A_k},\right), \mathbf{A_k}\right)\frac{dp_i(t)}{dt}dt.\end{aligned} \tag{13}$$

Vartia described several algorithms that can be used to solve this equation numerically over the price path $\mathbf{p}(t)$ so that, when evaluated at $t = 1$, we obtain $E(\mathbf{p}^1, V^0, \mathbf{A_k})$. As long as the demands satisfy the integrability conditions, the solution to (13) will be independent of the price path used in the algorithm. This method is valid for multiple price and expenditure changes and, because a closed-form solution is unnecessary, facilitates flexibility in estimating demand patterns.

Aggregation

The methods described to this point provide estimates of the change in welfare for individuals. In practice, analysts are more concerned about the impact of policies on groups. Micro-level estimates are an essential first step, but, for welfare economics to be useful to practitioners, a method of aggregation is essential. The easiest approach is to assume that market demands are generated by a representative consumer. Under this condition, the methods described previously can be applied to aggregate demands and the utility function of the representative agent can be recovered.

While frequently applied, this is unsatisfactory for a number of reasons. Market demands need not be consistent with a rational representative consumer. Even if every individual has demands that are consistent with utility maximization, aggregate demands need not satisfy any of the integrability conditions other than homogeneity of degree zero in prices and income (Sonnenschein 1972). Moreover, it is unclear what this utility function actually represents. Kirman (1992) presents an example in which the representative agent prefers (aggregate) market basket A to B even though all individuals prefer the reverse. This violation of the most basic principle of social choice suggests that the utility of the representative agent should not be used for policy analysis even in the unlikely event that aggregate demands are integrable.

An alternative approach is to define aggregate welfare to be a function of the individual surplus measures. Such an approach was advocated by Harberger (1971) in his effort to make consumer surplus the standard tool for applied welfare analysis. At a conceptual level, such an indicator of aggregate welfare appears to be a natural extension of the positive analysis of welfare measurement at the micro level. This is obviously not the case because aggregation necessitates normative judgements in which the gains to some must be weighed against the losses to others. Simply summing the surplus measures, for example, embodies a version of utilitarianism and ignores distributional concerns.

Since any method of measuring welfare for groups of individuals necessarily involves subjective judgements, it seems reasonable to state explicitly the underlying ethical basis for the method of ordering outcomes in the aggregate. The social choice theoretic framework used by Sen (1970) provides a reasonable way of presenting the normative assumptions related to the measurability and comparability of individual welfare levels that facilitate well-behaved social orderings of outcomes. Under conditions described by Sen and others, these orderings can be represented by a social welfare function:

$$W = W(V_1, V_2, \ldots, V_k)$$

where V_k is a welfare indicator of individual k.

A monetary measure of social welfare can be obtained using Pollak's (1981) concept of a social expenditure function:

$$M(\mathbf{p}, W) = \min\left\{Y : W(V_1, \ldots, V_k) \geq W, \sum Y_k = Y\right\}.$$

This function is exactly analogous to its micro-level counterpart and is the minimum level of aggregate income required to attain a specified social welfare contour. If W^0 is the social welfare under policy 0 and W^1 is the welfare under policy 1, the monetary measure of the change is social welfare is exactly analogous to the generalized equivalent variation:

$$\Delta W = M\left(\mathbf{p}, W^1\right) - M\left(\mathbf{p}, W^0\right).$$

ΔW is clearly ordinally equivalent to the changes in social welfare, and normative judgements are represented explicitly through the specification of the social welfare function.

Consumption and Production

C. A. Gregory

Neoclassical economic analysis is carried out within a conceptual framework that views the economic process as a 'one way avenue' leading from 'factors of production' to 'consumption goods' (Sraffa 1960, p. 93). This stands in striking contrast to the approach of classical political economy which views the system of consumption and production as a circular process. This perspective was first developed by Quesnay (1759) and elaborated by Marx (1859) in his analysis of the economy in general. Marx developed a distinction between 'production and productive consumption' and 'consumption and consumptive production' and related this to the concepts of exchange and distribution. This distinction fell into diuse with the rise of neoclassical economics but has been rehabilitated by Sraffa (1960) in his famous critique of modern economics. The concept 'production and productive consumption' provides the general conceptual framework within which his particular theory of commodities is elaborated (see Sraffa 1960, p. 3). Sraffa's exposition not only advances our understanding of the theory of commodities, it also enables us to grasp the essence of Marx's important distinction between consumption and production. Marx expressed himself in rather obscure Hegelian terms and Sraffa's simple numerical examples clarify much of Marx's argument.

Following Sraffa, let us suppose that an extremely simple society is producing just enough wheat and iron to maintain itself. If 400 quarters of wheat (hereafter 400 W) were produced using 280 W and 12 tons of iron (12I) and 1/2 of the annual labour supply (1/2 L) as inputs, while 20I were produced using 120 W, 8I and 1/2 L, then the methods of production and productive consumption can be tabulated as follows:

$$1/2\mathrm{L} + 280\mathrm{W} + 12\mathrm{I} \rightarrow 400\mathrm{W}$$
$$1/2\mathrm{L} + 120\mathrm{W} + 8\mathrm{I} \rightarrow 20\mathrm{I}$$

In order for the process to be repeated the wheat industry must exchange 120 W for 12I. This restores the original distribution of products and enables the process to be repeated.

A three-product model takes us from barter to triangular trade: an *n*-product model to more complex forms of exchange and distribution.

The general formulation of the concept 'production and productive consumption' implicit in Sraffa's analysis is:

$$\text{labour} + \text{things} \rightarrow \text{things}.$$

In other words, the methods of production and productive consumption describe the process of the production of things by means of things and labour. The production by commodities by means of commodities is one historically specific form of these general relations. The emergence of things and labour as commodities presupposes private property and the emergence of a class of proletarians (Marx 1867). This is only one of many social forms that things and labour can take. In tribal economies, for example, things and labour assume the social form of gifts. The social precondition for this to arise is a relatively egalitarian distribution of land between clans. Social data of this kind mean that the principles governing the exchange and distribution of products will vary greatly from economy to economy. In a 'pure' tribal economy, for example, profit maximization is not the central organizing principle of economic life and wages, prices and profits are not be found (Polanyi 1944).

A corollary of this general formulation of production is that 'consumption and consumptive production' can be described as follows:

$$\text{things} + \text{people} \rightarrow \text{people}.$$

In other words 'consumption and consumptive production' describes the methods of production of people by means of people and things.

Neither Marx nor Sraffa analysed these relations which under capitalism would be called the 'household economy' or 'kinship'. However, anthropologists who have studied third world tribal and peasant societies have tended to focus almost exclusively on these relations, a fact, I would suggest, which tells something about the relative importance of production and consumption in capitalist and tribal/peasant societies respectively.

Some indication of what is involved in this concept of consumption can be gleaned by elaborating its meaning in the context of Sraffa's 'extremely simple economy'. Suppose that the iron and wheat were produced by two different households, each household consisting of a father (M), a mother (F), a boy (m) and girl (f). Reproduction of the households, and hence of labour, requires that the children set up new households and produce their own children. Incestuous relations aside, it is clear that the households must exchange children in a way that is analogous to the exchange of wheat for iron discussed above. This can be seen from the following formulation of the relations of consumption and consumptive production for this two-household economy:

$$\begin{aligned} M_1 + F_2 &\rightarrow m_1 + f_1 \\ M_2 + F_1 &\rightarrow m_2 + f_2 \end{aligned}$$

where the subscripts represent the respective households. This particular example is an example of what anthropologists call 'cross cousin' marriage or 'sister exchange'. By tracing the relationships out it will be seen that a man marries his mother's brother's daughter who is also his father's sister's daughter. Take m_1 for example. His father is M_1, his father's sister is F_1, and the latter's daughter is f_2 with whom he will set up a household in the next generation. Tracing the relationships through m_1's mother (F_2) it is obvious that f_2 is also his mother's brother's daughter. Relations of this kind are very important in clan-based societies where a number of households, usually related either matrilineally or patrilineally, occupy a common piece of territory and forbid marriage within the households that make up the clan. In our own society, where the clan has no operational significance, and where marriage is a matter of personal choice rather than a formal arrangement between groups, the political and economic significance of kinship and marriage is relatively unimportant (Gregory 1982).

Every economic analysis of a particular socio-economic form such as 'profits', 'prices' or 'wages' involves, either implicitly or explicitly, a general conceptual framework within which the analysis is carried out. The general model implicit in Quesnay's analysis of 18th-century French agriculture has been elaborated and developed to provide an extremely useful framework not only for the development of a 20th-century theory of the value and distribution of commodities but also for the

analysis of comparative economic systems. By focusing on the circular process of production and reproduction, consumption becomes a dynamic process rather than the dead end of a one way avenue.

Consumption Externalities

Robert H. Frank

Abstract

Consumption externalities occur when consumption by some creates costs or benefits for others. According to Duesenberry's 'relative income hypothesis', spending is influenced by the individual's own standard of living in the recent past and the living standards of others in the present. This hypothesis tracks observed behaviour more closely than Friedman's 'permanent income hypothesis', which assumes that context has no influence on spending. When context is more important for some goods (positional goods) than for others (non-positional goods), positional goods crowd out non-positional goods, causing welfare losses like those that occur when bombs crowd out consumption in military arms races.

Consumption externalities occur when consumption by some creates external costs or benefits for others. Their recognition by economists dates at least as far back as Adam Smith's discussion of how local consumption standards influence the goods that people consider essential (or 'necessaries', as Smith called them). In the following passage, for example, he described the factors that influence the amount someone must spend on clothing in order to be able appear in public 'without shame':

> By necessaries I understand, not only the commodities which are indispensably necessary for the support of life, but whatever the custom of the country renders it indecent for creditable people, even of the lowest order, to be without. A linen shirt, for example, is, strictly speaking, not a necessary of life. The Greeks and Romans lived, I suppose, very comfortably, though they had no linen. But in the present times, through the greater part of Europe, a creditable day-labourer would be ashamed to appear in publick without a linen shirt, the want of which would be supposed to denote that disgraceful degree of poverty which, it is presumed, no body can well fall into without extreme bad conduct. (Smith 1776, pp. 869–70)

Consumption externalities received only limited attention in Smith's *Wealth of Nations* and only occasional mention by economists during the century that followed its publication. Karl Marx (1847), for example, noted that 'A house may be large or small; as long as the neighboring houses are likewise small, it satisfies all social requirement for a residence. But let there arise next to the little house a palace, and the little house shrinks to a hut.'

It was not until Thorstein Veblen's *The Theory of the Leisure Class* appeared in 1899 that

consumption externalities received their first serious, book-length treatment in economics. Veblen's thesis was that much of consumption is undertaken to signal social position. But although his book is still widely read and cited by scholars in numerous disciplines, its general theme was largely ignored by economists during the 50 years following its publication.

Duesenberry's Relative Income Hypothesis

Interest in this theme was rekindled with the publication of James Duesenberry's *Income, Saving, and the Theory of Consumer Behavior* in 1949. In this volume, Duesenberry offered his 'relative income hypothesis', in which he argued that an individual's spending behaviour is influenced by two important frames of reference – the individual's own standard of living in the recent past and the living standards of others in the present. Thus, in Duesenberry's account, people are subject to both intrapersonal and interpersonal consumption externalities.

His theory attempted to explain three important empirical regularities: (*a*) long- run aggregate savings rates remain roughly constant over time, even in the face of substantial income growth; (*b*) aggregate consumption is much more stable than aggregate income in the short run; and (*c*) individual savings rates rise substantially with income in cross-section data. When Duesenberry's book was first published, individual consumption was generally modelled by economists as a linear function of income with a positive intercept term. This model could accommodate rising savings rates in cross-section data and the stability of consumption over the business cycle, but not the long-run stability of aggregate savings rates.

Duesenberry's hypothesis was hailed as an advance because of its ability to track all three stylized fact patterns. The poor save at lower rates, he argued, because they are more likely to encounter others with desirable goods that are difficult to afford. Moreover, since this will be true no matter how much national income grows, unfavorable comparisons will always occur more frequently for the poor – and hence the absence of any tendency for savings rates to rise with income in the long run.

To explain why consumption is more stable than income in the short run, Duesenberry argued that families compare their living standards not only to those of others around them but also to their own standards from the past. The high consumption level once enjoyed by a formerly prosperous family thus constitutes a frame of reference that makes cutbacks difficult when income falls.

Despite Duesenberry's success in tracking the data, many economists felt uncomfortable with his relative income hypothesis, which to them seemed more like sociology or psychology than economics. The profession was therefore immediately receptive to alternative theories that purported to explain the data without reference to softer disciplines. The most important among these theories was Milton Friedman's permanent income hypothesis, variants of which still dominate today's research on spending.

In hindsight, however, there remain grounds for scepticism about whether Friedman's theory was a real step forward. For example, its fundamental premise – that savings rates are independent of permanent income – has been refuted by numerous careful studies (see, for example, Carroll 1998). Some modern consumption theorists have responded by positing a bequest motive for rich consumers, a move that begs the question of why leaving bequests should entail greater satisfaction for the rich than for the poor.

Another problem is that, contrary to Friedman's assertion that the marginal propensity to consume out of windfall income should be nearly zero, people actually consume such income at almost the same rate as permanent income (Bodkin 1959). To this observation, Friedman (1963) himself responded that consumers appear to have unexpectedly short planning horizons. But if so, then consumption does not really depend primarily on permanent income.

Abundant evidence suggests that context influences evaluations of living standards (see, for example, Veenhoven 1993; Easterlin 1995; Luttmer 2005). In the light of this evidence, it seems fair to say that Duesenberry's hypothesis

not only has been more successful than Friedman's in tracking how people actually spend but also rests on a more realistic model of human nature. And yet the relative income hypothesis is no longer even mentioned in most leading economics textbooks. Its absence appears to signal the profession's continuing reluctance to acknowledge concerns about relative consumption.

Welfare Implications

In traditional economic models, individual utility depends only on absolute consumption. These models lie at the heart of claims that pursuit of individual selfinterest promotes aggregate welfare. In contrast, models that include concerns about relative consumption identify a fundamental conflict between individual and social welfare. This conflict stems from the fact that concerns about relative consumption are stronger in some domains than in others. The disparity gives rise to expenditure arms races focused on 'positional goods' – those for which relative position matters most. The result is to divert resources from 'non-positional goods', causing welfare losses. (The late Fred Hirsch 1976, coined these terms.)

The nature of the misallocation can be made clear with the help of two simple thought experiments. In each, you must choose between two worlds that are identical in every respect except one. The first choice is between world A, in which you will live in a 4,000-square-foot house and others will live in 6,000-square-foot houses; and world B, in which you will live in a 3,000-square-foot house, others in 2,000-square-foot houses. Once you choose, your position on the local housing scale will persist.

If only absolute consumption mattered, A would be clearly better. Yet most people say they would pick B, where their absolute house size is smaller but their relative house size is larger. Even those who say they would pick A seem to recognize why someone might be more satisfied with a 3,000-square-foot house in B than with a substantially larger house in A.

In the second thought experiment, your choice is between world C, in which you would have four weeks a year of vacation time and others would have six weeks; and world D, in which you would have two weeks of vacation, others one week. This time most people pick C, choosing greater absolute vacation time at the expense of lower relative vacation time.

The modal responses in these two thought experiments suggest that housing is a positional good and vacation time a non-positional good. The point is not that absolute house size and relative vacation time are of no concern. Rather, it is that positional concerns weigh more heavily in the first domain than in the second.

When the strength of positional concerns differs across domains, the resulting conflict between individual and social welfare is structurally identical to the one inherent in a military arms race. When deciding how to apportion available resources between domestic consumption and military armaments, each country's valuations are typically more context-dependent in the armaments domain than in the domain of domestic consumption. After all, being less well armed than a rival nation could spell the end of political independence. The familiar result is a mutual escalation of expenditure on armaments that does not enhance security for either nation. Because the extra spending comes at the expense of domestic consumption, its overall effect is to reduce welfare. Note, however, that if each country's valuations were equally context-sensitive in the two domains, there would be no arms race, for in that case the attraction of having more arms than one's rival would be exactly offset by the penalties of having lower relative consumption.

For parallel reasons, the modal responses to the two thought experiments suggest an equilibrium in which people consume too much housing and too little leisure (for a formal demonstration of this result, see Frank 1985a). In contrast, conventional welfare theorems, which assume that individual valuations depend only on absolute consumption, imply optimal allocations of housing and leisure.

In addition to leisure, goods that have been classified as non-positional by various authors include workplace safety, workplace democracy, savings and insurance. And since public goods

are, by definition, available in equal quantities to all consumers, they, too, are inherently non-positional. The general claim is that unregulated market exchange will tend to emphasize the production of positional goods at the expense of these and other non-positional goods (Frank 1985b). Among the policies suggested as remedies for this imbalance have been income and consumption taxes, overtime laws, hours laws for commercial establishments, legal holidays, workplace safety and health regulation, non-waivable workers' rights, and tax-financed savings accounts.

Consumption externalities also have implications for the theory of revealed preference, which says that, if a well-informed individual chooses a risky job that pays $600 a week rather than a safer one that pays only $500, he reveals that the safety increment is worth less than $100 to him. If safety is a non-positional good, however, this inference does not follow, for it ignores the fact that, if all workers exchange safety for increased income, the anticipated increase in relative consumption does not occur. The value that workers assign to safety may thus be revealed as much in the patterns of safety regulation they favour as in the nature of the jobs they choose.

Consumption Function

Michael R. Darby

Keynes (1936) introduced the consumption function as the relationship between consumption and income. Although Keynes (pp. 95–6) believed this relationship 'a fairly stable function', substantial shifts in the function were soon observed by empirical workers. Much work in the post-World War II era achieved functional forms by the 1970s which admirers and critics alike could agree were relatively shiftless. Most recent work has considered not functional form but whether or not observed changes in consumption are consistent with models of efficient markets.

The Keynesian Conception

Keynes conceived of the consumption function as relating consumption to disposable income as these are now conventionally measured in the national income accounts. These concepts were basic to the model of *The General Theory* and Keynes was doubtless pedagogically correct to posit a simple relationship which could be refined by future research.

The need for refinement became apparent shortly. In longer time series, consumption seemed to vary around a constant fraction of disposable income. In contrast, consumption functions fitted to depression-era or cross-section data seemed to indicate that this ratio (which Keynes called the average propensity to consume or APC) declined as disposable income rose. In other words, these studies estimated that the derivative of consumption with respect to disposable income (the marginal propensity to consume or MPC) was less than the APC.

Alvin Hansen (1939) among others predicted that a *secular stagnation* would result unless government spending filled this growing gap between output and consumption. When the gap failed to appear, the time was ripe for more sophisticated theories of the relationship between consumption and income. These theories were the earliest and perhaps still most successful resorts to microeconomic foundations for macroeconomics.

Permanent Life-Cycles

In the early 1950s our two dominant models of consumption developed: the permanent-income and life-cycle hypotheses. While these models were once viewed as competing, they can now be seen as complementary with differences in emphasis which serve to illuminate different significant problems. Both models emphasized the distinction between consumer expenditures measured by the national income accounts and pure consumption which was to be explained by optimal allocation of present and future resources over time. The permanent income hypothesis (PIH) stressed stochastic variations in income (and consumption) over time and viewed saving in terms of a bequest motive. The life-cycle hypothesis (LCH) stressed predictable variations in income (and consumption) over the life cycle and viewed saving as resulting from the greater wealth and numbers of younger savers in comparison to older dissavers.

The original published references are to Friedman (1957) for the PIH and Modigliani and Brumberg (1954) for the LCH. Given the delays in NBER publication of Friedman's work which was widely circulated in manuscript form, the two hypotheses are generally regarded as distinct, contemporaneous responses to the described conflict between earlier studies and Simon Kuznets' data on the national income accounts for the 20th century. From the perspective of the monumental careers of the two principal proponents, priority does not seem an issue that need be resolved here.

The PIH relates (pure) consumption to the perpetuity stream that could be consumed forever. The agent is typically regarded as an infinitely lived individual. This represents the underlying notion of a family whose generations are linked by operative transfers from parent to child or vice-versa. Saving arises to equate the ratio of marginal utility of present and future consumption to the marginal rate of transformation implicit in market (real) interest rates. In this way the PIH is said to emphasize the bequest motive for saving.

In contrast, the strict LCH had individuals consuming their entire endowments over their lifetime. Saving was supposed to arise because young workers were more numerous and wealthy (due to technological progress) than the older generation who were dissaving to finance retirement. This provides an avenue by which faster growth can increase saving. Alternatively, as discussed below, factors such as social security which change the extent of mismatch between lifetime consumption and income patterns are predicted to have profound effects on aggregate saving.

These approaches – and their synthesis with inter-generationally linked utility functions – have led to a rich literature quite apart from the consumption function, but those developments are beyond the scope of this essay.

From the point of view of the consumption function per se, the PIH and LCH imply that pure consumption is a fraction (variable in principle but rarely in practice) of wealth or permanent income. Here wealth is inclusive of human as well as non-human capital and permanent income is a (conventionally constant) long-term *ex ante* real interest rate times this wealth. (Note that, contrary to Sargent (1978) and others this wealth is not the discounted present value of expected future income to the extent, as in the PIH, that future income is expected to rise through planned saving.) The empirical estimation of wealth or permanent income became a central issue in the specification of the consumption function.

Friedman proposed a computationally simple estimator of permanent income as a geometrically weighted average of past income. Since on this scheme, permanent income changes – besides normal growth – by a fraction, say β, of the difference between current income and permanent income, Friedman related this scheme to the adaptive-expectations approach recently introduced by his student Phillip Cagan (1956).

Modigliani and his associates proxied normal labour income by current income and the product of this variable and the unemployment rate and attempted to measure non-human wealth by collecting estimates of the national balance sheet at market values. In principle, this method seemed more clearly related to the underlying framework than Friedman's permanent-income proxy, but in practice it suffered several comparative disadvantages: (1) major components of non-human wealth had no market valuation; (2) the wealth estimates were not part of the national income accounts and competing variants were available with substantial delay and at irregular intervals; (3) for forecasting purposes, substantial additional equations were required to forecast (often poorly) future movements in wealth.

Darby (1974) reconciled these empirical measures of wealth by demonstrating that under the PIH, Friedman's geometrically weighted measure could be derived as the constant real interest rate β times a (backward-looking) perpetual inventory of wealth. This β value was estimated as about 0.10 per annum in contrast to higher values such as Friedman's 0.35 per annum. These higher values were explained by biases that arise as data deviate from pure consumption toward expenditures by consumers.

Empirical work on consumption functions has frequently floundered on the use of theories of pure consumption to explain data which are in whole or part consumer expenditures. Both the PIH and LCH were theories of pure consumption. Modigliani and Ando provided one link to consumer expenditures in their MPC model by modelling household investment in durable goods analogously to firm's investment behaviour. Operating in the PIH tradition, Darby (1972, 1974) argued that aggregate transitory income represented a change in wealth, part of which change would be invested in consumers' durable goods. (Darby (1972) in particular argued that because transitory income is received in non-human form, a disproportionate effect on durable-goods purchases may arise during the adjustment process, a result which explains the results of Hayashi 1982.) Darby (1975, 1977–8) later combined pure consumption and durable investment equations to obtain a unified consumer expenditure function which avoided some of the inherent difficulties in dividing consumer expenditures into durable and nondurable portions.

The PIH and LCH thus evolved to explain aggregate consumer expenditures by wealth as a determinant of pure consumption and by *changes* in wealth and other variables which determine household investment in durable goods. The correlation of the determinants of this household investment with short-run (transitory) fluctuations in income explain a MPC which is substantial in magnitude even though substantially below the APC.

This brief development has omitted discussion of alternative views of the consumption function. Perhaps the most notable of these is the view that the substantial value of the MPC reflects liquidity constraints which prevent a substantial share of consumers (measured by wealth and consumption) from following their optimal intertemporal consumption plan. The author of this essay regards these alternative views as providing qualification of the dominant wealthbased view.

Efficient-Market Approaches

Hall (1978) proposed to sidestep Friedman's backward-looking measure of wealth as well as the substantial empirical problems involved in measuring the market value of wealth. Instead, he posed the question of whether or not changes in consumption can be modelled empirically as determined by 'news'. Specifically, the assertion is that if wealth estimates and hence consumption are based on rational expectations, no past information including past changes in consumption or income should affect current changes in consumption.

Hall (1978) answered his question affirmatively, Flavin (1981) dissented, but Hayashi (1982) showed that excess sensitivity of spending to changes in wealth appeared to be confined to consumers' durable goods purchases. Taken as a whole, these studies seem to confirm the basic Friedman–Modigliani conceptions that aggregate consumption as determined by wealth but that it is important to distinguish between consumer expenditures and consumption.

Bequest Versus Life-Cycle Saving

Saying that consumers optimally allocate wealth leaves several important questions unanswered: Do consumers have operative linkages in utility functions across generations? Are consumers able to see through the veil of government to the ultimate production possibilities faced by society? If the first of these questions is answered affirmatively, transfer programmes such as social security which change the life-cycle pattern of income receipts will not affect aggregate consumption and saving. (The representative infinitely lived individual does not care whether he or she pays social security taxes which are refunded as equal benefits. Intergenerational transfers can be adjusted so that this representation is acceptable where utility functions are linked across generations.) If the second question is also answered affirmatively, then Ricardian equivalence holds (it is irrelevant whether government taxes or borrows) and the relevant income concept for the aggregate consumption function is net national product less government spending for goods and services.

Feldstein (1974) claimed that aggregate saving had been significantly reduced by the US social security programme. As pointed out by Barro (1978), this effect would not arise with intergenerationally linked utility functions. Using different methodology, White (1978) and Darby (1979) concluded that life-cycle motives accounted for an at most small fraction of aggregate saving and wealth. Kotlikoff and Summers (1981) relaxed Darby's assumptions on smooth growth of population and labour income without substantially changing the estimates on the range of assets attributable to life-cycle motives. These estimates seem to suggest that intergenerational linkages are indeed very important, as assumed by the PIH. The life-cycle effects highlighted in the LCH would appear more important for analysing cross-sectional data than as determinants of aggregate consumption.

The Ricardian equivalence idea was urged by Barro (1974) and Kochin (1974). It requires a certain suspension of disbelief to assume that bonds and taxes have equivalent effects on consumer behaviour, but the data are not very inconsistent with that notion. Indeed recent studies by Seater (1982) and Kormendi (1983) provide some evidence that Ricardian equivalence is a better working hypothesis than its denial.

Conclusions

The consumption function suggested by Keynes provided a useful challenge to theoretical and empirical economists. The relationship between changes in consumer expenditures and current income has been explained generally in a way which is consistent with microeconomic foundations and which is adequate in a multitude of specifications for most forecasting purposes. (Technical differences among empirical specifications are as large in number as they are uninteresting to the nonspecialist.) For policy analytic purposes, two key questions are outstanding: are life-cycle effects significant in the aggregate,

and do individuals effectively see through government? This author's reading of the evidence suggests answers of no and maybe, but it is hard to put much certainty in any answer unless one starts with dogmatic priors.

The consumption function has faded as a topic of intense research largely because of the success of previous work in achieving a workable consensus. The unsettled issues, however, have crucial policy implications and there is much value yet to be added.

Consumption Sets

Peter Newman

JEL Classifications
E2

The idea of consumption sets was introduced into general equilibrium theory in July 1954 in Arrow and Debreu (1954, pp. 268–9) and Debreu (1954, p. 588), the name itself appearing only in the latter paper. Later expositions were given by Debreu (1959) and Arrow and Hahn (1971) and a more

general discussion by Koopmans (1957, Essay 1). Although there have been several articles concerned with nonconvex consumption sets (e.g. Yamazaki 1978), in more recent years their role in general equilibrium theory has been muted, especially in approaches that use global analysis (see for example, Mas-Colell 1985, p. 69). Such sets play no role in partial equilibrium theories of consumer's demand, even in such modern treatments as Deaton and Muellbauer (1980). Since general equilibrium theory prides itself on precision and rigour (e.g. Debreu 1959, p. x), it is odd that on close examination the meaning of consumption sets becomes unclear. Indeed, three quite different meanings can be distinguished within the various definitions presented in the literature. These are given below (in each case the containing set is the commodity space, usually R^n): M1 The consumption set C1 is that subset on which the individual's preferences are defined. M2 The consumption set C2 is that subset delimited by a natural bound on the individual's supply of labour services, i.e. 24 hours a day. M3 The consumption set C3 is the subset of all those bundles, the consumption of any one of which would permit the individual to survive. Each definition in the literature can (but here will not) be classified according to which of these meanings it includes. In probably the best known of them (Debreu 1959, ch. 4), the consumption set appears to be the intersection of all three subsets C1–C3. M1 is plain. After all, preferences have to be defined on *some* proper subset of the commodity space, since the whole space includes bundles with some inadmissibly negative coordinates. M2 is also reasonable, although a full treatment of heterogeneous labour services does raise problems for what is meant by an Arrow–Debreu 'commodity' (see for example, that of Arrow–Hahn 1971, pp. 75–6). It is M3 that gives real difficulty, both in itself and in relation to the others.

First, there is little reason to expect either C1 or C3 to be a subset of the other, and so still less to expect M1 and M3 to define the same set. No individual would have any problem in preferring one bundle, the consumption of which would ensure her survival, to a second bundle, the consumption of which would result in her death by starvation. However, she might well prefer the second bundle to a third, whose consumption would cause her to die from thirst (the representation of such preferences by a real-valued utility function might pose problems, but that is another matter). On the other hand, the same individual might not be able to rank in order of preference two bundles each of which contains exotic food and drink, even though fully assured that the consumption of either bundle would allow her to survive.

More importantly, M3 implicitly introduces *consumption* activities, the actual eating and drinking and sheltering that are essential to survival. Such activities constitute what are sometimes called, by analogy with production, the consumption technology. Some partial equilibrium models, such as 'the new home economics' and the theory of characteristics, have treated aspects of such technologies but so far general equilibrium theory has not. In particular, Arrow–Debreu theory has not done so. As a consequence (and unlike some forms of the classical 'corn model') it does not give a coherent account of the birth and death of individual persons, any more than it does of the birth and death of individual firms (*see* general equilibrium). Hence the third meaning M3, which in effect presumes that the model contains such an account when it does not, is hard to interpret. One major difficulty of interpretation arises with the Slater-like condition that each individual's endowment of goods and services, valued at the competitive prices p^*, should be strictly greater than inf $\{(x, p^*): x \in C\}$, where $< .,. >$ denotes inner product and C is 'the' consumption set (see cost minimization and utility maximization). This condition is important in proofs of existence of competitive equilibrium, to ensure for example that the budget correspondence is continuous, or that a compensated equilibrium is a competitive equilibrium. It is itself guaranteed by assumptions (discussed by McKenzie 1981, pp. 821–5) on the relations between 'individual' consumption sets and the aggregate production set.

If C is taken to contain C3 then the assumptions just referred to imply that every consumer

survives in every competitive equilibrium, not merely for one period but over the whole (finite) Arrow–Debreu span. This is a breathtaking assertion of fact which recalls irresistibly Hicks's wry observation: 'Pure economics has a remarkable way of producing rabbits out of a hat – apparently *a priori* propositions which apparently refer to reality. It is fascinating to try to discover how the rabbits got in' (1939, p. 23).

On the other hand if C is taken to be C1, then the assumptions take on a purely technical (and so less objectionable) aspect, whose role is essentially to ensure that the system stays within the (relative) interior of the sets concerned and so displays appropriate continuity. But then there is no presumption that individual agents survive in a competitive equilibrium, even for one period (cf. Robinson 1962, p. 3). The multi-period versions of the Arrow–Debreu model are then at risk, since individuals disappear and take their labour service endowments with them. This should not come as a surprise – the problems of time in economics are really too complicated to be overcome simply by adding more dimensions to the one-period model.

Some models that include C3 in C attempt to justify Slater-like conditions directly, on the grounds that ' Not many economies in the present day are so extremely laissez faire as to permit people to starve' (Gale and Mas-Colell 1975, p. 12). This justification clearly fails as long as the behaviour of the public agency whose actions allegedly prevent such starvation is not modelled *explicitly*, like that of the private agents.

It is usually assumed that consumption sets are bounded below, closed and convex. The first two assumptions are innocuous but the third poses issues of a conceptual kind, which spring from difficulties in interpreting the idea of a convex combination $x^t = tx^1 + (1 - t)x^2$ of two bundles x^1 and x^2, where $t\varepsilon[0, 1]$. Consider the example, sometimes used, in which x^1 is a house in London and x^2 a house in Paris. We cannot take seriously the claim that x^t is a house in the Channel, so t cannot refer to distance. An alternative claim that t refers to the proportion of the period that is spent in London could arise from many different finite partitions of the time interval, not all of which need to be ranked equally by the individual. In effect, convexity of the consumption set comes down to the divisibility of consumer goods, an assumption which in the past has proved not such a bad approximation if one is interested mainly in general equilibrium aspects of market demand, and representative rather than actual consumers. Indivisibilities of producer goods are of course much more serious.

Consumption Taxation

James M. Poterba

Abstract

Whether to tax households based on their income or on their consumption is one of the central and long-standing questions of tax design. Most developed nations rely on a combination of income and consumption taxes to raise revenue. The debate over alternative tax bases involves both philosophical arguments about what constitutes a fair measure of ability to pay and economic arguments about the relative efficiency of different tax bases. Consumption taxes can be implemented in a variety of ways, including value added taxes, retail sales taxes, and savings-exempt income taxes.

Whether household income or household consumption constitutes a better measure of a household's ability to pay taxes, and whether there are substantial efficiency gains to choosing one tax base rather than the other, are two of the central questions of public finance. The debate between advocates of income taxes and advocates of consumption taxes has spanned several centuries. While income has often been viewed as the basis for taxation, and Adam Smith discusses taxation relative to household incomes, Thomas Hobbes, John Stuart Mill and Irving Fisher were all strong proponents of taxing consumption. Consumption tax supporters argue that the amount that an individual draws from the economy's resource pool should determine his or her tax burden. They also point out that an income tax levies a 'double tax' on saving, since saved income is taxed both when it is earned and when the savings yield a return to capital. Kaldor (1955) offers a broad review of the case for consumption taxation. Two notable reports in the late 1970s, one by the Meade Commission (Meade 1978) in the United Kingdom and the other by the staff of the US Treasury Department (1977), outlined the modern cases for consumption taxation and developed specific proposals.

Proponents of income taxation argue that the change in an individual's command over resources between one period and the next is an appropriate measure of 'ability to pay', even if those resources are not immediately consumed. This is the measure of taxable capacity suggested by Robert Murray Haig and Henry Simons: 'Haig–Simons' income. Moreover, they argue that changes in resources should be taxed regardless of whether they arise from labour income or from the returns to past saving.

Income taxes and consumption taxes exhibit different time profiles over the course of a lifetime. When individuals experience a period of retirement before they die, the time profile of tax payments under a consumption tax will fall later in the lifetime than the corresponding payments under an income tax. This is because individuals continue to consume after they stop earning labour income. Retirees under an income tax pay tax only on their capital income, while retirees under a consumption tax pay tax on their total outlays, which are likely to exceed their capital income.

The debate between proponents of consumption taxation and proponents of income taxation concerns whether or not capital income should be taxed. The foregoing philosophical issues notwithstanding, the efficiency cost of taxing capital income has been an active subject of economic research. Chamley (1986) and Judd (1985) argue that the effective distortions from capital taxes cumulate over time as the difference between discounting the future at before-tax and after-

tax interest rates increases with the compounding horizon. They claim that the optimal steady-state capital income tax rate should be zero. However, they also point out that a one-time capital levy is an efficient device for raising revenue. A number of recent studies, described in Auerbach (2006), have examined the robustness of the theoretical claim that the optimal capital tax rate is zero.

Consumption tax proponents, such as Bradford (1980), claim not only that taxing consumption rather than income avoids intertemporal distortions, but also that it solves many of the most difficult measurement and accounting problems associated with income taxation. Under a consumption tax, for example, there would be no distinction between the tax burden on investment projects financed with debt and those financed with equity, or between realized and unrealized capital gains. There would be no need to measure the rate at which long-lived physical assets depreciate, as one must do under an income tax. Income tax proponents respond that some components of consumption may be difficult to measure, and that it is more difficult to tailor consumption taxes than income taxes to achieve redistributive goals.

Formalizing Consumption Taxation Vs. Income Taxation

The essential difference between a consumption tax and an income tax can be illustrated by comparing the lifetime budget constraints that consumers would face under each tax system. An income tax is levied on both labour and capital income. When a household has assets of A_{t-1} at the beginning of period t, these assets earn a pre-tax return r and the household earns labour income of wL where w equals the real wage and L denotes labour supply, the income tax base is $wL + rA_{t-1}$. The income tax not only reduces the after-tax real wage but also lowers the after-tax return to saving. In a life-cycle model in which a household lives for T periods and in which there is no inflation, the life-cycle budget constraint with an income tax is

$$\sum_{t=1}^{T} C_t/(1+r(1-\tau))^t = \sum_{t=1}^{T} (1-\tau)w_t L_t/(1+r(1-\tau))^t + A_0 \quad (1)$$

In this expression, C denotes real consumption spending, and A_0 is the household's initial wealth endowment.

In contrast, the life-cycle budget constraint with a consumption tax levied at rate θ is

$$\sum_{t=1}^{T} (1+\theta)C_t/(1+r)^t = \sum_{t=1}^{T} w_t L_t/(1+r)^t + A_0 \quad (2)$$

The discount rate in this case is the pre-tax return. The consumption tax levied on outlays in each period is equivalent to a tax on labour income *and* the household's initial endowment. If $(1 - v) = 1/(1 + \theta)$, then Eq. 2 can be rewritten as.

$$\sum_{t=1}^{T} C_t/(1+r)^t = \sum_{t=1}^{T} (1-v)w_t L_t/(1+r)^t + (1-v)A_0 \quad (3)$$

The timing of tax payments under the 'wage-and-endowment tax' in (3) is different from that under the consumption outlays tax in (2), but the present value of taxes and the effects on economic incentives are the same under the two systems. The tax on initial endowment is an essential component of this equivalence: a wage tax alone is *not* equivalent to a consumption tax because initial assets escape taxation when only wages are taxed.

The current tax system in most developed nations is a hybrid structure, reflecting some elements of income taxation but also embodying components of a consumption tax. This is most apparent in nations that rely on both an income tax and a consumption tax, such as a value added tax, for a substantial share of government revenue. Even within many income tax systems, however, there are provisions that move toward an income

tax-consumption tax hybrid. In the United States, for example, capital income that accrues in employer-provided pension plans and in a variety of taxpayer-directed retirement saving accounts, such as Individual Retirement Accounts (IRAs), is excluded from income taxation. Some types of capital income are taxed at rates below the top statutory tax rates on wage income. Realized capital gains have often been taxed at preferential rates, and in some cases dividend income to households is also subject to reduced rates of tax. There is substantial variation in tax structures across nations, but the principle of allowing some tax reduction on capital income is widespread. This makes it difficult to assess where any particular nation's tax system falls on the spectrum between an income tax and a consumption tax.

Types of Consumption Taxes

In practice, there are many ways to implement a consumption tax. Two, the retail sales tax and the value added tax, are widely used in practice. Both are examples of indirect consumption taxes, because they are levied without any reference to the consumer's identity. Direct consumption taxes, in contrast, are levied on households by computing their total consumption. In contrast to indirect consumption taxes, direct consumption taxes can be levied at progressive rates. While direct consumption taxes have never been used as the primary revenue source in any nation, they have been actively debated in the policy reform literature. Tax structures that closely resemble direct consumption taxes have been adopted as components of existing tax systems. The two most widely discussed direct consumption tax options are the savings-exempt income tax and the 'X-tax,' a combination of a cash-flow tax on business income and a household wage tax.

A *retail sales tax* (RST) is the simplest consumption tax. It is collected by retailers at the point of final sale, and it corresponds directly to the tax on consumption spending described in Eq. 2 above. In 2006, 44 of the 50 US states levied some form of sales tax, with rates typically between four and seven per cent. There is little experience with RSTs above ten per cent. One unresolved question with regard to proposals that call for significantly higher RSTs is whether the difficulty of monitoring all points of purchase would lead to substantial problems of tax evasion.

A *value added tax* (VAT) is a very common form of consumption tax. Virtually all developed nations with the exception of the United States levy some form of VAT, with rates ranging up to 25 per cent in Denmark, Norway and Sweden. The VAT is collected from businesses on the difference between the gross value of their sales and the cost of any inputs that they purchase from other entities that have already paid VAT.

To illustrate the operation of VAT, consider a bakery that produces and sells bread for $100. The baker's input costs are $30 for flour and $65 for an employee. The bakery earns a $5 profit. If flour is purchased from another firm that has already paid VAT, then the bakery's VAT liability equals $70 times the VAT tax rate, since its value added equals its sales of $100 minus input purchases that have already paid VAT, or $30. Wages are *not* deducted from sales when computing value added. Although the VAT is collected in stages from all firms in a production chain, it is equivalent to an RST at the same rate. One attractive feature of the VAT is that downstream firms, such as the baker in this example, help ensure VAT compliance by upstream firms that supply intermediate goods. In this example if the flour seller cannot provide documentation for its VAT payment, the baker will face tax on value added of $100. Thus the baker has an incentive, all else equal, to purchase inputs from suppliers who pay VAT.

Ebrill et al. (2001) offer a comprehensive discussion of VAT implementation issues and summarize experience with the VAT in both developed and developing nations. The VAT accounts for a substantial share of revenue in most industrialized nations. The treatment of international transactions has proven a source of difficulty in some nations, since exporting firms are typically granted a rebate for their VAT payments. Some tax evasion schemes involve exporting goods to qualify for the rebate and re-importing the same goods without paying VAT on the import. The

taxation of financial services also proves challenging under the VAT.

A *savings-exempt income tax* (SEIT) is a consumption tax that is built on an income tax model. For those who are familiar with an income tax system, it provides a way of shifting to a consumption tax without drastic administrative changes in the tax system. The Nunn-Domenici 'USA Tax', introduced in the US Senate in the mid-1990s and analysed in Ginsburg (1995), was a based on this type of consumption tax.

Under the SEIT, the tax base is income less saving. To prevent taxpayers from simply claiming high levels of saving and thereby avoiding tax liability, saving must be documented in the form of a contribution to a 'qualified account'. Income earned on assets held in the qualified account is not taxed, but withdrawals from the qualified account are included in the tax base. Thus a taxpayer who earns $50,000 and contributes $5,000 would be taxed on $45,000 in the contribution period. If, some years later, when earnings equal $25,000, the taxpayer withdraws $10,000 from the qualified account, she would be taxed on $35,000.

Even though the SEIT taxes the earnings that have accrued on the contributions to the qualified account when the funds are withdrawn from this account, the return on capital is untaxed in this setting. Taxing accumulated capital income when the proceeds are withdrawn is *not* equivalent to taxing capital income as it accrues: this is the reason Individual Retirement Accounts, 401(*k*) plans and other tax-deferred saving programmes provide an incentive for personal saving. When capital income is taxed as it accrues, the value of earning one dollar, paying tax on it at rate τ, and then investing it for T periods at a pretax rate of return r but with an accrual tax rate τ, is $(1-\tau)(1+(1-\tau)r)^T$. In contrast, if the initial earnings are excluded from taxation, there is no taxation of accruing capital income, and withdrawals are taxed at 100τ per cent, then the value after T periods is $(1-\tau)(1+r)^T$. The qualified account approach eliminates the tax burden on the 'inside build up' of capital assets.

One of the key challenges in implementing a SEIT is avoiding the wholesale reallocation of existing wealth into 'qualified accounts' at the time the SEIT is adopted. Such transfers could sharply reduce tax collections, but, since they involve previously accumulated assets, they would not translate into marginal incentives for new saving. If it were possible to inventory the assets of each taxpayer when the SEIT was implemented, this would make it possible to design regulations to limit the transfer problem. Absent such information on previously accumulated wealth, however, transfers of pre-existing wealth into qualified accounts are likely to prove a difficult implementation issue for the savings-exempt income tax.

An *X-tax* combines a cash flow tax on businesses, much like a VAT with a deduction for wages, with a household-level tax on wage income. The X-tax and its relatives are descended from proposals in the US Treasury Department's (1977) report on fundamental tax reform. Bradford (1986) discusses several plans of this type, and one widely discussed variant was developed by Hall and Rabushka (1995). The X-tax has greater flexibility than a VAT for achieving distributional goals, since the household level tax can include progressive rates or transfers to low-earning households. This illustrates the distributional flexibility of direct rather than indirect consumption taxes. If the household tax is a flat rate tax on wages at the same rate as the corporate cash flow tax, then the X-tax is equivalent to a VAT or an RST. When the rates are different, then the X-tax becomes a combination of a VAT and an additional tax or subsidy on labour income. The cash flow nature of the business tax eliminates the need to measure depreciation, since firms can claim an immediate deduction – expensing – for purchases of capital goods.

In practice, neither the RST nor the VAT is implemented strictly along the principles described above. Proposals for both the SEIT and the X-tax also include additional features that often introduce efficiency costs that would not arise in 'textbook' versions of these taxes. The RST, for example, typically exempts some goods and services. Expenditures on food, medical care and clothing are often excluded from the tax base, thereby achieving a more progressive distribution of tax burdens while creating

distortions between various classes of consumption goods. The VAT is often implemented at different rates on different goods, with exemptions for some goods, creating the same distortionary effects. Because both the savings-exempt income tax and the X-tax require households to file tax returns, they are prone to modification to allow deductions for some expenditure categories, such as mortgage interest or health insurance premiums. While neither of these consumption tax plans has been tried in practice, they probably would be influenced by the same political pressures that have generated a wide array of tax expenditures in the current income tax code.

Efficiency Gains from Replacing an Income Tax with a Consumption Tax

Income taxes create two distortions: one between the before-tax and the after-tax real product wage, which distorts the labour–leisure margin, and one between the beforetax and the after-tax real rate of return to saving. The latter distorts the lifetime allocation of consumption relative to the pattern that would be chosen if the return to delaying consumption equalled the economy's pre-tax marginal product of capital. Shifting from an income tax to a consumption tax eliminates the second distortion. The key analytical issue in evaluating the welfare consequences of replacing an income tax with a consumption tax is therefore measuring the efficiency costs associated with the taxation of saving and investment. This efficiency cost depends on the underlying structure of consumer preferences. The interest elasticity of saving is often invoked as a summary measure of the key preference parameters. When changes in after-tax returns induce only modest changes in household saving, the efficiency gain from switching from an income tax to a consumption tax will be smaller than when the interest elasticity of saving is large.

Auerbach and Kotlikoff (1987) use a dynamic general equilibrium model, including a realistic treatment of household life-cycle income and consumption streams, to evaluate the efficiency gains from replacing an income tax with a consumption tax. Their results suggest that for a given revenue requirement, the steady-state capital stock is larger with a consumption tax than with an income tax. This translates into higher steady-state per capita utility under the consumption tax than the income tax.

The steady-state comparison is not the only consideration when evaluating two alternative tax systems, however. It is possible to design tax reforms that raise steady-state welfare but cause welfare losses in the transition from an initial equilibrium to the new steady state. The trade-off between short-run and long-run policy effects depends on the policymaker's discount rate and in calibrated general equilibrium models it is possible to compute the present discounted value of the gains and losses to the cohorts alive at different dates.

Transition from One Tax Regime to Another

Focusing on the present value of welfare gains and losses draws attention to the transitional rules that govern the switch from one tax system, say an income tax, to another, such as a consumption tax. These transition rules can determine whether a policy reform represents a net gain or a net loss relative to continuation of the initial income tax regime. Altig et al. (2001) illustrate this important point using a more elaborate version of the model developed in Auerbach and Kotlikoff (1987). They find that if the tax basis of existing assets is extinguished when the income tax is replaced by a consumption tax, so that depreciation allowances are no longer claimed after the reform, and if investors who accumulated savings under the income tax regime do not receive any relief from the consumption tax burden they will face when they draw down their assets, then the efficiency gains from adopting a consumption tax may be as large as five per cent of national income.

'Grandfathering' existing assets sharply reduces these efficiency gains, because it reduces the base of the consumption tax and requires

higher tax rates to satisfy a given revenue constraint. This results in greater distortions on the labour–leisure margin. Designing transition relief that participants in the political process will view as fair, without forgoing most of the efficiency gains from a stark consumption tax transition, is likely to be one of the greatest challenges in any consumption-oriented tax reform.

Consumption-Based Asset Pricing Models (Empirical Performance)

Fatih Guvenen and Hanno Lustig

C

Abstract

Asset pricing is a branch of financial economics that is rich in puzzles and anomalies – that is, stylized empirical facts not easily explained by the canonical asset pricing models. These range from the equity premium puzzle and the risk-free rate puzzle to the fact that stock returns are highly predictable. This article discusses different consumption-based asset pricing models that have been developed to resolve these puzzles, and it evaluates their empirical performance.

The aim of consumption-based asset pricing models is to explain a number of important and puzzling features of asset returns using standard economic theory. Perhaps the best-known challenge for these models is the *equity premium puzzle.* Let us start from the Euler equations for stock and bond choice, and let us assume that both of these Euler equations hold with equality. If agents have constant relative risk aversion (CRRA) preferences and if returns and consumption growth are jointly log-normal, then the

Sharpe ratio (that is, the equity premium per unit of risk) can be decomposed as:

$$\frac{E(R^e)}{std(R^e)} \approx \alpha \times std(\Delta c) \times corr(\Delta c, R^e), \quad (1)$$

where R^e is the excess return on stocks over bonds, α is the relative risk aversion (RRA) parameter, and Δc denotes log consumption growth. The equity premium is about 6 per cent per year in the US data with a standard deviation of 15 per cent, producing a Sharpe ratio ($E(R^e)/std(R^e)$) of 0.4. Mehra and Prescott (1985) used the construct of a representative agent who consumes the aggregate endowment stream. Constantinides (1982), Rubinstein (1974) and Wilson (1968) derived aggregation results that rely on either complete markets or the absence of idiosyncratic income risk. By appealing to these aggregation results, Mehra and Prescott could substitute *per-capita* consumption growth into (1). This series has a standard deviation of less than 2 per cent in the post-war US data, and a low correlation with stock returns – less than 0.25 by most estimates. Substituting these values into the expression above implies a lower bound for the relative risk aversion coefficient of 80, which is implausibly high judging by its implications for an individual's choices in other settings. In other words, we need extremely high risk aversion to rationalize the observed equity premium, and that is the puzzle. Furthermore, even if one is willing to accept such a high coefficient of risk aversion, this choice creates different puzzles itself – a point first noted by Weil (1989).

To understand Weil's 'risk-free rate puzzle', first note that the Euler equation for the risk-free asset choice can be linearized to obtain:

$$E\left[R^f\right] \approx -\ln \beta + \alpha E(\Delta c) - \frac{\alpha^2}{2} var(\Delta c). \quad (2)$$

Let us assume a positive time discount rate ($\beta < 1$), and an average consumption growth rate of 1.5 per cent per year. Let us also abstract from uncertainty for the moment. Then a risk aversion of 40 would imply an implausibly high interest rate of nearly 60 per cent per year simply because these households are extremely unwilling to substitute consumption over time. As a result, they desire a flat consumption profile and, therefore, would like to transfer resources from the future to today. But since this is not feasible in an endowment economy, the equilibrium risk-free rate needs to be very high to discourage this type of consumption smoothing and make individuals willing to consume their endowment every period.

The last term in (2) captures the precautionary savings motive, which becomes active in the presence of uncertainty. For very high levels of risk aversion, this effect dominates the intertemporal substitution effect, and an increase in the RRA coefficient *reduces* the risk-free rate. Epstein and Zin (1989) developed a class of recursive preferences that disentangles the inverse of the elasticity of intertemporal substitution from the coefficient of risk aversion. As discussed below, these preferences allow one to make progress on the equity premium puzzle without running into the risk-free rate puzzle.

Against the backdrop of Mehra and Prescott's benchmark model, subsequent papers that attempt to resolve these puzzles can be categorized according to whether they modify (i) the preferences, (ii) the endowment process, or (iii) the market and asset structure. We discuss each of these approaches in turn.

The Utility Function

Recursive Preferences

In the case of CRRA utility, the stochastic discount factor (SDF) has the following form: $M_{t,t+1} = \beta(C_{t+1}/C_t)^{-\alpha}$, where C denotes the level of consumption. A drawback of this specification is that it restricts the elasticity of intertemporal substitution (EIS) to be the reciprocal of the RRA parameter when in fact these two parameters capture conceptually distinct aspects of individuals' preferences. Building on work by Kreps and Porteus (1978), Epstein and Zin (1989) and Weil (1989) introduced 'recursive preferences' (also called 'non-expected utility'):

$$U_t = \left[(1-\beta)C_t^{\rho} + \beta E_t\left(U_{t+1}^{1-\alpha}\right)^{\rho/1-\alpha}\right]^{1/\rho}, \quad (3)$$

where α is still the RRA parameter, but now the EIS is captured by a separate parameter: $1/(1-\rho)$. In this case, the SDF is given by:

$$M_{t,t+1} = \left[\beta\left(\frac{C_{t+1}}{C_t}\right)^{\rho-1}\right]^{\gamma}\left(\frac{1}{R_t^M}\right)^{1-\gamma},$$

where $\gamma = \alpha/\rho$, and R_t^M is the total return on the investors' wealth portfolio (including human capital which must be tradable for this representation to be derived; see Epstein and Zin 1989 and Weil 1989). An appealing feature of this SDF is that it combines two components that are each central to separate asset pricing theories: in particular, the SDF is a geometric average of consumption growth and the market return, where the latter is the relevant SDF in the standard capital asset pricing model (CAPM). Moreover, when $\alpha = 0$ (logarithmic risk preferences), then the CAPM emerges as a special case whereas $\alpha = \rho$ reduces it to the standard case of expected utility (see Epstein and Zin 1989; Campbell 2000).

In addition, this preference specification is flexible enough to allow a choice of a coefficient of relative risk aversion that is high enough to match the equity premium without being forced to accept a very low EIS. The low EIS is responsible for the risk-free rate puzzle, as explained above. Bansal and Yaron (2004) exploit this agent's concern for long-run consumption risk by introducing a small predictable component in consumption growth.

Habit Formation and Catching-Up with the Joneses

Another approach, pioneered by Sundaresan (1989), Abel (1990) and Constantinides (1990), starts from the following specification of the investor's preferences over consumption streams C_t:

$$U_t = \frac{(C_t - X_t)^{1-\alpha}}{1-\alpha}$$

where X_t is some function of either (i) the individual's own past consumption or (ii) the past consumption of a reference group, such as an individual's peers, neighbours, or the population as a whole. Abel's specification features the ratio of C_t to X_t instead of the level difference. The first approach allows an individual's marginal utility to depend on her own past consumption history. This is commonly referred to as habit formation, endogenous habit, or internal habit. The second interpretation allows an individual's utility to depend on her status *relative* to her peers, neighbours or the population as a whole. This is referred to as catching-up with the Joneses or as external habit. These preference specifications amplify the effect of consumption growth shocks on the marginal utility growth of investors, in turn generating a high equity premium.

A particularly successful version of the catching-up-with-the-Joneses specification was developed by Campbell and Cochrane (1999) (henceforth CC) who choose the sensitivity of X to consumption growth shocks to match the conditional and unconditional moments of returns. In the baseline CC model, aggregate consumption and dividend growth are i.i.d. over time. Menzly et al. (2004) introduce additional cash flow dynamics to explain the time series and cross-section of stock returns, while Santos and Veronesi (2005) emphasize the importance of labour income share variation to understand time variation in risk premia. Wachter (2002) applies a version of the CC model to the term structure, while Verdelhan (2004) uses the same model to explain the forward premium puzzle.

Looks Like Habit

Several recent papers have proposed models with standard preferences (such as CRRA) but consider economic environments that give rise to SDFs similar to those resulting from external habit preferences (such as the one used in CC). Examples include work by Piazzesi et al. (2007) who introduce housing services consumption into this framework, and by Yogo (2006) who considers durable consumption broadly defined, building on earlier work by Dunn and Singleton (1986) and Eichenbaum and Hansen (1990). Finally, Guvenen (2005) studies a model with limited stock market participation and shows that

while the asset pricing implications of his model are similar to those in CC, the implications for macroeconomic questions (such as policy analysis, and so on) are quite different.

Additional Arguments in the Utility Function

The models discussed so far assume that investors only derive utility from non-durable consumption. In exchange economy models (in which the consumption process is exogenous) this is equivalent to assuming that non-durable consumption enters the utility function in a separable manner. Some recent papers explicitly model the utility flow from housing consumption (in a non-separable manner), and find that such an extension improves the asset pricing performance (see Grossman and Laroque 1990; Piazzesi et al. 2007; Flavin and Yamashita 2002). Similarly, a labour–leisure choice was introduced by Boldrin et al. (2001) and Danthine and Donaldson (2002), in a representative agent framework, and by Uhlig (2006) in an incomplete markets framework. However, these authors find that this extension negatively affects the performance of asset pricing models, because it allows households to smooth their marginal utility by adjusting on the labour–leisure margin. As a result, one needs to introduce additional – typically labour market – frictions to counteract this new smoothing opportunity.

Consumption Dynamics

In consumption-based asset pricing models, it is common to assume that aggregate consumption growth is i.i.d. over time, because the evidence for consumption growth predictability in the data is weak. In the i.i.d. case, the conditional market price of risk, which can be approximated by the conditional standard deviation of the log SDF, $\sigma_t(logM_{t,t+1}) = \alpha \times \sigma_t(\Delta c)$, is constant. Therefore, these models cannot generate any time variation in risk premia on equity or any other asset.

In the context of a standard representative agent model, Kandel and Stambaugh (1990) generate time-variation in risk premia by introducing heteroskedasticity in aggregate consumption growth. Bansal and Yaron (2004) deviate from the i.i.d. assumption by introducing a small predictable component in consumption growth that is statistically hard to detect. This long-run component increases the market price of consumption risk. In addition, they add some time variation in the size of the long-run risk component. Colacito and Croce (2005) show these long-run risk models can reconcile the low volatility of exchange rate changes with the large market price of risk. Finally, Longstaff and Piazzesi (2002) argue that corporate earnings are much more risky than aggregate consumption growth, and that this can account for a large share of the equity premium puzzle.

Production Economy Models

These asset pricing puzzles have also attracted a lot attention from macroeconomists because the same basic framework used in Mehra and Prescott (1985) also forms the backbone of the Kydland and Prescott (1982) model and the subsequent real business cycle literature. Therefore, understanding why individuals dislike risk in financial markets could help shed light on individuals' perceptions of macro risk and consumption fluctuations, which are key issues for macroeconomic policy. However, macroeconomists are also interested in the determination of quantities, such as output, investment and consumption, making the exchange economy framework unsuitable for their purposes. Therefore, macroeconomists replace the exogenous endowment stream with the endogenous equilibrium consumption process generated by a standard neoclassical production economy that faces technology shocks. One of the first findings of this approach, summarized in Rouwenhorst (1995), is that resolving the equity premium puzzle in a production economy is far more challenging than in an exchange economy, because this endogenous consumption process becomes too smooth if one increases risk aversion. As a result, one needs to resort to real frictions such as large adjustment costs in Jermann's (1998) model. Furthermore, and as noted above, allowing for an endogenous labour supply choice, as is common in macroeconomic analysis, gives

consumers another margin to smooth marginal utility and further reduces the equity premium. Boldrin et al. (2001) and Uhlig (2006) have successfully introduced labour market frictions to effectively shut down this channel.

Market and Asset Structure

The aggregation results we appeal to in order to use a representative agent in asset pricing depend on market completeness. A natural question is to ask what happens if some of these markets are shut down.

Incomplete Markets

In an attempt to resolve the equity premium puzzle, *uninsurable* idiosyncratic income risk has been introduced into consumption-based asset pricing models by Aiyagari and Gertler (1991), Telmer (1993), Lucas (1994), Heaton and Lucas (1996), Krusell and Smith (1997) and Marcet and Singleton (1999), among others. Their main results, obtained numerically for a range of parameter values, suggest that the impact of uninsurable labour income risk on the equity premium is small, because agents manage to smooth consumption quite well by trading a risk-free bond. In fact, Levine and Zame (2002) show that under general conditions the equilibrium allocations and prices in incomplete market economies converge to the complete market counterparts as households become more patient, rendering the incompleteness moot.

So when does imperfect risk sharing matter? Mankiw (1986) derives a sufficient condition for imperfect risk sharing to increase the equity risk premium: the cross-sectional variance of consumption growth needs to increase when returns are low (that is, in recessions). Constantinides and Duffie (1996) embed this counter-cyclical cross-sectional variance mechanism in a general equilibrium model. Grossman and Shiller (1982) show that the Mankiw-Constantinides-Duffie (MCD) mechanism breaks down in continuous-time diffusion models, because the cross-sectional variance of consumption growth is deterministic.

Discussion of Other Models

Rietz (1988) was the first to argue that countries like the United States may simply have been very lucky. Hence, the observed history of the US economy may understate the actual probability of economic disasters, such as the Great Depression (at least as perceived by investors). In this case, the volatility of the SDF may be significantly higher than the one estimated from historical time series. As a result, investors will shun stocks and demand a much higher equity premium to hold them. One difficulty with this explanation is that many economic disasters also result in governments reneging on their debt obligations. Barro (2006) extends Rietz's framework by distinguishing between two types of disasters – those that only affect the stock market and those that affect all asset markets – and explores the empirical implications of this mechanism in recent work.

Consumption-Based Asset Pricing Models (Theory)

Fatih Guvenen and Hanno Lustig

Abstract

The essential element in modern asset pricing theory is a positive random variable called 'the stochastic discount factor' (SDF). This object allows one to price any payoff stream. Its existence is implied by the absence of arbitrage opportunities. Consumption-based asset pricing models link the SDF to the marginal utility growth of investors – and in turn to observable economic variables – and in doing so they provide empirical content to asset pricing theory. This article discusses this class of models.

Keywords

Consumption-based asset pricing models study the pricing of payoff streams using the covariance of these payoffs with the marginal utility growth of investors.

The central component of a consumption-based asset pricing model is the Euler equation, which imposes restrictions on the covariance between asset returns and the marginal utility growth of investors. An easy and intuitive way to derive this equation is by using a variational argument. Suppose that the optimal consumption path of investor i is given by $\{C_t^i\}_{t=0}^T$ where T is possibly infinite. Suppose further that an asset j is available with a return $R_{t,t+1}^j$ between periods t and $t+1$, and the investor is not facing a binding portfolio constraint with respect to this asset. Then a feasible strategy is to reduce consumption at time t by a small amount ε, invest it in asset j, and consume the proceeds, $C_{t+1}^i + \varepsilon R_{t+1}^j$, in the next period. Assuming a time-separable utility function, with the one-period felicity function denoted by U and a time discount factor of β, this strategy changes the investors' expected lifetime utility by $-U_c(C_t^i, X_t)\varepsilon + E_t\left[\beta U_c\left(C_{i+1}^i \varepsilon R_{t+1}^j\right)\right]$, where E_t is the mathematical conditional expectation operator; X represents the arguments of the utility function other than consumption; and U_c denotes the partial derivative with respect to consumption. The optimality of the original sequence implies that this strategy cannot be profitable for any amount ε and any asset available. Setting this gain to zero and rearranging yields the Euler equation:

$$E_t\left[M_{t,t+1}R_{t,t+1}^j\right] = 1 \qquad \text{where}$$
$$\mathrm{M}_{t,t+1} = \beta\frac{U_c\left(C_{t+1}^i, X_{t+1}\right)}{U_c\left(C_t^i, X_t\right)}. \tag{1}$$

This Euler equation was first derived by Rubinstein (1976) and Lucas (1978) in discrete time, and by Breeden (1979) in continuous time. While this class of models can in principle be used to study a broad variety of assets, this article will focus on stocks and short-term bonds, which have received the greatest attention in the consumption-based asset pricing literature.

In the case of a one-period discount bond with gross return $R_{t,t+1}^f = 1/P_t^f$ – a bond that costs P_t^f dollars today and pays off 1 dollar tomorrow – the Euler equation can be rewritten as

$$P_t^f = E_t\left[M_{t,t+1}\right]. \tag{2}$$

Similarly, when the asset is a stock with ex-dividend price P_t^s and dividend payment D_t, the Euler equation can be rearranged to read $P_t^s = E_t\left[M_{t,t+1}\left(P_{t+1}^s + D_{t+1}\right)\right]$. By forward substitution this equation yields:

$$P_t^s = E_t\left[\sum_{s=1}^{\infty} M_{t,t+s} D_{t+s}\right], \tag{3}$$

which determines the price of a share of equity as the value of all future dividends it entitles discounted by the SDF.

Lucas (1978) and Mehra and Prescott (1985) used a representative-agent endowment economy structure in which the dividend stream, $\{D_t\}_{t=1}^{\infty}$, is exogenously produced by a 'tree'. Furthermore, these dividends are assumed to be perishable ('fruit'), so in equilibrium the price of equity (in the tree) adjusts to the point where the representative agent is *willing* to consume all available dividends: $C_t = D_t$. Substituting this condition into the expression for M in Eq. (1), and then using M in Eqs. (2) and (3) shows that the price of this stock and that of the one-period bond are entirely determined by the stochastic process for D_t together with the functional form for U (we ignore X_t for now).

Hansen and Singleton (1983) tested the representative agent's Euler equation on US consumption data, and found that the model was rejected. In a famous paper, Mehra and Prescott (1985) showed that when one chooses the properties of C_t to match the moments of aggregate consumption in the data ('calibrate the model to data'), the equity premium $E\left(R_{t+1}^s - R_t^f\right)$ generated by the model was about 60 *times* smaller than that observed in the historical US data. This 'equity premium puzzle' has generated enormous interest and led to the development of a wide range of consumption-based asset pricing models in an attempt to resolve it. For further discussion of the empirical performance of these models, see consumption-based asset pricing models (empirical performance).

An alternative way to explain the hurdles these models face is by deriving an empirical lower bound on the volatility of the stochastic discount factor (SDF). Subtracting the Euler equation for bond returns from the one for stock returns yields: $E\left[M_{t,t+1}\left(R_{t+1}^s - R_t^f\right)\right] = 0$. Noting that the left-hand side of this condition can be rewritten as $Cov\left(M_{t,t+1}\left(R_{t+1}^s - R_t^f\right)\right) + E(M_{t,t+1})E(R_{t+1}\ s - R_t^f)$, some simple manipulations yield the following key decomposition:

$$\frac{E\left(R_{t+1}^s - R_t^f\right)}{\sigma\left(R_{t+1}^s - R_t^f\right)} = -\frac{\sigma\left(M_{t,t+1}\right)}{E\left(M_{t,t+1}\right)} corr \left(M_{t,t+1}, R_{t+1}^s - R_t^f\right), \tag{4}$$

where $\sigma(\cdot)$ denotes the standard deviation. Observing that the correlation term is bounded from above in absolute value by 1, we get

$$\frac{E\left(R_{t+1}^s - R_t^f\right)}{\sigma\left(R_{t+1}^s - R_t^f\right)} \le \frac{\sigma\left(M_{t,t+1}\right)}{E\left(M_{t,t+1}\right)}. \tag{5}$$

The left-hand side of this inequality is the 'Sharpe ratio' – the (expected) excess return demanded by investors per unit (standard deviation) of risk they bear – which averages about 0.40 in annual US data. The right-hand side is called the 'market price of risk' or the 'maximum Sharpe ratio'. This inequality bound implies that a consumption-based model must be able to generate an SDF with a coefficient of variation (standard deviation normalized by mean) of at least 40 per cent to be consistent with the Sharpe ratio observed in the data. This observation – developed by Shiller (1982) and further generalized by Hansen and Jagannathan (1991) – provides a 'volatility bounds' test for potential candidate models. As discussed in consumption-based asset pricing models (empirical performance), the majority of plausibly calibrated asset pricing models fail this test.

When the investor faces a binding borrowing constraint, she cannot increase her consumption today by reducing the holdings of asset j. As a result, her marginal utility today will remain higher than the value implied by the equality condition in (1), and the Euler condition for that asset will instead be an inequality: $E_t\left[M_{t,t+1} R_{t,t+1}^j\right] < 1$. This relaxes the lower bound on the volatility of the SDF derived in Eq. (5) (cf. Luttmer 1996).

To develop further implications of consumption-based models it is necessary to

impose additional structure on $M_{t,t+1}$, which requires being more specific about (1) the functional form and the arguments of the utility function; (2) the stochastic properties of variables affecting marginal utility (that is, consumption, leisure, and so on); and (3) the market structure. The latter determines whether an appropriate aggregation theorem holds (which happens for example when markets are complete), in which case C_i can be replaced with aggregate consumption. Therefore, consumption-based models can be broadly categorized based on the assumptions they make along these three dimensions. These different models are discussed in consumption-based asset pricing models (empirical performance).

Another feature of asset markets that has received much attention in the literature concerns the high volatility of stock prices. For example, the standard deviation of the log price/dividend (P/D) ratio of stocks is about 40 per cent per annum in the US data. In a world with a constant SDF (as would be the case with risk-neutral investors), it is impossible to rationalize this high volatility with the relatively low variability of the underlying dividend stream (LeRoy and Porter 1981; Shiller 1981). Let p_t denote the log price, d_t denote the log dividend, and r_t denote the log stock return. Using a first-order approximation, Campbell and Shiller (1988) show that the log P/D ratio can be decomposed as follows:

$$p_t - d_t = constant + E_t \sum_{j=1}^{\infty} \rho^{j-1} \left[\Delta d_{t+j} - r_{t+j} \right]$$

with $\rho = \exp(\overline{pd})/1(1+\exp(\overline{pd}))$ and $\overline{pd}$ denotes the average log P/D ratio. The first term in the square brackets is referred to as the cash flow component, and the second part is referred to as the discount rate component. This decomposition implies that the variance of the log P/D ratio can be stated as:

$$var(p_t - d_t) cov\left(p_t - d_t, \sum_{j=1}^{\infty} \rho^{j-1} \Delta d_{t+j}\right) - cov\left(p_t - d_t, \sum_{j=1}^{\infty} \rho^{j-1} r_{t+j}\right).$$

This expression shows that the P/D ratio moves only because it predicts future returns on stocks or because it predicts future dividend growth. In the data, most of the volatility in P/D ratio is due to news about future expected returns ('discount rates'), not due to future dividend growth ('cash flows') (Campbell 1991; Cochrane 1991). There is a large literature that documents the predictability of stock returns over longer holding periods, starting with work by Campbell and Shiller (1988, 1998), Poterba and Summers (1986) and Fama and French (1988, 1989). Other variables that predict returns include the spread between long and short bonds (Fama and French 1989) and the T-bill rate (Lamont 1998). More recently, more attention has been paid to macroeconomic variables that predict returns, most notably in the work by Lettau and Ludvigson (2001a) who document that the consumption/wealth ratio is a powerful predictor of stock returns.

So, the volatility of P/D ratio implies that excess returns on stocks are highly predictable. In other words, expected excess returns change a lot over time, even per unit of risk. We use the conditional version of the expression in (4) to understand the implications of this finding:

$$\frac{E_t\left(R^s_{t+1} - R^f_t\right)}{\sigma\left(R^s_{t+1} - R^f_t\right)} = \frac{\sigma_t\left(M_{t,t+1}\right)}{E_t\left(M_{t,t+1}\right)} corr_t\left(M_{t,t+1}, R^s_{t+1} - R^f_t\right), \tag{6}$$

where σ_t denotes the conditional standard deviation. Good models need to produce a lot of time variation in the right-hand side of (6) and this happens mostly through variation in the conditional market price of risk (first term). This is an upper bound on the conditional Sharpe ratio. (See also Lettau and Ludvigson 2001b, on how to measure variation in the conditional Sharpe ratio.) Another test of consumptionbased asset pricing models is whether they are able to generate as much predictability as found in the data. Examples of early models that match the variation in the conditional market price of risk include Kandel and Stambaugh (1990), Campbell and

Cochrane (2000) and Barberis et al. (2001). More recent work includes the work by Santos and Veronesi (2005), Menzly et al. (2004), Piazzesi et al. (2007), Guvenen (2005), Lustig and Van Nieuwerburgh (2005, 2006) and Bansal and Yaron (2004). These models are discussed in detail in consumption-based asset pricing models (empirical performance).

Contemporary Capitalism

William Lazonick

Abstract

The key to understanding 'capitalism' as a mode of resource allocation that generates economic growth is the organization and performance of its most innovative business enterprises. The 'Old Economy business model' that made the United States the world's most powerful nation in the post-Second World War decades came under challenge in the 1970s and 1980s, and the ideology of 'maximizing shareholder value' arose to legitimize a redistribution of income from labour interests to financial interests. The 'New Economy business model' emerged in the 1980s and 1990s to drive the innovation process, contributing, however, to unstable and inequitable economic growth.

What Is 'Capitalism'?

At the beginning of the 21st century, 'capitalism' has triumphed as the dominant system for allocating a society's economic resources. The last time in history in which the persistence of capitalism in the world's most advanced economies was seriously called into question was the Great Depression of the 1930s – a decade during which the unemployment rate in the United States remained at 15 per cent or higher, notwithstanding unprecedented state intervention under the New Deal. It took the Second World War to pull the United States and the world economy out of depression, and in the subsequent decades it took substantial and sustained government spending in the rich economies of North America and western Europe to hold unemployment to acceptable levels.

In the post-war era, the Soviet Union's highly planned economy posed as a possible alternative to capitalism. The purported strength of the Soviet challenge, however, turned out to be based at least as much on Cold War ideology emanating from the United States as on the actual productive power of the Soviet Union and its satellites. By the 1990s the Soviet model had virtually vanished, as Russia itself sought to make the transition to a 'market economy', guided, tragically, by a mythical ideology of how capitalism is supposed to operate, imported from the United States.

Over the same period capitalism entrenched itself in East Asia. During the 1970s and 1980s Japan became a rich economy on the basis of a distinctive model of 'collective capitalism', and in the 1980s and 1990s the East Asian 'Tigers' – Hong Kong, Singapore, South Korea

and Taiwan – closed the gap, each with its own variant of the Japanese model. More recently China and India, with one-third of the world's population, have experienced rapid economic growth, driven by what many would call 'capitalist' institutions. Yet, even as firms cross the globe to access Indian software engineers, and vice versa, India remains a nation with one-third of the world's illiterates. Meanwhile the fact that China, the world's second largest economy since the early 1990s, continues to be guided by an avowedly Communist government raises the question of what 'capitalism' really is.

Defining contemporary capitalism is not merely a question of semantics. If, as has been demonstrated since the mid-20th century, 'capitalism' is a powerful engine of economic growth, we want to know how it functions as a mode of resource allocation and the social conditions under which capitalist growth is not only strong but also stable, and equitable. We also want to know how the institutions of contemporary capitalism that generate growth might be transferred to those parts of the world – first and foremost Africa but also eastern Europe and Latin America as well as parts of the Middle East – that have economically been left behind. Given its pervasiveness and dominance, a depiction of the institutions that define contemporary capitalism is tantamount to a description of the economic world in which perhaps one-half of the world's population now lives and to which much of the other half now aspires.

There is no consensus among economists on the definition of contemporary capitalism. The dominant approach to analysing resource allocation and the economic performance of an advanced economy rests on the notion that a capitalist economy is essentially a market economy that allocates resources to their most productive uses. But what at any time and in any place, the student of economic development asks, explains how those most productive uses come to exist? And why in certain times and places? Fundamental to capitalist growth is 'innovation', the process that generates goods and services that, even with factor prices held constant, are of higher quality and lower cost than those previously available (Lazonick 2006c). Can a theory of capitalism as a market economy comprehend the innovation process?

In the early 20th century a young Joseph Schumpeter asked this question. As a Viennese economics student, Schumpeter was versed in the relatively recent, and increasingly influential, Austrian and Walrasian theories of how, through the equilibrating mechanism of the market, the economy could achieve an 'optimal'allocation of resources across productive uses. Schumpeter's insight was to recognize that such a view of the economic world could not explain economic development. In 1911 Schumpeter wrote *The Theory of Economic Development* (first translated into English in 1934) to argue that entrepreneurial activity that results in innovation – what he called the 'Fundamental Phenomenon of Economic Development' – can disrupt the 'Circular Flow of Economic Life as Conditioned by Given Circumstances' to change the ways in which the economy operates and performs. Without such disruption of equilibrium conditions, the economy would not develop. Over the next four decades Schumpeter sought to elaborate a theory of economic development informed by his own, evolving, understanding of the changing reality of the most advanced capitalist economies.

In particular, Schumpeter sought to understand the role of the business enterprise in advanced capitalist development. By the 1940s he had taken definitive leave of his youthful conceptions of the innovative entrepreneur as an individual actor and innovation as simply 'new combinations' of existing resources. Rather, he saw that powerful business organizations both developed and utilized productive resources to create new technologies and access new markets. The creation of new technologies, moreover, destroyed the commercial viability of old technologies. In *Capitalism, Socialism, and Democracy*, first published in 1942, Schumpeter argued that the process of 'creative destruction' had become embodied in established corporations as 'technological "progress" tends, through systematization and rationalization of research and of management, to become more effective and surefooted', being 'the business of teams of trained specialists who turn out what is

required and make it work in predictable ways' (Schumpeter 1950, pp. 118, 132).

This article takes as its point of departure the proposition, suggested by Schumpeter, that the key to understanding 'capitalism' as a mode of resource allocation that generates economic growth is the organization and performance of its most innovative business enterprises. That is not to say that markets and states are unimportant to the operation, and hence definition, of capitalism. Historically, however, well-functioning markets are outcomes of successful capitalist development. For the individual, markets create the possibility of choosing what to consume and for whom to work, including the prospect of working for oneself. But markets cannot explain the development of the new products and processes that drive the growth of the capitalist economy. The innovation process is uncertain, collective and cumulative (see O'sullivan 2000). The uncertain character of innovation means that investments in innovation require *strategic control* over resource allocation by individuals who have intimate knowledge of the technologies, markets and competitors that an innovative strategy must confront. The collective character of innovation means that the implementation of an innovation strategy requires the *organizational integration* of a hierarchical and functional division of labour into a process of organizational learning. The cumulative character of innovation means that the process requires *financial commitment* until it can generate financial returns. Enterprises, not markets, engage in strategic control, organizational integration and financial commitment (Lazonick 2003).

Nor can one explain innovation by appealing to the notion of the developmental state as its driving force, as has often been done for the East Asian economies. Implicit, and at times explicit, in this view is an acceptance of the ideology that the economic development of the United States is an exemplar of the workings of the market economy. Yet from gun manufacture and interchangeable parts in the first half of the 19th century to the computer revolution and Internet in the late 20th century, as well as railroads, aviation and the life sciences in between, the history of US capitalism is replete with examples of the critical role of the developmental state in allocating resources to the processes of knowledge creation that then provided the foundations for US industrial leadership. Yet, as important as the developmental state has been even in a so-called 'market economy' such as the United States, the allocation of resources to knowledge creation would have been wasted, and would probably never have been made, had it not been for the presence and influence of innovative enterprises that have made use of this knowledge to generate higherquality, lower-cost products than had previously been available.

In this article I focus on the changing role of innovative enterprise in determining resource allocation and economic performance in contemporary capitalism. Space constraints dictate that I confine the analysis of contemporary capitalism to the case of the United States, with the caveat that, even in a highly globalized economy in which one might expect convergence to a common business model, there are almost as many distinctive 'varieties of capitalism' in terms of governance, employment and investment institutions, as there are advanced capitalist nations. The US economy is, however, the world's largest and richest economy. It is also the one in which market ideology is most virulent and the actual mode of resource allocation most misunderstood. Section "The Old Economy business model" of this article provides historical background to understanding contemporary US capitalism by describing the key characteristics of the 'Old Economy business model' (OEBM) that made the United States the world's most powerful nation in the decades after the Second World War. Section "Maximizing shareholder value" analyses the challenges that confronted OEBM in the 1970s and 1980s, and how the ideology of 'maximizing shareholder value' arose to legitimize a redistribution of income from labour interests to financial interests. Section "The New Economy business model" shows how the 'New Economy business model' (NEBM) emerged in the 1980s and 1990s to drive the innovation process, but in ways that have contributed to unstable and inequitable economic growth. Section "Stable

and equitable growth?" concludes with some questions about the future of the US model in a global economy in which many distinctive business models still compete.

The Old Economy Business Model

The United States emerged from the Second World War as the undisputed world leader in GDP per capita, a position that it still retains. With western Europe and Japan still in recovery from the war, the United States was at its peak of dominance in the 1950s on the basis of a highly collective model of capitalism embodied in the managerial corporation, and personified in the concept of the 'organization man' (Whyte 1956). The stereotypical 'organization man' was white, Anglo-Saxon and Protestant, obtained a college education, got a well-paying job with an established company early in his career, and then worked his way up and around the corporate hierarchy over decades of employment, with a substantial 'defined benefit' pension, complete with highly subsidized medical coverage, awaiting him on retirement. The employment stability offered by an established corporation was highly valued, while inter-firm labour mobility was shunned.

'Organization men' rose to top executive positions where, as salaried managers rather than owners, they exercised strategic control. This separation of share ownership and managerial control, which continues to characterize the US industrial corporation, resulted from the widespread distribution among shareholders of the corporation's publicly traded stock. In principle, boards of directors representing the interests of shareholders monitor the decisions of these managers. In practice, incumbent top executives choose the outside directors and are themselves members of the board. Shareholders can challenge management through proposals to the annual general meeting, but over the course of the 20th century a body of law evolved that enables management to exclude shareholder proposals that deal with normal business matters (for example, downsizings) as distinct from social issues (for example, sex discrimination).

The separation of ownership from control has worked effectively to generate innovation when the interests of salaried executives who exercise strategic control have been aligned with those of employees who engage in the development and ensure the utilization of the company's productive resources. In the post-Second World War decades the organizational integration of the capabilities of administrative and technical specialists enabled US firms to develop the world's most competitive systems of mass production. These personnel were products of the US system of higher education, which since the early decades of the century had prepared the labour force to enter employment in bureaucratic organizations.

A distinctive feature of the US business model was the organizational segmentation between these salaried managers, in whose training and experience the corporation made substantial investments, and so-called 'hourly' workers. (Nonsalaried employees were classified as 'hourly', or 'non-exempt', workers because of the stipulation of the National Labor Relations Act that emerged from the New Deal era that required employees who were paid an hourly wage receive 150 per cent of that wage if they worked longer than the normal working hours. The overtime work of salaried personnel is exempt from this provision.) The corporation viewed these operatives, who were typically high-school graduates, as interchangeable commodities in whose capabilities the company had no need to invest, notwithstanding the fact that they often spent their entire working lives with one company. At the same time, these industrial corporations needed reliable even if lowskill workers to tend mass production processes. The combination of dominant product-market positions and union power, which advanced the pay and protected the employment of senior workers, enabled the hourly worker to receive good pay and benefits, including a defined-benefit pension that assumed long-term employment with a single company.

The developmental state played an indispensable role in the innovation process by partially funding the system of higher education as well as, in the forms of research labs, subsidies and

contracts, programmes for technology development in sectors such as aerospace, computers and life sciences. The development of the productive potential of these government investments relied in turn on corporate research capabilities. Retained earnings formed the foundation of committed finance for new corporate investments in innovation. When corporations needed additional investment financing, they issued corporate bonds at favourable rates that reflected the established position of the company as well as its conservative debt–equity ratios. Companies used bank loans almost exclusively for working capital, and made only limited use of the stock market as a source of investment funds.

These social conditions enabled US corporations to grow very large in the post-war decades. The 50 largest US industrial corporations by revenues on the Fortune 500 list averaged 87,070 employees in 1957, 117,393 in 1967, and 119,093 in 1977. These figures do not include employment at AT&T, the regulated telephone monopoly, which in 1971 employed 1,015,000 people, of whom 700,000 were union members with good wages, stable employment and excellent benefits. By the late 1960s and early 1970s increasing numbers of blacks were moving into union jobs in the steel, automobile, electrical equipment, consumer durable and telecommunications industries. The growth of established corporations in these industries in the three decades after the Second World War contributed to a more equal distribution of family income in the US economy.

'Maximizing Shareholder Value'

During the 1970s the US model faltered in the face of Japanese competition. Building on innovative capabilities developed for their home markets during the 1950s and 1960s, Japanese companies gained competitive advantage over US companies in industries such as steel, memory chips, machine tools, electrical machinery, consumer electronics and automobiles. US companies had entered the 1970s as world leaders in these industries. Many US observers attributed the rapid increase in Japanese exports to the United States in the 1970s to Japan's lower wages and longer working hours. By the early 1980s, however, with real wages in Japan continuing to rise, it became clear that Japanese advantage was based on the superior organization of their enterprises, and in particular on a more thoroughgoing integration of participants in the functional and hierarchical divisions of labour for the dual purposes of transforming technologies and accessing new markets. Indeed, during the 1980s Japan exported management practices as well as material goods to the West. From the second half of the 1980s, with the yen strengthening and trade surpluses generating political backlash, Japanese companies made a transition to direct investment in the United States and other advanced economies.

A growing financial orientation of US business that had surfaced in the conglomerate movement of the 1960s undermined the abilities and incentives of established US corporations to respond to the Japanese challenge. To some extent the growth of the US industrial corporation in the post-war decades had been based on strategic investments in new product lines and geographic areas that built on the corporation's existing productive capabilities, and yielded economies of scale and scope. The conglomerate movement, however, saw major corporations invest in scores of *unrelated* businesses, often through mergers and acquisitions, based on the prevailing, but erroneous, ideology that a good corporate executive could manage any type of business, and that conglomeration offered the synergies of superior corporate management. The conglomerate movement failed because it segmented top executives, in positions of strategic control, from the rest of the managerial organization that had to develop and utilize productive resources to sustain the firm's competitive advantage (Lazonick 2004).

In the late 1970s and early 1980s the conglomerates unraveled. In the mid-1970s Michael Milken, a Drexel Burnham investment banker, had created the junk bond market by convincing institutional investors, in search of higher yields in an inflationary era, to hold downgraded corporate securities, many of them 'fallen angels' from

Contemporary Capitalism, Table 1 US corporate stock and bond yields, 1960–2005. Average annual per cent change

unsuccessful conglomeration. By the late 1970s, with the junk-bond market well developed, it became possible to issue new junk bonds to finance leveraged buyouts (LBOs) in which the top managers of a conglomerate division turned it into an independent company to recapture strategic control over resource allocation. By the late 1980s, however, the junk bond had become an instrument for the hostile takeover of entire companies, with KKR's 1989 LBO of RJR Nabisco for $24.5 billion marking the height of what became known as 'the deal decade'.

The ideology that justified hostile takeovers was that the corporation should be run to 'maximize shareholder value' (see Lazonick and O'sullivan 2000). Proponents of shareholder value charged that, either because of opportunism or incompetence, many incumbent corporate managers were making poor allocative decisions. By exercising their influence through the market for corporate control, shareholders could force incumbents to alter their allocative decisions, replace them with those who would maximize shareholder value, or distribute cash to shareholders in the forms of dividends and stock repurchases so that shareholders themselves could, so the argument goes, reallocate the economy's resources to their best alternative uses.

While the hostile takeover movement did not directly threaten high-tech companies (in which the most valuable assets could walk out the door), by the end of the 1980s the top executives of virtually all US industrial corporations had embraced the ideology of maximizing shareholder value and made it their own. By the 1980s executive stock option compensation was a well-established practice. Since in the United States option awards did not require that the company's stock price outperform the stock market or even the stock prices of a group of competitors, those who received these awards could only gain from what, from July 1982 to August 2000, turned out to be the longest stock market boom in US history, with the Dow Jones Industrial Average and the S&P500 Index both rising about 1,300 per cent.

As Table 1 shows, stock-price appreciation drove the extraordinary real stock yields that were sustained over the 1980s and 1990s. The relatively low dividend yields in the 1990s did not reflect stinginess on the part of US corporations; the US corporate payout ratio – the amount of dividends as a percentage of after-tax corporate profits (with inventory evaluation and capital consumption adjustments) – averaged 48 per cent in the 1980s and 57 per cent in the 1990s compared with 39 per cent in the 1960s and 41 per cent in the 1970s. It was just that the rate of increase of stock prices outstripped the rate of increase of dividend payments, thus depressing the dividend yield. The form that the stock yield takes is of significance because investors can capture the dividend yield by holding stocks, whereas they can capture the price yield only by buying and selling stocks. Inherent in high-price yields, therefore, is a volatile stock market.

A volatile stock market benefits those who are compensated in stock options on an annual basis, especially when, as is the case in the United States, options vest as quickly as one year from the date of grant and can be exercised for up to ten years. It has been estimated that, largely because of the gains from exercising stock options, on average the ratio of CEO pay of an S&P500

company to that of a production worker was 42 in 1985, 107 in 1990, 525 in 2000, and 411 in 2005. Top executives took a keen interest in their company's stock price, and in the 1980s and 1990s, in the name of 'maximizing shareholder value', they found ways in which they could use their positions of strategic control over corporate resource allocation to influence it. They could cook the corporate books to boost current earnings, a practice that became widespread in these decades and one for which a few executives have been fined or even jailed. The American Competitiveness and Corporate Accountability Act of 2002, better known as Sarbanes–Oxley, has sought to stem this practice. But quite apart from artificially inflating corporate earnings, top corporate executives also found that downsizing the labour force and repurchasing corporate stock helped to boost a company's stock price, even though these resource allocations did not necessarily improve the company's competitive performance.

The era of corporate downsizing took hold in the recession of 1980–2 when hundreds of thousands of stable, well-paid blue-collar jobs were lost that were never subsequently restored (see Lazonick 2004). It would appear that the blacks who had relatively recently moved into these types of jobs were particularly hard hit; last hired, they tended to be the first fired. The subsequent 'boom' years of the mid-1980s witnessed hundreds of plant closings. In the 'white-collar' recession of the early 1990s tens of thousands of professional, administrative and technical employees found that their jobs had been eliminated, although once again it was blue-collar workers who bore the brunt of the downturn. In 1980 manufacturing employment was 22 per cent of the labour force; by 1990 it had fallen to 17 per cent and by 2001 to 14 per cent. While the employment picture generally became much better during the Internet boom of the last half of the 1990s, job cutting remained a way of life for many major US corporations. According to data on layoff announcements by companies in the United States collected by the recruitment firm, Challenger, Gray and Christmas, announced job cuts averaged just under 550,000 per year for the period 1991–4, 450,000 per year in 1995–7, and 656,000 per year during the boom years 1998–2000.

Meanwhile, from the mid-1980s US corporations began to actively support their stock prices through large-scale stock repurchases. Companies included in the S&P500 in March 2006 distributed more cash to shareholders in repurchases than in dividends in 1997 through 2000 and again in 2004, and just slightly less in 2001 through 2003. Since 1978 net equity issues by US non-financial corporations has been positive in only six of 28 years (1980, 1982, 1983, 1991, 1992, 1993); since the early 1980s US industrial corporations have in aggregate been supplying capital to the stock market rather than vice versa. In 2005 the net flow of cash from non-financial corporations to the stock market was a record $366 billion, 1.42 times in real dollars the previous high in 1998 (Lazonick 2006d).

The New Economy Business Model

On 29 December 1995, AT&T announced that, as part of the process of breaking itself up into three separate companies, it would be cutting 40,000 jobs. AT&T was a company that could trace its origins back to the 1870s, had created the world's most advanced telephone system, was the home of the famous Bell Labs that among many other accomplishments invented the transistor in 1947, and, despite having lost its status as a regulated monopoly in 1984, still employed 308,700 people. Now, however, AT&T became emblematic of the failure of US Old Economy corporations to continue to provide employment opportunities. With campaigning for the 1996 presidential election picking up steam, Patrick Buchanan, a right-wing politician, caught the attention of the media by denouncing the highly paid executives of AT&T and other downsizing corporations as 'corporate hit men'. Fuel was added to the fire by the revelation that, in the name of 'creating shareholder value', Al Dunlap, whom the American public came to know as 'Chainsaw Al', had in 20 months as CEO of Scott Paper devastated the 115-year old company while putting an estimated

Contemporary Capitalism, Table 2 Comparing business models in ICT

	Old economy business model (OEBM)	New economy business model (NEBM)
Strategy, product	Firm growth based on multidivisional structure: multi-product firm	New firm entry into specialized ICT markets; accumulate new capabilities by acquiring (other) young technology firms
Strategy, process	Vertical integration of the value chain; in-house standards and proprietary R&D	Vertical specialization of the value chain; industry technology standards; R&D for cross-licensing and alliances; outsourcing routine work to specialist contract manufacturers and/or offshoring routine work to low-wage nations
Finance	Venture finance from savings, family and business associates; NYSE listing, growth finance from retentions, after dividends, and bond issues	Organized venture capital; early IPO on NASDAQ; retentions with zero dividends; use of own stock as a compensation and combination currency; systematic stock repurchases to support stock price
Organization	Secure employment; 'organization man' (career with one company), industrial union; defined-benefit pension, good medical coverage in employment and retirement	Insecure employment; interfirm mobility of labour, broad-based stock options, nonunion, defined contribution pension, employees bear more burden of medical insurance

$100 million in his own pocket. In March 1996, the *New York Times* ran a seven-part series, later released as a paperback, on 'the downsizing of America' (Lazonick 2004).

By the spring of 1996, however, the furor over corporate downsizing had disappeared. In its place, Americans became enthralled by the prosperity promised by what in the second half of the 1990s came to be called the 'New Economy'. In the United States the previous half-century had seen a massive accumulation of information and communications technology (ICT) capabilities. The development of computer chips from the late 1950s had provided the technological foundation for the microcomputer revolution from the late 1970s, which in turn had provided the technological infrastructure for the Internet boom of the second half of the 1990s. The research funding for this accumulation of ICT capabilities had come mainly from the US government and the research laboratories of established Old Economy high-technology corporations. Each wave of technological innovation, however, created opportunities for the emergence of start-up companies that were to become central to the commercialization of the new technologies.

Although by the mid-1980s the Japanese had outcompeted even the leading US semiconductor firms in the memory chip market, US companies such as Intel, Motorola and Texas Instruments continued to dominate the microprocessor and logic chip markets that drove product innovation in the microelectronics industry (Lazonick 2006a). While Silicon Valley was not the only US location for innovation in this industry, the concentration of semiconductor start-ups in the region from the late 1950s resulted in the emergence by the 1980s of a distinctive mode of combining strategy, finance and organization: the 'New Economy business model' (NEBM) (see Table 2). During the 1990s NEBM spread beyond Silicon Valley start-ups and was adopted successfully by leading Old Economy ICT companies such as Hewlett-Packard and IBM. In the Internet boom of the late 1990s elements of NEBM diffused to other ICT companies, including an Old Economy company such as Lucent Technologies, spun off from AT&T in its 1996 trivestiture, which almost destroyed itself in attempting to adopt the business model. In the 2000s NEBM characterizes the most innovative sectors of the US economy (for the case of biotechnology, see Pisano 2006).

The founders of New Economy firms have typically been scientists and engineers who have gained specialized experience in existing firms, although in some cases they have been university faculty members intent on commercializing their academic knowledge. Some of these entrepreneurs have come from existing Old Economy

companies, where it was often difficult for their new ideas to get internal backing. But New Economy companies themselves have become increasingly important as sources of new entrepreneurs who left their current employers to start new firms. Large numbers of high-tech entrepreneurs in the United States have been foreign-born, coming mainly from India and China (Saxenian 2006).

Typically, the founding entrepreneurs of a New Economy start-up seek committed finance from venture capitalists with whom they share not only ownership of the company but also strategic control. In the 2000s Silicon Valley remains by far the leading location in the United States and the world for venture-backed high-tech start-ups. The region acquired this position from the 1960s as a distinctive venture capital industry emerged out of the opportunities for start-ups created by the microelectronics revolution. Besides sitting on the board of directors of the new company, the venture capitalist generally recruits professional managers, who are given company stock along with stock options, to lead the transformation of the firm from a new venture to a going concern. This stock-based compensation gives these managers a powerful financial incentive to develop the innovative capabilities of the company to the point where it can do an initial public offering (IPO) or private sale to a listed company, thus enabling the start-up's privately held shares to be transformed into publicly traded shares. Both before and after making this transition, their tenure with, and value to, the company depends on their managerial capabilities, not their fractional ownership stakes (Lazonick 2006a).

The stock market speculation of the 'dotcom' era made it all too easy to cash out of a start-up, as many high-tech firms that had not engaged in innovation did IPOs or were sold to established companies. When start-ups do innovate, the key to making the transition from new venture to going concern has been the organizational integration of an expanding body of technical and administrative 'talent'. As Silicon Valley developed from the 1960s, this educated and experienced labour had to be induced to trade secure employment with an Old Economy company for insecure employment with a start-up. To attract these highly mobile people and retain their services, Silicon Valley firms increasingly adopted 'broad-based' employee stock option plans that extended this form of compensation to a large proportion, sometimes all, of the firm's non-executive employees rather than just to top executives. In start-ups, stock options usually served as a partial substitute for cash salaries, and the eventual gains from exercising options were viewed as a substitute for a company-funded pension (Lazonick 2006a).

Again, the underlying stock would become valuable if and when the start-up did an IPO or a private sale to a publicly listed company. Shortening the expected period between the launch of a company and an IPO was the practice of most venture-backed high-tech start-ups of going public on NASDAQ, created in 1971 as an electronic exchange for the over-the-counter markets with less stringent listing requirements than the 'Old Economy' New York Stock Exchange (NYSE). The 1978 cut in the capital gains tax rate to 28 per cent, after it had been raised to 49 per cent just two years before, provided further encouragement to entrepreneurs and venture capitalists to found new companies, and for employees of these companies, rewarded with stock options, to provide the skills and efforts needed to transform new ventures into going concerns. In 1979 the clarification of the 'prudent man' rule as applied to the Employee Retirement Income Security Act (ERISA) of 1974 gave asset managers the green light to allocate a portion of their portfolios to riskier stocks and venture capital funds, and resulted in a flood of new money, especially from pension funds, into the venture capital industry. The American Electronics Association and the National Venture Capital Association, with their strongest and deepest roots in Silicon Valley, were the frontline Washington lobbyists for these regulatory changes.

While institutional money provided capital to NEBM, high-tech labour became more mobile from one firm to another than it had been in the Old Economy. Employee stock options induced this mobility, but what made it possible in terms of the knowledge bases that managers and engineers possessed were *industry* standards, as distinct

from *in-house* standards, that emerged in the various sectors of ICT. In the Old Economy in-house standards promoted the growth of large vertically integrated firms on the basis of proprietary technologies, whereas in the New Economy industry standards encouraged new entry. Nevertheless, as demonstrated by the important cases of Intel and Microsoft in the development of the microcomputer industry, those New Economy firms that dominated in the setting of the industry standards could also grow very large (at the end of fiscal 2005 Intel employed 99,900 and Microsoft 61,000). By establishing industry standards, their growth encouraged rather than discouraged start-ups, which in turn depended on the availability of not only venture capital (which came from many sources besides the formal venture capital industry) but also mobile labour whose knowledge and experience could be easily integrated into the start-up's learning processes.

Of critical importance in setting industry standards in microelectronics was IBM's decision in 1980 to enter what became known as the personal computer (PC) industry with Intel supplying the microprocessor and Microsoft the operating system. At the time IBM controlled about 80 per cent of the computer market, had over 341,000 employees, and, with an explicit system of 'lifelong employment', trumpeted the fact that since 1921 it had not terminated an employee involuntarily. Yet between 1990 and 1994 IBM slashed its employment from 374,000 to 220,000. In 1991–3, the company had losses of $16 billion (including more than $8 billion in 1993, at the time the largest annual loss in US corporate history) on total revenues of $192 billion, and encouraged the media to believe that the mass layoffs were necessary to avoid bankruptcy. Yet virtually all of the losses came from 'restructuring' charges, that is, the cost of terminating employees (Lazonick 2006a).

In retrospect, it is clear that these charges were the cost of ridding the company of its 70-year-old system of lifelong employment. The industry standards in ICT, which IBM had played a leading role in establishing, served to reduce the value to the company of older employees with experience accumulated at IBM over the course of their careers and to increase the value of younger employees who may have had experience working for other ICT companies. Explicitly reflecting this change in employment policy, in 1999 IBM announced that it would replace its traditional defined-benefit pension plan, which favoured long-term employees, with a portable 'cash-balances' plan that would be much more attractive to younger employees who did not envisage a lifelong career with IBM. In December 2004, as its employment reached 329,000, IBM announced that new employees would no longer be eligible for the cash-balances pension fund. Instead the company would offer them a defined-contribution pension, with the company matching the employee contribution up to six per cent of his or her compensation.

From the mid-1990s, with the Old Economy commitment to its employees out of the way, IBM adopted all of the elements of NEBM. It shifted out of hardware into services, and outsourced its manufacturing. It became by far the leading patenter in the United States, even as it cut R&D from the ten per cent of sales that prevailed in the 1980s to six per cent of sales since the mid-1990s, this change reflecting an expressed shift to product development and away from basic research. Since the early 1990s IBM has engaged in patenting much less to control proprietary technologies, as had been the case in the past, and much more to gain access through cross-licensing to technologies controlled by other companies and to generate intellectual property revenue ($1.3 billion per year in the 2000s).

As it rid itself of lifelong employment in the early 1990s IBM began to extend stock options, previously reserved for top executives, to a broad base of employees. In 1990 options outstanding were only four per cent of all shares outstanding; in 2005, 15.2 per cent. As for distributions to shareholders, in New Economy fashion, subsequent to its early 1990s restructuring IBM has favoured repurchases over dividends. In 1981–90 IBM's dividends were 48 per cent and repurchases 12 per cent of net income; in 1993–2005 dividends were 15 per cent and repurchases 91 per cent. In an effort to offset dilution of shareholdings as employees exercise

stock options, and more generally to boost its stock price, in 1995–2005 IBM has spent $62.6 billion on stock repurchases. Over the same period the company has spent $56.6 billion on R&D.

As for a New Economy company that, unlike IBM, started out that way, Cisco Systems, which since the late 1990s has controlled about 75 per cent of the Internet router market, is a prime example of the importance, and implications, of broad-based stock options in NEBM compensation. Founded in Silicon Valley in 1984, Cisco grew from about 200 employees at the time of its IPO in 1990 to 40,000 employees during 2000. Throughout its history Cisco has awarded stock options to virtually all of its employees. By the end of fiscal 2000 stock options outstanding accounted for 14 per cent of the company's total stock outstanding; by 2005 that number was 23 per cent. In March 2000, at the peak of the Internet boom, Cisco had the highest market capitalization of any company in the world. Under such conditions its stock options were very lucrative. I have estimated that over the 11 years 1995–2005 (all years for which data are reported refer to fiscal year's end, the last week in July), Cisco employees, totaling about 256,000 employee-years, shared $21.5 billion in gains from exercising stock options, for an average of $84,000 per employee-year. The annual averages per employee ranged from less then $9,000 in 2003 to more than $281,000 in 2000. Of the total amount, the highest paid executives, totaling 57 executive-years, shared $893 million, for an average of $15.7 million per executive-year, with annual averages ranging from $1.3 million in 2003 to $51.3 million in 2000. The annual ratios of average top-executive to average employee gains from exercising stock options ranged from 36:1 in 1997 to 594:1 in 2005 (Lazonick 2006d). Cisco employees have a clear financial interest in the company's stock price, and the company's top executives even more so.

Besides using their own stock as a compensation currency, during the 1990s some New Economy companies grew large by using their stock, instead of cash, to acquire other, smaller and typically younger, New Economy firms in order to gain access to new technologies and markets. Cisco mastered this growth-through-acquisition strategy. From 1993 through 2005 Cisco made 106 acquisitions valued in nominal terms at $46.9 billion, over 80 per cent of which was paid in the company's stock rather than cash. In 1999 and 2000 alone, Cisco did 41 acquisitions at a cost of $26.7 billion with over 99 per cent paid in stock (Carpenter et al. 2003).

At the same time, like many if not most New Economy companies, Cisco conserved cash by paying no dividends. Along with its use of stock as a combination currency, this payout policy enabled Cisco to become a giant company in the 1990s without taking on any long-term debt. Since the bursting of the Internet bubble from mid-2000 through 2005, however, Cisco has spent $27.2 billion repurchasing its own stock to support its sagging stock price. In 2004–5, as it spent $19.3 billion on stock repurchases, Cisco used $8.3 billion in cash – including $6.5 billion of it raised through its first-ever bond issue – to do 24 acquisitions rather than continue to use its stock as an acquisition currency that it would then feel compelled to offset with repurchases. (Cisco's decision to use cash rather than stock for acquisitions was helped by the Financial Accounting Standards Board's 2001 closing of the 'pooling-of-interests' loophole that enabled companies like Cisco that did all-stock acquisitions to record them on their balance sheets at book values, which were generally a small fraction of market values, and thus inflated future earnings. Nevertheless, in 2002 and 2003, with pooling-of-interests accounting outlawed, Cisco still used stock for payment of over 97 per cent of the price of its nine acquisitions.)

The corporate obsession with supporting its stock price through massive stock repurchases has therefore taken hold of companies in the most innovative sectors of the US economy. As further notable examples, for the years 1995–2005 Intel distributed $51.3 billion in repurchases along with $6.0 billion in dividends compared with R&D spending of $38.0 billion, while Microsoft distributed $45.4 billion in repurchases and $38.7 billion in dividends compared with R&D spending of $40.8 billion.

Microsoft's dividends included a one-time payment of $36.1 billion in November 2004.

These companies would argue that R&D spending and stock repurchases are both working toward the same end: to enhance the company's innovative capabilities by, in the case of R&D, generating new knowledge, and in the case of repurchases, competing for high-tech labour capable of transforming that knowledge into innovative products and processes. By boosting stock prices, it is argued, repurchases help to attract, retain and motivate people who choose to work for companies in which they are partially compensated with stock options. In the case of Microsoft the argument has had less weight since July 2003 when the company ended its option programme (although many Microsoft employees still have unexercised options awarded prior to that date). In the 2000s, moreover, the extent and location of the talented labour supplies for which companies like Cisco, IBM, Intel and Microsoft compete have changed dramatically with the rise of India and China (Lazonick 2006b). These dramatically changed labour market conditions for high-tech labour raise serious questions concerning which employees benefit from a company's stock price performance and for how long, and indeed whether established high-tech companies even need to use employee stock options to compete successfully for high-tech labour.

The offshoring to India and China in the 2000s of high value-added jobs of software engineers and computer programmers that it was previously thought could not go abroad represents the latest stage in four decades of the globalization of NEBM. Beginning in the early 1960s Silicon Valley semiconductor companies were among the first to offshore assembly to East Asia, and by the early 1970s virtually every US semiconductor manufacturer had followed suit. When these companies set up plants in places like South Korea, Taiwan, Hong Kong, Singapore and Malaysia, they employed, alongside unskilled and predominantly female assembly labour, indigenous university graduates as managers and engineers. Over time the US companies upgraded their facilities in these locations, and offered more and better employment opportunities for the indigenous well-educated labour force. As a striking example, in 1984 Intel claimed that, of its 8,500 employees outside of the United States (of 26,000 employees worldwide), only 60 were US citizens. This indigenous employment through foreign direct investment encouraged the national governments to increase the level of investment in their already well-developed systems of higher education, thus augmenting the future high-tech labour supply (Lazonick 2006b).

In the 1990s established US ICT companies, led by IBM and Hewlett-Packard, dramatically reduced their employment of production workers by outsourcing manufacturing operations to electronic manufacturing service providers, also known as contract manufacturers (Lazonick 2006c). Indeed, younger companies like Cisco grew rapidly without doing any in-house manufacturing. Initially the contract manufacturers would set up operations or take over existing plants of their customers in the United States. But a key capability of the leading contract manufacturers is to shift production that has become more routine and cost-sensitive to lower wage areas of the world. In the late 1990s and early 2000s the leading contract manufacturers grew at a rapid pace; at the end of 2005 employment at the five largest – Flextronics, Solectron, Sanmina-SCI, Celestica and Jabil Circuit – totalled 260,000. While we do not know the global distribution of this labour force, North America accounts for only an estimated 25 per cent of the sales of these five companies.

Meanwhile, in the 1990s and 2000s hundreds of thousands of foreigners, especially Indians, with college degrees in science and engineering have migrated to the United States for graduate education and work experience (Lazonick 2006b). Many acquired permanent resident (immigrant) status in the United States, as the US government expanded employment-based preferences in the issuance of immigrant visas. For access to US work experience, however, the most important mode of entry for high-tech employees has been on non-immigrant H-1B and L-1 visas. The H-1B programme enables

non-immigrants, the vast majority of whom have at least a bachelor's degree and whose skills are purportedly unavailable in the United States, to work in the United States for up to six years. In the first half of the 2000s about 70 per cent of H-1B visa holders had science or technology degrees, and 40–50 per cent came from India (the next largest national group is from China, at less than ten per cent). The L-1 visa programme permits a company with operations in the United States to transfer foreign employees to the United States to acquire work experience, with no limitation of time. In 2001, there were an estimated 810,000 people on H-1B visas in the United States, and possibly as many on L-1 visas.

Many of these non-immigrant visa holders have continued to work in the United States by obtaining permanent resident status. But most have returned to their native countries with valuable industrial experience that can be used to start new firms and, more typically, to work as technical specialists for indigenous or foreign companies. As a result of both the migration of US companies abroad in search of high-tech labour as well as the migration of foreign high-tech labour to the United States, and then back to their home countries, in the 2000s, to an extent never before imagined, even the best-educated US high-tech employees compete with a truly global labour supply for jobs.

Stable and Equitable Growth?

On 16 March 2005 the Semiconductor Industry Association (SIA) organized a Washington, DC press conference in which it exhorted the US government to step up support for research in the physical sciences, including nanotechnology, to assure the continued technological leadership of the United States. Intel CEO Craig Barrett was there as a SIA spokesperson to warn: 'U.S. leadership in technology is under assault' (*Electronic News* 2005):

> The challenge we face is global in nature and broader in scope than any we have faced in the past. The initial step in responding to this challenge is that America must decide to compete. If we don't compete and win, there will be very serious consequences for our standard of living and national security in the future. . .U.S. leadership in the nanoelectronics era is not guaranteed. It will take a massive, coordinated U.S. research effort involving academia, industry, and state and federal governments to ensure that America continues to be the world leader in information technology.

At the time Barrett was a member of the US National Academy of Sciences Committee on Prospering in the Global Economy in the 21st Century, which delved into deficiencies in the development of science and engineering capabilities in the United States. Notwithstanding his obvious concern about these problems from a public policy perspective, on a radio talk show in February 2006 Barrett (by this time Chairman of Intel) remarked: 'Companies like Intel can do perfectly well in the global marketplace without hiring a single US employee' (wbur.org 2006).

The problem with this statement is not that US workers should have privileged access to jobs at a US-based company like Intel (which still employs half of its almost 100,000 employees in the United States). The problem is that, if a powerful company like Intel is not dependent on US high-tech employees for its future labour force, why should it be concerned about supporting the mass educational infrastructure in the United States needed to develop this future labour force? And what does it mean to say that 'America must decide to compete' if, as I would argue is the case (Lazonick 2006b), the most innovative US corporations have more of an interest in the Malaysian or Indian system of mass education than in the US system?

Since the mid-1970s the US mass education system has been performing poorly in science and mathematics by the standards of both the advanced and many developing economies. Such was much less the case in the three decades or so after the Second World War, when the Old Economy corporation was more dependent upon a labour force that was well-educated at the primary and secondary levels in the United States. This shift in the performance of the mass education

parallels the reversal of post-war progress towards a more equal distribution of income that began about three decades ago. The much less secure employment of most US corporate employees in the shift from OEBM to NEBM would seem to have contributed to this reversal.

Meanwhile in the 2000s the compensation of the CEOs of US corporations has long since passed levels that are at a minimum unseemly and some would say obscene. The 'explosion in CEO pay', which has been discussed in the United States since the mid-1980s, seems to have no limits, especially if, when the corporate stock price falls, it can be once again pumped up or boards of directors can replace the 'lost' stock option income by other forms of remuneration such as salaries, bonuses or restricted stock. The seemingly endless explosions in top-executive pay reflect the obsession of US corporate executives with 'maximizing shareholder value' and, cash flow permitting, disgorging billions upon billions of corporate cash to shareholders in the forms of repurchases and dividends to try to make it happen.

In terms of public policy initiatives, virtually nothing has been done to control top executive pay in the United States. One well-known attempt was misguided. In 1993 President Clinton carried out a campaign promise to control CEO pay by legislating a cap of $1 million on the amount of 'non-performance-related' top executive compensation – salary and bonus – that a corporation could claim as a tax deduction. One perverse result of this law was that companies that were paying CEOs less than $1 million in salary and bonus *raised* these components of CEO pay towards $1 million, which executives now viewed as the government-approved CEO 'minimum wage'. The other perverse result was that companies increased CEO option compensation, for which tax deductions were not in any case being claimed, as an alternative to exceeding the $1 million salary-and-bonus cap.

That having been said, the limits to the gains from stock options, not just for top executives but also for broad bases of the employees of US high-tech corporations, would long ago have been reached if not for the fact that many of these corporations have been in the forefront of innovation. Given the unchallenged sway that the ideology of 'maximizing shareholder value' has over the governance of these corporations, I have no doubt that instability, as reflected in the boom and bust of the stock market in the late 1990s and early 2000s, and inequity, as reflected in the worsening of the distribution of income, will continue to beset the US economy.

Whether US corporations will remain in the forefront of innovation that, by necessity, must underpin long-term economic growth is another matter. Notwithstanding globalization, the US model of contemporary capitalism is not a global model. No other contemporary capitalist economy has made the commitment to 'shareholder value' that is the most distinctive feature of the US model. Japan has come through the stagnation of the 1990s as a highly innovative economy, while eschewing shareholder value ideology and practices (Lazonick 2005). In western European nations the ideology has been tempered by a commitment to 'social inclusion'; the question is whether the equity and stability that social inclusion brings can be harnessed to support innovative enterprise. In the emerging giants, India and China, the stock market has come to play a more important, and possibly dangerous, role. In all of these economies, the success of innovative companies has been based, however, not on the stock market, but on the principles of strategic control, organizational integration, and financial commitment. Historically these principles also underpinned innovative enterprise in the United States. Many corporate executives who exercise control over resource allocation in the US economy may, however, have forgotten these principles, or worse yet, while they have been busy enriching themselves, they may have never bothered to learn them.

Contestable markets are those in which competitive pressures from potential entrants exercise strong constraints on the behaviour of incumbent suppliers. For a market to be contestable, there must be no significant entry barriers. Then, in order to offer no profitable opportunities for additional entry, an equilibrium configuration of the industry must entail no significant excess profits, and must be efficient in its pricing and in its allocation of production among incumbent suppliers. This is so of a contestable market whether it is populated with only a monopolist or with a large number of actively competing firms, because it is potential competition from potential entrants rather than competition among active suppliers that effectively constrains the equilibrium behaviour of the incumbents.

Perfectly contestable markets (PCMs) are a benchmark for the analysis of industry structure – a benchmark based on an idealized limiting case. Perfectly contestable markets are open to entry by entrepreneurs who face no disadvantages vis-à-vis incumbent firms and who can exit without loss of any costs that entry required to be sunk. The potential entrants have available the same

best-practice production technology, the same input markets and the same input prices as those available to the incumbents. There are no legal restrictions on market entry and exit, and there are no special costs that must be borne by an entrant that do not fall on incumbent firms as well. Consumers have no preferences among firms except those arising directly from price or quality differences in firms' offerings.

Potential entrants into perfectly contestable markets are profit-seekers who respond with production to profitable opportunities for entry. They assess the profitability of their marketing plans by making use of the current prices of incumbent firms. Thus, for example, an entrepreneur will enter a market if he anticipates positive profit from undercutting the incumbent's price and serving the entire market demand at the new lower price. Potential entrants are undeterred by prospects of retaliatory price cuts by incumbents and, instead, are deterred only when the existing market prices leave them no room for profitable entry.

These features of the behaviour of potential entrants are key to the workings of perfectly contestable markets, and they are fully rational only where entry faces no disadvantages and is costlessly reversible. Hence, the benchmark case of perfect contestability excludes the sunk costs, precommitments, asymmetric information and strategic behaviour that characterize many real markets and that are the focus of much current research attention in the field of industrial organization. With irreversibilities and the inducements for strategic behaviour absent, industry structure in PCMs is determined by the fundamental forces of demand and production technology.

Of course, this is also true of perfectly competitive markets. However, this most familiar idealized limiting case is not a satisfactory benchmark for the study of industry structure in general, because it is intrinsically inapplicable to a variety of significant cases. In particular, where increasing returns to scale are present, perfectly competitive behaviour is logically inconsistent with the long-run financial viability of unsubsidized firms.

Perfectly contestable markets can serve in place of perfectly competitive markets as the general standard of comparison for the organization of industry whether or not scale economies are prevalent. Where they are not, perfectly competitive behaviour is necessary for equilibrium in PCMs, and, where scale economies do prevail, equilibrium in PCMs entails behaviour different from that found in perfectly competitive markets but which none the less tends to exhibit desirable welfare properties. In other words, perfect contestability is a generalization of perfect competition that has strong implications in significant circumstances where the latter is inapplicable.

In order to clarify and expand on these ideas, subsequent sections offer analytic outlines of the theory of perfectly contestable markets and applications of the theory to single-product and multiproduct industries. Finally, observations are offered on the implications of this theory for the formulation of government policy towards industry.

Perfectly Contestable Markets: Definitions and Basic Properties

The theory presented here lies in the realm of partial equilibrium. It deals with the provision of the set of products $N = \{1, \ldots, n\}$, some of which may not actually be produced, and which is a proper subset of all the goods in the economy. The prices of these products are represented by vectors $p \in \mathrm{R}^n_{++}$, and other prices are assumed to be exogenous and are suppressed in the notation. $Q(p) \in R^n_+$ is the vector-valued market demand function for the products in N, and it suppresses consumers' incomes which are assumed to be exogenous. For any output vector $y \in \mathrm{R}^n_+$, $C(y)$ is the cost at exogenously fixed factor prices when production is efficient. The underlying technology is assumed to be freely available to all incumbent firms and all potential entrants. Where necessary, $C(y)$ and $Q(p)$ will be assumed to be differentiable.

Definition 1 A *feasible industry configuration* is composed of m firms producing output vectors $y^1, \ldots, y^m \in \mathrm{R}^n_+$, at prices $p \in R^n_{++}$ such that the markets clear, $\sum_{i=1}^m y^i = Q(p)$, and that each firm at least breaks even, $p \cdot y^i - C(y^i) \geq 0, i = 1, \ldots, m$.

Thus, the industry configuration is taken to be comprised of m firms, where m can be any positive integer, so that the industry structure is monopolistic if $m = 1$, competitive if m is sufficiently large, or oligopolistic for intermediate values of m. The term 'feasibility' refers to the requirements that each of the firms involved selects a non-negative output vector that permits its production costs, $C(y^i)$ to be covered at the market prices, p, and that the sum of the outputs of the m firms satisfies market demands at those prices.

Definition 2 A feasible industry configuration over N, with prices p and firms' outputs $y^1,\ldots,y^m$, is *sustainable* if $p^e \,.\, y^e \leq C(y^e)$, for all $p^e \in R^n_{++}$, $y^e \in R^n_+$, $p^e \leq p$, and $y^e \leq Q(p^e)$.

The interpretation of this definition is that a sustainable configuration affords no profitable opportunities for entry by potential entrants who regard incumbents' prices as fixed (for a period sufficiently long to make $C(\cdot)$ the relevant flow cost function for an entrant). Here, a feasible marketing plan of a potential entrant is comprised of prices, p^e, that do not exceed the incumbents' quoted prices, p, and a quantity vector, y^e, that does not exceed market demand at the entrant's prices, $Q(p^e)$. The configuration is sustainable if no such marketing plan for an entrant offers a flow of profit, $p^e \,.\, y^e - C(y^e)$, that is positive.

Definition 3 A *perfectly contestable market* (PCM) is one in which a necessary condition for an industry configuration to be in equilibrium is that it be sustainable.

A PCM so defined may be interpreted, heuristically, as a market subject to potential entry by firms that have no disadvantage relative to incumbents, and that assess the profitability of entry on the supposition that incumbents' prices are fixed for a sufficiently long period of time. Then, since one requirement for equilibrium is the absence of new entry, an equilibrium configuration in a PCM must offer no inducement for entry; that is, it must be sustainable.

Definition 4 A feasible industry configuration over N, p; $y^1,\ldots, y^m$, is a *long-run competitive equilibrium* if $p \,.\, y \leq C(y)\ \forall\ y \in R^n_+$.

So defined, a long-run competitive equilibrium has precisely the characteristics usually ascribed to it. Together, $p \,.\, y^i \geq C(y^i)$ and $p.y \leq C(y), \forall y \in R^n_+$, imply that $p \,.\, y^i = C(y^i)$ and that the $y^i \in \arg\max_y [p \,.\, y - C(y)]$. Thus, each firm in the configuration takes prices as parametric, chooses output to maximize profits, earns zero profit, and equates marginal costs to prices of produced outputs. It is now easy to show

Proposition 1 A long-run competitive equilibrium is a sustainable configuration, so that a perfectly competitive market is a PCM.

Proposition 2 Sustainable configurations need not be long-run competitive equilibria, and a PCM need not be perfectly competitive.

The simplest example sufficient to prove this second proposition is an industry producing a single product with increasing returns to scale over the relevant range of output. Here, the only feasible configuration that is sustainable entails one firm producing the maximal output level y^* given by the intersection of the declining average cost curve with the industry demand curve, and selling at the price p^* given by the corresponding level of average cost. This configuration is sustainable because, at a price equal to or less than p^*, sale of any quantity on or inside the demand curve yields revenue no greater than production cost; in this range, price does not exceed average cost. Yet this configuration is not a long-run competitive equilibrium, as defined above, because sale of a quantity greater than y^* would earn positive profit if the price could remain at p^*, and because at y^* price exceeds marginal cost which is less than average cost. In fact, in this example there is no possible long-run competitive equilibrium since marginal cost lies below average cost throughout the relevant range of output levels given by demand. In contrast, there is a sustainable configuration.

Hence, Propositions 1 and 2 show that the sustainable industry configuration is a substantive generalization of the long-run competitive equilibrium, and that the PCM is a substantive generalization of the perfectly competitive market. The

following propositions summarize some characteristics of equilibria in PCMs.

Proposition 3 Let $p; y^1,\ldots, y^m$ be a sustainable industry configuration. Then each firm must (i) earn zero profit by operating efficiently, $p \cdot y^i - C(y^i) = 0$; (ii) avoid cross-subsidization, $p_s \cdot y_s^i \geq C(y^i) - C\left(y_{N-s}^i\right), \forall SCN$ (where the vector x_T agrees with the vector x in components $j \in T$ and has zeros for its other components); (iii) price at or above marginal cost, $p_j \geq \partial C(y^i)/\partial y_j$.

The interpretation of condition (ii) is that the revenues earned from the sales of any subset of the goods must not fall short of the incremental costs of producing that subset. Otherwise, in view of the equality of total revenues and costs, the revenues collected from the sales of the other goods must exceed their total stand-alone production cost. In PCMs, such pricing invites entry into the markets for the goods providing the subsidy.

Proposition 4 Let $p; y^1,\ldots, y^m$ be a sustainable configuration with $y_j^k < \sum_{h=1}^m y_j^h$. Then $p_j = \partial C(y^k)/\partial y_j$. That is, if two or more firms produce a given good in a PCM, they must select input–output vectors at which their marginal costs of producing it are equal to the good's market price.

The implications of this result are surprisingly strong. The discipline of sustainability in perfectly contestable markets forces firms to adopt prices just equal to marginal costs, provided only that they are not monopolists of the products in qst. Conventional wisdom implies that, generally, only perfect competition involving a multitude of firms, each small in its output markets, can be relied upon to provide marginal-cost prices. Here we see that potential competition by prospective entrants, rather than rivalry among incumbent firms, suffices to make marginal-cost pricing a requirement of equilibrium in PCMs, even those containing as few as two active producers of each product. The conventional view holds that the enforcement mechanism of full competitive equilibrium requires the smallness of each active firm in its product market, in addition to freedom of entry. We see that the smallness requirement can be dispensed with, almost entirely, with exclusive reliance on the freedom of entry that characterizes PCMs.

Proposition 5 Let $p; y^1,\ldots, y^m$ be a sustainable configuration. Then, for any $\hat{y}^1, \ldots, \hat{y}^k$ with

$$\sum_{j=1}^{k} \hat{y}^j = \sum_{j=1}^{m} y^j, \sum_{j=1}^{k} C\left(\hat{y}^j\right) \geq \sum_{j=1}^{m} C(y^j).$$

That is, a sustainable configuration minimizes the total cost to the industry of producing the total industry output.

This proposition is a generalization to PCMs of a well-known result for perfect competition. It can be interpreted as a manifestation of the power of unimpeded potential entry to impose efficiency upon the industry. For example, the proposition implies that if a monopoly occupies a PCM it must be a *natural* monopoly – production by a single firm must minimize industry cost for the given output vector. Thus, Propositions 3, 4 and 5 are powerful tools for the analysis of industry structure in PCMs. Proposition 5 permits information on the properties of production costs to be used to assess the scale and scope of firms' activities in PCMs. Then, Propositions 3 and 4 permit inferences to be drawn about the corresponding equilibrium prices.

PCMS with a Single Product

This analytic approach leads to very strong results in the single-product case. Propositions 3–5 show that there are only two possible types of sustainable configurations in single-product industries. The first type involves a single firm which charges the lowest price that is consistent with nonnegative profit. The firm must be a natural monopoly when it produces the quantity that is demanded at this price. And, in this circumstance, the result maximizes welfare subject to the constraint that all firms in question be viable financially without subsidies. Such a second-best maximum is referred to as a 'Ramsey optimum'.

The second type of sustainable configuration involves production by one or more firms of

outputs at which both marginal cost and average cost are equal to price. Here, in the long run, all active firms exhibit the behaviour that characterizes perfectly competitive equilibrium. And, of course, the result involves both (first-best) welfare optimality and financial viability. Hence, in this case, Ramsey optimality and the first-best coincide. This establishes the result that in a single-product industry any sustainable configuration is Ramsey optimal.

However, in general, because of the 'integer problem', sustainable configurations may generally not exist. This problem arises, for example, where there is only one output at which a firm's marginal and average costs coincide, and where the quantity of output demanded by the market at the competitive price is greater than this, but is not an integer multiple of that amount. Then, no sustainable configurations exist.

There is, however, a plausible assumption, supported by empirical evidence, at least to some degree, that eliminates the integer problem. Suppose that a firm's average cost curve has a flat-bottom rather than being 'U'-shaped. In particular, suppose that the minimum level of average cost is attained not only at one output, but (at least) at all outputs between the minimum efficient scale, y_m, and twice the minimum efficient scale. Then any industry output, y^1, that is at least equal to y_m can be apportioned among an integer number of firms, each of which achieves minimum average cost. Specifically, y^1 can be divided evenly among $\lfloor y^1/y^m \rfloor$ firms (where $\lfloor x \rfloor$ is the largest integer not greater than x) and each firm's output, $y^1/\lfloor y^1/y^m \rfloor$ must lie in the (half-open) interval between y_m and $2y_m$. Hence, in this case, the Ramsey optimum can either be a sustainable configuration of two or more firms performing competitively, or a sustainable natural monopoly. Such a monopoly may either produce an output at which there are increasing returns to scale and it will then price at average cost, or it may produce an output between y_m and $2y_m$ with locally constant returns to scale and adopt a price equal both to average and marginal cost. This, together with the preceding argument, establishes the following result.

Proposition 6 In a single-product industry in which the firm's average cost curve has a flat-bottom between minimum efficient scale and twice minimum efficient scale, a configuration is sustainable if and only if it is Ramsey optimal.

This result shows that, under the conditions described, there is equivalence between welfare optimality and equilibrium in PCMs. This extends the corresponding result for perfectly competitive equilibria to cases of increasing returns to scale. Moreover, since the behavioural assumptions required for a PCM are weaker than those underlying perfectly competitive markets, the equivalence result is more sweeping. In particular, Proposition 6 implies that PCMs can be expected to perform well, whatever the number of firms participating in equilibrium. It is the potential competition of potential entrants, rather than the active competition of existing rivals, that drives equilibrium in PCMs with a single product to welfare optimality.

Multi-Product Perfectly Contestable Markets

In industries that produce two or more goods, a rich variety of industry structures become possible, even in PCMs. Here, while the constraints imposed upon incumbents by perfect contestability are not nearly as effective in limiting the range of possible outcomes as they are in single product industries, they nevertheless provide a helpful basis for analysis. In particular, Propositions 3–5 indicate connections among various qualitative properties of multi-product cost functions and various elements of industry structure in PCMs. These connections constitute one theme of this section. The other theme is the normative evaluation of the industry structures that arise in multi-product PCMs.

Before proceeding, it may be useful to provide definitions of some of the multiproduct cost properties that are used in the analysis.

Definition 5 Let $P = \{T_1, \ldots, T_k\}$ be a non-trivial partition of $S \subseteq N$. There are (weak)

economies of scope at y_s with respect to the partition P if $\sum_{i=1}^{k} C(y_{Ti}) > (\geq) C(y_s)$. If no partition is mentioned explicitly, then it is presumed that $T_i = \{i\}$.

Definition 6 The *degree of scale economies* defined over the entire product set, $N = \{1,\ldots, n\}$, at y, is given by $S_N(y) = C(y)/y.\nabla C(y)$.

Returns to scale are said to be increasing, constant or decreasing as S_N is greater than, equal to or less than unity. This occurs as the elasticity of ray average cost with respect to t is negative, positive or zero; where *ray average cost* is RAC $(ty^0) \equiv C(ty^0)/t$.

Definition 7 The *incremental cost* of the product set $T \subseteq N$ at y is given by $IC_T(y) \equiv C(y) - C(y_{N-T})$. The *average incremental cost* of T is $AIC_T(y) \equiv IC_T(y)/\sum_{j \in T} y_j$.

The average incremental cost of T is decreasing, increasing or constant at y if $AIC_T(ty_T + y_{N-T})$ is a decreasing, increasing or locally constant function of t at $t = 1$. These cases are labelled respectively, increasing, decreasing or constant *returns to the scale of the product line T*. The degree of scale economies specific to T is

$$IC_T(y) / \sum_{i \in T} y_i \frac{\partial C(y)}{\partial y_i}.$$

Definition 8 A cost function $C(y)$ is *trans-ray convex* through some point $y^* = (y_1^*, \ldots, y_n^*)$ if there exists at least one vector of positive constants $w_1, \ldots, w_n$ such that for every two output vectors $y^a = (y_1^a, \ldots y_n^a)$ and $y^b = (y_1^b, \ldots y_n^b)$ that lie on the hyperplane $\sum w_i y_i = w_0$ through point y^*, $C[ky^a + (1-k)y^b] \leq kC(y^a) + (1-k)C(y^b)$ for $k \in (0, 1)$.

In view of the general result that sustainable configurations minimize industry-wide costs (Proposition 5), these cost properties permit inferences to be drawn about industry structure in multi-product PCMs. The first issue that arises is when multicommodity production is characteristic of equilibrium in a PCM.

Proposition 7 A multi-product firm in a PCM must enjoy (at least weak) economies of scope over the set of goods it produces. When strict economies of scope are present, there must be at least one multi-product firm in any PCM that supplies more than one good.

The second basic question that arises is whether there can be two or more firms actively producing a particular good in a PCM. If there are, then, by Proposition 4, marginal cost pricing must result. The answer depends upon the availability of product-specific scale economies.

Proposition 8 Any product with average incremental costs that decline throughout the relevant range (that is, that offers product-specific increasing returns to scale) must be produced by only a single firm (if it is produced at all) in a PCM. Further, such a product must be priced above marginal cost, unless the degree of product- specific scale economies is exactly one.

Thus, regardless of the presence or absence of economies of scope, globally declining average incremental costs imply that a product must be monopolized in a PCM. It is an immediate corollary that if all goods in the set N exhibit product- specific scale economies, and if there are economies of scope among them all, then the industry is a natural monopoly that must be monopolized in a PCM.

Another route to this result is provided by the 'weak invisible hand theorem of natural monopoly'.

Proposition 9 Trans-ray convexity of costs together with global economies of scale imply natural monopoly. If, in addition certain other technical conditions are met, a monopoly charging Ramsey-optimal prices is a sustainable configuration.

In general, there may exist natural monopoly situations in which no sustainable prices are possible for the Ramsey optimal product set. Further, even where sustainable prices exist, the Ramsey optimal prices may not be among them. However, under the conditions of the weak invisible hand theorem, the Ramsey optimal prices for the Ramsey optimal product set are guaranteed to be sustainable, so that PCMs are consistent with (second-best) welfare optimal performance by a natural monopoly.

PCMs will yield first-best welfare optimality if there exist sustainable configurations with at least

two firms actively producing each good. For in this case Propositions 4 and 5 guarantee industry-wide cost efficiency and marginal-cost pricing of all products. Here, two issues must be resolved: Does industry-wide cost minimization require at least two producers of each good? And if so, do sustainable configurations exist?

The existence problem can be solved in a manner analogous to its solution in the case of single-product industries: by assuming that ray average costs remain at their minimum levels for output vectors that lie (on each ray) between minimum efficient scale and twice minimum efficient scale. And the presence of at least two producers (or one operating in the region where constant returns prevail) of each good is assured if the quantities demanded by the market at the relevant marginal-cost prices are no smaller than minimum efficient scale (along the relevant ray) and if the cost function exhibits trans-ray convexity.

Policy Implications of PCMS

One of the principal lessons of the analysis of PCMs is that monopoly does not necessarily entail welfare losses. Rather, the 'weak invisible hand th' shows that under certain conditions sustainability and Ramsey optimality are consistent, so that the total of consumers' and producers' surpluses may well be maximized (subject to the constraint that firms be self-supporting) in the equilibrium of a monopoly which operates in contestable markets.

Even stronger results follow from the discussed results that under certain conditions sustainability and a first-best solution are consistent in an oligopoly with a small number of firms. When minimization of industry cost requires that each good be produced by at least two firms, sustainability requires any equilibrium to satisfy the necessary conditions for a first-best allocation of resources. Thus, in these cases, the invisible hand has the same power over oligopoly in perfectly contestable markets that it exercises over a perfectly competitive industry.

This theory suggests that in a market that approximates perfect contestability, the general public interest is well-served by a policy of laissez-faire rather than active regulation by administrative or antitrust means. Small numbers of large firms, vertical and even horizontal mergers and other arrangements which have traditionally been objects of suspicion of monopolistic power, are rendered harmless and perhaps even beneficial by the presence of contestability.
